Abstract

Background: Fitness trackers and smart watches are frequently used to collect data in longitudinal medical studies. They allow continuous recording in real-life settings, potentially revealing previously uncaptured variabilities of biophysiological parameters and diseases. Adequate device accuracy is a prerequisite for meaningful research.

Objective: This study aims to assess the heart rate recording accuracy in two previously unvalidated devices: Fitbit Charge 4 and Samsung Galaxy Watch Active2.

Methods: Participants performed a study protocol comprising 5 resting and sedentary, 2 low-intensity, and 3 high-intensity exercise phases, lasting an average of 19 minutes 27 seconds. Participants wore two wearables simultaneously during all activities: Fitbit Charge 4 and Samsung Galaxy Watch Active2. Reference heart rate data were recorded using a medically certified Holter electrocardiogram. The data of the reference and evaluated devices were synchronized and compared at 1-second intervals. The mean, mean absolute error, mean absolute percentage error, Lin concordance correlation coefficient, Pearson correlation coefficient, and Bland-Altman plots were analyzed.

Results: A total of 23 healthy adults (mean age 24.2, SD 4.6 years) participated in our study. Overall, and across all activities, the Fitbit Charge 4 slightly underestimated the heart rate, whereas the Samsung Galaxy Watch Active2 overestimated it (−1.66 beats per minute [bpm]/3.84 bpm). The Fitbit Charge 4 achieved a lower mean absolute error during resting and sedentary activities (seated rest: 7.8 vs 9.4; typing: 8.1 vs 11.6; laying down [left]: 7.2 vs 9.4; laying down [back]: 6.0 vs 8.6; and walking slowly: 6.8 vs 7.7 bpm), whereas the Samsung Galaxy Watch Active2 performed better during and after low- and high-intensity activities (standing up: 12.3 vs 9.0; walking fast: 6.1 vs 5.8; stairs: 8.8 vs 6.9; squats: 15.7 vs 6.1; resting: 9.6 vs 5.6 bpm).

Conclusions: Device accuracy varied with activity. Overall, both devices achieved a mean absolute percentage error of just <10%. Thus, they were considered to produce valid results based on the limits established by previous work in the field. Neither device reached sufficient accuracy during seated rest or keyboard typing. Thus, both devices may be eligible for use in respective studies; however, researchers should consider their individual study requirements.

Introduction

Background

Wearables such as smart watches and fitness trackers enable data recording in real-life settings, where biomedical signals cannot be easily captured with conventional or clinical devices. They can provide unobtrusive, economic, high-resolution, longitudinal recording capabilities for various signals, including accelerometer and photoplethysmogram (PPG) data [1,2]. This makes them particularly interesting for use in longitudinal medical studies and biomedical research. Observational studies especially benefit from the unobtrusive and longitudinal recording characteristics of fitness trackers and wearables across a variety of medical disciplines [3-9]. In addition to clinical studies, fitness trackers are also usable in other applications. These include activity feedback, activity promotion, weight management, disease monitoring, disease diagnostics, stress and sleep monitoring, and health care surveillance [10-15].

An important prerequisite for the use of wearables in studies and connected applications is adequate accuracy and, thus, data quality. Without sufficient validation, the reliability of the recorded data is unknown, which is the case for many modern end consumer devices. Thus, stringent upfront validation is not only a necessity for meaningful research but also prospective applications.

Related Work

The Fitbit Charge HR series (Fitbit) is one of the most frequently validated devices. The study by Lee [16] reviewed the first device generation with 10 college students under free-living conditions. Each participant was asked to conduct normal day activities for 8 hours, and the heart rate (HR) was recorded and evaluated every minute against a Polar HR chest strap monitor. They concluded that the device was not accurate, with a mean absolute percentage error (MAPE) of 9.17% (SD 10.9%) when worn on the nondominant hand. Brazendale et al [17] evaluated the HR measurements of 39 children. The evaluation was performed on a per-minute basis, and the MAPE was reported as 6.9%. Thus, the authors concluded that wearable fitness trackers provide HR measurements comparable with a criterion field–based measure.

The data of 50 intensive care unit patients monitored over 24 hours were used for evaluation by Kroll et al [15]. They recorded HR values every 5 minutes and identified a median difference of 1 beats per minute (bpm) between the derived HR of the fitness tracker and the electrocardiogram (ECG)–derived HR.

A higher comparison frequency was chosen by Jo et al [18]. By measuring and comparing the HR every second, 24 participants completed a 77-minute protocol comprising several activities, including cycling, walking, jogging, running, and other sports exercises. A 12-lead ECG served as the criterion device. The authors reported a mean bias of −8.8 bpm and concluded that the device by Fitbit does not satisfy the validity criteria, particularly during higher exercise intensities.

The second release of the Fitbit Charge HR series was evaluated by Reddy et al [19], Thomson et al [20], and Benedetto et al [21], yielding different results on the device accuracy. To the best of our knowledge, the only validation study for Fitbit Charge 3 was performed by Muggeridge et al [22], who stated that the Fitbit Charge 3 performed well only during resting and walking-like conditions but otherwise assessed the accuracy to be overall poor.

To the best of our knowledge, no validation studies on the Samsung Galaxy Watch Active series exist as of today. However, other Samsung smart watches have been validated in the past. The measurements of the Samsung Gear S were investigated by Wallen et al [23], with 22 participants in rest, walking, running, and cycling. Out of a total of 4 devices, Samsung Gear S demonstrated the greatest variability in HR measurements. Shcherbina et al [24] examined the Samsung Gear S2 among 6 other devices with 60 participants from diverse backgrounds, performing a range of activities, including sitting, walking, running, and cycling. Of the validated devices in the study, Samsung Gear S2 showed the highest overall error, particularly during sitting. In another study by El-Amrawy and Nounou [25], the device also showed the lowest accuracy compared with 17 other devices and a clinical pulse oximeter as a criterion device.

Objective

The validation study presented here was conducted as an initial groundwork for a large-scale observational study in obstetrics. As a pilot study, we aim to assess the performance of the selected devices in a healthy population to initially determine eligibility for longitudinal medical studies in general. We were particularly interested in the performance and accuracy of HR measurements, which are analyzed in detail in the following sections. This work is the first to validate the Fitbit Charge 4 and Samsung Galaxy Watch Active2 (Samsung Group).

Methods

Overview

Details on the participants, experimental procedure, used devices, validation metrics, processing, and evaluation are outlined in the following sections. Where applicable and possible, we adhered to several common grounds, guidelines, and best practices for wearable HR validation, which have been published in the more recent past [2,12,26].

Ethics Approval

The study was approved by the ethics committee of Friedrich–Alexander Universität Erlangen-Nürnberg (106_13 B). The participants provided informed consent to participate.

Recruitment

Recruitment was conducted via mailing lists and direct contact. We were unable to perform a power calculation for sample size estimation as the selected devices have not been investigated in the past, and thus, no information on effect sizes or variances was available. Consequently, we aimed at a sample size of approximately 20 to 25 participants, which is in line with previous HR evaluation studies [18,19,22,27,28]. Exclusion criteria was a major underlying medical condition affecting the participants' physical capability or increasing the risk of injury. Assessment was conducted using the Physical Activity

XSL•FO

RenderX

Readiness Questionnaire [29]. Ultimately, 23 participants were recruited.

Devices and Gold Standard

We aimed to investigate the accuracy of Fitbit Charge 4 and Samsung Galaxy Watch Active2. Fitbit Charge 4 was released in March 2020. According to the manufacturer, it has a battery runtime of up to 7 days, which makes it particularly interesting for longitudinal studies [30].

The Galaxy Watch Active2 is a smart watch using Tizen OS as the operating system. Its PPG sensor uses 8 photodiodes [31]. The smart watch is available in several sizes and editions; our study used a 40 mm–sized version without long-term evolution. Furthermore, the device is able to record the ECGs. It is possible to derive blood pressure measurements through the PPG sensor; an upfront validation with a blood pressure cuff is required beforehand, and it is recommended to repeat this validation every 4 weeks [32,33]. Tizen OS is extendable, and a documentation of several available application programming interfaces (APIs) to create custom applications and interact with the device is available on the web [34]. This includes functions for accessing nearly all the built-in sensors. The available functions are not limited to the reading of HR and RR intervals but also allow raw data access to nearly all built-in sensors, particularly the PPG sensor. These features make the device interesting for medical studies, as their own algorithms for data processing can be used.

A Mind Media NeXus-10 MKI (Mind Media BV) was used as the gold standard. The ECG Holter device is a certified medical device of class 2a (EU). Data are transferred in real time via Bluetooth to a computer running a manufacturer-supplied software called Biotrace+ (Mind Media) [35], which displays and allows the export of HR, heart rate variability, and ECG data.

Study Procedure

The study was conducted in an indoor laboratory environment on 7 different days between July 30, 2020, and September 21, 2020. As the data recording was conducted during summer without air conditioning, ambient temperatures were comparably high for Northern Bavaria, causing sweaty skin surfaces in some cases. This can induce additional noise, electrode loss, or affect the PPG signal measurement of wearable devices.

After receiving information on the study procedure and aims, participants filled out the activity readiness questionnaire and respective consent forms. Participants were then supplied with the 2 wearable devices and were asked to place 1 device on each arm, ensuring that the sensor was in good contact with the skin and that the devices were fitted comfortably on the arms. The study adviser determined which device should be placed onto which arm, and devices were equally placed on the left or right arm across all participants. As the Fitbit app has a setting to determine whether the device is placed on the dominant or nondominant arm, this setting was configured accordingly by the study adviser based on the participant information. No such setting exists for the Galaxy Watch Active2. Subsequently, the Mind Media NeXus-10 MKI's electrodes were placed in a lead two position. To reduce noise, electrodes were placed on the torso, not the extremities. As the Holter device was equipped with a handbag-like body strap, it was hung over the shoulder of participants to increase freedom of movement. This positioning method was supported by the manufacturer. Recording started at least 30 seconds after placement of the electrodes, ensuring sufficient time for adaption for both wearables and the ECG algorithms.

The participants conducted an experimental protocol covering 10 subsequent tasks. Each task lasted between 1 and 2 minutes. The protocol anticipated a total length of 15 minutes. The chosen activities originate from activity recommendations for women with pregnancies, who are the prospective target group in our anticipated larger study. Participants were asked to conduct activities at their own pace to resemble activities as they would be conducted *free living* by the target group. With transitions between the individual study protocol phases, the recordings had an average duration of 19:03 minutes. We tried to minimize transition or relaxation phases between activities to ensure that the respective HR levels were similar between adjunct activities. If minor slack times (usually <10 seconds) occurred between activities (eg, because of instructions by the study adviser or a move of position between activities), these slack times were not included in the individual activity analysis. Our overall goal was to initially start with resting and sedentary activities (seated rest, typing, laying down [left], and laying down [back]), then continually increase HR using low intensity (standing up and walking at a slow pace) and high intensity (walking at brisk pace, climbing stairs, and squat work out) activities. The full list of activities and tasks is presented in Table 1.

Table 1. List of conducted activities.

Activities	Duration (minute)	Description
Seated rest	2	• Sit comfortably on a chair while breathing normally, without any physical movements • Considered resting or baseline condition
Keyboard typing	1.5	• Type a neutral text on a computer keyboard provided by the study advisor • Aims to assess the effects of hand movement without general body movement
Laying on left side	1.5	• Lay on the left body side on a flat mattress
Laying on back	1.5	• Turn and lay down fully on the back
Standing up	1	• Stand up and maintain an upright position without movement
Walking at a slow pace	1	• Walk slowly and naturally around the laboratory at one's own pace
Walking at a brisk pace	2	• Increase the walking speed to the maximum walking speed without running at one's own pace
Climbing stairs	1.5	• Climb stairs up and down at one's own pace Simulation of a workout for a woman with pregnancy
Squat workout	1.5	• Conduct squats at one's own pace • Simulation of a workout for a woman with pregnancy
Seated rest	1.5	• Sit down directly after the workout, relax your breathing, and remain without motion. • Aims to assess drastic changes in heart rate from high activity to rest

Data Recording and Processing

Fitbit Charge 4

To increase the sampling frequency of the Fitbit Charge 4, the device was set to the training mode before the first study run. This produced a HR measurement every 1 to 5 seconds, thus resulting in a sampling frequency between 0.2 and 1 Hz. As the fitness tracker is linked to a user account in Fitbit's cloud, the data were accessed through the Fitbit Web API using representational state transfer queries and the Postman software. The API only provides access to HR measurements, and no PPG raw data or RR intervals are provided.

To compare data on a per-second basis, the HR values required upsampling. When not provided with a HR measurement every second, missing values were imputed using the next available HR value.

Samsung Galaxy Watch Active2

A custom application for Samsung's Tizen OS was developed. The *Human Activity Monitor API* was used to retrieve HR and RR intervals. All retrieved data were saved in JSON format to files and downloaded to a computer. The *Human Activity Monitor API* provides HR and RR interval data with a sampling rate of 25 Hz (the provided callback function to the *humanactivitymonitor.start* function is called every 40 milliseconds). However, the data are inconclusive: the HR changes more frequently than physiologically explainable; that is, the API provides up to 5 HR changes (from 86 to 85 to 86 to 85 to 84) within a time frame as small as 300 milliseconds. At the same time, the reported RR interval occasionally remains unchanged over periods >10 seconds. Thus, we decided to sample the HR and RR interval data at 1 Hz. A minority of the data was sampled at a higher frequency and manually downsampled to 1 Hz.

Mind Media NeXus-10 MKI

The criterion device recorded ECG data at a sampling frequency of 256 Hz. Furthermore, it contained internal peak detection algorithms, also providing derived HR and RR interval data at 32 Hz. As stated before, data were transferred via Bluetooth from the Holter device to a computer running Mind Media Biotrace+. The data were then exported from the Mind Media Biotrace+ software as a CSV file. Activity sections were recorded and annotated by the study adviser during the study execution in software running on a laptop computer.

Owing to the nature of the study protocol, some activities were prone to noise. Particularly during squats and stair climbing, ECGs were sometimes noisy, and the manufacturer-supplied software was apparently unable to correctly identify R peaks, resulting in erratic and evidently wrong HR and RR interval data. This was particularly true for squat and stair-climbing activities.

To cope with this issue, the raw criterion ECG was again processed in Python, using the ECG function from the BioSPPY library [36]. Subsequently, the R peaks were manually revised by a human annotator and corrected. We then used a self-developed function to extract the HR from the RR intervals.

Finally, the data were downsampled to 1 Hz. If >1 HR value occurred during 1 second (as the HR was >60 bpm), the respective values were averaged.

Data Exclusion

Although manual data processing was applied to ensure high data quality, some recorded criterion ECGs were too noisy and

unusable for comparison. Data were excluded if adequate criterion device recordings were unavailable but not if the measured data of the examined devices were evidently incorrect, as this situation could also appear in real-life use.

As a result, data of 3 participants (IDs 6, 8, and 23) had to be completely excluded. In addition, data of 2 participants were excluded for the *squat* and *walking stairs* activity (ID 5 and ID 7). After the *squat* activity, electrodes of 2 participants (ID 2 and ID 7) detached, and thus, no data were available. As stated before, a detailed overview of the conducted manual data correction and excluded activities of individual participants is provided in Table 2.

Data Synchronization

As the software of the validated fitness trackers is mostly closed source, their exact time measurement and determination mechanism are unknown. Furthermore, the on-device signal processing may cause additional delays. Therefore, we did not rely on exact time stamps for device synchronization but instead used another synchronization technique.

Synchronization of the signals was performed on the previously downsampled signals of all 3 devices (1 Hz, ie, 1 HR value per second). We conducted the synchronization between the individual validated devices and our HR reference by maximizing the Pearson correlation coefficient (PCC). The

measurements were then shifted by the respectively determined time delays. This provided very similar and, in many cases, equal results to a shift through cross-correlation but showed better visual and metric results in a minority of edge cases.

Statistical Analysis

All statistical analyses were conducted in Python (version 3.8.7) on a Windows 10 machine using Numpy 1.19.5 [37], Scipy 1.6.0 [38], Pandas 1.2.0 [39], and Pingouin 0.3.11 [40]. Raw data and respective scripts are available from the authors upon request.

Absolute error analysis was conducted using the mean absolute error (MAE) and MAPE as key metrics. We defined MAE as

the average absolute distance between the HR of the validated device and the criterion device. MAPE is the percentage difference between the reference and the respective device values. The limits of agreement and mean error (bias) were derived from Bland–Altman plots, which also visually aided in the interpretation of the results. Correlation analysis was performed using the Lin concordance correlation coefficient (CCC), as suggested by Sartor et al [12,41,42]. PCC was additionally reported for completeness but not analyzed.

Results

Participants

In total, 23 healthy individuals participated in the study (n=10, 43% women and n=13, 57% men). The demographics and details of the participants are shown in Table 3. Most participants were university students and staff members. Given the location of the university, Fitzpatrick skin type 2 was overrepresented (3×type 1, 15×type 2, 2×type 3, 1×type 4, and 2×type 5).

Table 3. Demographics and details of the participants.

Characteristics	Values, minimum	Values, maximum	Values, mean (SD)
Age (years)[a]	20	36	24.2 (4.6)
Height (cm)	156	193	175.7 (10.48)
Body weight (kg)[b]	50	88	71 (12.75)

[a]One participant did not provide his or her date of birth.

[b]One participant did not provide his or her body weight.

HR Measurement

The key results of this validation study are summarized in Table 4. In total and across the entire experiment duration (ie, all activities), both devices achieved very similar values for MAE, MAPE, and PCC. Although the Fitbit Charge 4 slightly underestimated the HR by −1.66 bpm (bias), the Samsung Galaxy Watch Active2 overestimated the HR by 3.84 bpm (bias).

In resting and sedentary activities (seated rest, typing, and laying down) and slow walking, the Fitbit Charge 4 achieved lower absolute and absolute percentage error rates. During standing up and all other physical activities, the Samsung Galaxy Watch Active2 outperformed the Fitbit Charge 4.

A particularly high bias (ie, mean difference) was observed by the Fitbit Charge 4 during standing up (−7.95 bpm) and squats (−12.52 bpm). The Samsung Galaxy Watch Active2's highest bias was measured during typing (8.63 bpm) and laying down on the left side (6.01 bpm).

The level of agreement of the Samsung Galaxy Watch Active2 is particularly broad during activities 1 to 5. The cause was a non- or excessive recorded HR in participant 20 during these activities, where the device recorded an average HR of 146, 148, 181, and 176 bpm. This HR trend is displayed in Figure 1. If this participant was excluded from the data analysis, the metrics drastically improved: MAE and MAPE were consistently lower than those of the Fitbit device for activities 1 to 5, and both widths of limits of agreement and bias were reduced significantly.

CCC was consistently higher in the Samsung Galaxy Watch Active2. Both devices achieved particularly low scores (<0.250) during typing and slow walking. The resting phase resulted in the highest individual activity of CCC in both devices.

Bland–Altman plots for both devices are shown in Figures 2 and 3. A large cluster of points in the top-right section of Figure 3 is particularly noticeable. These data points are a result of the previously mentioned mismeasurement of the Samsung Galaxy Watch Active2. If participant 20 is excluded from the data set, the respective cluster disappears from the plot.

Table 4. Validation metrics of heart rate measurements across different activities and devices.

Discussion

Comparison With Previous Work

Our study aimed to evaluate 2 consumer wearable devices in healthy participants over a range of activities. The results from our study indicate that both devices achieved a MAPE <10%. Although no previous work exists for the Samsung Galaxy Watch Active2, our results are somewhat in line with previous validation trials for the Fitbit Charge series.

A previous evaluation of the Fitbit Charge 3 by Muggeridge et al [22] used a notably different experimental protocol, emphasizing strenuous activities (with a focus on treadmill running, sprinting, and cycling). The authors report an overall MAPE of 7.37 (as compared with 9.74 in our study) and note that the device underestimates the HR by −7 bpm (here, −1.66 bpm). Overall, the study states that the Fitbit device performs poorly during high-intensity activities and results in a higher error in that area. In our study, the Fitbit device's mean bias

was highest while climbing stairs and squatting, with a bias of −3.99 bpm and −12.52 bpm, respectively.

Reviewing studies on the Fitbit Charge 2, underestimations of the HR have been reported by several other studies [19,21,43]. The study by Baek et al [44] only reported this underestimation in the <100 bpm category and an overestimation of >120 bpm. With respect to the MAPE, the study by Reddy et al [19] reported a value of 11.33%, and the study by Nelson et al [43] reported a value of 5.96% across all activities. Our measured CCC of 0.805 across all activities is lower than the CCC of 0.906 reported by Nelson et al [43] in a 24-hour period.

Measurement Validity

Different validation definitions exist in the literature. Some prior studies have used an error rate of +5% to −5% as a limit, as it "approximates a widely accepted standard for statistical significance [...]" [24] and is "widely accepted" [19]. A limit of +10% to −10% is established by various organizations and

institutions and has been equally used by other validation studies [43]. The latter value is also proposed by previously mentioned validation guidelines [12] and thus, used for further reference in our work.

Similarly, different interpretations of correlation coefficients have been used in the literature. Owing to the large number of different definitions, ranging from a *weak* or *poor* interpretation starting between <0.2, <0.50, and <0.9 [23,43,45], we refrain from the use of an exact definition.

In our study and across all activities, both devices achieved a MAPE <10% and, per definition, produced valid results. With respect to individual activities, neither device produced valid results for seated rest and typing activities. Furthermore, the Fitbit Charge 4 did not record valid data for the standing up and squat activities, and the Samsung Galaxy Watch Active2 produced invalid results for laying down in either of the 2 evaluated positions.

Limitations

Participants and Demographic Structure

Our study mainly included healthy young participants aged between 20 and 36 years. Wearables may provide different validation results for older participants, particularly with respect to their skin properties and changes in the PPG curve. Furthermore, as most of our participants were local university students in middle Europe, Fitzpatrick skin types 1 to 3 were overrepresented in our study.

Selected Activities

The overall duration of individual activities was rather short, mostly because our aim was to set a low burden for study participation. Although the HR of all participants increased during the study duration (especially during the second half of the study), some participants may require a longer activity duration for optimal HR adaption. A shorter activity duration makes the collected data less meaningful and results in a lower number of recorded data points, thus decreasing statistical expressiveness.

As all activities were conducted consecutively and without breaks, splits between individual recorded activities always resulted in minor transitional phases. Some participants may react faster to the instructions of the study instructor than others. This leads to additional time slack between individual activities and may cause a slight metric profusion between the 2 subsequent activity metrics.

Laboratory Conditions and Environmental Factors

Although we aimed to replicate real-life activities as much as possible, our study was still conducted in a laboratory setting. Real-life use patterns may differ from those in our study and, as such, may have an impact on the accuracy of the investigated devices. Furthermore, our study was mostly conducted during warm summer days, and our laboratory was not equipped with air conditioning. Sweat is known to have an influence on ECG electrode conductance. It may also have an impact on PPG measurements by the examined wearable devices.

Data Annotation and Exclusion

Owing to various influencing factors—mainly ECG electrode loss, heat, selected activities, and other unknown skin factors—less data than anticipated were ultimately included in our study (20/23, 87% participants). A solid baseline (ground truth) was of the utmost importance in our study. Our manual data annotation of the criterion device data underlines this effort. As the annotation affects only the criterion device, it has no impact on the data recorded by the evaluated devices and, therefore, on future studies.

For participants 2, 5, and 7, only a subset of activities was included in our statistical analysis (Table 2). Although the respective individual activity metric averages reported in Table 4 do not include data for the respective activities, we did not exclude these individual participants for the overall metrics. This may lead to a minor bias toward resting and sedentary activities, as activities with higher physical activities were more prone to noise and, thus, data exclusion. Metrics only show minor changes if the data of these participants are excluded from the overall metric. The overall Fitbit Charge 4 MAE changed from 8.589 to 8.614 upon exclusion, and the Samsung Galaxy Watch Active2 MAE increased from 8.13 to 8.429.

The inclusion of data of participant 20 is controversial. A main argument for potential exclusion is that the data are clearly erroneous, and such data would be equally excluded in the study settings. On the other hand, faulty recordings may also occur in real-life settings. Excluding the data would lead to a positive bias in favor of the Samsung Galaxy Watch Active2 and, thus, to a nonobjective comparison. Therefore, we decided to include these data.

Conclusions

We evaluated 2 previously unvalidated wearable devices by conducting a study featuring various activities and 23 participants. Throughout the entire experimental procedure, both devices achieved results just <10% MAPE and thus, presented acceptable HR measurement capabilities. The Fitbit Charge 4 outperformed the Samsung Galaxy Watch Active2 during resting and sedentary activities, and the Samsung device was more accurate during high-intensity activities. Neither device reached sufficient accuracy during seated rest and keyboard typing.

Our study was a prequel to a larger interdisciplinary study in obstetrics. Researchers should consider the intended use of wearable devices when reviewing validation studies and evaluating their respective findings with respect to their full requirements. This is not only the case for the experimental design but also for other aspects. Accuracy may not be the only decisive factor. Features such as raw data access, battery runtime, or additional sensors may be equally relevant for individual research.

Abstract

Background: Individuals' self-tracking of subjectively experienced phenomena related to health can be challenging, as current options for instrumentation often involve too much effort in the moment or rely on retrospective self-reporting, which is likely to impair accuracy and compliance.

Objective: This study aims to assess the usability and perceived usefulness of low-effort, in-the-moment self-tracking using simple instrumentation and to establish the amount of support needed when using this approach.

Methods: In this exploratory study, the One Button Tracker—a press-button device that records time stamps and durations of button presses—was used for self-tracking. A total of 13 employees of an academic medical center chose a personal research question and used the One Button Tracker to actively track specific subjectively experienced phenomena for 2 to 4 weeks. To assess usability and usefulness, we combined qualitative data from semistructured interviews with quantitative results from the System Usability Scale.

Results: In total, 29 barriers and 15 facilitators for using the One Button Tracker were found. Ease of use was the most frequently mentioned facilitator. The One Button Tracker's usability received a median System Usability Scale score of 75.0 (IQR 42.50), which is considered as good usability. Participants experienced effects such as an increased awareness of the tracked phenomenon, a confirmation of personal knowledge, a gain of insight, and behavior change. Support and guidance during all stages of the self-tracking process were judged as valuable.

Conclusions: The low-effort, in-the-moment self-tracking of subjectively experienced phenomena has been shown to support personal knowledge gain and health behavior change for people with an interest in health promotion. After addressing barriers and formally validating the collected data, self-tracking devices may well be helpful for additional user types or health questions.

Introduction

Personal Science

An increasing number of people collect data on personal health or lifestyle phenomena, such as physical activity levels, mood, or sleep quality, for the purpose of self-reflection or personal knowledge gain. This practice of *self-tracking* or *self-quantification* can be supported with technological instruments such as wearable devices or mobile apps [1]. Enhancing personal knowledge supports health maintenance and may facilitate behavioral change [2-4]. In a clinical context, self-tracked data may be used for shared decision-making because it can improve communication, enhance bilateral coordination of care, and boost patient engagement and sense of autonomy [5-7]. Effective self-tracking not only mediates personal health behavior but also holds promise as a complementary field of knowledge creation and discovery. As a data acquisition method, self-tracking is integral to participant-led research (PLR) and personal science [8-11]. In PLR and personal science, patients or participants transcend their traditional role as a source of data by initiating and conducting research projects themselves. This includes acquisition and reflection of personally relevant data by and for themselves. Such an active role of a patient or citizen leading their own research is what defines and also connects PLR and personal science.

Self-tracking

In self-tracking, objective measures of an increasing range of physiological and behavioral phenomena can be automatically and accurately recorded by wearable sensors incorporated in activity trackers, smart watches, or other self-tracking devices. However, tracking subjectively experienced phenomena that manifest as physical sensations such as different moods, stress, discomfort, pain, mental flow, thoughts, emotions, or social interaction remains challenging. Instruments aimed at tracking these subjective phenomena as a primary or secondary outcome measurement using empirical methods typically involve diary entry or experience sampling methods with prompted self-reports, which can lead to inaccurate data due to associated memory recall biases [12-14]. Alternative options for in-the-moment registration, such as paper-based tracking, involve high effort, which may impair sustained use. These barriers limit discovery using self-tracking of subjectively experienced phenomena. To overcome these barriers, self-tracking devices that facilitate low-effort, in-the-moment tracking have attracted research interest. A pilot study exploring the use of a smart button device for the purpose of self-tracking medication adherence found that participants generally considered the device acceptable to use, but the collected data had poor concordance with electronic data collection [15].

One Button Tracker and Objectives

In recent case studies, the use of One Button Tracker instrumentation was introduced to facilitate low-effort, in-the-moment self-tracking [16,17]. The One Button Tracker is a data acquisition instrument that allows users to track any subjectively experienced phenomenon in the moment it occurs with little effort by a push of the single button. The point in time and duration of the button press are recorded, and the acquired data points can be loaded into a web-based data analytics tool. There, the collected data are automatically displayed in a calendar overview and graphs showing hourly and weekly distribution of observations. In one study [16], a patient with posttraumatic stress disorder was able to learn about the nature of his symptoms and the conditions in which they would arise by tracking a subjectively experienced precursor to one of his symptoms. In another study [17], the One Button Tracker enabled the investigation of temporal dynamics of and relations between two different subjectively experienced symptoms (intrusions and ruminations related to posttraumatic stress disorder). These studies suggest that the One Button Tracker in combination with a web-based data analytics tool can support low-effort, in-the-moment self-tracking. However, this promise remains a matter of research. Therefore, this exploratory study has two aims: to assess the usability and perceived usefulness of the One Button Tracker as instrumentation and to establish the amount of support needed using this approach.

Methods

Study Design and Setting

In this pilot study, we used a mixed methods approach to assess the usability and perceived usefulness of low-effort, in-the-moment tracking using simple instrumentation and to evaluate the support needed to allow individuals to self-track effectively. The qualitative part of the study consisted of semistructured interviews exploring facilitators and barriers to the use of this self-tracking method, perceived positive and negative effects of its use, and participant views on the potential value of support during the self-tracking process. The quantitative data were generated through a usability survey. Data were collected from February to August 2020. Ethical approval was granted by the local medical ethics committee (Medisch Ethische Toetsingscommissie Oost-Nederland, review number 2019-6066) and standards for reporting qualitative research were followed [18]. All participants provided written informed consent before participating in the study.

Participants

Participants were recruited from an existing cohort of employees from Radboud University Medical Center (Radboudumc, Nijmegen, the Netherlands) enrolled in the hospital's health promotion program *Healthy Professionals*. This program strives to educate employees on health and lifestyle topics to help them remain resilient and healthy in the rapidly changing health care environment [19]. This study was embedded within the Healthy Professionals program as self-tracking may aid participants in working toward their formulated lifestyle goals and because of the pioneering character of the program, which suited the explorative character of this study well. All 101 health care professionals enrolled in the program at the time of recruitment (May 2020) were invited to participate in the study by email. If they expressed interest, a researcher (AC) contacted them by phone to determine eligibility and answer any questions regarding the study's protocol. Applicants were eligible if they were aged ≥18 years. They were excluded if they were not able

to verbally communicate in Dutch or had cognitive dysfunction. We aimed to include 12-15 participants, which was deemed as sufficient for this exploratory study.

The One Button Tracker

For this study, we used a research prototype of the One Button Tracker, as depicted in Figure 1. The instrument was invented and developed by the coauthors JEL and TBC. The instrument is 41×31×12.5 mm in size, consists of a low-powered (3.3 V) press-button tracker within a 3D printed plastic casing, and can be charged via a USB port. When pressed, the device vibrates, thereby providing haptic feedback to the user. The point in time and duration of the button press were recorded. In the processing of the acquired data, these attributes can be used to distinguish between single, double, or more presses and shorter and longer durations of the presses, which can be used for different purposes depending on the user's needs. The One Button Tracker has no wireless or internet connection to ensure privacy, and the user is in control of the acquired data. The time required for a user to record an observation using the instrument was <1 second.

Figure 1. One Button Tracker. It is a data acquisition instrument in a 3D printed plastic casing that can be charged via a USB port. It was designed to track any subjectively experienced phenomenon.

Data stored on the device can be accessed by connecting the One Button Tracker to a laptop or desktop computer via a USB connection. The stored data file containing timestamps and button press durations can be loaded into a web-based data analytics tool. There, the collected data are automatically displayed in an overview table. In addition, several graphs are created that portray the average number of button presses per hour, day, week, and month (examples of visualizations from the data analytics tool are shown in Multimedia Appendix 1).

Study Procedures

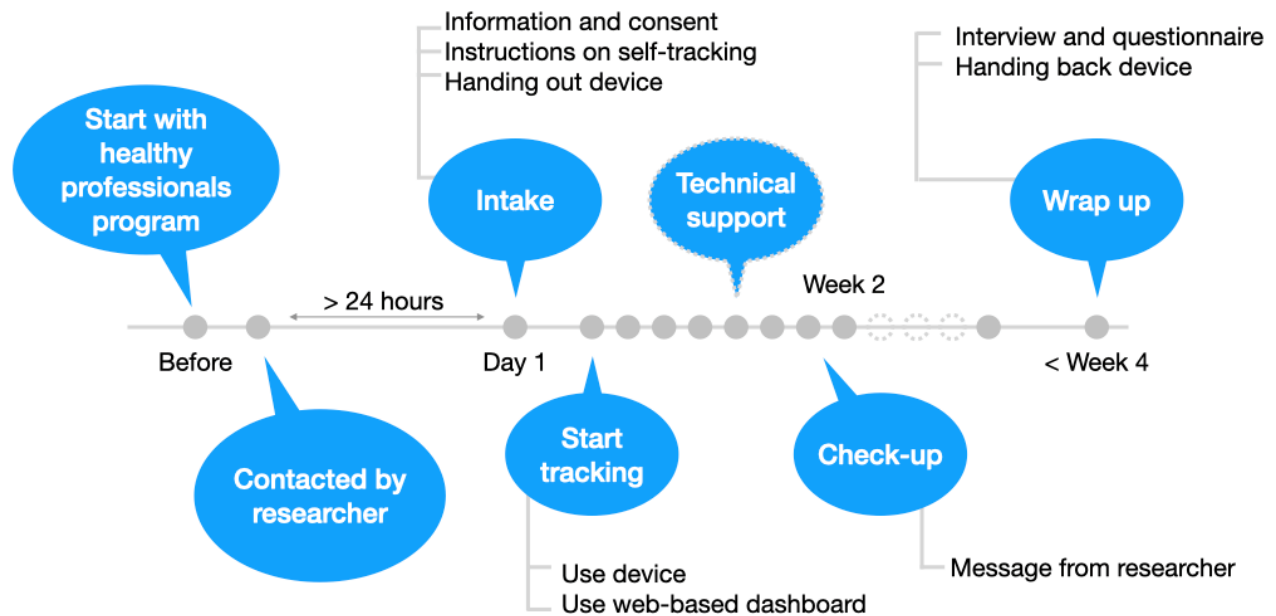
Participants were sent instructions on the use of the One Button Tracker and web-based data analytics tools by email. These detailed how to operate the device; explained its ability to distinguish between 1, 2, and 3 presses; and instructed participants to charge the device twice a week. In addition, the hyperlink to the web-based data analytics tool was provided, accompanied by written instructions in a step-by-step manner on how to transfer data to the tool. In an intake session, these instructions were restated, and remaining questions were answered.

Thereafter, participants worked toward a suitable personal research question with the help of a researcher (AC). If participants had already formulated questions related to their health promotion goals before the Healthy Professionals intake session, these questions were examined to determine their suitability. If formulating a question was revealed to be difficult, the researcher used open-ended questions to explore the knowledge gaps in the path toward their formulated health goals.

A research question was deemed suitable if it related to the participants' set health or lifestyle goals, was personally relevant, and was answerable by self-tracking a given phenomenon. Participants were strongly advised to pick a phenomenon that would result in ≥2 and ≤20 clicks per day to avoid tracking fatigue.

Subsequently, participants started the self-tracking process in which they used the One Button Tracker to actively track the chosen phenomenon for a minimum of 2 and a maximum of 4 weeks, depending on their research question and preferences. During this time, participants could view the collected data through the data analytics tool on their computer when desired. In case of problems, they could contact a technical support helpline by phone or email. In addition, we performed a weekly checkup by phone to answer any questions and gauge the use of the device. Any remarks regarding the One Button Tracker or the self-tracking process participants made in these calls were noted and added to the record for analysis.

When participants finished tracking, they handed the device back to the researchers. In individual interviews, their experiences using the One Button Tracker and doing self-tracking were explored. In these sessions, the data collected by the participants were loaded into the web-based data analytics tool and discussed. Afterward, all data were deleted permanently. Following the interview, participants were asked to fill out the System Usability Scale (SUS) questionnaire to determine the usability of the One Button Tracker. Figure 2 provides an overview of the study's timeline.

Figure 2. Overview of the study's timeline. Self-tracking was carried out by the participants for a duration of 2 to 4 weeks.


Data Collection

All semistructured interviews were conducted in July 2020 by a junior researcher (AC) with previous training in qualitative research. The interview guide was developed specifically for this study, drawing from insights from Li et al [20] and Almalki et al [21] regarding personal informatics systems. It included questions on participant expectations, their personal research question and approach, views of and experiences with the One Button Tracker and the web-based data analytics tool, and views of and experiences with self-tracking and support during this process (Multimedia Appendix 2). All interview questions were open-ended. In addition to these questions, participants were asked to grade the OBT on a scale from 1 (worst possible functioning) to 10 (best possible functioning).

During the interview sessions, we also collected demographic information, including birth year, education, and job description. We initially intended to interview all participants face-to-face at the participants' location of choice. However, owing to COVID-19 restrictions, half of the interviews were conducted via the internet using Skype for Business (version 7.0.2676.1, 2018; Microsoft Corporation). All interviews were audio-recorded, transcribed clean verbatim, and anonymized.

Following the interview, participants completed a Dutch version of the SUS [22] (Multimedia Appendix 3). This short 10-item validated questionnaire is widely used to determine the usability of devices or systems. It asks participants to rate the truthiness of 10 statements concerning the device's usability on a 5-point Likert scale.

Data Analysis

A total of 2 researchers (AC and FF) analyzed the anonymized transcripts independently using qualitative data analysis software (ATLAS.ti version 7.1; Scientific Software Development GmbH). They identified barriers, facilitators, and positive and negative effects of the use of the One Button Tracker for self-tracking. The identified codes were thoroughly discussed

until consensus was reached. Remaining disagreements were discussed with a third researcher (TB). To determine if the sample size was sufficient to gain a comprehensive overview of participant experiences, code saturation was assessed after each third interview by examining whether any previously unnamed barriers and facilitators or effects were identified in the newly gathered data. We defined saturation as 3 subsequent interviews with no new factors.

Facilitators and barriers regarding the use of the One Button Tracker were categorized according to the Gagnon framework concerning determinants of adoption of information and communications technologies in health [23,24]. New barriers and facilitators were added to the framework. The Donabedian framework for the quality of health care was used to present all identified positive and negative effects [25]. This framework distinguishes structure (context in which health care is delivered), process (all actions that make up health care), and outcome (all effects on patients' health). Dutch quotes and themes used in this paper were translated into English and checked by all authors.

Participants' answers on the SUS were computed as described by Brooke et al [22], resulting in a score between 0 and 100. Scores were interpreted in accordance to Bangor et al [26], where with a score of ≤50.9, the usability of a device is deemed *poor*; with a score of >50.9, usability is deemed *sufficient*; with a score of >71.4, usability is deemed *good*; with a score of >85.5, usability is deemed *excellent*; and with a score of >90.9, usability is deemed the *best imaginable*.

Analysis and statistics were performed in the Radboudumc using SPSS (version 25.0; IBM). Normally distributed continuous variables are described using mean and SD. Median and interquartile values were shown in case variables were not normally distributed. Qualitative or categorical variables were described using frequencies and percentages.

Data Storage and Privacy

After each interview, the pseudonymized audio record was stored within the Radboudumc data storage environment until transcription was finished, in accordance with Dutch privacy law. After transcription and coding, the anonymized transcripts were archived according to the Radboudumc research policy.

Results

Participants

Of the 101 professionals who were invited to participate, 58.4% (59/101) actively declined. Provided reasons for not participating included no time, increased workload due to the COVID-19 pandemic (7/59, 12%) already able to reach health goals (3/59, 5%), not wanting to use this particular self-quantification system (3/59, 5%), changing jobs (2/59, 2%), and illness (2/59, 2%). A total of 13 professionals expressed interest and were included, resulting in a recruitment rate of 12.8% (13/101). Table 1 provides an overview of all participants' characteristics.

Table 1. Participant characteristics (n=13).

Characteristic	Value
Gender, n (%)	
Female	11 (85)
Male	2 (15)
Age (years), median (range)	56 (35-67)
Educational background, n (%)	
Vocational	3 (23)
Applied sciences	6 (46)
Academic	4 (31)
Job type, n (%)	
Management	7 (54)
Medical staff	
Nursing and care	3 (23)
Medical doctor and specialists	0 (0)
Staff, administration, or secretary	3 (23)

Self-tracking

All participants successfully formulated a personal research question and used the One Button Tracker for self-tracking. A total of 85% (11/13) of the participants made use of the device's ability to distinguish between 1, 2, and 3 button presses. Some used this feature to indicate the intensity of the tracked phenomenon, where more presses indicated a stronger or more intense experience, whereas others assigned different relevant phenomena to different numbers of presses to explore their relationships. Table 2 provides an overview of all personal research questions and tracked phenomena. When participants were asked to restate their formulated personal question during the interviews, they often posed their focus as a behavioral goal or an aim, rather than as a (research) question.

Table 2. Topic, question, and description of the self-tracked phenomenon of each of the 13 participants' personal research projects.

ID	Topic	Personal research question	Phenomenon description
01	Creativity	How can I identify and facilitate creative moments in my day-to-day work?	1 press=creative moment; 2 or 3 presses=more intense experience
02	Snacking	How often do I snack?	1 press=snack
03	Stress	What factors influence my (experience of) heart palpitations?	1 press=palpitations; 2 or 3 presses=more intense experience (used diary to record contextual factors)
04	Stress	To what extent do I experience physical stress symptoms?	1 press=muscle tension; 2 presses=tensed breathing; 3 presses=cannot eat
05	Stress	What is for me the relation between stress and movement?	1 press=stress; 2 presses=moving a little; 3 presses=moving a lot
06	Hydration	How much do I drink and how does this relate to thirst?	1 press=thirst; 2 presses=drinking
07	Creativity	How can I get out of a rut, using music?	1 press=effective music-based intervention
08	Hydration	How much do I drink and how does this influence my headaches?	1 press=drinking; 2 presses=headache; 3 presses=pain killers
09	Drinking	How much coffee and wine do I consume?	1 press=cup of coffee; 2 presses=glass of wine
10	Wellness	At what times do I feel energetic?	More presses=feeling better; fewer or no presses=feeling worse
11	Disquiet and food	What is for me the relationship between mental unrest and thinking of food?	1 press=thinking of food; 2 presses=mental unrest
12	Fidgeting	Does my fidgeting habit follow a recognizable pattern, and how might knowledge of this pattern help me to fidget less?	1 press=fidgeting with fingers; 2 presses=touching face
13	Hydration and stillness	How much do I drink, and how can I intercept my working day with mindfulness exercises to improve stillness?	1 press=drinking; 2 presses=mindfulness exercise

The duration of the self-tracking projects ranged from 6 to 38 days, with a median of 23. Of the 13 participants, 3 (23%) deviated from the self-tracking period of 2 to 4 weeks. From these 13 participants, 1 (8%) ended the tracking project after 8 days because of a perceived lack of usefulness and high burden, another (1/13, 8%) ended the project after 6 days because she had answered her personal research question, and the last (1/13, 8%) extended the tracking period because of illness. During the tracking period, 54% (7/13) of the participants visualized the collected data using the web-based data analytics tool. Moreover, of the 13 participants, 2 (15%) used the tool for data interpretation, whereas the other 5 (38%) used it to check whether the One Button Tracker was still fully operational. Of the 6 participants who did not successfully load their data into the web-based tool, 1 (17%) intended to but encountered technical issues, whereas the others had no interest in viewing the collected data.

Technical Challenges

Of the 13 participants, 6 (46%) participants encountered technical difficulties during the tracking period. After troubleshooting, it turned out that a technical error had resulted in the loss of all software and data files. In 3 cases, no personal data were lost, as the technical error had occurred before self-tracking commencement. However, 23% (3/13) of the participants lost (a proportion of) their collected data when this transpired.

Multiple possible causes for this issue were identified. Of the 13 participants, 1 (8%) had accidently connected the One Button Tracker to the hospital's computers, which had been warned against in the written instructions, as this was known to elicit a faulty reset of the One Button Tracker. Another (1/13, 8%) participant inadvertently caused an error by incorrectly detaching the One Button Tracker from their PC. In other cases, the cause of the errors remained unclear. After consultation with the coauthors JEL and TBC, all One Button Trackers received a software update. From there on, no further technical issues with the One Button Trackers were encountered.

Qualitative Results

The interviews ranged from 15 to 56 minutes in length. Analysis of the interviews revealed 29 barriers and 15 facilitators, as well as 2 negatively and 12 positively perceived effects. Textbox 1 presents all identified barriers and facilitators. Textbox 2 presents an overview of the experienced effects. Data saturation could not be confirmed.

Textbox 1. Barriers to and facilitators regarding the use of the One Button Tracker as a self-tracking instrument according to the Gagnon framework of determinants of adoption of information and communications technologies in health care. Barriers and facilitators are ordered in three categories (technological, individual, and external), including the number of participants who mentioned each identified barrier (B, n) or facilitator (F, n).

Technological barriers and facilitators related to mobile health characteristics

1. Design and technical concerns
   - Unattractiveness of design (B, 1)
   - Physical aspect of the device reminds user to track (F, 1)
   - Data analytics tool's visualizations are attractive (F, 1)
   - Device is too small to be aware of (B, 1)
   - Device's button (cannot be pressed or [lack of] confirmation; B, 1)
   - Device's button (vibrations assure user of correct press; F, 1)
   - Device is not compatible with operating system (B, 1)
   - Disfunction not further specified (B, 1)

2. Perceived usefulness
   - Set goal is personally important to user (F, 1)
   - Lack of usefulness after research question has been answered (B, 1)
   - No need to use device or dashboard (B, 4)
   - Lack of confidence that research question will be answered (B, 1)

3. Perceived ease of use
   - Device is handy (F, 3)
   - Device is easy to use (F, 5)
   - Carrying device is a bother: already have to bring a smartphone (B, 1)
   - Challenging to transport the device, especially when the user has no pockets (B, 5)
   - Visualizing the data in the data analytics tool involves too much effort (B, 3)
   - User needs instructions on how to interpret the data analytics tool's visualizations (B, 2)
   - Fear to lose device (B, 1)
   - Psychological stress of using the device is zero, which facilitates use (F, 1)

4. Privacy and security concerns
   - Data cannot be removed accidently (F, 1)
   - Good privacy protection when compared with other tools such as app (F, 1)

5. Satisfaction about content available (completeness)
   - Lack of in-the-moment feedback (B, 1)
   - Hard to determine when to use the device specifically with subjective phenomena (B, 1)

6. Content appropriate for users (relevance)
   - Sense of failure each time a negatively judged phenomena is tracked (B, 1)

7. Accuracy
   - User forgets to bring the device when on the move (B, 7)
   - User forgets to track when device is out of sight (B, 1)
   - User forgets to track when distracted by other activities (B, 1)
   - Incorrect categorization of measure due to changes midactivity or midexperience (B, 1)
   - Button cannot be pressed accidently (F, 1)
   - User forgets device when clothes are regularly changed, for example, health care workers (B, 1)

- After a few weeks user forgets to track (B, 1)

Individual barriers and facilitators: knowledge, attitude, and sociodemographic characteristics

1. Time issues

   - User is too busy to view the data analytics tool (B, 2)

   - Interpreting the data analytics tool visualizations is too time-consuming (B, 1)

2. Outcome expectancy

   - While working night shifts, life differs so substantially that tracking during these shifts does not lead to generalizable knowledge (B, 1)

3. Agreement with mHealth (welcoming or resistant)

   - Tracking is fun (F, 1)

   - Not motivated to use data analytics tool (B, 1)

External barriers and facilitators: social and training environment

1. Social pressure (associated with peers)

   - Device can be used unnoticed by others (F, 1)

   - Lack of use when other people are around (B, 1)

   - Less comfortable to use device among others: fear of having to explain him or herself or to disturb group progress (B, 1)

2. Training

   - Support and guidance during the process of designing a personal research question (F, 1)

   - No behavioral goal formally set in collaboration with researcher (B, 1)

3. Communication and collaboration effort

   - Regular checkups support user motivation (F, 1)

4. External environment

   - Research context elicits motivation (F, 2)

Textbox 2. Positive and negative effects of the use of the One Button Tracker as a self-tracking instrument according to the Donabedian framework for quality of care. Effects are ordered in two categories (process and outcome) including the number of participants who mentioned each positive effect (P, n) or negative effect (N, n).

Process

1. Self-tracking process

   - It is enjoyable to consciously focus on a certain experience or behavior (P, 2)

   - Tracking causes confrontation with failure in the set goal (N, 1)

   - The device causes annoyance (N, 1)

2. Tracked personal data

   - Gathered data can be related to lived experiences (P, 3)

   - The ability to differ between the number of presses facilitates a differentiated overview of the user's progress (P, 1)

   - Data analytics tool visualizations increase insight into temporal fluctuations in the tracked phenomenon (P, 1)

Outcome

1. Self-awareness

   - Enhanced awareness of tracked experience or phenomenon (P, 8)

2. Personal knowledge

   - (Objective) confirmation of existing beliefs (P, 3)

   - Gain of personal insights (P, 4)

   - Reassurance that user can take control of own health (P, 1)

3. Action

   - User is incentivized to turn goal setting into action (P, 4)

   - Behavioral change (P,4)

   - The device functions as an incentive to perform the desired behavior (P, 3)

   - The device functions as a reinforcement to put the gained insights into practice (P, 3)

We identified a diverse number of barriers and facilitators that influence the uptake of the One Button Tracker. However, 3 aspects of the One Button Tracker's usability were emphasized by participants. The *user-friendliness of the device* was one such aspect. Because of its small size and the simplicity of its design, the One Button Tracker was generally considered easy to use. Second, most participants thought of the One Button Tracker as *easily portable*, as users can carry the device with them in a trouser or shirt pocket. A third mentioned asset of the One Button Tracker was that its *size facilitates pressing its button unseen by others*, which was considered to be of added value:

> *I could just quickly press it, use it unnoticed. So I er, I didn't need to grab some clumsy-looking apparatus, "what have you got there?". You can just nicely...just quietly press it.* [Participant 03]

Although collecting personal data with the One Button Tracker was regarded to be convenient, there were certain aspects of the data collection process that participants viewed as possibly troublesome. Although the One Button Tracker was considered to be easily portable, it could be *challenging for users to remember bringing the device* when they were on the move. This effect was said to be more pronounced when participants'

clothing lacked pockets to transport the One Button Tracker. Even when participants brought the One Button Tracker with them, missed tracking points still occurred. Participants explained that they *sometimes forgot to track experiences when distracted by other activities* or when they had placed the One Button Tracker out of their line of sight. Because of these occurrences, of the 13 participants, 5 (38%) reported instances of missed or misregistered data points. However, even with these missed data points, the majority still felt that the collected data accurately represented their experienced reality:

> *One time, I wasn't wearing trousers with pockets. And then I realized, oh shoot, forgot it. No trousers, no tracker.* [Participant 05]

Another factor of which the importance was emphasized is the availability of tailored support during the tracking process. Without guidance, it would be difficult to design a personally relevant research question and to select an appropriate phenomenon to track. Furthermore, some participants felt that the points of contact with the researchers during the weekly checkups facilitated a boost in motivation to persist in the tracking process. Appropriate support was also judged to be essential for correct interpretation of collected data presented in the web-based data analytics tool. Overall, 31% (4/13) of the

participants mentioned that they were interested in looking at their personal data but needed support interpreting the data visualizations. Some stated they thought connecting the device to their desktop and loading the collected data involved too much effort or was too time-consuming. All in all, support and guidance during all stages of the self-tracking process were judged as very important:

> *Well, I did see those graphs. And I did have a look at them, but I thought yeah, I'm going to need some explanation from you here, what you guys think of this.* [Participant 03]

Participants experienced a range of effects to be the result of the use of the One Button Tracker for self-tracking. Although most of these effects were judged positively, of the 13 participants, 1 (8%) described that she experienced negative emotions throughout the tracking process. This participant had chosen to track a behavioral phenomenon that she wanted to perform less often, which resulted in a sense of failure each time this behavior was registered. As for positive effects, 62% (8/13) of the participants stated that the use of the One Button Tracker led to enhanced awareness of the tracked phenomenon. This facilitated an objective confirmation of existing beliefs but could also lead to the gain of entirely new personal insights. For 31% (4/13) of the participants, enhanced awareness and gained personal knowledge culminated in or contributed to behavioral change. Another important effect mentioned was the functioning of the One Button Tracker as an incentive for desired behavior. Participants explained that the device reminded them or even motivated them to act more in line with their stated behavioral goal:

> *Seeing that thing laying there, thinking oh right, oh I can do that now! That does have a certain action effect, so to speak.* [Participant 06]

Quantitative Results

The One Button Tracker received a median grade of 7.5 (IQR 2.0) on a scale of 1 to 10, with individual grades ranging from 5 to 10. The SUS was completed by all participants. The median SUS score was 75.0 (IQR 17.50) out of a possible maximum score of 100, with individual scores ranging from 50.0 to 97.5. This corresponds to a percentile rank of 73% and indicates that the One Button Tracker's usability can be considered as *good usability* [26,27].

Discussion

Principal Findings

In this study, we explored the potential of low-effort, in-the-moment self-tracking of subjectively experienced phenomena to support self-knowledge gain by focusing on one such option, the One Button Tracker.

All participants in this study successfully designed a personal research question in the context of a health promotion program and tracked one or more chosen phenomena with the device. The findings suggest that instrumentation options such as these can aid individuals in the pursuit of personal knowledge gain. However, such an approach may not suit everyone. Participants

highlighted the user-friendliness of the One Button Tracker instrument; however, some barriers to swift data collection were also identified.

Participants generally considered the One Button Tracker as user-friendly, which was reflected by the median SUS score and grade the device received. However, technical issues encountered initially by some of the participants posed a risk to loss of the collected personal data, and with it, the instrument's usability. Although such difficulties can occur in instruments that have not been tested extensively [15], problems of this type will have to be resolved through design testing before such self-tracking options are rolled out on a bigger scale [28,29]. Additional usability challenges associated with the physical design of the One Button Tracker, for instance, how to carry it when wearing clothes without pockets, were also a limitation.

Despite these barriers the One Button Tracker provided enhanced awareness and personal knowledge gain. Most participants felt using the One Button Tracker helped raise their awareness of the tracked phenomenon. They indicated that this awareness led to confirmation or gain of personal insights. This benefit was reported even though some participants experienced limited accuracy of the collected data caused by missed or misregistered observations. This suggests that high accuracy of the collected data may not be necessary to effectuate the positive effects, as almost all participants also reported instances of missed or misregistered data points. Further research is needed to evaluate how the accuracy of collected data might influence the quality of gained self-knowledge, a question that has been raised before [30], and how this quality might in turn influence users' perceptions of health or health behavior.

Most participants experienced a change in health behavior, yet the measurability and sustainability of this change remained unclear. In line with the *self-improvement hypothesis of personal informatics*, participants believed that the increased awareness and gained personal knowledge resulting from the self-tracking process led them to change their behavior [31,32]. In addition, some participants felt the change in behavior was incentivized specifically by the sight of the instrument. Importantly, it is an experience of behavioral change that was assessed here; we did not measure actual change.

Participants emphasized the value of support during the different stages of the self-tracking process. The need for support is exemplified by the fact that most participants in present and previous studies struggled with interpreting the collected data on their own [20,21]. Furthermore, in line with previous research, regular interaction with the researchers was stated to be a motivating factor [4,32]. However, evidence that such support contributes to enhanced health effects as compared with self-tracking with no assistance is lacking [29,33,34]. Interview data indicate that the need for support was often related to help with the web-based data analytics tools.

Implications

The diversity in participant views emphasizes the importance of providing an appropriate self-tracking option to each individual. It turned out that the low-effort in-the-moment

approach is a good fit for some individuals, but not all. Previous research supports the notion that a one-size-fits-all approach does not exist; rather, different options should be developed for user groups with different needs [35-37]. Self-tracking can lead to negative effects such as feelings of failure and incompetence associated with individuals being reminded of the incongruence between their behavioral goal and the behavior actually performed [32,37-40]. Therefore, it is important to determine what does and does not work for different users or user groups.

The results found here have several implications for scientific research and medical practice. Academic researchers are becoming more aware of the contributions PLR can make to knowledge creation, such as generating hypotheses, enriching questionnaires, or answering questions through real-life data. However, before low-effort, in-the-moment tracking can be used as a scientifically sound data acquisition method, more clarity is needed on the quality of the collected data. In addition to the barriers described above, the tracked experience may also be distorted because it is being tracked, a phenomenon that is addressed as the *observer effect* [32,41]. Therefore, further research is needed into the validity and reliability of the collected data, and how these relate to those of other data collection methods. In a clinical context, it is clear that self-tracking of personally relevant phenomena may help some individuals gain self-insight and develop healthier behavior. However, for such methods to be successfully deployed in medical practice, it is important to gain a better understanding of the possible health effects, long-term effects, and potential differences in experiences between different user groups, as it has been shown previously that patients often differ in experiences from healthy volunteers [30,42]. This will help determine in which application areas self-tracking could be beneficial and how such a program could be best set up.

This study is among the first to explore this novel approach to self-tracking. An important strength of the study is that it provided participants with a chance to participate in a personalized form of PLR, in which they could set up and answer their own personally relevant research question. This provided a real-life setting, in which participants self-tracked for a purpose of their own choosing. In addition, the use of a mixed methods approach enhanced the strength of the findings, as the quantitative and qualitative findings converged well.

Limitations

This study has several limitations. Data saturation was not reached. As a result, we cannot ensure that the entire range of possible participant experiences was covered. The participation rate was sufficient for saturation; however, it was relatively low (n=13). In our experimental setup, participants were allowed to track different types of phenomena, which explains the wide range of facilitators and barriers that were identified. Although

this small group already provides valuable information in the context of an explorative study, a larger group may have revealed additional barriers and facilitators or may have provided a clearer image about the ones that stand out. Another limitation is related to the Hawthorne effect. Some participants found the research context itself to be motivating. This could mean that participants are less motivated to keep up a real-life self-tracking project. Finally, the participants included here were highly motivated, with an active participation in a health promotion program. This suggests that their experiences might not fully correspond with those of a population with less strong motivation or fewer support options.

Concluding Remarks and Future Work

This study explored the potential usability and usefulness of low-effort, in-the-moment self-tracking for acquiring new personal insights and supporting changes in health behavior. Although the prototype self-tracking instrument studied here has shown itself to be perceived as user-friendly and can be used to quantify subjective experienced phenomena effectively, experiences in the participant group varied widely. Although the study has demonstrated the utility of the instrument in individual cases, the potential efficacy of the instrument in general is inconclusive at this point.

Before the One Button Tracker instrument can be provided to patients or study participants on a larger scale, the technical challenges and specific usability issues identified in this study should be addressed. In particular, usability issues related to wearability would need to be addressed.

As the study participants appreciated the support they received during the study, it would be interesting to study which kind of and what level of support is conducive for the process in the different steps of self-tracking as part of PLR or personal science. Further research is needed to assess the exact benefits of support and to evaluate how this support would best be provided. Here, the role and usability of the data analytics tool is also a topic for further research.

The explorative nature of this study and the overall purpose for using the One Button Tracker to track anything related to personal health and well-being has led participants to track a wide range of different phenomena. This demonstrated that participants can use the instrument in everyday life settings and acquire real-world data on subjective experience. Future studies could focus on addressing the application of the instrument in specific health domains to identify where self-tracking of subjective experience could potentially benefit diagnostics, health monitoring, or behavior change. For example, future studies could be conducted to understand to what extent the observed experiences would translate to objectively measurable change and how sustainable this change in behavior could be [14,31,32,43].

Abstract

Background: Remote patient monitoring (RPM) devices are increasingly being used in caring for patients to reduce risks of complications. Temperature monitoring specifically has been shown in previous studies to provide a useful signal of inflammation that may help prevent foot ulcers.

Objective: In this cross-sectional study, we evaluated utilization data for patients who were prescribed smart socks as remote temperature monitoring devices.

Methods: This study evaluated data from a patient registry from January to July 2021. The utilization data, which were collected starting from the first full month since patients were prescribed the smart socks, were evaluated along with retention over time, the average time that the socks were worn, and the number of days that the socks were worn per month and per week.

Results: A total of 160 patients wore the smart sock RPM device for 22 to 25 days per month on average. The retention rate was 91.9% (147/160) at the end of the 7-month period; a total of 13 patients were lost to follow-up during this period. The average number of days that the socks were worn per week was 5.8. The percentage of patients with a utilization rate of >15 days ranged from 79.7% (106/133) to 91.9% (125/136) each month.

Conclusions: This study shows a high level of utilization for a smart sock RPM device and a high compliance rate. A future prospective study on the clinical outcomes after the use of the smart socks may further solidify the idea of conducting temperature monitoring for foot ulcer prevention.

Introduction

Remote patient monitoring (RPM) has emerged as a critical method in disease prevention. A wide range of devices are designed to monitor physiologic indicators of clinical interest for a variety of health conditions, especially diabetes and related complications. Studies have demonstrated the efficacy and promise of RPM in diabetes management. Su et al [1] examined glycemic control for 1354 patients and concluded that patients who underwent more frequent and regular remote monitoring had lower hemoglobin A_{1c} levels than those of patients with lower adherence to the program. Further, the willingness to adopt remote monitoring was evaluated in 1577 patients with diabetes, and perceived intrusiveness was a main factor for

XSL·FO
RenderX

whether a patient would adopt monitoring in diabetes management [2].

Diabetic foot ulcers (DFUs) are a highly prevalent complication for people living with diabetes, who have an estimated 25% lifetime risk of developing DFUs [3]. Temperature was first identified as a predictive factor for ulceration by Benbow et al [4]. Researchers further developed temperature monitoring by measuring multiple sites on each foot to assess temperature differentials that may predict the onset of a neuropathic ulceration [5]. "Areas that are likely to ulcerate have been associated with increased local skin temperatures due to inflammation and enzymatic autolysis of tissue" [6]. Identifying areas of injury through inflammation tracking allows patients and their providers to intervene to reduce inflammation before a wound develops [6].

Various technologies have been developed that use temperature differentials to remotely monitor diabetic foot health [7]. One technology is a smart sock that can be worn by patients and has a regular connection to the cloud for the capture and sharing of temperature data with health care professionals. The socks have temperature sensors embedded inside of the fabric, so that it is soft and comfortable for the user. The patient data are monitored for an elevation in temperature that indicates inflammation—an early sign of wound formation. Although the socks are mainly intended for preventative therapy, this product has also been used to track the course of developing ulcers. Additionally, the socks can be used by people who have undergone an amputation; the socks use an ipsilateral temperature algorithm to detect temperature elevations in 1 foot. Reyzelman et al [8] first evaluated the smart socks in a 35-patient study; patients reported that the socks were easy to use and comfortable, ranking them with a median score of 9 and 10 for comfort and ease of use, respectively, on a 10-point scale. These ratings for ease of use and comfort indicate potentially low intrusiveness and a high willingness to use smart socks as an RPM device.

In this cross-sectional study, we reviewed real-world data from patients using a smart sock temperature monitoring device (Siren Socks; Siren Care) to assess compliance and utilization levels. The purpose of this study is to determine how patients adhere to an RPM program for DFU prevention that involves the use of smart socks.

Methods

Study Design

Patients in the Siren Care registry who were enrolled throughout July 2021 were retrospectively reviewed. This registry is an institutional review board (IRB)–approved protocol (IRB submission title: *Temperature and Activity Data from the "Siren Socks and Foot Monitoring System" – A Multicenter Post Market Registry Study with Retrospective and Prospective Analysis*; WCG IRB study number: 1284366). The qualification for subscribing to the smart socks was the diagnosis of peripheral neuropathy. The inclusion criteria were patients using the smart sock temperature monitoring device for at least 1 day, those who were at participating sites, and those who consented to the registry, as per the IRB-approved protocol. The first calendar month of utilization was excluded due to the variability in which days of the month patients began using the RPM device. The utilization data were measured as the amount of time that the socks were worn, as measured by the smart sock device, in terms of wear time per day as well as the number of days that the socks were worn per month and per week.

Description of the Temperature Monitoring Device

The smart sock device takes continuous measurements of temperature at 6 points on each foot (the hallux, the heel, the arch, metatarsal 1, metatarsal 3, and metatarsal 5). The temperature is measured automatically throughout the day. The socks turn on upon wear and turn off automatically when they are no longer worn. No charging is necessary by the patient. No smartphone is necessary to be used by the patient for data transmission. A hub is plugged into the wall for data transmission, and monitoring data are also stored on the socks to allow for monitoring when patients are away from home. The socks are designed to be machine washable and can be reused for a period of up to 1 year (Figure 1). The socks' lifetime is around 1 year, but this can be longer depending on usage. Socks are replaced after normal wear and tear. Data were collected and monitored by prescribing physicians and their designated staff. Any temperature differentials greater than 2.2 °C resulted in an alert to a monitoring nurse that required follow-up via a phone call to the patient.

Figure 1. The smart sock remote temperature monitoring device (Siren Socks; Siren Care).
Description of Outcome Measures

The primary outcome measure was the number of days that the socks were worn per month and per week. The secondary outcome measure was the amount of time that the socks were worn per day.

Statistical Analysis

Descriptive statistics were performed, and the analysis was performed by using Microsoft Excel (version 16.51; Microsoft Corporation).

Ethics Approval

This study was approved by the WCG IRB (study number: 12843666). If an individual wished to participate in the study, they were informed about the study objectives, and they could consent through a mobile app or over the phone after having started using the socks.

Results

A total of 160 patients met the inclusion criteria as of July 2021. Data from previous months of enrollment were included, beginning in January 2021 (Table 1).

Table 1. Smart sock utilization (>15 days and >5 days of wear).

Utilization characteristics	January 2021	February 2021	March 2021	April 2021	May 2021	June 2021	July 2021
Active patients, n	10	20	23	62	110	133	136
Patients with >15 days of wear, n (%)	8 (80)	17 (85)	20 (87)	55 (89)	95 (86)	106 (80)	125 (92)
Patients with >5 days of wear, n (%)	10 (100)	20 (100)	22 (96)	60 (97)	108 (98)	125 (94)	132 (97)

Across the entire studied period, patients wore the socks for 5.8 (SD 1.7) days per week on average. The median number of days that the socks were worn was 7 days per week. Further, 93% of the time, socks were worn for at least 3 days per week (Table 2).

XSL•FO
RenderX

Table 2. Smart sock utilization (number of days worn per month and week and number of hours worn per day).

Utilization characteristics	January 2021	February 2021	March 2021	April 2021	May 2021	June 2021	July 2021
Number of wear days per month, mean (SD; median)	23.0 (7.8; 26)	23.1 (7.8; 27)	24.8 (8.3; 28)	23.7 (7.2; 26)	23.9 (7.4; 26.5)	22.0 (8.3; 24)	25.6 (7.4; 29)
Number of wear days per week, mean (SD; median)	5.5 (2.0; 6.5)	6.1 (1.5; 7)	5.8 (1.7; 7)	5.9 (1.5; 7)	5.7 (1.7; 6)	5.7 (1.7; 6)	6.0 (1.6; 7)
Number of wear hours per day, mean (SD; median)	12.4 (3.1; 12.5)	13.8 (4.6; 13.7)	12.6 (5.2; 13.0)	11.7 (4.4; 11.8)	11.0 (4.7; 10.6)	11.0 (4.9; 11.4)	10.0 (5.2; 9.7)

The wear time per day was assessed across all of the months that the socks were worn. The average wear time per day was 11.0 (SD 4.9) hours, and the median was 11.1 hours (Table 2).

In total, 24 people ceased to be active during the studied period; 11 patients temporarily paused their use of the socks, and 13 were lost to follow-up and went off service (Tables 3 and 4).

Table 3. Smart sock retention.

Retention characteristics	January 2021	February 2021	March 2021	April 2021	May 2021	June 2021	July 2021
Active patients, n	10	20	23	62	110	133	136
Patients retained (ie, those still active at the end of July), n (%)	9 (90)	17 (85)	20 (87)	52 (84)	95 (86)	122 (92)	N/A[a]

[a]N/A: not applicable.

Table 4. Smart sock retention: reasons for inactivity.

Reason	Patients, n
Paused temporarily due to other health conditions (eg, healing from surgery, open wounds, or other health issues)	6
Paused while resolving technical issues	3
Paused while waiting for cooler weather	2
Deceased	1
Changed providers when moving into a permanent nursing home	1
Returns related to comfort	2
Returns due to a lack of education on the use and intent of the device	4
Lost to follow-up and did not respond to repeated calls	5

Patients' average age at the time of enrollment was 69.9 (SD 10.7; median 71) years. The youngest patient was 37 years old, and the oldest was 94 years old.

Discussion

Principal Findings

This study appears to be the first to use data from patients who were being tracked over time during normal pediatric practice to analyze adherence to and compliance with an RPM device for plantar foot temperature. Overall, the temperature monitoring smart socks offered patients with peripheral neuropathy a reliable, easy-to-comply, and real-time device designed to help reduce the risk of foot ulceration. Our findings indicated a high utilization rate of 22 to 25 days per month and a retention rate of 91.9% (147/160; Table 1). The information transmitted from the temperature monitoring smart socks thus allowed providers to closely monitor these high-risk patients.

A number of novel RPM technologies have been developed to provide patients and clinicians with options for monitoring temperature, as temperature is a physiological indicator of inflammation and possibly an early warning sign of foot ulcer formation [4-6]. However, these RPM technologies' promise for preventing foot ulcers is based on patients' ability and willingness to use such devices in their activities of daily living. Patients' compliance with the use of medical devices is known to be poor when it is burdensome to their daily life. A prior study by Armstrong et al [9] found that the utilization rate of using a removable cast walker as an offloading device for DFUs was low [10]. The compliance rate for the offloading device was only as high as 28%. The compliance and utilization rates for the smart socks were considerably higher, despite the average age of the enrollees at the time of enrollment being 69.9 (SD 10.7) years. This suggests that the technology is easy to use, even for older users, who are at increased risk of diabetes and DFUs.

Smart socks, smart pads, and smart insoles are among the RPM devices discussed in the literature [9,11,12]. The reported utilization rate of smart insoles is roughly 6.1 to 6.9 hours per day, and that of the smart pad averages from 1.6 to 4.1 days per week [13,14]. The smart socks in this study reported a high utilization and compliance rate; the socks were used for 22 to 25 days per month and 5.8 days per week on average (Table 2).

The results of this study suggest that the smart sock was used by patients to a high degree, as patients wore the device for an average of 22 to 25 days per month during the period studied. Notably, the percentage of patients that wore the device for at least 15 days in a month ranged from 79.7% (106/133) to 91.9% (125/136) for any particular month (Table 1). The number of patients who wore the RPM device for >5 days per month was high, ranging from 94% (125/133) to 100% (20/20) each month (Table 1). This high number of patients suggests that many patients who fail to achieve >15 days of wear time can be guided to increase their frequency of wear. The wear time per day was, on average, 11.1 hours (Table 2). This suggests that the smart socks were not worn for a brief period but rather were worn extensively throughout the day. Given our findings, the smart socks achieved a high compliance, utilization, and retention rate.

The retention rate was analyzed to be 91.9% (147/160), with only 13 patients dropping out by going off service either through returns or by being lost to follow-up. Further, 11 patients were still on service, but they temporarily paused their use of the socks due to comorbidities or technical issues (Table 4). A total of 160 patients were enrolled, and 149 were still on service by the end of the study period. Patient retention was reviewed by month, and many of the patients in the registry were added in the middle of the study period.

No specific user research was done into the reasons for the high compliance and utilization rates, but a possible reason for these may be that socks are a simple and unintrusive form for an RPM device. Additionally, the lack of charging and regular contact with a nurse for assistance with the RPM services may have also contributed to the high level of utilization. Further analysis, perhaps through patient questionnaires, may provide further insight into the reasons for high utilization. Self-management and the actual utilization of preventative services and devices are important factors for determining health outcomes in chronic conditions. In general, compliance is defined as "the extent to which a person's behavior coincides with medical advice" [15]. The International Working Group on the Diabetic Foot released guidelines in 2019 that included a recommendation for temperature monitoring and a daily self-inspection of feet for patients at risk of ulceration [16]. The level of compliance to foot care advice has been studied to a limited degree. One study found that only 38.7% of a sample of 331 patients examined their feet 5 to 7 days per week [17]. Adherence to recommendations for foot temperature monitoring has not been extensively studied. One study did demonstrate that a 50% rate of adherence to recording foot temperature resulted in a significantly lower likelihood of developing an ulcer when compared with lower rates of adherence [18]. These findings suggest that adherence may be a challenge with regard to self-management behaviors among patients with diabetes and that adherence is a meaningful factor. In our study, based on the early results of the utilization of the smart socks, patients have a high level of adherence to prescribed advice on wearing smart socks in a real-world setting.

This study also has a few limitations. The period of observation was limited to 7 months, and many patients entered the registry during the middle and later parts of the evaluation period. Further follow-up and a greater number of patients would be necessary to better assess changes in utilization and retention over time.

Conclusion

The usefulness of temperature monitoring for podiatric patients with limited or no protective sensation has been demonstrated [5,19,20]. The level of adherence to and the utilization of various temperature monitoring devices need further evaluation. This study shows a high level of utilization and compliance for a smart sock remote temperature monitoring device. Further studies with larger patient groups and a longer follow-up period are warranted to better understand the sustained adherence to RPM among patients with diabetes.

Abstract

Background: Electronic medical records (EMRs) offer the promise of computationally identifying sarcoidosis cases. However, the accuracy of identifying these cases in the EMR is unknown.

Objective: The aim of this study is to determine the statistical performance of using the International Classification of Diseases (ICD) diagnostic codes to identify patients with sarcoidosis in the EMR.

Methods: We used the ICD diagnostic codes to identify sarcoidosis cases by searching the EMRs of the San Francisco and Palo Alto Veterans Affairs medical centers and randomly selecting 200 patients. To improve the diagnostic accuracy of the computational algorithm in cases where histopathological data are unavailable, we developed an *index of suspicion* to identify cases with a *high index of suspicion* for sarcoidosis (confirmed and probable) based on clinical and radiographic features alone using the American Thoracic Society practice guideline. Through medical record review, we determined the positive predictive value (PPV) of diagnosing sarcoidosis by two computational methods: using ICD codes alone and using ICD codes plus the *high index of suspicion*.

Results: Among the 200 patients, 158 (79%) had a high index of suspicion for sarcoidosis. Of these 158 patients, 142 (89.9%) had documentation of nonnecrotizing granuloma, confirming biopsy-proven sarcoidosis. The PPV of using ICD codes alone was 79% (95% CI 78.6%-80.5%) for identifying sarcoidosis cases and 71% (95% CI 64.7%-77.3%) for identifying histopathologically confirmed sarcoidosis in the EMRs. The inclusion of the generated *high index of suspicion* to identify confirmed sarcoidosis cases

XSL•FO
RenderX

increased the PPV significantly to 100% (95% CI 96.5%-100%). Histopathology documentation alone was 90% sensitive compared with *high index of suspicion*.

Conclusions: ICD codes are reasonable classifiers for identifying sarcoidosis cases within EMRs with a PPV of 79%. Using a computational algorithm to capture *index of suspicion* data elements could significantly improve the case-identification accuracy.

Introduction

Background

Sarcoidosis is a complex disease with an unknown etiology that can involve multiple organs, and no universal or standardized measures can fully secure its final diagnosis [1-3]. In fact, it was only recently that the American Thoracic Society (ATS) published its first practice guideline to provide recommendations for diagnosing sarcoidosis and the necessary screening tests [3]. The ATS practice guideline for diagnosis requires the presence of specific clinical and radiographic features, tissue biopsy revealing nonnecrotizing granulomas, and exclusion of alternative conditions that can mimic sarcoidosis [1,3,4].

Data from electronic medical records (EMRs) are commonly used in research and by health care systems, including the United States Department of Veterans Affairs (VA), to predict outcomes or assess care quality [5]. EMR data are generally captured in two forms: (1) *structured data*, including billing codes such as the International Classification of Diseases (ICD) codes, laboratory test results, and procedural codes; and (2) *narrative or unstructured data*, including progress notes, pathology reports, and imaging reports. ICD codes cast a wider net to capture patients in the EMR because they include both inpatient and outpatient claims compared with other classifiers such as Diagnosis-Related Group that only capture inpatient claims [6]. Unstructured data contain many more details of the clinical conditions, but extracting these details is challenging and time consuming. In contrast, structured data are easier to search for, and they allow for identifying cases computationally using diagnostic codes. However, diagnostic codes can be inaccurate and difficult to verify. This is particularly true for the case definition of sarcoidosis, which is considered a diagnosis of exclusion and requires a review of clinical, radiological, and histopathological data for accurate diagnosis [3,7,8]. A few studies have reported the development of sarcoidosis-specific "computationally identifying algorithms" based on structured data elements in the EMR, although they were not validated by manual chart review [9-13]. Another study assessed the accuracy of using diagnostic codes to identify sarcoidosis cases [14] but only used the ICD, Ninth Revision (ICD-9) code and not the ICD, Tenth Revision (ICD-10) code, and it did not include any computational algorithm development. In addition, previous studies on the diagnostic accuracy of ICD codes for other common pulmonary diseases that have less or similar complexity compared with sarcoidosis, such as chronic obstructive pulmonary disease, idiopathic pulmonary fibrosis, and asthma, showed positive predictive values (PPVs) of 42%-67% [15-17].

Moreover, researchers have previously developed predictive models and risk scores to use advanced computational methods to predict, commonly, less-complex case definitions in the EMR [18-24]. For example, in a study published by Himes et al [19], Bayesian network machine learning models were constructed to predict chronic obstructive pulmonary disease. Therefore, given the complexity of securing a sarcoidosis diagnosis in the realm of real-world clinical data, it is essential to develop automated algorithms to detect confirmed and probable cases of sarcoidosis using data elements from structured and unstructured domains by incorporating the ATS diagnostic criteria [3,25].

First Step

As the first step in evaluating the knowledge gap in developing future sarcoidosis-specific "computationally identifying algorithms," we designed this study (1) to estimate the statistical performance of using diagnostic codes (ICD-9 and ICD-10) alone compared with a new approach that uses additional information from radiology and clinical domains, but not histopathology, to inform the utility of these codes for performing clinical phenotyping of sarcoidosis cases in large EMR data sets of the VA and (2) to assess the computational challenges in querying sarcoidosis cases and extracting high-quality sarcoidosis-related research variables from the EMR accurately.

Methods

Data Source and Collection

This was an observational retrospective study of EMRs available through VA Informatics and Computing Infrastructure (VINCI). VINCI provides access to comprehensive and integrated veterans' national deidentified data sets and offers the necessary computational and analytical tools in a secure, high-performance computing environment [26,27]. This study was approved by the institutional review board of the University of California San Francisco and the Veterans Health Administration Research and Development Committee (15-16660). Patients or the public were not involved in the design, conduct, reporting, or dissemination plans of our research.

We searched the EMR data in VINCI from 1989 to 2019 and identified all patients coded as having sarcoidosis in the VA health care system, as defined by the documentation of the ICD-9 and ICD-10 codes of 135 and D86.x (including subcodes), respectively. Data were extracted through executing

SQL queries in an SQL Server 2017 database. A total of 14,833 sarcoidosis cases were identified.

Study Design

To determine the statistical performance of using diagnostic codes (ICD-9 and ICD-10) in identifying patients with sarcoidosis from the EMR, initially, we identified patients with at least one claim (inpatient or outpatient) of ICD diagnosis code for sarcoidosis. To ascertain the true diagnosis of sarcoidosis based on the ATS diagnostic criteria (clinical, radiographic, and pathological findings, as well as exclusion of other causes) [3], 2 clinicians (MIS and IM) performed a comprehensive chart review. Of the 14,833 identified cases, a total of 200 (1.35%) were reviewed to limit the required chart review to a manageable level. As our access to the detailed medical records was limited to the two medical centers of San Francisco VA (SFVA) and Palo Alto VA (PAVA), the reviewed charts were selected from these two centers. We stratified the list of sarcoidosis cases from the 2 centers by site and used the *lottery* method to randomly select 100 patients from each site without a replacement [28] (Figure 1).

Figure 1. Strengthening the Reporting of Observational Studies in Epidemiology flowchart. Selection criteria for sarcoidosis cases. ATS: American Thoracic Society; ICD: International Classification of Diseases; PA: Palo Alto; SF: San Francisco; VA: Veterans Affairs.
On the basis of the ATS practice guidelines, the diagnosis can be confirmed for those who had a biopsy consistent with sarcoidosis, as well as consistent clinical and radiological findings and no evidence for an alternative diagnosis. However, the ATS practice guideline committee acknowledged that there were clinical situations in which a confirmatory biopsy may not be indicated or possible. Accordingly, based on the ATS practice guideline, those patients without biopsies can be classified as probable sarcoidosis [3]. Therefore, given that not all suspected patients have a tissue biopsy in clinical practice, we generated an *index of suspicion* for sarcoidosis to identify patients with sarcoidosis (confirmed and probable) based on clinical and radiographic information, regardless of the availability of biopsy data, and to assess whether this approach would improve the diagnostic accuracy. The *index of suspicion* was applied to the initial cohort of patients with ICD codes for sarcoidosis (n=200). The clinical and radiological features were extracted from the available structured and unstructured data without including the histopathology results. If the patients were documented to have one or more of these features, they were assigned to the *high index of suspicion* group (Textbox 1); otherwise, the patients were assigned to the *low index of suspicion* group.

Textbox 1. Criteria to determine high index of suspicion.

Clinical and radiological features supportive of the diagnosis of sarcoidosis that were used for the determination of a *high index of suspicion*. Any patients with at least one of these features were included in the *high index of suspicion* group:

- Clinical

    - Lofgren syndrome (defined as erythema nodosum, bilateral hilar lymphadenopathy, and polyarthralgia or polyarthritis)

    - Heerfordt syndrome (defined as facial nerve palsy, parotid gland enlargement, anterior uveitis, and low-grade fever)

    - Lupus pernio or erythema nodosum

    - Maculopapular or erythematous skin lesions or nodules

    - Facial nerve palsy

    - Symmetrical parotid enlargement

    - Optic neuritis, scleritis, uveitis, or retinitis

    - Lacrimal gland swelling

    - Evidence of granulomatous disease on direct laryngoscopy

    - Hepatomegaly or splenomegaly

    - Shortness of breath, dyspnea on exertion, cough, dizziness, or chest pain

    - Pulmonary function test with obstruction, restriction, or low diffusing capacity of the lungs for carbon monoxide

    - Cardiomyopathy, cardiac arrhythmia, or atrioventricular node block

    - Hypercalcemia, hypercalciuria, nephrolithiasis, or abnormal vitamin D levels

    - Elevated angiotensin-converting enzyme inhibitors or soluble interleukin-2 receptors

    - Bronchoalveolar lavage lymphocytosis

- Radiological

    - Bilateral hilar lymphadenopathy (chest radiograph, computed tomography, and positron emission tomography)

    - Computed tomography chest with perilymphatic nodules tracking the peribronchovascular bundle

    - Diffuse infiltrates (chest radiograph, computed tomography, and positron emission tomography) or computed tomography chest or chest radiograph with fibrosis

    - Cardiac magnetic resonance imaging or positron emission tomography–computed tomography consistent with sarcoidosis

    - Enlargement or nodules in liver or spleen (computed tomography, positron emission tomography, or magnetic resonance imaging)

    - Magnetic resonance imaging brain with increased inflammation

    - Extrathoracic enlarged lymph nodes (computed tomography, magnetic resonance imaging, and positron emission tomography)

We then further classified the patients into 3 groups. Patients with a high index of suspicion and documented histopathological evidence of nonnecrotizing granulomas were categorized into the group of *sarcoidosis with confirmed biopsy*. Patients with a high index of suspicion and either no documented biopsy in the EMR or a biopsy showing no histopathological evidence of nonnecrotizing granulomas were categorized into the group of *sarcoidosis without confirmed biopsy* (probable sarcoidosis). Finally, those with a low index of suspicion were categorized into the group of *unlikely sarcoidosis* (Figure 1).

Using the *index of suspicion* restricts the initially developed sarcoidosis cohort to capture those with a *high index of suspicion* for sarcoidosis from whom we identified confirmed cases. As we started with a random sample of those with sarcoidosis diagnostic codes, the further restriction of the sample to those with a *high index of suspicion* was still a random sample of the combination of both ICD codes and the *index of suspicion*. We compared the statistical performance of the two methods (ICD

code alone vs ICD code with *index of suspicion*) to determine whether the use of this *index of suspicion* could improve the PPV of identification of sarcoidosis cases in the EMR.

This approach provides more information than just relying on ICD codes alone to develop robust computational sarcoidosis-specific algorithms consistent with the recent ATS practice guideline recommendations.

Disease-Related Variables

Organ involvement was assessed based on the clinical history obtained from physicians' notes and imaging and biopsy reports available in the computerized patient record system. For this assessment, to adjust for the variability in providers' documentation, we adapted a set of criteria previously introduced in the National Institutes of Health–sponsored Genomic Research in Alpha-1 Antitrypsin Deficiency and Sarcoidosis (GRADS) study [29].

We collected the following data from the chart review: clinical site, gender, race, ICD-9 and ICD-10 codes for sarcoidosis (135 and D86, respectively), the pathological diagnosis from any available biopsy, organ involvement as described in Textbox 2, Scadding staging of chest x-ray (as described in radiology reports), history of bilateral hilar lymphadenopathy (based on radiology reports and clinical notes), pulmonary function test (PFT) pattern (as reported in PFT reports), the clinical status (acute, chronic, or remitting disease), and the treatment status of sarcoidosis.

Pathological diagnoses were categorized into *primary* histopathological if the data were available in the pathology report domains and *secondary* if the data were available only in the clinical note domains because of either a remote history of biopsy or because the biopsy had been performed outside the VA. The PFT reports at the SFVA and PAVA used Crapo reference equations to calculate the lower limit of normal values for spirometry and lung volume measurements.

Using the clinical data from chart abstraction, we classified the patients into the clinical phenotypes proposed by the GRADS study, with the exception of *multi-organ phenotype*, which we defined as the involvement of ≥3 organs.

Textbox 2. Organ involvement assessment for sarcoidosis (with and without confirmed biopsy).

Organ and assessment

Lung

- Positive lung biopsy and positive mediastinal or hilar lymph node biopsy

- Chest x-ray, computed tomography (CT) chest, or positron emission tomography (PET) demonstrating bilateral hilar lymphadenopathy; CT chest with perilymphatic nodules tracking the peribronchovascular bundle; chest X-ray, CT chest, or PET with diffuse infiltrates; and CT chest or chest x-ray (CXR) with fibrosis

- Pulmonary function test (PFT) with obstruction, restriction, or low diffusing capacity of the lungs for carbon monoxide (DLCO)

Skin

- Positive skin biopsy

- Lupus pernio and erythema nodosum

Eye

- Positive conjunctival or scleral biopsy

- Optic neuritis, scleritis, uveitis, or retinitis

Cardiac

- Positive heart or pericardium biopsy

- Atrioventricular node block (second or third degree)

- Cardiomyopathy responsive to treatment

- Cardiac arrhythmia (eg, ventricular tachycardia)

- Cardiac magnetic resonance imaging (MRI) or PET-CT consistent with sarcoidosis

Liver or spleen

- Positive liver or spleen biopsy

- Enlargement or nodules in liver or spleen (CT, PET, or MRI)

- Abnormal liver enzymes

Neurosarcoidosis

- Positive brain or dura or peripheral nerve biopsy

- Clinical syndrome or symptoms consistent with central nervous system sarcoidosis along with a positive MRI

Ear, nose, and throat

- Positive biopsy from ear, nose, or throat

- Direct laryngoscopy consistent with granulomatous disease

Multi-organ involvement

- ≥3 organs involved based on other criteria in this table

Statistical Analyses

All statistical analyses were performed with R software (The R Foundation for Statistical Computing) using RStudio (version 1.2.5). Descriptive statistics were computed to summarize the data. Categorical variables were presented as the frequency in percentages, and continuous data were presented as means and SDs. We estimated the PPV of the two aforementioned computational diagnostic criteria for sarcoidosis (ICD codes alone and ICD codes along with *index of suspicion*). We did not report the positive likelihood ratio, given that the specificity for using ICD codes alone could not be calculated because our study design did not include a review of noncases. The PPV for the criterion of using only the ICD code was calculated as the number of patients with an ICD code for sarcoidosis divided by the total number of patients verified to have sarcoidosis by chart review (*gold standard*). The PPV for the criterion of using the ICD codes and *index of suspicion* was calculated as the total number of patients with a high index of suspicion divided by the number of patients verified to have sarcoidosis by chart review (*gold standard*). The sensitivity of histopathology reports alone compared with chart review was calculated as the total number of patients with a high index of suspicion and confirmed biopsy divided by the number of patients verified to have sarcoidosis by chart review (*gold standard*). We computed 95% CIs using the exact binomial method. For our estimates, significance was defined as *P*<.05.

Results

Patients' Characteristics

A total of 14,833 patients with at least one ICD-9 or ICD-10 diagnostic code of sarcoidosis were identified. The study cohort included patients identified by the ICD codes of sarcoidosis (n=200). Of the 200 patients, 158 (79%) had a *high index of suspicion* for sarcoidosis based on clinical or radiographic findings. Of these 158 patients, 108 (68.4%) were identified with the ICD-9 code of 135 and 50 (31.6%) with the ICD-10 code of D86, and 142 (89.9%) had confirmed sarcoidosis based on histopathological evidence of nonnecrotizing granuloma and were classified as having *sarcoidosis with confirmed biopsy*; the remaining 16 (10.1%) patients with a *high index of suspicion* did not undergo a biopsy and were classified as having *sarcoidosis without confirmed biopsy* (probable sarcoidosis; Figure 1). No patient had nondiagnostic biopsy results for sarcoidosis.

Table 1 summarizes the demographic data and baseline characteristics of patients with sarcoidosis (with and without confirmed biopsy). Among these patients, 89.9% (142/158) were men and there was a higher representation of African American patients than non-Hispanic White patients (85/158, 53.8%, vs 52/158, 32.9%, respectively). Overall, 90.5% (143/158) had a predominant pulmonary phenotype. Among these, 129 had PFT (36, 27.9%, 28, 21.7%, and 25, 19.4%, with restrictive, obstructive, and mixed patterns, respectively) and most were in Scadding stage II (47/143, 32.9%), followed by stage 0 and stage I (27/143, 18.9%, and 26/143, 18.2%, respectively). There was no significant difference in age between those who had a biopsy performed to diagnose sarcoidosis and those who did not (mean 65.5, SD 10.8, years vs mean 69.3, SD 10.3, years, respectively; *P*=.18). In terms of clinical phenotypes, 37.9% (60/158) had a *multi-organ* disease (≥3 organs; there were none with involvement of ≥5 organs), followed by stage II or stage III treated (45/158, 28.5%). Our study cohort did not include any individuals with acute presentation (acute, untreated). Some patients overlapped with multiple clinical groups.

Table 1. Distribution of characteristics and clinical phenotype groups of patients with sarcoidosis (with and without confirmed biopsy; N=158).

Characteristics	Sarcoidosis with confirmed biopsy (n=142), n (%)	Sarcoidosis without confirmed biopsy (n=16)[a], n (%)	P value

[a]Probable sarcoidosis: cases with clinical and radiological features consistent with sarcoidosis and do not have confirmatory biopsies.

[b]Chi-square test.

[c]Fisher exact test.

[d]Evaluated based on pulmonary function test reports available in the computerized patient record system.

[e]Scored based on reviewers' interpretation of imaging reports using Scadding staging. Stage 0: normal chest radiograph; stage I: hilar or mediastinal nodal enlargement only; stage II: nodal enlargement and parenchymal disease; stage III: parenchymal disease only; stage IV: end-stage lung disease (pulmonary fibrosis).

[f]Clinical phenotype groups [29]: some patients overlapped with multiple clinical groups. Group 1: multi-organ involvement, patients with ≥3 organs involved; group 2: nonacute, stage I, untreated: patients with nonacute sarcoidosis, stage I, never treated for sarcoidosis; group 3: stage II-III, treated: patients with nonacute sarcoidosis, stage II or III, formerly treated for sarcoidosis or treated within 3 months of data review; group 4: stage II-III, untreated: patients with nonacute sarcoidosis, stage II or III, never treated for sarcoidosis; group 5: stage IV, treated: patients with nonacute sarcoidosis, stage IV, formerly treated for sarcoidosis or treated within 3 months of data review; group 6: stage IV, untreated: patients with nonacute sarcoidosis, stage IV, never treated for sarcoidosis; group 7: acute sarcoidosis, untreated: patients with acute sarcoidosis (Lofgren syndrome); group 8: remitting, untreated: patients who have had no evidence of active clinical disease for >1 year; group 9: cardiac sarcoidosis, treated: patients with cardiac manifestations of sarcoidosis, formerly treated for sarcoidosis or treated within 3 months of data review.

Diagnostic Accuracy of ICD Codes

We then calculated the PPV using ICD codes to identify VA patients who met the ATS definition of sarcoidosis from the VINCI database. For this calculation, we used the curated data set of 200 patients. The PPV of using only ICD codes was 79% (95% CI 78.6%-80.5%) for identifying sarcoidosis cases and 71% (95% CI 64.7%-77.3%) for identifying histopathologically confirmed sarcoidosis in the EMR. After chart review, the inclusion of the generated *high index of suspicion* to identify confirmed sarcoidosis cases increased the PPV significantly to 100% (95% CI 96.5%-100%) with 90% sensitivity of histopathology reports alone compared with chart review (Table 2).

Table 2. Contingency 2×2 table of using histopathology reports compared with high index of suspicion for sarcoidosis cases identification (N=200).

Among patients with International Classification of Diseases code for sarcoidosis	High index of suspicion[a] (chart review)		
	Yes	No	Total
Histopathology report[b]			
Confirmed sarcoidosis	142[c]	0[d]	142
Not available[e]	16[f]	42[g]	58
Total	158	42	200

[a]High index of suspicion for sarcoidosis based on both clinical and radiographic evidence but not biopsy.

[b]Available biopsies with primary or secondary histopathological reports.

[c]Sarcoidosis group with histopathological evidence of nonnecrotizing granuloma.

[d]No sarcoidosis group because of lack of sufficient clinical and radiological features consistent with sarcoidosis even in the presence of the histopathological evidence of nonnecrotizing granuloma.

[e]No biopsies were ordered or available in the electronic medical record.

[f]Probable sarcoidosis group without histopathological evidence of nonnecrotizing granuloma.

[g]No sarcoidosis group because of lack of sufficient clinical and radiological features consistent with sarcoidosis, in addition to the absence of the histopathological evidence of nonnecrotizing granuloma.

Discussion

Principal Findings

In this observational retrospective study of VA EMRs, we reviewed the medical records of 200 randomly selected patients with ICD diagnostic codes for sarcoidosis from the SFVA and PAVA medical centers (Figure 1). In this sample, we found that ICD diagnostic codes performed reasonably well with a PPV of 79% for detecting patients with sarcoidosis and 71% for detecting patients with histopathologically confirmed cases as defined by the ATS clinical practice guideline. After applying the developed *index of suspicion* to the initial cohort, we also demonstrated that including a *high index of suspicion* that incorporated information from radiology and clinical domains, but not histopathology, significantly increased the diagnostic accuracy to 100% (95% CI 96.5%-100%). The results of this study will help researchers and health care systems better understand the accuracy of using diagnostic codes alone versus using ICD codes with a *high index of suspicion* for sarcoidosis as classifiers in detecting a complex disease such as sarcoidosis in the EMR. Furthermore, the study highlighted other

computational challenges in querying sarcoidosis cases and accurately extracting high-quality sarcoidosis-related research variables from the EMR. This approach could be adapted to develop automated chart review algorithms using additional data elements from structured and unstructured domains by applying advanced computational methodologies such as natural language processing (NLP) and machine learning.

The randomly selected cohort of veterans in this study with sarcoidosis (with and without confirmed biopsy) consisted of 89.9% (142/158) of men and 10.1% (16/158) of women. Although the gender distribution in our study was different from that in A Case Control Etiologic Study of Sarcoidosis [30], it is closely reflective of the demographics in the veterans' population [31]. This study confirmed the higher prevalence of sarcoidosis in African American individuals (85/158, 53.8%) compared with non-Hispanic White individuals (52/158, 32.9%), a finding that many other epidemiological studies on sarcoidosis have previously reported [32-36]. At the same time, the study population was racially diverse, highlighting the potential utility of the VA EMRs for studying sarcoidosis in medically underserved populations [37]. In our study, the PPV was reasonable compared with the study conducted by Ungprasert et al [14] for detecting patients with sarcoidosis in the EMR. This difference could be due to not using the ICD-10 code and having a less diverse population (85% White vs 9% Black).

Using ICD codes alone to extract health information is far more convenient than the time-consuming process of manually reviewing narrative data sets in unstructured data. However, using ICD codes to identify sarcoidosis cases in large data sets with thousands of patients poses several practical challenges. First, given the heterogeneity of sarcoidosis, it is challenging to efficiently confirm the presence of the disease. The verification process requires careful analysis of the available narrative data such as progress notes, imaging reports, and pathology reports to establish the case definition based on the sarcoidosis diagnostic criteria [3]. Second, the precise identification of the type of organ involvement through the EMR is a complex process and requires a thorough review of unstructured data. Although there are subcodes for ICD diagnostic codes that aim to capture the involvement of various organs, health care providers may or may not be familiar with these subcodes and may or may not use them correctly.

Moreover, there are no specific ICD codes for classifying the involvement of some organs in sarcoidosis (such as the central nervous system or gastrointestinal tract) [38]. Third, ICD codes do not determine the extent of the disease, such as described by the stages of a chest x-ray [39], because of a lack of ICD codes for different stages of pulmonary sarcoidosis [38]. Analysis of pulmonary features requires a manual review of every patient's radiology reports and cannot be performed using only ICD codes. Finally, ICD codes do not specify the various sarcoidosis presentations such as acute, remitting, or chronic disease [29,38]. Thus, they cannot be used to classify patients into the previously described phenotype groups.

The definition of clinical phenotypes has become an essential goal for the sarcoidosis scientific community because genetic studies have identified different patterns of gene expression

associated with disease severity and disease course [40,41]. In 2015, the National Heart, Lung, and Blood Institute held a workshop to leverage current scientific knowledge and define platforms to address disease disparities, identify high-risk phenotypes, and improve sarcoidosis outcomes [25]. A total of 9 different steps and research strategies were recommended to expand the scope of sarcoidosis research, including EMR-based research, to provide a unified and multidisciplinary approach. Such an approach is expected to bring together stakeholders interested in reducing the burden and severity of sarcoidosis. However, the major barrier in the efficient use of EMR data is the accurate extraction of research-quality variables, case definitions, and outcomes [42]. Thus, the rapid identification of cases and extraction of relevant clinical variables from the EMR using computational phenotype algorithms have emerged as an important next step in EMR-based research. Furthermore, computational phenotype definitions are also essential for conducting pragmatic clinical trials and comparative effectiveness research, increasing the health care system's capacity to effectively deliver precision medicine for patients with sarcoidosis [43].

The two most applied approaches to defining computational phenotypes are (1) a *high-throughput* phenotype algorithm using only structured data (traditionally, the ICD diagnosis codes) and (2) a *low-throughput* phenotype algorithm that accesses structured and unstructured data to develop a sequential flowchart that should end with a case definition. Such a low-throughput approach uses high-performance computational tools such as NLP to process text and extract information using linguistic rules, thereby eliminating the need for a labor-intensive manual review by researchers [7]. Accordingly, this approach is expected to streamline the development of registries and help enrich EMR-based research studies [44]. Our study highlights the need to develop such automated methods to improve the computational case definition of sarcoidosis. Besides, there are other high-quality sarcoidosis-related research variables, including determining the date of the diagnosis, organ involvements, Scadding stages, and the clinical status (acute, chronic, or remitting disease). This approach will assist in automating the extraction of pre-existing or novel clinical phenotypes more precisely and efficiently from the EMR.

Limitations

Our study includes several limitations. First, primary histopathological reports were not available for all the patients. In the cases where the biopsy report was unavailable (either because of a remote history of the biopsy or because the biopsy had been performed outside the VA), we relied on the *secondary* histopathological reports documented in the providers' narrative within the clinical notes. This approach made the diagnosis of sarcoidosis less robust because the confirmatory biopsy reports in these patients could not be directly verified. However, we used the *index of suspicion* approach to define probable sarcoidosis cases regardless of whether a confirmatory biopsy report was available, which is consistent with the diagnostic algorithm recommended by the ATS practice guideline [3]. Second, our definition of *multi-organ phenotype* involved ≥3 organs, instead of ≥5 organs as proposed by the GRADS study [29]. We chose this approach because none of the evaluated

patients were documented to have involvement of ≥5 organs, thus avoiding having no patients with *multi-organ phenotype*. Lack of patients with involvement of ≥5 organs could be due to EMR-related limitations such as missing data and variability in documentation among providers or simply because these patients were cared for at non-VA tertiary medical centers. Third, the generalizability of our findings obtained from VA EMRs to other populations could be limited because the veterans form a special population with a different demographic distribution and exposure from the general population. However, the EMR data of the VA health care system cover >22 million veterans across the United States and >14,000 patients with sarcoidosis ICD diagnosis codes, providing an enormous number of patients to study a rare disease. Moreover, the number of patients whose records were examined in this study was 200, which could be considered a small sample size. However, we analyzed data from nearly two-third of all patients with diagnostic codes for sarcoidosis in the VA health care system across northern California.

Conclusions

Although ICD codes can be used as reasonable classifiers to identify sarcoidosis cases within EMRs with a PPV of 79%, using computational algorithms to extract clinical and radiographic information (*index of suspicion*) from unstructured data could significantly improve the accuracy of case identification. Furthermore, to increase the efficiency of identifying sarcoidosis cases from large health care databases, more studies are required to develop a novel sarcoidosis-specific computational phenotype algorithm using automated emerging methods (such as machine learning and NLP). Moreover, our study sets the stage for promoting research on developing other such algorithms aiming to generate high-quality sarcoidosis-related research variables, such as determining the date of the diagnosis, organ involvements, Scadding stages, and the clinical status (acute, chronic, or remitting disease).

Authors' Contributions

MIS and MA obtained funding. MIS, LK, and MA conceived and designed the study research and developed the study protocol. MIS, IM, SZ, CEM, LK, and MA worked on the methods. MIS, IM, SZ, CEM, LK, and MA analyzed and interpreted the data. MIS and IM wrote the original draft. MIS, IM, SZ, GL, MAW, CEM, LK, and MA reviewed and edited the manuscript. All authors read and approved the final manuscript.

Abstract

Background: Increasing physical activity (PA) behavior remains a public health priority, and wearable technology is increasingly being used to support behavior change efforts. Using wearables to capture and provide comprehensive, visually persuasive, multidimensional feedback with real-time support may be a promising way of increasing PA in inactive individuals.

Objective: This study aims to explore whether a 6-week self-monitoring intervention using composite web-based multidimensional PA feedback with real-time daily feedback supports increased PA in adults.

Methods: A 6-week, mixed methods, 2-armed exploratory randomized controlled trial with 6-week follow-up was used, whereby low to moderately active (PA level [PAL] <2.0) adults (mean age 51.3 years, SD 8.4 years; women 28/51, 55%) were randomly assigned to receive the self-monitoring intervention (36/51, 71%) or waiting list control (15/51, 29%). Assessment of PA across multiple health-harnessing PA dimensions (eg, PAL, weekly moderate to vigorous intensity PA, sedentary time, and steps), psychosocial cognitions (eg, behavioral regulation, barrier self-efficacy, and habit strength), and health were made at the prerandomization baseline at 6 and 12 weeks. An exploratory analysis of the mean difference and CIs was conducted using the analysis of covariance model. After the 12-week assessment, intervention participants were interviewed to explore their views on the program.

Results: There were no notable differences in any PA outcome immediately after the intervention; however, at 12 weeks, moderate-to-large effects were observed with a mean difference in PAL of 0.09 (95% CI 0.02-0.15; effect size [Hedges *g*] 0.8), daily moderate-intensity PA of 24 (95% CI 0-45; Hedges *g*=0.6) minutes, weekly moderate-to-vigorous intensity PA of 195 (95% CI 58-331; Hedges *g*=0.8) minutes, and steps of 1545 (95% CI 581-2553; Hedges *g*=0.7). Descriptive analyses suggested that the differences in PA at 12 weeks were more pronounced in women and participants with lower baseline PA levels. Immediately after the intervention, there were favorable differences in autonomous motivation, controlled motivation, perceived competence for PA, and barrier self-efficacy, with the latter sustained at follow-up. Qualitative data implied that the intervention was highly informative for participants and that the real-time feedback element was particularly useful in providing tangible, day-to-day behavioral support.

Conclusions: Using wearable trackers to capture and present sophisticated multidimensional PA feedback combined with discrete real-time support may be a useful way of facilitating changes in behavior. Further investigation into the ways of optimizing the use of wearables in inactive participants and testing the efficacy of this approach via a robust study design is warranted.

Introduction

Background

The health benefits of leading a physically active life are well-established with higher volumes of physical activity (PA), reducing the risk of numerous chronic diseases, mood disorders, and premature mortality [1-3]. In contrast, physical inactivity and prolonged sedentary time have been shown to be independent risk factors for noncommunicable conditions, including type 2 diabetes, cardiovascular disease, cancer, and musculoskeletal disease [4-6]. In addition to health and well-being ramifications, it is estimated that physical inactivity costs US $53.8 billion for health care systems around the world [7]. Collectively, such data stress the need for wide-reaching, cost-effective solutions. The availability, accuracy, and popularity of wearable technology for capturing PA behavior has surged in recent years and presents a potentially useful, affordable, and accessible tool for driving increases in PA levels [8,9]. However, commercial activity monitors are typically marketed at, and used by, young adults who have relatively high baseline PA levels as a means of monitoring exercise performance. Thus, the effectiveness of PA monitoring in inactive populations remains understudied and undetermined [10]. Sophisticated monitoring technology enables personalized motivational and persuasive feedback for individuals who would benefit from an increase in PA [11].

There are multiple dimensions of PA behavior that can independently affect health and well-being [12,13]. Analysis of wearable-derived data shows that individuals can score high and low on any number of these health-harnessing dimensions such as sedentary time, moderate to vigorous PA (MVPA), and overall energy expenditure [14,15], which could present a challenge when providing feedback on the appropriateness of one's behavior. However, this understanding could also be beneficial, as each dimension can be presented as a unique opportunity for behavior change and, in principle, help individuals find bespoke solutions across a person's day, which can help them overcome personal barriers or anchor them to their particular health goals [16]. Moreover, recipients can use reliable multidimensional PA feedback to understand and mitigate against compensatory changes in one aspect of their behavior in response to an attempt to alter another (eg, replacing moderate habitual activity with sedentary time in response to a new exercise regime). Preliminary qualitative data suggest that presenting multiple health-harnessing dimensions to adults is an acceptable, comprehensible, and motivating means of communication that could be readily implemented to support behavior change [17].

The Multidimensional Individualized Physical Activity (MIPACT) trial [18] examined whether a 12-week self-monitoring intervention incorporating multidimensional feedback alongside brief trainer support led to increases in PA behavior among adults at risk of chronic disease. After 3 and 12 months, there was very little change in behavior using this approach despite excellent compliance and adherence [19]. In MIPACT, participants received personal feedback on their multidimensional PA profile and both time spent and energy expended at different PA intensities via the manual upload of data from the monitor to a web-based *app* for viewing their behavior retrospectively. Although this approach is educational and might raise awareness about past behavior [20,21], other persuasive behavioral techniques to support ongoing, acute regulation of behavior or habit formation may be important precursors of sustained change [22,23].

Interventions that have used continuous *real-time* PA feedback (eg, pedometers) have shown promise in supporting changes in PA behavior [24-27]. By extending such work, real-time feedback provided across multiple PA dimensions might compliment a more holistic composite of PA feedback to provide both a *bigger picture* as well as a time-segmented appreciation of PA within the context of people's daily lives. In other words, providing informative data about their progress toward a discrete and achievable activity target in real time can allow people to make quick behavioral adjustments and work toward their overall weekly health goal. The key to such an endeavor is the use of wearable technologies to provide informational feedback and primes based on real-time assessments so as to best capitalize on within-activity motivation *quality* [28].

To best use technological advancements to improve health and well-being, the use of an appropriate motivational theory is a necessity [28]. Self-determination theory (SDT) is a broad and empirically based theory of motivation that provides insight into how to translate informational feedback [29]. At the heart of the SDT is the proposition that people have 3 universal and essential necessities for wellness, healthy functioning, development, and growth, namely the satisfaction of the psychological needs of autonomy, competence, and relatedness [28]. In PA and exercise settings, empirical research has supported the role of need satisfaction in supporting high-quality forms of motivation (ie, autonomous, wherein intrinsic enjoyment and value of the behavior or identified congruence with self-identity guide behavior), better experiences, and higher well-being [28]. Research has also shown autonomous motivation toward exercise to positively predict objectively assessed exercise bouts [30].

Within SDT, it is postulated that when social inputs such as those inherent within interpersonal interactions or embedded in informational, *real-time* feedback satisfy basic psychological needs for autonomy, competence, and relatedness, people are motivated to act for high-quality reasons and experience greater well-being and better experiential outcomes [31]. Applied to the current work, the use of sophisticated PA data visualizations with light touch trainer support, self-monitoring, and real-time feedback was designed to support autonomy (eg, via the provision of choice, exploring new activities or options, and use of meaningful rationales), competence (eg, through the promotion of self-monitoring and clear, constructive, and relevant feedback), and relatedness (eg, demonstrating interest

in people and acknowledging and respecting their perspectives and feelings).

Objective

The primary aim of the present work is to explore whether the provision of sophisticated visual feedback with additional real-time feedback across multiple dimensions of PA supports changes in PA behavior. The secondary aims are to examine whether any changes in behavior lead to meaningful changes in health status over 12 weeks or whether any psychological variables change in response to the intervention. A supplementary aim is to explore the thoughts and feelings of intervention participants to further understand and explain their engagement with and impact of the program.

Methods

Study Design

To explore the efficacy of using combined, multidimensional, composite, and real-time PA feedback on behavior change, a pilot 12-week, 2-armed randomized controlled trial (RCT) design with quantitative and qualitative evaluation was used. The study was registered at ClinicalTrials.gov (NCT02432924) and received ethical approval from the University of Bath's research ethics approval committee for health (reference number: EP 14/15 10). Study outcomes were assessed on 3 occasions. The first 2 assessments were taken before and after a 6-week self-monitoring intervention (or usual behavior if control), with the third assessment following a further 6-week follow-up period in which participants were without feedback. Control participants were offered a 6-week feedback intervention after their third assessment, whereas the intervention group participants were invited to undertake a one-on-one, semistructured interview to provide rich insights into their experience of the intervention.

Participants

Participants were men and women aged between 40 and 70 years who responded to advertisements through the external university webpages, Twitter, and local newspaper articles for people who did not feel they were currently very active. All participants who inquired were sent a participant information sheet and subsequently screened for eligibility via a telephone call. Volunteers were deemed ineligible if they were actively being treated for a chronic disease that might have impeded their ability to change their PA (coronary heart disease, chronic kidney disease [stages 3-5], diabetes mellitus, stroke, heart failure, and peripheral arterial disease) or if they had a PA level (PAL; total energy expenditure divided by resting metabolic

rate) of <2.0, which has been categorized by the World Health Organization as representing a highly active lifestyle [32]. The exploratory nature of this study meant that no formal sample size calculation was undertaken.

Intervention

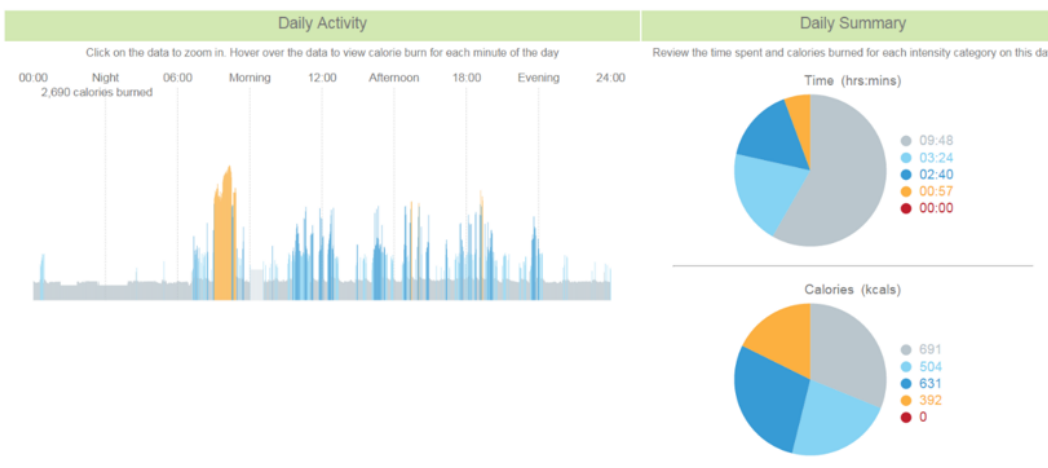
Waiting List Control Arm

The waiting list control group was encouraged to conduct their usual behavior until they had had 2 further assessments in line with those of the intervention group (ie, 6 and 12 weeks after randomization). At the time of revealing their allocation, waiting list participants were informed that upon completion of the third assessment, they would be able to receive the 6-week self-monitoring intervention in full (without any further follow-up assessment) but to carry on as normal in the meantime.

Intervention Arm (6-Week Active Intervention and 6-Week Follow-up)

Participants randomized to the intervention group returned to the University of Bath at their earliest convenience to undertake a set-up session. Here, participants were shown multidimensional feedback on their weekly PA using the MIPACT web platform, as described by Peacock et al [18]. Briefly, the website provides informational feedback in the form of visual representations of their behavior across a 7-day period. To this end, the feedback encompasses five key health targets (Figure 1A): daily calorie burn, sedentary time, accumulated daily minutes of moderate-intensity activity, weekly MVPA in at least 10-minute bouts, and weekly vigorous-intensity activity accumulated in at least 10-minute bouts. Using a simplified and more detailed graphic, participants were shown each target attainment using a traffic light system where green would indicate a hit target, amber would indicate close to the target, and red would indicate a missed target.

Additional feedback was provided in the form of 24-hour PA patterns that were color coded to indicate the intensity of activity at a given minute of the day (Figure 1B). The web platform also included 2 interactive tabs whereby participants could tag activities to learn about and explore the specific intensity and energy expenditure of a given activity or period (Figure 1C) and forward plan future activities that could be superimposed on a given week's PA patterns to visualize and explore the impact of adding new or existing activities on their health targets (Figure 1D). The Ainsworth Compendium of Physical Activities [33] was used as the basis for calculating the intensity category and personalized energy expenditure for each added activity in the menu of PAs.

Figure 1. Features and examples of feedback and functions included on the Multidimensional Individualized Physical Activity web-based platform. (A) Participants were provided feedback using a traffic light–colored health target attainment schematic across the five dimensions and (B) detailed activity patterns and time use summaries colored in accordance with the intensity of activity during each given minute. (C) Participants were also able to review specific segments of a day to learn about the energy cost and intensity of particular activities and (D) were provided with a planning section where they could see how the addition of new activities, derived from the Ainsworth compendium [33], would affect their health targets if imposed over their existing week.


For the real-time feedback element, participants were provided with a Bodymedia Mini (Sensewear; version 8.0) monitor, a smaller model that uses the same algorithms and sensors as the Bodymedia Core used for the assessments, and an accompanying real-time analog display that synced data directly from the armband. The small clip-on display provided feedback on daily accumulated minutes of moderate-intensity activity and minutes of vigorous-intensity activity, calories, and steps that were contextualized alongside the web platform's moderate, vigorous, calorie burn, and nonsedentary time goals, respectively. In

XSL•FO
RenderX

addition to real-time data, the display also stores the total 24-hour values for the previous day and enables users to set personalized targets for each of the 4 activity metrics. If targets were met, a congratulatory message was displayed on the screen, and an alarm sounded to inform the user of their success.

Participants were given an operating manual for the device and encouraged to use it as often as they felt necessary during the 6-week period. Over the course of the intervention period, the participant and researcher met a further 3 times to upload new data from the armband to the MIPACT web platform at weeks 2, 4, and 6. These 15-minute informal sessions afforded each participant the opportunity to troubleshoot any technical queries, get help interpreting their personal multidimensional web feedback, and discuss new plans of action for change. Each session was delivered in a need-supportive manner, encompassing the provision of participant choice; exploration of new activities or plans; and promotion of self-monitoring with clear, constructive, and relevant feedback while taking a clear interest in the perspectives and feelings of the participant [34].

Measurement Procedures

Overview

The baseline laboratory session lasted approximately 45 minutes and involved the signing of informed consent, completion of a questionnaire pack, measurement of brachial seated blood pressure, measurement of anthropometric elements, and retrieval of a fasting venous blood sample from the antecubital vein. Participants were asked to attend the session having abstained from food or caffeine for a minimum of 10 hours. At the end of the session, participants were provided with a PA monitor and instructed to wear the device for 7 consecutive days, removing solely for water-based activities. Participants were also provided with a preaddressed envelope with which to return the activity monitor. The Index of Multiple Deprivation was calculated using participants' postcode on the UK government English indices of deprivation webtool [35], and deprivation decile was extracted for each participant [36]. All procedures other than the signing of informed consent were replicated at the 6- and 12-week follow-up assessment time points.

Primary Outcome: PA

PA was measured using the Bodymedia Mini (Sensewear; version 8.0), which has been shown to accurately measure minute-by-minute energy expenditure [37,38]. To be included in the analysis, participants required a minimum of 6 valid days that included 80% of an assumed 16-hour waking day. On occasions where participants removed the device during sleep or at other times, the estimated resting metabolic rate [39] was assigned to missing data points to complete the 24-hour period. Minute-by-minute energy expenditure was used to determine time (minutes) spent in each of the activity intensity thresholds (sedentary: <1.8 metabolic equivalent of tasks [METs]; light: ≥1.8 and <3.0 METs; moderate: ≥3.0 and <6.0 METs; vigorous: ≥6.0 METs) [40]. These data were used to determine changes in each of the key health-harnessing PA dimensions used in the feedback, including (1) PAL (total energy expenditure divided by resting metabolic rate), (2) sedentary time (percentage of

waking day) and accumulated 1-minute bouts of moderate-intensity activity (minutes per day), (3) MVPA accumulated in bouts of ≥10 minutes (per week), and (5) vigorous-intensity activity accumulated in bouts of ≥10 minutes (per week). The mean daily steps were also determined for each assessment.

Secondary Outcomes: Health Markers

Blood pressure was measured using an automatic sphygmomanometer immediately after 15 minutes of isolated rest. A total of 3 measurements were taken at least 1 minute apart, and the mean of the readings was used as the recorded value. Height was measured without shoes to the nearest millimeter using a Seca stadiometer and weight to the nearest 100 g using a set of digital Tanita (BC-543) scales. These measures were used to calculate BMI (kg/m^2) for each participant. Waist circumference measurements were taken to the nearest millimeter using a Hoechstmass tape measure placed parallel to the floor at the midpoint between the iliac crest and the lowest palpable rib after gentle exhalation. The mean of 3 measurements was taken provided they were within 0.5 cm of one another. A 10 mL fasted venous blood sample was taken at each assessment and used to measure concentrations of plasma glucose, insulin, total cholesterol, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol, triglycerides, and C-reactive protein. These metabolic biomarkers were quantified using commercially available spectrophotometric assays (Randox Laboratories, Co) and enzyme-linked immunosorbent assay (serum insulin only: Mercodia AB). The homeostasis model assessment calculator was used to estimate insulin resistance (Homeostatic Model Assessment of Insulin Resistance-2).

Each participant also completed the EuroQol (EQ) 5-dimension 5-level questionnaire [41], which measures the quality of life across five dimensions: mobility, self-care, usual activities, pain or discomfort, and anxiety or depression. The EQ visual analog scale was used to record patients' overall perception of their health from 0 (worst imaginable) to 100 (best imaginable). The Short Form-36 (SF-36) Health Survey Questionnaire was used to determine any changes in perceived physical and mental health [42]. In total, eight health concepts were measured by the SF-36, with four scales each loaded onto two higher-order factors: physical (physical functioning, physical impact on role, bodily pain, and general health) and mental (ie, vitality, social functioning, emotional impact on role, and mental health) health [43]. Using the standardized scoring algorithms outlined by Ware et al [43], component summary scores were computed for physical and mental health ranging from 0 to 100, with higher scores representing better health status.

Secondary Outcomes: Motivation and Psychological Variables

The questionnaire pack included a collection of instruments for which the reliability and validity of the scores have been described at length by the respective cited authors. Where necessary, the stem of the respective questions was altered from its original wording to refer to *PA* rather than *exercise*. To measure participants' motivation, as propagated within SDT, the Psychological Need Satisfaction in Exercise scale [44] was

used to measure autonomy, competence, and relatedness, and the Behavioral Regulation in Exercise Questionnaire-2 [45] was used to explore the participants' motivation to engage in PA (ie, autonomous and controlled reasons). Perceived competence in PA [46] was also included as a more specific measure of an individual's self-belief. The Barrier Self-Efficacy scale [47] was included to determine whether the intervention changed people's confidence to undergo PA in the face of common obstacles, and the Self-Report Habit Index [48] was used to determine the automaticity of PA behavior. The Subjective Vitality Scale [49] was used to detect changes in vitality.

Postintervention Interviews

Participants who successfully completed the intervention were invited to attend a one-on-one semistructured interview to discuss their experience with the program once all follow-up assessments were completed. The topic guide for these interviews (shown in full in Multimedia Appendix 1) included questions to capture participants' views on the utility and retrospective and prospective impact of the intervention for them and unpick the aspects that were most useful and those that might be improved. The interviews typically lasted between 15 and 25 minutes and were recorded using an Olympus digital voice recorder. In addition, all intervention participants completed a feedback form that included rating scales for aspects of the real-time display (overall, personal targets, calories, steps, moderate and vigorous activity) and web-based feedback (overall, health targets, activity patterns, review function, and planning function). Scores ranged from 1=not useful at all and 3=somewhat useful to 5=extremely useful, with a 0 option if the element in question was not used.

Analysis

Mean differences between intervention and control group participants for 6- and 12-week PA and 95% CIs across each of the 6 feedback dimensions were calculated using an analysis of covariance model [50]. Covariates included baseline values of each outcome variable to control for chance imbalances at baseline (accounting for any unequal variance because of unequal group allocation) and the factors used in balancing the groups (sex and weight status) [51]. Bias-corrected and accelerated bootstrapping was used to verify CIs via 5000 replications, as this approach has been recommended to provide more accurate estimates of SEs and CIs with smaller sample sizes [52-54]. The same analysis was used to explore differences

in health outcomes and psychosocial variables at 6 and 12 weeks. Effect sizes (Hedges g) are provided for the mean difference between intervention and control across each variable and are interpreted as 0.2, 0.5, and 0.8 for small, moderate, and large effects, respectively [55]. A post hoc subgroup analysis to explore interactions with covariates observed at 12 weeks was performed, whereby unadjusted means and SDs were calculated to explore whether male versus female and participants with low versus high baseline PA had more pronounced changes in PA data.

Qualitative interviews were interpreted using descriptive deductive and inductive qualitative analyses based on the principles of thematic analysis [56]. Audio files were transcribed verbatim and uploaded to NVivo (version 11; QRS International) for coding and analysis. The lead author, who conducted the interviews, reread through each participant transcript for familiarization and then coded themes within the data. When all transcripts were coded, the themes were compared among participants, and common recurring viewpoints and other important insights were presented in the *Results* section as themes.

Results

Participants

Figure 2 shows the flow of the participants through the study. Of the 102 inquiries, 57 (55.9%) participants were eligible, of whom 5 (9%) were excluded for being too active (PAL ≥2.0) at baseline, and 1 (2%) withdrew because of an allergic reaction to the PA assessment device; therefore, 51 (89%) participants were randomized into either the intervention group or the waiting list control group in a 2:1 allocation ratio to learn more about the intervention. A statistician external to the research team completed randomization and did not disclose any of the details before the completion of recruitment. The statistician stratified the participants by sex (male or female) and weight status (with BMI ≥30 kg/m^2 as the binary cutoff point) using a block size of 6 (which was revealed to the researcher team after the study), giving an overall allocation of 36:15 in favor of the intervention group. No participant withdrew from the study, although one of the intervention participants declined to undergo the end-of-intervention interview. The baseline characteristics of the participants are displayed in Table 1.

Primary Outcome: PA

All 51 participants provided complete PA data at the 6- and 12-week time points and baseline and were therefore included in the exploratory analysis of the primary outcome. The baseline characteristics of the participants are shown in Table 1. The total 24-hour wear time across the week for the 3 assessment time points was, on average, 98% (SD 1.6%), 96% (SD 8.2%), and 95% (SD 8.1%) in the intervention group and 95% (SD 7.9%), 95% (SD 8.7%), and 94% (SD 12.4%) in the control group, respectively. Table 2 shows the adjusted mean difference (95% CIs) between the intervention and control groups at the 6- and 12-week time points and effect sizes for each PA outcome.

There were no observed differences in any PA outcomes at the 6-week end-of-intervention assessment. At 12 weeks, relative to control participants, the intervention group had reduced mean daily sedentary time by −40 (95% CI −76 to −4) min/day and increased light-intensity activity by 14 (95% CI −78 to 45) minutes per day, moderate-intensity activity by 22 (95% CI 1-45) minutes per day, and vigorous-intensity activity by 2 (95% CI −1 to 6) minutes per day. Post hoc descriptive analysis of subgroups indicated that changes in PA were more pronounced in female participants than in males and for individuals with lower baseline PA levels at 12 weeks (Multimedia Appendix 2, Tables S1 and S2).

Table 2. Mean scores, adjusted mean difference between intervention and control groups, and effect sizes (with 95% CIs) across physical activity dimensions at 6 and 12 weeks.

Outcome and time point	Intervention (n=36)[a], mean (95% CI)	Control (n=15)[a], mean (95% CI)	Adjusted mean difference[a,b] (95% CI)	Effect size, Hedges g (95% CI)

Week 12	8782 (7987 to 9656)	7236 (6496 to 7991)	1545 (581 to 2553)	0.7 (0.1 to 1.3)

[a]CIs were verified using a bias-corrected and accelerated bootstrap with 5000 replications.

[b]Covariates included stratified randomization factors (BMI at baseline and sex) and baseline scores for the respective outcome variables.

[c]PAL: physical activity level.

[d]Mean total daily energy expenditure divided by daily resting metabolic rate.

[e]TEE: total energy expenditure.

[f]RMR: resting metabolic rate.

[g]N/A: not applicable.

[h]Percentage of waking day.

[i]All minutes ≥3 metabolic equivalents of task.

[j]Activity ≥6 metabolic equivalents of task (vigorous) or ≥3 metabolic equivalents of task (MVPA) accumulated in ≥10 minutes was counted.

[k]MVPA: moderate to vigorous physical activity.

[l]Mean daily step count.

Secondary Outcomes: Health and Well-being

There were no 6- or 12-week differences in any of the cardiometabolic health outcomes measured between the intervention and control groups, except for insulin resistance calculated at week 12. The mental health component summary of the SF-36 improved in the intervention group at 12 weeks; however, neither the SF-S6 nor the physical component summary, EQ 5-dimension 5-level questionnaire, or visual analog scale scores were different at any other time point. The baseline, 6-week, and 12-week scores for all variables are shown in Table 3.

Table 3. Secondary health and psychosocial outcomes at 6 and 12 weeks (N=51)[a].

Outcome and week	Baseline, mean (SD)	Intervention, mean (95% CI[b])	Control, mean (95% CI[b])	Adjusted mean difference (95% CI[b])	Effect size (Hedges *g*)
Health and well-being					
Systolic blood pressure (mm Hg)					
6 weeks	124 (14)	123 (118 to 128)	123 (118 to 128)	0.2 (−4.69 to 4.86)	0.02
12 weeks	124 (14)	124 (120 to 127)	120 (113 to 127)	4.33 (−3.33 to 11.43)	0.43
Diastolic blood pressure (mm Hg)					
6 weeks	86 (10)	86 (83 to 90)	88 (83 to 93)	−1.53 (−6.03 to 3.21)	−0.20
12 weeks	86 (10)	88 (85 to 91)	86 (81 to 91)	1.85 (−3.88 to 7.79)	0.21
Body mass (kg)					
6 weeks	81.9 (14.4)	81.6 (77.8 to 85.4)	82.3 (78.6 to 86.1)	−0.74 (−1.86 to 0.49)	−0.44

12 weeks	1.6 (1.0)	2.1 (1.8 to 2.3)	1.7 (1.3 to 2)	0.41 (−0.04 to 0.86)	0.58

[a]Covariates include baseline score for each parameter (as indicated in the pooled mean baseline column), BMI, and sex.

[b]CIs verified using bias-corrected and accelerated bootstrapping with 5000 repetitions.

[c]HDL: high-density lipoprotein.

[d]LDL: low-density lipoprotein.

[e]CRP: C-reactive protein.

[f]EQ-5D VAS: EuroQol 5-dimension visual analog scale.

[g]EQ-5D-5L: EuroQol 5-dimension 5-level questionnaire.

[h]SF-36: Short Form-36.

Secondary Outcomes: Motivation and Psychosocial Variables

Relative to the control group, the intervention group had a reduction in controlled behavioral regulation (external and introjected regulation), and increases in autonomous behavioral regulation (intrinsic, integrated and identified regulation), perceived competence for PA and habit strength at the 6-week assessment but not at 12 weeks. Barrier self-efficacy was increased in the intervention group at 6 weeks and was sustained at the 12-week follow-up. Subjective vitality was also increased in the intervention group at 6 weeks but was not sustained until 12 weeks. No changes in overall psychological need satisfaction or its subscales were observed (Table 3).

Intervention Component Evaluation

Participants were asked to provide their subjective ratings of the *usefulness* of intervention features at the 6-week assessment and qualitative feedback following their 12-week assessment. From the subjective ratings participants ranked the real-time display (mean 4.5, SD 0.8) higher than the web-based MIPACT platform (mean 3.3, SD 1.5) using a scale from 1 *not useful at all* to 5 *very useful*, or 0=*not used*. Each aspect of the real-time display consistently rated as more useful than the features of the web platform. Specifically, the display of calorie data (mean 4.0, SD 0.9), steps (mean 4.3, SD 0.7), moderate-vigorous activity (mean 4.3, SD 1.2) and having personal targets (mean 4.0, SD 1.5) was rated higher than the composite health target

(mean 3.6, SD 1.5) and activity pattern (mean 3.7, SD 1.5) data. The lowest-ranked features were the more interactive web-based tools, namely the review (mean 2.3, SD 2.0) and planning (mean 2.0, SD 1.9) sections of the MIPACT website.

Qualitative Evaluation

Qualitative feedback offers further insight into these ratings. Textbox 1 provides a summary of the key themes identified in the analysis of intervention participants' interviews and quotations to illustrate each theme. All intervention participants championed the feedback as useful for raising their consciousness and awareness of their own PA behavior, with many mentioning an improved understanding of the time they spent inactive (theme 1). More than half of the intervention participants postulated that PA was now more of a priority after having been through the program and that it reinforced their belief that PA was a means of improving health (theme 2). The self-monitoring element helped individuals gauge how much PA was required to meet certain health recommendations (theme 3). According to many of the participants, the program inspired them to increase their PA levels, and two-thirds alluded to the fact that the multidimensional nature of the feedback assisted them in finding personal solutions (theme 4). Some participants said that during the 6-week program, they would consciously go out of their way to achieve the targets, and many put added emphasis on steps as a key and achievable daily motivator (theme 5).

Textbox 1. Key themes identified in the qualitative analysis and example quotations (participant information provided as sex, age, baseline physical activity level).

Theme 1: personalized feedback improved understanding of one's own behavior

- *I think it's, it's changed, it's changed my day-to-day activity, and I am a lot more conscious of the fact that I am sitting a lot, and part of it, there was a realisation that I wasn't very active.* [male, 46 years, 1.48]

- *Yeah, I think I was probably overestimating what I was doing, I thought I was more active than I was in a way so...when you see it's like oh you are actually doing as much as I thought I'd probably on my feet but I'm not necessarily so doing anything that is going to benefit me stop so yeah it's definitely made me more aware of the need.* [female, 42 years, 1.42]

Theme 2: physical activity is now more of a priority or reinforced importance

- *Um, well it certainly hasn't become any less important. I probably would say that it has become more important because the awareness breeds that sort of feeling, you know, that this is something that is not just a one-off, you know. Over a three-month period, it's, it's life and it should continue.* [male, 59 years, 1.72]

- *And then hopefully, my hope is, as ie, as I lose weight...Because that's one thing I haven't done is lost weight...um, is once I have lost more weight that I will feel fitter and then I can up that target. But I don't want to try and do too much, too soon.* [female, 62 years, 1.25]

Theme 3: feedback helped people understand how to meet recommendations

- *I found it interesting, you know? Because I know how many steps it takes me to go down our town and round and back to the house it's at about 1800, I think. And I know how many is to go to the railway and things like that.* [female, 63 years, 1.37]

- *But of course, that whole thing then tipped me nicely over and I was...So, it had that useful upturn, and equally, as I said before, it helps me gauge just exactly how much distance I need to be covering to meet a, sort of a standard target.* [male, 48 years, 1.65]

Theme 4: feedback helped motivate and find personalized solutions to increase physical activity

- *So, I knew that I had to just get back into doing something...And having that monitor was almost like a critical friend, it was there to say 'you can do this.'* [female, 48 years, 1.55]

- *Yes, that really helped and then over the six-week period, every week I was trying to do a little bit more and like I say, it's not very difficult to do it's just that now you are conscious of it and you are aware of it that you have to achieve so many steps per day.* [male, 48 years, 1.87]

- *Definitely. Anything is worth it. Any...Any activity, it doesn't have to be gym five days a week. If I wasn't doing five days a week at the gym, I didn't consider myself to be active, basically. So now I know that because I wasn't training five days a week, and I was actually able to show some green lights when I wasn't doing the fi...it makes me realise that all of it counts. It's completely changed. I'm actually more active because I'm down on myself for not doing five days a week at the gym.* [female, 44 years, 1.52]

- *And it's achievable without knocking myself flat you know I can do it in little steps and I can move myself forward in little ways rather than try and charge at a wall and break through a wall. It is much easier that way. So again, using the word empowerment it has sort of empowered me into thinking I could do this.* [male, 54 years, 1.39]

Theme 5: real-time feedback prompted attainment of acute daily goals

- *Um, and I did find it motivating, and I did, um, you know, I was known to leave the house at kind of five minutes to bedtime to walk around the block at the time...Or spend five minutes doing star jumps to try and get vigorous activity in. So yes, having the targets I found very helpful, and yeah, and motivating and interesting and fun.* [female, 56 years, 1.56]

- *Um, I did actually, I surprised myself in how easy it was to make step goals. I did not think I walked that much but as soon as I was just tracking it, it was like "actually I'm not far off daily amounts if I just do a little bit more and better hit that target.* [male, 41 years, 1.53]

Theme 6: now able to fit more physical activity into routine

- *Making a conscious almost, not a plan, plan is probably a bit too grand, but saying 'right each week I must do a certain amount of activity' and I plan that and think about it and so...The type of person I am, I'm quite a sort of structured and quite organised person so just building that into my routine is a change in my behaviour.* [male, 53 years, 1.86]

Theme 7: injury and illness hampered progress during intervention

- *Right, um, it was slightly complicated by the fact that I was ill right in the middle of it so...I started off really motivated and felt really good about it and it was building very well. And then unfortunately, after about a month I guess, I got this fluey type thing, which really did kick in and, made it a bit of a struggle to do as much and build as much as I wanted to do it. And then of course it's sort of came to the end of the programme really so I don't feel like I did it as much justice as I would have liked to have done.* [female, 67 years, 1.58]

Theme 8: felt confident in keeping up or increase physical activity further

- *Yeah, it definitely made me think a bit more about the moderate bouts of activity and how important they are. And it made me more keen to do things like walking the dogs and, you know, walks to school and I wouldn't the thought that to be useful before. And I think 'oh they are quite a useful way of getting in extra steps.'* [female, 43 years, 1.71]

Theme 9: intervention led to improved confidence and enjoyment of physical activity

- *Yeah. I mean, variety...yeah, I think that's been really helpful, actually. Because it's less boring and, um, you don't perceive it as...I think my perception of what exercise was and what it actually is very different now. So now activity isn't exercise. Activity is just anything.* [female, 45 years, 1.52]

- *Knowing how more confident I am, which I, perhaps if I wasn't recording it somewhere I wouldn't have been aware of that...So that's erm, yeah that's a nice position to be in, having seen confidence increase with various things, various types of activities, it's a nice position to be in for sort of in the future.* [female, 48 years, 1.51]

Theme 10: intervention prompted participants to purchase or consider purchasing a real-time feedback device

- *It has spurred me on to get one of these, to actually buy one of these Fitbits. Which is just going to continue to let me know in real-time exactly what I'm doing and very similar in fact it is in steps and calories burnt off and what have you and the fact everyone else in the office have got one.* [female, 60 years, 1.52]

- *Which I suppose sounds really obvious when you say it, but it hadn't ever linked with me before. And, I now have a little Fitbit because I want to now...I've become slightly obsessed with steps.* [female, 63 years, 1.37]

Theme 11: real-time feedback element considered the most useful element of the intervention

- *The instant display I think is what...I mean, I did go online that that's in retrospect, you didn't get to see that until you had already done it. Whereas in today's society we want instant answers so having the display and being able to look at it, um, was, you know, was motivating.* [female, 62 years, 1.25]

- *Um, the, the monitoring device, I found I used the little tiny daily, daily monitor, all the time...that was almost obsessive!* [male, 46 years, 1.48]

Theme 12: web-based feedback useful initial picture

- *You see on the computer screen and it was just flat line, I think that that is, visually, or when you look at it and you look at the figures and you look at that...that had probably quite an impact. And I think that that is...Probably the wake-up call which will remain with me, yeah, visually seeing it.* [male, 64 years, 1.72]

Theme 13: web-based component could be improved

- *Because I could only look at it at certain times at home without being able to do it when I wanted to do it was frustrating...If you see what I mean? So, just only having a sort of biweekly uploaded my information...I wish I could have just done it as and when and seen more feedback.* [male, 41 years, 1.53]

- *I think to be perfectly honest it was...it was sort of time element of it. I didn't feel that I had the time just to sit and...and look at it, which I probably should have done, but it felt as if the more instantaneous response from the monitor was actually...or the display was...was what I needed on a day-to-day basis.* [female, 52 years, 1.64]

Theme 14: some issues with device comfort or data trust

- *The exercise I tend to do is like cycling and the bottom half of my body it probably won't show a great deal of vigorous activity. Which, okay it is the limitation of the technology and the technology at that time, but I was mildly irritated by that.* [male, 55 years, 1.50]

Theme 15: suggested improvements

- *10,000 steps is nice and easy cause that's just walking, you can just incorporate that into your daily activity, but then the vigorous activity, I could do it if I go for a run, but any other way I wouldn't know. I only had ideas of cycling and rowing and though there are suggestions, but a programme of how you can achieve them would have been helpful.* [female, 45 years, 1.60]

- *So, if you said to me your cholesterol is 5 at the end of the study you told me my cholesterol...well...I found out my cholesterol...because you know cholesterol response to exercise had dropped to 3.5 that would have been a big encouragement.* [female, 55 years, 1.61]

Most of the intervention group felt that they were now being more proactive about fitting PA into their routine after the intervention (theme 6), whereas a handful of participants alleged to have had an illness or injury during the program that hampered their progress (theme 7). Approximately two-thirds of participants expressed further intentions to take up new, or perform more, PA, and approximately half of the group felt confident that they could maintain their PA levels after the program and had made lasting behavioral changes (theme 8). In addition, some participants felt that they had improved their confidence and sense of competence for PA, whereas others expressed a greater enjoyment for PA and an improved sense of health and well-being (theme 9). Many participants said that they missed not having the real-time activity monitor once it was removed after 6 weeks, and by the time of the interview, approximately one-third of participants had purchased a commercial PA tracker for personal use, with many more considering acquiring a device (theme 10).

For many of the intervention participants, the real-time display was a favorable component for the self-monitoring of activity and more important than website feedback (theme 11). That said, there was still a reasonable proportion of participants who made reference to the multidimensional feedback as a useful way of viewing the overall picture, and some even described it as a wake-up call (theme 12). Some participants suggested that

their engagement with the feedback on the web platform may have been improved if it was more readily available and that sitting down at a computer felt counterintuitive to being (more) physically active (theme 13). The data also revealed that for certain participants, there were minor issues with the device itself in terms of either trusting the feedback or its wearability (theme 14). Finally, a handful of participants made recommendations for the improved utility of the monitor and feedback system, which included the need for more prompts and guidance or links to their health data collected during assessment sessions to help them evaluate the impact of more PA or for motivation (theme 15).

Discussion

Principal Findings

In this exploratory RCT, we evaluated a 6-week intervention using personalized real-time digital PA feedback and sophisticated web-based multidimensional PA feedback combined with brief trainer support. Exploratory analysis demonstrated no change in PA between groups immediately after the intervention; however, improvements were found for several PA metrics that formed part of the feedback at the 12 weeks follow-up. Subgroup analysis suggests that this effect was more pronounced in female participants and in those with lower baseline activity levels. Very little changed in respect to secondary health outcomes, with the exception of insulin resistance and self-reported mental health, which showed signs of improvement after 12 weeks. Qualitative data suggest that participants found the multicomponent intervention informative and motivating, with the real-time feedback being heralded as the single most memorable and supportive component within the context of the overall treatment package.

Comparison With Other Literature

A novel aspect of this study was the multidimensional approach that, we hypothesized, helps individuals to understand their behavior and find bespoke behavioral solutions for increasing their PA [16]. We hypothesized that using a multidimensional approach to PA promotion and feedback would provide options and self-endorsed choices to foster autonomous motivation and would satisfy the needs for autonomy and competence. Following the 6-week active phase of the intervention, we witnessed favorable improvements in autonomous versus controlled motivation, perceived competence, and barrier self-efficacy, which offers support for the proposed mechanism and the multidimensional approach. Moreover, the qualitative evaluation aligns with our previous development work, which found that receiving detailed, visual multidimensional PA feedback is helpful for raising awareness, understanding, and intention to change [17,20]. We hypothesized that the addition of real-time feedback might help translate those intentions into behavior [57,58]. However, beneficial differences in PA were only observed after a 6-week period in which the whole treatment package (including the real-time display) was removed rather than immediately after the active intervention. Participants expressed that they valued the real-time feedback during the interview more than other components of the intervention and highlighted that it empowered them to adjust their behavior on

a more discrete basis as they strive toward a desired daily target (eg, serving as a prompt to take an additional 1000-step walk if they were short toward the end of a day).

Other studies have observed real-time feedback to be an effective tool for increasing PA when used in conjunction with detailed web-based feedback and trainer support. Vandelenotte et al [27] demonstrated that adding a Fitbit device to their theory-informed web-based PA intervention increased total PA and MVPA by up to 3 times relative to a nontracker, web-only group. Their study, whose website went beyond the provision of feedback to provide individually tailored advice on a number of self-regulation strategies, found that real-time monitoring also improved engagement and adherence to the main web content and the overall package of behavioral support. Similarly, a large RCT by Harris et al [25] found that combining brief nurse support, retrospective accelerometer feedback, and continuous pedometer feedback led to significant, sustained changes in PA in the intervention versus control groups at 3 and 12 months. In another trial, the same research team demonstrated that continuous pedometer feedback provided effective support both with and without trainer input versus a control group with no feedback or trainer support [24]. The effects observed in these studies, albeit modest in size, were maintained after 3- to 4-year follow-up periods [59], suggesting that technology-based PA interventions such as the one used in this study can help individuals make long-lasting changes.

Our qualitative findings corroborated key findings from the Pedometer And Consultation Evaluation-U and Pedometer Accelerometer Consultation Evaluation-Lift studies, which were conducted by Harris et al [24,25]. Specifically, participants who received the nurse-led pedometer intervention experienced greater awareness of the PA guidelines and their own PA levels. They also placed more importance on being active and helped participants to embed PA in their own routines [25,60,61]. Participants also found real-time feedback useful for initiating and monitoring behavior change in relation to personalized goals, and, mirroring the findings reported in the present work, some went on to invest in other wearable trackers after their intervention, although distrust in the accuracy was identified as a potential barrier to effectiveness [60]. A set of themes derived from this study (eg, illness and injury) and the work of Harris et al [25] (eg, weather and lack of time) was the fact that common external barriers still existed for participants that could not be overcome by the real-time feedback interventions. Recommendations from participants in these and other qualitative studies suggest that more interpersonal prompts and guidance, resources for planning activities, meaningful challenges, and links to health data may be avenues to overcome barriers and enhance intrinsic motivation and behavioral maintenance in real-time feedback-based interventions [62-64].

The incongruent findings observed at 6 (immediately after the intervention, no difference) and 12 weeks (after a 6-week follow-up, moderate to large effects) warrant further consideration. The assessment used in this study and most RCTs with device-based PA outcomes relied on weekly snapshots of participants' behavior. The small sample size and variability around the mean scores of the control group suggest that any fluctuations might be because of noise in the assessment. In the

intervention group, a weekly snapshot may not give an accurate representation of a person's true behavior [65]. Continuous measurement in both intervention and control groups would help decipher whether the 6-week observation is, for example, indicative of a dip in behavior following the removal of feedback, or whether the 12-week observations is, for example, indicative of the intervention participants learned rather than new habitual behavior. Given the advancing technology that enables long-term data capture, future studies would do well to investigate the stability and representativeness of PA behavior to guide trials on the most appropriate assessment window.

Strengths and Limitations

The strengths of this study include the almost complete 24-7 objective, PA assessment and high compliance to the intervention, measured as the completeness of attendance to upload sessions and PA monitor wear time in the intervention group, and assessments in all groups (all 100%). The use of quantitative and qualitative evaluations also provides rich insights into the effectiveness of this approach. Limitations include the small sample size, short follow-up period, and use of a nonclinical population, which prevents the performance of more robust statistical analyses and means that any interpretation of these results should be viewed as preliminary rather than definitive and generalizable.

There is also a need to improve the synchronicity of the wearable devices as, in this study, technical issues meant that global web-based feedback could not be fully self-monitored without the trainer needing to recalibrate the personal targets and user profile used within the real-time display. This lack of autonomy over the web platform use may contribute to a more favorable evaluation of the real-time feedback element. Accordingly, we can determine neither the respective contributions of the real-time, web-based, or trainer support on individual participants' behavior change nor whether favorable perceptions of the real-time element would have been the same without the more comprehensive web-based feedback. Recent meta-analyses of SDT-based techniques support the notion that different self-regulatory and trainer-delivered strategies may be useful for optimizing an individual's motivation for PA [66,67]. Therefore, it is unlikely that any single component will be effective in isolation and that multicomponent interventions are required to provide optimal behavioral support. Nonetheless, future trials using more adaptable, multiple-group designs such as the multiphase optimization strategy would be advised to augment the complex intervention and evaluate the relative and complementary importance of the different elements [68].

Conclusions

In conclusion, this exploratory RCT represents the first attempt at combining multidimensional feedback with real-time data and light touch trainer support across several important health-harnessing dimensions of PA as a means of helping individuals change their behavior. The results suggest that this approach may be a useful strategy for helping individuals with low levels of PA change their behavior. These findings can inform the design of future studies with larger and more diverse sample sizes, detailed process evaluations, and longer follow-up periods to explore the effectiveness of real-time, multidimensional feedback.

Abstract

Background: Chronic pain affects approximately 30% of the general population, severely degrades quality of life (especially in older adults) and professional life (inability or reduction in the ability to work and loss of employment), and leads to billions in additional health care costs. Moreover, available painkillers are old, with limited efficacy and can cause significant adverse effects. Thus, there is a need for innovation in the management of chronic pain. Better characterization of patients could help to identify the predictors of successful treatments, and thus, guide physicians in the initial choice of treatment and in the follow-up of their patients. Nevertheless, current assessments of patients with chronic pain provide only fragmentary data on painful daily

experiences. Real-life monitoring of subjective and objective markers of chronic pain using mobile health (mHealth) programs can address this issue.

Objective: We hypothesized that regular patient self-monitoring using an mHealth app would lead physicians to obtain deeper understanding and new insight into patients with chronic pain and that, for patients, regular self-monitoring using an mHealth app would play a positive therapeutic role and improve adherence to treatment. We aimed to evaluate the feasibility and acceptability of a new mHealth app called eDOL.

Methods: We conducted an observational study to assess the feasibility and acceptability of the eDOL tool. Patients completed several questionnaires using the tool over a period of 2 weeks and repeated assessments weekly over a period of 3 months. Physicians saw their patients at a follow-up visit that took place at least 3 months after the inclusion visit. A composite criterion of the acceptability and feasibility of the eDOL tool was calculated after the completion of study using satisfaction surveys from both patients and physicians.

Results: Data from 105 patients (of 133 who were included) were analyzed. The rate of adherence was 61.9% (65/105) after 3 months. The median acceptability score was 7 (out of 10) for both patients and physicians. There was a high rate of completion of the baseline questionnaires and assessments (mean 89.3%), and a low rate of completion of the follow-up questionnaires and assessments (63.8% (67/105) and 61.9% (65/105) respectively). We were also able to characterize subgroups of patients and determine a profile of those who adhered to eDOL. We obtained 4 clusters that differ from each other in their biopsychosocial characteristics. Cluster 4 corresponds to patients with more disabling chronic pain (daily impact and comorbidities) and vice versa for cluster 1.

Conclusions: This work demonstrates that eDOL is highly feasible and acceptable for both patients with chronic pain and their physicians. It also shows that such a tool can integrate many parameters to ensure the detailed characterization of patients for future research works and pain management.

Trial Registration: ClinicalTrial.gov NCT03931694; http://clinicaltrials.gov/ct2/show/NCT03931694

Introduction

Chronic pain affects approximately 30% of the general population [1-6] and was 1 of the top 5 leading causes of years lived with disability in 2016 [7], especially among older people [8]. Societal and economic issues are also crucial, as 60% of people with chronic pain are less able or unable to work, and 20% report having lost their job as a result [9]. The overall cost of chronic pain is estimated to be approximately €441 billion in Europe (equivalent to approximately US $496 billion) and $560 to $635 billion in the United States [10-12]. At the same time, the market for analgesic drugs represented approximately $68 billion in 2016, and an increase from 2% to 5% was forecast for 2021, with a further 5% increase by 2025 [13,14]. Unfortunately, available analgesics are old, their effectiveness is limited, with undesirable effects, and little progress has been made in recent years [15]. Thus, innovation is limited despite prolific basic research [16].

Various reasons are given for this, including the relevance of animal research [17]. In particular, because of the low success rate of validation of preclinical concepts during the transition to the clinic. Developments in this area could help progress, but such progress could also come from better patient characterization that would help to identify the predictors of successful treatments through research programs and enable physicians to carry out better decision-making regarding the initial choice of treatment and its follow-up. Subgroups of patients and criteria for response to particular treatments, for example, in patients with neuropathic pain [18], have been

identified; however, such characterization should not be limited to biomedical assessment but should also include biopsychosocial assessment. Moreover, current assessments of patients with chronic pain provide only fragmentary data on daily experiences because of recall bias. Thus, it is essential to modify the temporality in which patients' sensations are assessed, with real-life monitoring of subjective and objective markers of chronic pain. This strategy is currently being developed by several research teams evaluating smartphone apps or web platforms for use in managing the treatment of patients with chronic pain [19-24].

We hypothesized that regular self-monitoring by patients using a digital app would generate in-depth knowledge and new insights for physicians, and would allow patients to be active in their own care and benefit from web-based counseling. Regular self-monitoring would not only contribute to better patient characterization and help in choosing the most appropriate treatment but may also improve adherence to treatment. Moreover, recent studies [19,20,24-31] have highlighted the urgent need to develop eHealth self-monitoring programs for chronic pain and their therapeutic value—web-based pain management programs (The Pain Course) based on principles of cognitive behavior therapy were found to be beneficial for patients by reducing pain symptoms and associated comorbidities [20,32-34], and there is therapeutic interest in mobile health (mHealth) technologies for managing the medical treatments of patients suffering from chronic pain [27]. In this pilot study, we aimed to evaluate the feasibility and

XSL•FO

RenderX

acceptability of a new mHealth app and web platform, called eDOL, for patients and physicians.

Methods

Ethics

The study was approved by the *Comité de Protection des Personnes Ile de France V* (2018-A01790-5546) and is registered (NCT03931694). The study was conducted in accordance with French laws and regulations on research on human beings and data protection and with the Declaration of Helsinki [35].

Confidentiality and Data Entry and Processing

Data were collected and managed using the eDOL app, developed by Bepatient and hosted by Avenir Télématique. In accordance with the provisions relating to the confidentiality of information concerning, in particular, the people who took part in the research and the results obtained [36], individuals with direct access have taken all the necessary precautions to ensure the confidentiality of the information relating to the participants. These persons and the investigators themselves are subject to professional secrecy [37]. All data collected and transmitted to the sponsor (University Hospital of Clermont-Ferrand) were anonymized, and each patient had a single coded number. The head of research ensured that each patient was informed of which data were collected and that they did not object to their use or disclosure.

Answers to questionnaires and medical data were transmitted in spreadsheet format (Excel 2013, Microsoft Inc). All anonymized data were accessible to the biostatisticians (BP, SC, and AJD), the coordinator (ND), and the project manager (NK). Only the investigators could access their patients' personal data to identify them. A dashboard linking patients' identities and study IDs was available only on the investigators' professional interface on the eDOL web platform. The final database, used for statistical analyses, included only study IDs to preserve anonymity.

Study Design and Population

To evaluate the feasibility and acceptability of the eDOL app for the characterization, real-life monitoring of patients with chronic pain from 12 pain clinics in France took place between February 8, 2019 and January 8, 2020. The study was offered to all physicians in the investigating centers.

Participation in the study was offered to patients with chronic pain who did not have cancer, who were owners and regular users of a smartphone, and who were followed up in a pain clinic. All adult (≥18 years old) patients able to read and understand French and provide consent to participate in the study were included (with a yes-or-no choice on the eDOL app). Participants were free to withdraw their consent at any time by informing the sponsor. Each patient had access to the information document (paper or electronic) detailing the purpose, content, and conduct of the study. If they agreed to participate, they were asked to download the eDOL app and complete the questionnaires using the eDOL app. The URL to access this app was sent by email from physicians to their

patients. After downloading the app and creating their profile, patients could accept the general terms and conditions of use and confirm that they agree to the use of their medical data in this study.

Each patient had 1 initial study visit, during which, the physician introduced the study to the patient, checked their eligibility, explained the eDOL tool, and gave the patient a brief training document on how to use the eDOL smartphone app. Participants completed several questionnaires and assessments using the eDOL app over a period of 2 weeks (initial patient characterization) and then repeatedly over a period of 3 months and up to 6 months for patients who wished to continue using the app (weekly, quarterly, and half-yearly depending on the questionnaire). Physicians saw their patient at a follow-up visit that took place at least 3 months after the inclusion visit, with the possibility of continuing the follow-up for up to 6 months. The study was considered complete for patients who completed their questionnaires and assessments for at least 3 months and made a follow-up visit 3 to 6 months after the inclusion visit.

eDOL App

All data were collected using the eDOL digital health tool, which includes a smartphone app for patients that allows self-questionnaires and assessments to be completed for semiological monitoring (pain, anxiety, sleep quality), and a web interface for physicians, to allow them to graphically visualize the summary of data provided by their patients for clinical and therapeutic monitoring.

Patients completed questionnaires and weekly assessments (Multimedia Appendix 1). The questionnaires were divided into general questionnaires that were systematically filled in once only (sociodemographic, lifestyle and professional data, Pain Beliefs and Perceptions Inventory [38]; Evaluation of level of precariousness [39]; Injustice Experience Questionnaire [40]; Maslach Burn-out Inventory [41]; Toronto Alexithymia Scale [42]; Life Orientation Test-Revised [43]; Belief in a just world [44]; Job Content Questionnaire [45]; Big Five Inventory [46]) and questionnaires, assessing symptoms, comorbidities, and psychological and physiological states related to chronic pain, that were completed quarterly (Brief Pain Inventory [47]; Medical Outcomes Study Sleep Scale [48]) and, according to duration of follow-up, half-yearly (Tampa Scale of Kinesiophobia [49]; Pain Catastrophizing Scale [50]; Fear-avoidance beliefs [51]; EQ-5D-3L [52]; Hospital Anxiety Depression Scale [53]; Satisfaction With Life Scale [54]; Subjective Cognitive Complaints [55]). Some questionnaires were specific to a type of chronic pain (Neuropathic Pain Scale Inventory [56]; Western Ontario and McMaster Universities [57]; Rheumatoid Arthritis Impact of Disease [58]; Roland Morris Disability Questionnaire [59]; Irritable Bowel Severity Scoring System [60]; Fibromyalgia Impact Questionnaire [61]; Headache Impact Test [62]). Follow-up of patients (daily monitoring of various objective and subjective parameters related to the pathology), using assessments, was also integrated in the app, which allowed us to monitor the evolution of patients' pain and its repercussions. Assessments were in the form of an 11-point numeric rating scale (from 0 to 10), assessing the intensity of pain (average, minimum, or maximum intensity),

anxiety, fatigue, and the quality of sleep, morale, body comfort were assessed weekly for 3 to 6 months.

For physicians, the eDOL internet platform included a simple and ergonomic dashboard which allowed the physician to find all of their patients included in the study, with the following tabs: (1) Management, in which all of the medical records completed by the physician could be found (history, pain diagnosis, initial characterization, next appointment, consultation sheets and treatment sheets); (2) Health Measures, which showed a graphic display of the real-life follow-up of all the weekly assessments; and (3) Questionnaires, which showed all the questionnaires completed by the patients (display of questionnaire scores and answers to all the questions). The eDOL platform enabled physicians to complete medical elements during consultation visits with various medical form

(diagnosis, current treatments, examination results). The physicians could also activate new questionnaires to be filled in by their patients, either to complete the characterization (eg, specific questionnaires for pain diagnosis) or to evaluate other criteria (eg, evaluation of the Patients' Global Impression of Change after the introduction of a new treatment [63]). Diagnostic questionnaires (Posttraumatic stress disorder Checklist [64]; Neuropathic pain 4 [65]; Fibromyalgia Rapid Screening Tool [66]), reminders of the criteria for diagnoses (ROME IV for irritable bowel syndrome; Widespread pain index and Symptom severity scale of American college of rheumatology for fibromyalgia; Neuropathic Pain IASP Special Interest Groups for neuropathic pain), and screening tools for opioid misuse (Prescription Opioid Misuse Index [67] and Opioid Risk Tool [68]) were also at their disposal (Table 1).

Table 1. eDOL features.

Feature	Included in	Assessment point or interval	Details
Inclusion form	Investigator web platform	Initial visit	Last name, first name, email, ID number
		Initial visit	History (clinical, psychiatric, drug), clinical examination, medico-economic aspect (type of medical consultations), diagnosis of pain according to International Classification of Disease, 11th revision
Personal information	Smartphone app	Initial visit	Sociodemographic (work, alcohol use, tobacco use)
		Initial visit	Pain characterization: frequency, duration, aggravating and alleviating factors
Treatment forms	Investigator web platform	Updated at each consultation	Analgesics (name, dates, dosage, side effects); list of nonmedicinal techniques and other treatments (free text)
Assessments	Smartphone app	Repeated weekly	11-point numeric rating scale (0-10): sleep, morale, fatigue and energy, body comfort, anxiety, pain
Self-questionnaires	Smartphone app	During the first 2 weeks	5 sessions of questionnaires
		Not repeated	Fear-avoidance beliefs[a], Injustice Experience Questionnaire, Maslach Burn-out Inventory[a], Pain Beliefs and Perceptions Inventory, Evaluation of level of precariousness, Job Content Questionnaire[a], Life Orientation Test-Revised, Belief in a just world, Posttraumatic Stress Disorder Checklist[b], Toronto Alexithymia Scale Big Five Inventory
		Every 3 months	Fibromyalgia Impact Questionnaire[c], Headache Impact Test[c], irritable bowel severity scoring system[c], Prescription Opioid Misuse Index[b], Patients' Global Impression of Change[b], Neuropathic Pain Scale Inventory[b], Rheumatoid Arthritis Impact of Disease[b], Brief Pain Inventory, Medical Outcomes Study Sleep Scale
		Every 6 months	Tampa Scale of Kinesiophobia, Roland Morris Disability Questionnaire[c], Western Ontario and McMaster Universities[c], Pain Catastrophizing Scale, EuroQol 5 dimensions 3 levels, Hospital Anxiety Depression Scale, Satisfaction With Life Scale, Subjective Cognitive Complaints
Hetero-questionnaires	Investigator web platform	N/A[d]	Diagnostic validation: Neuropathic pain 4 + NEUPSIG (neuropathy), Widespread pain index and Symptom severity scale and Fibromyalgia Rapid Screening Tool (fibromyalgia), ROME IV (irritable bowel syndrome)
		Updated at each consultation	Others: Opioid Risk Tool
Consultation form	Investigator web platform	Updated at each consultation	clinical examination, medico-eco aspect, observance, benefit-risk ratio of treatments

[a]Work-related questionnaires.

[b]Optional questionnaires.

[c]Disease-specific questionnaires

[d]N/A: not applicable.

Study Outcomes

The primary study endpoint reflected the acceptability of the eDOL app and the feasibility of its use and was assessed with a satisfaction survey (based on the Patient Satisfaction Questionnaire Short Form [69] and the Client Satisfaction Questionnaire [70,71]) for patients (10 questions) and for participating physicians (12 questions) at the end of the study. The satisfaction survey (in French language) was sent to each patient 6 months after their inclusion visit and was sent to the physicians after the last patient follow-up, via the eDOL tool. Response options for each question ranged from 0 (strongly disagree with the statement) to 10 (strongly agree with the statement). A mean score of at least 7 out of 10 was considered to reflect satisfactory acceptability and feasibility of the eDOL

tool. The questionnaire completion rate and center participation (inclusion rate) were also calculated.

Secondary analyses to characterize participating patients, pain disorders, and related comorbidities, as well as clustering analysis of the participants to determine the profile determination of patients who adhered to the use of the app were undertaken to gain insight into the capabilities and added value of the tool for the characterization and the follow-up of patients with chronic pain.

Statistics

Sample Size

A minimum of 100 patients were to be included and analyzed. Such a large number of patients is quite satisfactory in terms of

descriptive analyses to study the feasibility of a multimodal eHealth tool. This number of patients is in line with that specified by Sundararaman et al [27] and those used in other recent studies [19,23,24,72] evaluating smartphone apps in patients with chronic pain. This number of patients (n=100) allowed us to analyze in an exploratory way: (1) the characterization of patients with chronic pain followed-up in pain clinics, (2) the description and understanding of their pain, (3) the multiple dimensions and the numerous neuropsychiatric repercussions of chronic pain, and (4) the clustering of the participants and the determination of adhering patients' profiles.

Statistical Analysis

We performed statistical analyses to determine if patients and physicians were satisfied with the tool and adhered to its use, and to identify interesting pain profiles of patients, and which profiles are most adherent (and for how long).

Patients were described according to epidemiological characteristics, clinical characteristics, and treatment characteristics. The key indicators for acceptability (patient and physician) were questionnaire completion and completion of follow-up medical forms. We determined the association between adherence and all baseline variables. A patient was defined as adherent if 100% of baseline questionnaires and 75% of assessments after 3 months follow-up were completed.

Continuous variables and scale variables (treated as ordinal data) were presented as mean and standard deviation (for normal distributions), or median and quartiles (for asymmetric distributions). The normality assumption was assessed with graphical criterion and the Shapiro-Wilk test. Categorical variables were expressed in number and percentage.

We performed clustering analysis. Patients were clustered according the symptoms and comorbidity information y. This clustering analysis included data imputation, principal component analysis of baseline data, and ascending hierarchical classification gathering 90% of total inertia. From these components, the hierarchical classification [73] in Euclidean coordinates was used.

Comparisons (baseline vs 3-month follow-up, by patient adherence, and by cluster) were performed using the chi-square test or Fisher exact test when assumptions to apply chi-square were not met (minimal level of expected number of cases under independence assumption), for categorical variables, and using analysis of variance (or Kruskal-Wallis tests when the assumptions to apply analysis of variance were not met). When the omnibus P value was statistically significant ($P<.05$), posthoc tests (independent t test or Mann-Whitney) were applied to compare subgroups with each other. The results were expressed using effect sizes (Cramer V for categorical data and eta square for quantitative data) with 95% confidence intervals. Pearson (preferred between all distributions acknowledged as Gaussian) or Spearman correlation coefficients (otherwise) were calculated depending on the nature of the distribution.

We used Stata (version 15, StataCorp LLC) and R (version 4.0.3) software. All statistical tests were 2-sided with type I error set at 5%.

Results

Study Population

Of 133 patients from 12 French pain clinics, 28 patients (28/133, 21.0%) did not install the eDOL app; data from 105 patients were analyzed. The first patient was enrolled on February 6, 2019, and the last patient was enrolled on October 31, 2019.

At baseline, participating patients were mostly middle-aged women, in a couple, nonsmoking, and professionals. Among these patients, 35.3% (30/85) were in work stoppage due to their chronic pain. A more detailed characterization of the patients, with the help of several validated questionnaires, mainly showed that a significant number were considered precarious (43.0%; 40/93), with kinesiophobia (72.0%; 67/93), alexithymia (51/100, 51%), degraded life satisfaction (51/92, 55.4%), catastrophism (47/100, 47.0%) and a possible cognitive disorder (77/93, 82.8%). More than 65% (63/94, 67.0%) of patients had impaired sleep, and 37.2% (35/94) and 27.7% (26/94) had proven anxiety or depressive disorders respectively.

Regarding the characterization of pain disorders and their treatments, most patients (76/83, 91.6%) had moderate to severe pain intensity, of which 20.5% (17/83) had a high chronic pain interference score (called "high impact chronic pain" [74]). Most patients (50/80, 62.5%) suffered from nociplastic pain, with a duration longer than 5 years for more than 50% (55/105, 52.4%) of patients. The majority of patients (56/105, 53.3%) described their chronic pain as permanent (with painful paroxysms every day and lasting >2 hours) and inducing frequent nocturnal awakenings (45/105, 42.8%). Finally, analgesic treatments used by the patients were mainly antidepressants followed by weak opioids (with or without paracetamol), and antiepileptics to a lesser extent. In parallel, 89.2% (66/74) of patients used nonmedicinal analgesic treatments.

There was no difference in any of these characteristics between baseline and the 3-month follow-up (Multimedia Appendix 2).

Primary Objective: Feasibility and Acceptability

Among 105 patients, 65 (61.9%) adhered to the use of the eDOL tool and 50 patients continued using the eDOL tool up to 6-month follow-up (Figure 1).

In detail, the overall rate of patient who completed the baseline questionnaires was 89.3% (range 79.0%-95.2%). The quarterly questionnaires, Brief Pain Inventory and Medical Outcomes Study Sleep Scale, were repeatedly filled at 3-month follow-up by 63.8% (67/105) of patients. For the half-yearly questionnaires (Tampa Scale of Kinesiophobia; Pain Catastrophizing Scale; EQ-5D-3L; Hospital Anxiety Depression Scale; Satisfaction With Life Scale and Subjective Cognitive Complaints), 58.7% (range 53.8%-63.1%) of patients completed the questionnaires. The filling rate of the weekly assessments for the real-life monitoring of the different parameters (pain, moral, anxiety, fatigue, sleep and body comfort) was 88.6% (93/105) of patients at the end of the first week and 61.9% (65/105) at 3-month follow-up (Table 2; Figure 2; Multimedia Appendix 3). Due to the small number of patients, we did not show the results concerning the specific questionnaires, filled by only a few

patients according to their professional situation (questionnaires on work) and their type of pain (disease-specific questionnaires). The rate of patients whose various medical follow-up forms were completed by the investigators (inclusion, treatment and consultation) was 70.7% (range 62.9-76.2%) (Table 2).

[a]N/A: not applicable.

Figure 2. Completion rate over time.
Among the 12 pain clinics participating in the study, 10 (83.3%) included patients, and 2 withdrew from participation before the start of the study. The median inclusion number per center was 8 (IQR 5.0, 14.0) patients. The inclusion objective (at least 100 analyzable patients) was achieved in less than a year as requested from the investigating centers.

The satisfaction questionnaire was filled in by 65.7% (69/105) of patients at the end of the study. The median acceptability score was 7.0 (IQR 6.1, 7.6), with only 9.5% (10/105) of the patients providing a rating less than 5.0 out of 10. Moreover, 88.6% (93/105) of the patients who responded wanted to participate in the further development of the eDOL app. The items with the lowest scores corresponded to the patients' perception of the physicians' use of eDOL in their follow-up (mean 5.7, SD 3.1), patients' perception of the potential positive

impact of eDOL on their pain management (mean 5.8, SD 2.7), and quality of life (mean 5.6, SD 2.4).

A total of 21 physicians participated in the study and included at least one patient, and 15 (71.4%) answered the satisfaction questionnaire. The physicians were mostly women (14/21, 66.7%), approximately 50.1 years old (range 33-61), and were from various specialties (2 neurologists, 2 psychiatrists, 3 anesthesiologists, 3 rheumatologists, and 5 general practitioners). The median acceptability score was 7.2 (IQR 6.8, 8.3), with only 6.7% (1/15) of physicians rating less than 5.0 out of 10. The items with the lowest scores corresponded to the compatibility of eDOL with the electronic medical file systems (mean 5.0, SD 2.3) and the possibility of eventually replacing the electronic medical files with the eDOL tool (mean 4.4, SD 1.9) (Table 3).

Table 3. Physician and patient acceptability of eDOL.

Acceptability questionnaire	Score (out of 10), mean (SD)
Physician	
The training and support provided was sufficient to use eDOL correctly	7.3 (1.4)
After the first training session, it is easy to use eDOL on a daily basis	6.9 (2.3)
The technical support (email and phone) was available to assist me if needed	8.3 (1.2)
eDOL offers questionnaires and assessments adapted to the multidimensional characterization of my patients	8.3 (1.2)
The forms I had to fill in for each patient are adapted and they correspond to the information I usually collect	6.8 (2.0)
Thanks to the export function provided in eDOL, I was able to retrieve the completed information for my patients. I was then able to print it (for my patient records) and/or import it into my hospital's electronic management system	5.0 (2.3)
The eDOL platform is complete enough to be able to replace my medical records one day	4.4 (1.9)
I would like to continue using eDOL in the future	7.3 (2.0)
eDOL will be useful in my daily medical practice	6.8 (1.6)
eDOL will allow me to better monitor my patients to improve their care	7.1 (1.6)
eDOL will be useful for developing clinical research on pain (creation of an e-cohort of patients with chronic pain)	9.0 (0.9)
eDOL will be useful for the clinical research projects conducted by my pain clinic	8.5 (1.7)
Patient[a]	
After reading the explanatory document provided by the physician, it was easy for me to use eDOL	8.4 (2.1)
After the first use, it is easy to use eDOL on a daily basis	8.7 (1.9)
The technical support was responsive enough when I asked for it	7.0 (2.7)
eDOL offers questionnaires and assessments that I feel are suitable for monitoring my pain and its impact on my daily life	7.0 (2.1)
I believe that the information I have entered in eDOL allows my doctor to better understand my pain and improve its management	6.9 (2.5)
During the time that I have been using eDOL, I feel that my doctor has better monitored my symptoms and that my pain has been better managed	5.7 (3.1)
I believe that the information I have entered in eDOL will also help researchers to better understand chronic pain and to identify new avenues of research	7.5 (2.3)
I think that eDOL will help me in my daily life to better manage my pain and its impact on my daily life	5.8 (2.7)
I think that eDOL will gradually improve my quality of life	5.6 (2.4)
I would like to continue using eDOL in the future	7.6 (2.8)

[a]88.5% indicated they would participate in the next phase of study on the new version of eDOL.

Secondary Objectives

We obtained 4 clusters that did not differ with respect to sociodemographic and chronic pain characteristics (except for pain interference with daily life) and their treatments (Multimedia Appendix 4). Interestingly, all patient characteristics obtained from validated biopsychosocial questionnaires differed between profiles. In particular, the patients in cluster 4 had more severe scores in various biopsychosocial and comorbidity scales (precariousness, anxiety, depression, kinesiophobia, sleep and cognitive disorders; $P<.001$) associated with a greater impact of pain and conversely for cluster 1. Clusters 2 and 3 were intermediate groups.

In Cluster 4, 80.0% (24/30) of patients adhered to the use of the tool, compared with 51.0% (19/37), 64.3% (9/14), and 43.5% (10/23) in clusters 1, 2, and 3, respectively (Multimedia Appendix 4). Moreover, type of pain was also related to adherence, with patients suffering from nociplastic pain who seemed to be more adherent than others (30/45, 66.7%; $P=.01$). It is noteworthy that 2 other items (presence of cognitive disorders and alexithymia) were related to adherence ($P=.04$), but with a small effect size (Cramer $V=.03$ and Cramer $V=.20$ respectively).

With reference to the profile of patients in cluster 4, the most severe patients, with a significant impact of pain on their daily life ($P=.03$), seemed to be those who adhered most to eDOL (24/62, 38.7% of patients who adhered to the use of the tool were in cluster 4).

Discussion

Overview

As this was primarily a feasibility study, we first discuss considerations regarding the data collection and acceptability, and then our exploratory results with respect to conducting future works and improving eDOL. Because of the low number of patients (and thus the limited longitudinal outcome data collected), we did not explore the impact of eDOL on pain disorders and related comorbidities.

Feasibility

Our results showed a rate of adherence, after 3-month follow-up, of approximately 60% (65/105, 61.9%) of patients using eDOL. Three similar recent studies [24,27,31], which assessed a smartphone app that enables patients with chronic pain to assess, monitor, and communicate their status to their providers, showed that 76%, 70%, and 72% of patients used the app for 3 months. Another study [20], which assessed a remotely delivered pain management program in a web-based format (web platform), showed that 76% of patients adhered [20] for at least 3 months. A study [75] with adolescents with chronic pain showed a high level of adherence (78%) and satisfaction, and a study [72] with patients with multiple sclerosis and migraine that evaluated the feasibility of using a smartphone app for patient follow-up showed an adherence rate of 49% after 90 days. The eDOL tool seems to be accepted in a similar way to these other smartphone-based or web-based apps. In our study, only an email reminder was sent to our patients if they had not used the app within 2 weeks after their inclusion and only 1 visit (included in their usual care path) was scheduled after at least 3 months. The studies [20,24,27,31,72,75] cited above included regular telephone follow-up or frequent visits. Moreover, according to the mean score (5.7, SD 3.1) for the statement "During the time that I have been using eDOL, I feel that my doctor has better monitored my symptoms and that my pain has been better managed," patients perceived that there was a lack of involvement of physicians in the eDOL tool. A study [76] showed that strong involvement by physicians increases adherence and the effectiveness of eHealth tools. Therefore, we can assume that a closer relationship with our patients (medical follow-up rhythm and involvement of physicians) would have further increased their adherence. This is undoubtedly a direction of research that should be taken for the future use of the app and patient follow-up; however, we must keep in mind that the aim of a real-life eHealth app is to be of little or no constraint for patients and to improve their medical follow-up, while lightening the physician's workload.

The good acceptability score, from both patients and physicians, reflects the interest expressed for eDOL and its contribution to the follow-up. Thus, eDOL could meet the urgent need to develop self-management and chronic pain management strategies through eHealth programs (internet, smartphone apps), and their therapeutic interest, as described by several studies [19,20,24-30].

Exploratory Analyses

In our exploratory analyses, our study population was similar to the profile of patients suffering from chronic pain in France [77], Germany [78], the United Kingdom [2], Canada [79], or the United States [74,80,81]—predominantly female, middle-aged, active population of lower socioeconomic status (precariousness, employment status, level of education), with pain lasting more than 5 years and suffering from psychological distress and from fairly severe chronic pain that has a significant impact on their lives (92% with moderate-to-severe pain, 20% with high impact chronic pain [74] and 43% with sleep disorders, such as awakenings due to pain at least once a night), mainly treated by antidepressants, and weak opioids. Interestingly, most did not simultaneously explore sociodemographic, psychological, pain disorders, and treatments characteristics.

With our smartphone app, we were able to collect data on precariousness, kinesiophobia, catastrophism, alexithymia, feelings of injustice, personality, life satisfaction, beliefs about pain, anxiety-depression, sleep, quality of life, cognitive disorders, optimism and belief in a just world. We made this choice because all of these factors are related to chronic pain [38,40,50,77,82-90] and we wanted to evaluate the ability of eDOL to characterize our patients precisely. Thus, the strength of eDOL is that it enables the integration of a large panel of validated questionnaires that, in turn, enable the precise characterization of the patients, especially regarding their emotional and psychological state, chronic pain, and related comorbidities. This characterization will eventually provide a large amount of data for care and research, and rely on a multimodal exploratory analysis of the determinants and repercussions of chronic pain, and their evolution in a real-life context, taking into account all the environmental events likely to influence chronic pain (treatments, history, comorbidities).

Finally, the multifactorial analysis of all our data enabled us to group our study population into 4 clusters. Interestingly, subpopulations of our patients could be distinguished only on the basis of biopsychosocial questionnaires and impact of pain on daily life whereas sociodemographic aspects, symptomatology, seniority and treatment of pain did not differ between our clusters. Cluster 4 represented patients with more disabling chronic pain, more severe comorbidities, and more pronounced psychological disorders, while cluster 1 represented patients with chronic pain that has little impact on their daily life, as well as a lower presence of comorbidity. Cluster 4 had a higher proportion of adherent patients. Our findings were similar results to those in a recent study [31], which showed that adherent patients correspond to patients with high impact chronic pain. These results seem consistent because patients with high impact chronic pain [74] and associated comorbidities are more in need of a tool that potentially improves their medical follow-up and are therefore more inclined to use it. Moreover, nociplastic pain was related to adherence (P=.01). According to our experience with chronic pain treatment management, this characteristic could be explained both by the fact that patients suffering from nociplastic pain (especially fibromyalgia) are younger than the general chronic pain population (and thus, more digital friendly) and very involved in the management of

their pain. Interestingly, the presence of cognitive disorders and alexithymia, independent of clusters, was related to adherence (*P*=.04). We hypothesize that patients with these disorders are aware of this and compensate by using eDOL as a digital companion, resulting in better adherence.

In addition, our results support the importance of questionnaires assessing the biopsychosocial aspect of chronic pain in addition to the biomedical aspect in the medical follow-up and characterization of patients with chronic pain. Moreover, in a classical medical follow-up, patients typically only see their pain specialist every 3 to 6 months. During these interviews, patients often have difficulties recalling their various symptoms and the impact of their pain over the past few months, which corresponds to a recall or memory bias [91]. Nevertheless, a review [92] demonstrates that the results of previous studies investigating this topic are highly variable. Some studies have shown that pain is remembered accurately [93-95], but others highlighted that patients tend to overestimate [96,97] or underestimate their pain [98]. Thus, a definitive answer to this question is still lacking, but real-life monitoring of different biopsychosocial and biomedical factors related to pain (not only pain intensity), using digital tools such as eDOL, could be a benefit in treatment management and the follow-up of patients.

Limitations

There was a selection bias mainly because requiring the use of a smartphones excludes patients who do not have or do not know how to use this tool. This could exclude the older or more precarious patients. Nevertheless, in view of our results, the age of the participants and the rate of precariousness were similar to those found in the general French population, with and without chronic pain [77,99]. We also observed that our population included many patients with nociplastic pain (mainly fibromyalgia, 50/80, 62.5%), which was not the case in other foreign studies [20,24,27,31,72,75]. Another French study [77] also found a high rate of fibromyalgia (42%), which seems to show that the population of French pain clinics includes a large proportion of fibromyalgia patients. Thus, we can conclude that this bias has little impact on our results. The second limitation was a measurement bias, which occurs frequently in observational studies [100]. Nevertheless, self-reporting permits a wider range of responses than many other data collection designs [101]. Measurement bias can arise from recall period, selective recall, social desirability, or sampling approach. In our study, the recall period might be the major risk [100]. Since all the questions dealt with the present moment or, at the latest, 1 to 2 weeks earlier, the recall bias can be considered negligible.

Moreover, our satisfaction survey was not a standardized but was a custom-made tool. We built this tool based on existing tools, such as the Patient Satisfaction Questionnaire [69] and the Client Satisfaction Questionnaire [70,71], and adapted it to our study and to the eDOL tool so that we could have specific feedback for improvement. It should be noted that the tools on which ours were based have little or no relevance to mHealth interventions [70], hence the need to create one adapted specifically for our study.

Finally, only physicians were involved in this feasibility study; other members of the care team, such as nurses, physiotherapists, and psychologists, did not participate in the study. The absence of the point of view of the rest of care teams is a limitation to the interpretation of the acceptability of the eDOL tool. In future studies of the eDOL tool, we plan to include all the members of the care team as well as the addition of a chatbot and a new therapeutic education tool.

Conclusions

The study demonstrated the feasibility and acceptability of eDOL for both patients with chronic pain and their physicians. These points justify continuing the deployment of the tool while providing information to improve its use and adherence to provide patients with chronic pain and their physicians with a better longitudinal characterization of pain and its impacts for an optimized and more personalized therapeutic management.

Abstract

Background: Information behavior describes all human behaviors in relation to information. Individuals experiencing disruption or stigma often use internet-based tools and spaces to meet their associated information needs. One such context is pregnancy loss, which, although impactful and common, has been absent from much of feminist and reproductive health and information behavior scholarship. By understanding information behavior after pregnancy loss and accounting for it in designing internet-based information spaces, we can take a meaningful step toward countering the stigma and silence that many who experience such loss endure, facilitate coping, and make space for diverse pregnancy narratives in our society.

Objective: This study's objective is to provide a characterization of internet-based information behavior after pregnancy loss.

Methods: We examined internet-based information behavior after pregnancy loss through 9 in-depth interviews with individuals residing in the United States. We analyzed the data by using open and axial coding.

Results: We identified the following three themes in relation to participants' information behavior in internet-based spaces: needed information types, information-related concerns, and information outcomes. We drew from information behavior frameworks to interpret the processes and concerns described by participants as they moved from recognizing information needs to searching for information and to using information and experiencing outcomes. Specifically, we aligned these themes with information use concepts from the information behavior literature—information search, knowledge construction, information production, information application, and information effects. Participants' main concerns centered on being able to easily find information (ie, searchability), particularly on topics that had already been covered (ie, persistence), and, once found, being able to assess the information for its relevance, helpfulness, and credibility (ie, assessability). We suggest the following design implications that support health information behavior: assessability, persistence, and searchability.

Conclusions: We examined internet-based information behavior in the context of pregnancy loss, an important yet silenced reproductive health experience. Owing to the prevalence of information seeking during pregnancy, we advocate that generic pregnancy-related information spaces should address the needs related to pregnancy loss that we identified in addition to spaces dedicated to pregnancy loss. Such a shift could not only support those who use these spaces to manage pregnancies and then experience a loss but also help combat the silence and stigma associated with loss and the linear and normative narrative by which pregnancies are often represented.

Introduction

Background

When humans face uncertainty, disruption, stigma, or distress, helpful information encounters can be beneficial in making sense of their experiences and assist in deciding how to move forward. These encounters can occur through passive (eg, finding information without seeking information) or active information seeking. Information behavior is a concept that describes all human behavior related to information, including active seeking, browsing, and information use [1]. Social media and other internet-based tools such as search engines are important to modern information seekers, especially when information needs are not met through traditional means [2,3] and when a topic may carry a stigma in a given culture and context. This is particularly true for health information behavior.

In fact, 59% of US adults report seeking health information on the internet; 39% use the internet to determine their diagnosis, and 53% of these *internet-based diagnosers* use the information found on the internet in discussions with clinicians [4]. It is well-established that individuals experiencing health conditions (which can be disruptive, distressing, and stigmatizing) use internet-based tools to assist in managing their experiences. For example, prior work at the intersection of health and information behavior provides insights into information seeking [5], social support exchange [6,7], and how to design for better search [8-10] or educational experiences [11], including the utility of internet-based spaces in a range of reproductive health contexts (eg, infertility [12,13] or pregnancy while diabetic [14]). In this work, we examine health information behavior (including seeking, sharing, using, and the impact) as mediated and facilitated through internet-based spaces and tools in a key reproductive health context—pregnancy loss—for which such behavior remains to be explored.

Pregnancy loss is often colloquially referred to as *miscarriage.* By *pregnancy loss,* we mean the unintended loss of a desired pregnancy at any gestational stage. Pregnancy loss is an important context for investigating information behavior as it is distressing, stigmatizing, disruptive, and traumatizing for many. It challenges people's identities as expecting parents and changes interpersonal relationships but is generally absent from societal narratives of grief or reproduction [15]. Furthermore, individuals experiencing pregnancy loss report negative interactions with medical providers, family, and friends [15]. We aligned our work with that of Layne [16], a feminist anthropologist, and Andalibi [17], a human-computer interaction (HCI) researcher, who argued that pregnancy loss should be included in feminist reproductive health discourse and pregnancy-related technology design, respectively. Indeed, the analysis of pregnancy-related mobile apps by Andalibi [17] illustrates the lack of consideration for pregnancy loss as a possible outcome of pregnancy in most apps that individuals with pregnancies use and argues that this reinforces linear, normative narratives about pregnancy and is marginalizing and harmful. The sociocultural context surrounding pregnancy loss leaves many without basic information about it, which can complicate and hinder coping.

Prior information behavior research concerning stigmatizing and distressing experiences [2,18,19] has explored the challenges people face when engaging with authority figures (eg, care providers) and how they can leverage internet-based information to fill needs not met in clinical encounters. Such work provides insights into the information that specific groups seek [20,21], how privileged and other communities differ in their use of information to inform their care [22], and the benefits and challenges individuals face when finding information on the internet [12,21,23,24]. With respect to pregnancy loss, prior work has examined topics such as social support and self-disclosure at the intersection of pregnancy loss and technology [25-27], showing how internet-based spaces are sites for support exchange, sensemaking, and validation or invalidation [28-30]. A recent study provided insights into information needs after loss, including general information about loss, counseling resources, others' experiences, and information from providers [28]. We built on these works to explore the dimensions of information behavior after pregnancy loss in relation to existing internet-based spaces, the needs these spaces help meet, challenges they pose to individuals enduring a pregnancy loss, and outcomes.

We conducted interviews with women in the United States who had recently experienced a pregnancy loss and who used social media. We reported on 3 themes related to needed information types, information-related concerns, and information outcomes as mediated through internet-based spaces and tools. We interpreted these themes by drawing from conceptions of information use synthesized by Kari [31]: information search, knowledge construction, information production, applying information, and the effects of information. We found two main categories of information need—evidence-based and experience-based information—echoing health information needs research in other contexts [32,33]. Participants' main information concerns were related to their ability to find information and their ability to assess the credibility of the information they found. Finally, we found that internet-based information encounters could lead to not only finding answers to questions but also learning what questions to ask and sometimes how to advocate for oneself in clinical encounters or even consider advocating for oneself as an option.

By examining information behavior in relation to experiencing personal uncertainty, disruption, stigma, or distress, we can better understand the ways people go about meeting their information needs, thus uncovering the challenges and benefits they face in day-to-day information encounters. This knowledge will (1) allow technologists and researchers to design technologies that meet people's information needs in times of distress and fit into their existing practices with the potential to positively affect their well-being and (2) improve clinicians' understanding of the pregnancy loss experience.

It should be noted that we advocate that pregnancy loss is not just a women's health topic—individuals not identifying as women can also experience pregnancy and loss, and these experiences are important. In this study, although our recruitment efforts were not limited to individuals identifying as women, all participants were women. Therefore, we used this framing and terminology throughout this paper.

Related Work

Information Behavior

Wilson [1] presented a general model of information behavior comprising information need, seeking, processing, and use and consideration of the role that an individual's environment can play in their information behavior. The model by Wilson [1] has become a foundation for researchers exploring information behavior. However, Wilson [1] only accounts for when one has a known information need. Erdelez [34] extended the information behavior theories to encompass the processing of information that one was not actively seeking, termed *information encountering*. This concept allows for the exploration of the use of technologies in an information-saturated environment [34-36].

Prior scholarships have examined information behavior by examining information use. Kari [31] conducted a systematic literature review on information use within the information studies field and outlined 7 major conceptions that we draw from in interpreting our findings. In this paper, we explore the health information behavior of individuals who have experienced pregnancy loss and seek information on the internet. These conceptions, proposed by Kari [31], are relevant to our study of information behavior related to pregnancy loss:

- Information search: the processes of information seeking and information retrieval
- Knowledge construction: mental constructs are shaped or designed to function as a basis of thinking
- Information production: creating an expression of knowledge, which others can also observe
- Applying information: information functions as a resource in some processes
- Effects of information: changes brought about by information

HCI scholarship's examination of information behavior has mainly centered on the concepts of information need [28] and information search (eg, how social contexts, environments, specific disabilities, or even mood can influence individuals' information-seeking behavior [8-10,37,38]). In this study, we recognized the need to go beyond information seeking and consider information use concepts.

Health Information Behavior and Internet-Based Spaces

Health information behavior encompasses the general model created by Wilson [1] but with the information component being health information, which includes how individuals seek information about their health and health risks and examines their engagement or disengagement with health information in connection to information use concepts [31,39]. Health information seekers, both offline and on the internet, admit a heavy reliance on medical professionals for information. Medical professionals are often the first choice; however, the prevalence of internet-based resources and an optional social component has made internet-based health information seeking widespread in the United States [40,41]. Marginalized and stigmatized communities may especially benefit from finding additional health information, which they can present to their medical professionals to counteract language barriers, bias, and

general dismissal [20,42]. Therefore, these groups are primed to become innovative information seekers, as they are likely to turn to and trust outside sources of health information [20-22]. Internet-based spaces can provide sources for information and support for those who are denied it or who do not sufficiently trust sources such as medical professionals to consult them [27,43,44].

Prior research has identified two types of health information: expertise-based information, which is produced by medical professionals, and experience-based information, which refers to information shared based on subjective first-hand health experiences [32]. People use both evidence-based health information and experience-based health information found on internet sites, social networking sites, and blogs [33]. Experience-based information also affects people's health behaviors [33]. Examining health information behavior may allow us to better design health information needs.

Previous scholarship has emphasized investigating the behavior of medical professionals to better design future technology that can assist in streamlining their processes [45-48]. Noted as early as 10 years before this study [49], investigating the context of health information searching and use by individuals experiencing health conditions is also necessary to design information spaces on the internet in support of health. There have been developments in research on consumer health information behavior, even if not framed using information behavior theories, with communities such as older adults [50], pregnancy (excluding loss) [51,52], and HIV information seekers [24]. There remains a need to examine the breadth of health information topics, depth of health information seeker communities, and varied behaviors and outcomes once information is discovered. A context that is in and of itself important but that can also teach us about other stigmatizing and marginalized health experiences is pregnancy loss.

Pregnancy, Pregnancy Loss, and Information Behavior in Internet-Based Spaces

Information behavior scholarship related to coping with pregnancy loss is scarce, even as scholars examine the information behavior of individuals with pregnancies. Women with pregnancies use internet resources to manage pregnancies [53,54]. In fact, social media and other internet-based resources play an important role in the information needs of expectant individuals in the United States [53-56].

The information needs of individuals with pregnancies have been a research focus [57,58], although only with generic mentions of pregnancy loss, with few exceptions [28]. Similarly, design research [59,60] in the pregnancy space has largely not accounted for pregnancy loss. The significance of pregnancy loss is often minimized and rendered *invisible*. Gold et al [61] were among the first to examine internet-based support seeking of individuals who have experienced pregnancy loss, finding that internet-based support can provide a safe haven from in-person stigma and revealing a preference for moderators within these spaces. This highlights the need to understand pregnancy loss–related information needs and behavior, especially as there is no unique way in which loss is experienced [28].

We focus on pregnancy loss to examine how individuals who are enduring a loss use internet-based spaces to meet their information needs and identify the challenges and outcomes they face in this process. We effectively examine information behavior mediated through internet-based spaces for individuals enduring a pregnancy loss. Pregnancy loss, in this sense, is more broadly situated within both reproductive health and women's health.

Pregnancy loss is common, occurring in approximately 20% of the identified pregnancies [62]. It is linked to stigma, mental health challenges, and shifts in identity and personal relationships [15]. It is also difficult to find support because of the stigma, shame, and guilt attached to it, although it tends to be traumatizing [63]. Not only is the experience absent from dominant pregnancy narratives [16], but also grieving such losses is not socially acceptable, leading to inconsiderate or unsupportive reactions from others [15]. Research at the intersection of pregnancy loss and technology has examined how and why people choose to disclose it on social media [26,27,64], how and why others respond to such content [65], the outcomes of such disclosures [25], pregnancy-related apps' inclusion of pregnancy loss [17], validation seeking on the internet after a loss [30], and information needs [28]. Kresnye et al [28] found that forums, Facebook, and blogs are common internet-based sources after pregnancy loss and that people needed general loss-related information, counseling resources, information about others' experiences, and information from medical providers. However, they also found challenges such as difficulty in locating resources and stigma. We have built on such work to examine what needs are met by existing internet-based spaces and what challenges they provide. We address the following research question: What are information-related processes (eg, needs, challenges, and outcomes) for individuals enduring pregnancy losses, and how are these mediated through internet-based tools?

Methods

Recruitment

We conducted 9 remote in-depth semistructured interviews with individuals who had experienced pregnancy loss or losses within the past 2 years (to facilitate recall and similar social media landscape). Interviews averaged 92 (range: 80-104) minutes. In this study, pregnancy loss was defined as the unintentional loss of a pregnancy at any gestational stage. Research has suggested that the gestational stage of loss is not a causal factor in the severity of grief and coping experience [66]; therefore, we did not screen participants based on the loss stage. We used a screening survey to purposefully [67] sample participants who varied in experience, demographics, and technology use to the extent possible. The screening survey was shared on the lead researcher's social media accounts and, from there, beyond their network. This choice was informed by prior work [68-70] that used social media for reaching hard to reach populations. This was also appropriate as a criterion for inclusion was social media use. We do not know how many times the link was shared or who shared it. We did not ask participants to share the study call with those who may be eligible to participate.

Ethics Approval

This study was approved by the University of Michigan Institutional Review Board (HUM00156077).

Screening Survey

To qualify, respondents had to meet the following requirements: live in the United States, have experienced a pregnancy loss within the past 2 years, be a social media user, and be aged at least 18 years. Only respondents who met these criteria went on to the next stage of the screening survey, which included questions about the general use of internet-based platforms, internet-based platforms used in connection to pregnancy loss, needs after a loss to assist in processing, the month and year of the most recent pregnancy loss, age, self-description of gender, race, ethnicity, status within the LGBTQ (lesbian, gay, bisexual, transgender, and queer or questioning) community, self-description of whether they had children, relationship status, education level, household income, primary religion, and residence in an urban area (>50,000 residents) or rural areas (<50,000). We asked respondents to self-describe whether they had children or not (and how many) as this can be an emotionally charged question for those who have experienced pregnancy losses and to allow for diverse ideological views on the matter.

The screening survey received 49 responses. After survey completion, the lead researcher contacted respondents with an internet-based consent form, additional study information (eg, tools and devices they would need access to during the interview), and scheduling options. A total of 9 people completed this process and were included in the study. Participant ages ranged from 31 to 42 years. Of the 9 individuals, 8 identified as Caucasian or White and 1 as Black American; 5 identified as having children, 2 stated that they had none, and 2 chose not to answer. All identified as women, and all had some college education, with most having an advanced degree. Most were married, and one of the individuals identified as single. Of the 9 individuals, 1 identified as LGBTQ and 8 as heterosexual and cisgender. Of the 9 individuals, 1 made <US $50,000; the rest had an income of ≥US $75,000. Most lived in urban areas, and one of the individuals lived in a rural area. Table 1 presents the participants' information.

Interview Overview

Participants chose their preferred remote tool (eg, Skype or Google Meet) as long as it allowed viewing our screen when shared (required for a portion of the study that was not used in this paper). To preserve participants' privacy and facilitate their comfort, only audio was recorded.

Interview Guide Overview

First, participants were asked about their life when they found out they were pregnant and what followed. Next, participants were invited to 3 illustration tasks, with their choice of words or drawing on paper, their general social media use, and their technology use during pregnancy and in relation to pregnancy loss, respectively. After each illustration, participants were asked to photograph their work and send it (via email and text) to the interviewer during the call. They were then asked to provide detailed verbal descriptions of their submissions. Visual elicitation methods often help participants articulate mental models associated with sensitive topics, facilitating flexibility and reflection [71-73]. Studies on pregnancy support networks [74] have used similar methods. We emphasized that only *they*

needed to understand their submission and that we would ask them to explain it to us later.

Next, we focused on understanding participants' needs for coping and support after loss and how these needs were or were not met, including through the use of technology. Finally, participants used paper and pens to outline an ideal support system and then shared and explained these to us, as in the aforementioned activities. Here, we focus only on the results of information behavior.

Analysis

We recorded the audio during interviews and transcribed them for analysis. We conducted a qualitative analysis using open coding, followed by axial coding [75]. That is, we did not base our analysis on pre-existing codes as it was important to center participants' voices and pregnancy loss.

Guided by our research question, the first author (who also conducted the interviews) developed initial codes by open coding 3 interviews. They iterated these codes and refined them using memoing in the process. Then, a team member trained in qualitative analysis was given the data and codes who met with the first author to discuss the definitions. The team member

spent several weeks familiarizing themselves with all data and codes, discussing them weekly with the first author. After gaining a reasonable understanding, the team member independently applied the codes to the same 3 interviews coded by the first author. They created no new codes, despite keeping an eye out for new observations. The first author and the team member discussed any divergence in the coding of these 3 interviews to ensure mutual understanding. Then, the team member coded the rest of the data, discussing the interviews and code applications with the first author weekly. The first author then assessed the codes and excerpts to ensure consistency and grouped codes into larger categories. For example, codes for various information needs were grouped under the umbrella of information needs. The authors then refined the observed themes and discussed them in relation to the Kari [31] framework; in other words, we did not set out to use the Kari [31] framework in our study as we did not know what would be important to participants; we collected the data, analyzed them, and consulted the work by Kari [31] to interpret and organize our resulting themes. In this paper, we report themes related to our research question, focusing on information behavior.

Results

Overview

We report on our findings in three main themes related to the participants' information behavior: (1) needed information type, (2) information-related concerns, and (3) information outcomes. In interpreting these themes, we draw connections to the five information use conceptions conceived by Kari [31], presented in the *Information Behavior* section: knowledge construction, information search, applying information, information production, and effects of information. We describe how these concepts illuminate participants' use of internet-based spaces (ie, forums, pregnancy apps, search engines, and Facebook groups) for information related to pregnancy loss and coping, grieving, and sense making.

Knowledge Construction and Needed Information Types

Overview

An unmet need to gain knowledge motivated participants to turn to internet-based spaces to seek information. Individuals who are likely to face discrimination or stigmatization in health care settings often turn to other sources of information [2,3]. Our findings suggest that the main types of information participants sought fell within these categories: (1) science and evidence-based information about pregnancy loss, including information about the individual with pregnancy and their partner, and (2) experience-based information, including information about pregnancy-related medical conditions and others' experiences with pregnancy loss. According to the concept of *knowledge construction* by Kari [31], individuals turn to information seeking (ie, information search) to resolve unknown or unsure knowledge and enter the process of developing new knowledge, ideas, and beliefs.

Information sources for these needs were others' stories and experiences (experience-based) and scientifically oriented information (evidence-based), the categories in which knowledge construction [31] occurred. Notably, P9 said, "First and foremost I would say, I needed...information and...to hear other people's stories."

Similarly, 2 broad types of information paths were identified; P8 noted the following:

> So then there's the two paths...on the one side was that the evidence based in...things that were actually true like journal article or something that had qualitative and quantitative research...and that, in some ways, that led to this down arrow of information, which...was helpful...at times. But then after you become a statistic like losing two...sometimes the research doesn't mean as much anymore because you realize that you can be a two percent....

P8 continued by stating the following:

> But then on the other side was the real experiences and that's what I would find through some of those forums...that in some ways it didn't lead to that evidence-based information, but it led to in some ways validation.

Other people and academic, evidence-based information were important for P8's experience and were complementary. In fact, many differentiated between medical, evidence-based information, and other types. For example, P7 noted a distinction between the 2 information sources:

> And I think...the practical information doesn't necessarily have to be medically informed. Having towels under you when you sleep doesn't need to be medically informed.

This speaks to information that one would need that is not necessarily sourced from a medical professional but is still key. In what follows, we delve deeper into the types of information that participants sought on the internet.

Science- and Evidence-Based Information Needs

Participants often felt that medical professionals did not adequately meet their information needs:

> I think, if it were to happen to me again, I would wanna talk to my OB at length, like, "Why is it that some people do it, some people don't?"...stuff like that, being able to know specifically related to medical procedures, under what circumstances should one have a D&C? What are the implications of it? 'Cause I've heard that there's some negative side effects. [P7]

P7 had questions not answered by her provider about dilation and curettage. She turned to internet-based spaces such as support groups, forums, and search engines.

Medical information needs were also informed by the gap between the participants' needs and their level of trust in their medical care provider. Combined with the relationship aspect is a hesitancy and inability to reach out to their medical care

provider when concerns may be viewed as trivial but are nonetheless crucial to participants' experiences. Seeking evidence-based information via Google and other internet-based resources such as online support groups and forums was a way of complementing the information received from medical professionals.

P1 spoke of the role that her provider could have played to meet her information needs but did not:

> *I think that would have done wonders. Having my doctor able to answer all the little insane questions I would have all the time because when you're feeling things that you're not used to feeling...I automatically thought something was wrong...Like oh, this is happening to my body, let me Google it because I can't just call my doctor every five minutes. So, having access to a healthcare provider that doesn't mind you badgering them.*

Obtaining knowledge about loss before both pregnancy and loss was also important. A lack of such information increased confusion and difficulty when the loss occurred. As we see in P5's remarks, being kept in the dark by medical providers about the risks for and signs of pregnancy loss prompted her to seek information and others' stories via Google:

> *When I went into the first pregnancy, I was very oblivious to a lot of stuff...I wish I would have had the knowledge, either from the group or by reading, researching, looking things up...I just assumed everything's great, you're pregnant...my doctor pretty much kept me in the dark about it. He would just, "Okay. Everything's fine. Everything's fine." When, in reality, it wasn't. I had to learn that the second time around from other people.*

For her first pregnancy, P5 trusted that her health care provider had shared the needed knowledge and that trust contributed to P5 not looking for outside information. However, after experiencing the first pregnancy loss, P5 blamed herself for not independently seeking evidence-based information. P5 had unmet medical information needs, which were only learned after her experience with pregnancy loss. P5 expressed how much she would have benefited from the missing knowledge in coping with the first pregnancy loss. These accounts align with the finding by Kresnye et al [28] that individuals tend to attempt to find information after a loss occurs, not before it.

Some participants also noted an unmet need for information from their partners. This could take the form of resources for conveying the information they received from a medical provider to their partners and specific signs a partner could look out for.

P6 said the following:

> *I think, also information to help the partners. Cause like, I would go to my husband...but he didn't have any more information than I did. And...we're both highly educated...But...all the information we had, didn't really prep us for...understanding miscarriage.*

P2 discovered that internet-based groups could help fill that need:

> *It was also nice for my husband because...I don't do a very good job of explaining my physical. I tend to write everything off. I'm like "I'm fine."...And so it was nice for him to be able to read what I was physically going through since I was just saying I was fine. And it was helpful because then when he did read it, he would say "Stop doing the dishes. Go sit down." "Don't make dinner, I'm going to pick something up tonight."*

These quotes showed that P6 would appreciate guidance from medical professionals for partners of individuals navigating pregnancy loss, whereas P2 found guidance on how to express the toll of pregnancy loss to her husband and gain the support she needed from him. While some participants viewed that they experienced the loss *together* with their partner, the partner could not always be helpful partially because of lack of information. Partners can be caregivers and supporters in pregnancy journeys [76], and we suggest that future work should further consider partners experiencing losses as part of those journeys.

The turn to internet-based spaces for knowledge construction often stemmed from the unavailability of information from health care providers, whether because of participants' hesitancy to trust health care practitioners or the health care practitioners' unwillingness to provide it. What Kari [31] refers to as knowledge construction is the processing of information to develop new knowledge or validate unsure knowledge. Science- and evidence-based information related to pregnancy loss was an unmet need high in priority to participants, but so was practical information from others' experiences. In the next section, we address the importance of the latter information type in internet-based spaces and the comfort offered by such knowledge.

Experience-Based Information Needs

A need for medically related information, which may be considered more reliable when the provider has first-hand experience or shared cultural views and identities, related to specific medical conditions or physical experiences connected to pregnancy loss. This information, sought in spaces such as blogs or internet-based support groups, was helpful, as these concerns may have been thought of as trivial by health care providers.

P3 described a need that may not easily be met by medical professionals:

> *But I feel like a lot of my issues...are kind of cultural...and that being able to speak about them in a group that's more culturally similar...like Jewish rituals, superstitions...being able to have other people's input and guidance and what worked for them would have been nice.*

P3 wanted to find information sources who understood her cultural beliefs and had insight into dealing with pregnancy loss as a Jewish person. Determining whether a medical professional

could provide this insight may not be possible, so she turned to digital spaces.

Similarly, P6 emphasized the importance of receiving information from individuals who share similarities, particularly when one is a part of a group that can often receive less than the standard of care from medical professionals.

> *Well...there's been a series of studies...about how, oh black women are nearly four times more likely to die giving birth...more likely to be denied pain medication...their babies are more likely to die before the age of one. So that's something I think about as a researcher. Like the gap between logistics, because all of those are just the outcomes of logistic models...you have to understand that statistics are not a good way to tell the story. So, I started just paying attention more to women, black women telling their stories. And...anecdotes aren't data. But those stories do matter....* [P6]

P3 and P6 turned to internet-based spaces in search of information that they deemed critical to their specific experiences of pregnancy loss based on culture, race, medical beliefs, and medical statistics. Individuals who have experienced pregnancy loss may not have access to medical professionals who can provide information that speak specifically to such cultural or racial issues.

Often, medical information could originate from social ties with relevant personal experiences (as described above) or professional expertise. For example, P2 mentioned needing dietary information after her loss, which a family member who had a relevant scientific background was able to provide:

> *My kid's godfather...studies gut bacteria and he was like "Well here are some things that can actually help with...absorption of nutrients" And so that was really helpful. If I'm taking all these supplements, then I want to know how I'm actually absorbing them.*

These examples illustrate participants' needs to find information not only about pregnancy loss broadly but also about the variety of relevant conditions that may not be shared across all individuals experiencing pregnancy losses.

Participants also reflected on the need to know the basics of pregnancy loss symptoms, what to physically expect, and how to practically prepare:

> *I wish a girlfriend would have been like, hey, you should lay down a bunch of towels in the bed because the second day is worse...it would have been very useful...But people don't tell you this...Little tiny practical tips...Nobody would hurt from...sleeping on towels.* [P7]

In addition to information aligned with one's experience, condition, and identity and culture, participants noted that information from others who had experienced losses could also be practical.

Another example included not only looking for symptoms of loss but also gaining basic information on the stages of pregnancy:

> *Basically Glow was not only a way for you to track your symptoms of your cycle...Do you have your cervical discharge?, and any kind of other symptoms that you have and if you've gotten a positive OPK. The forums are also helpful because I didn't know a lot at the time. I didn't know that it takes 6-12 days for an egg to implant and 2-3 days...to get a positive after that.* [P4]

This basic information on the symptoms of loss and pregnancy stages may be overlooked by medical professionals as obvious or trivial, which makes internet-based groups an avenue for education. Furthermore, we see that some information needs after a loss tend to be about future pregnancies, which are necessarily positioned within one's pregnancy history, including the loss.

A combination of evidence-based, identity and culture–aligned, and practical information from others who have experience with pregnancy loss made up most of the information that participants sought or needed. However, participants also noted finding information that they would have preferred from their evidence-based sources that were not readily available. For example, some were able to find information on forums that were not available through Google searches (ie, deleted by clinic businesses) and may not be readily shared by health care professionals. For instance, P7 shared the following:

> *Those forums were super-duper useful. And...that information wouldn't be out there at Google, because these fertility clinics...don't want people to actually know how much these things cost. And...They clean the web of reviews and stuff, because it's a business.*

In this section, we described the information needs that health care providers were either unwilling or unable to meet and the sources that participants, in turn, used to construct knowledge. Our analysis highlights two main overarching types of information that participants sought: (1) science- and evidence-based information about pregnancy loss, including information about the pregnant individual's partner, and (2) experience-based information, including information about pregnancy-related medical conditions and others' experiences with pregnancy loss, especially those aligned with one's culture and identity. Participants were able to address many of these information needs in internet-based spaces but would appreciate and benefit from health care providers' input regarding the credibility of medically related information and their assistance in conveying their knowledge to partners. The next section covers specific concerns that participants expressed related to pregnancy loss–related information encounters in internet-based spaces.

Information-Related Concerns in Information Search

Overview

Our findings suggested two main concerns in information encounters: (1) being able to find information and (2) determining the credibility of information. These are aligned with the *information search* concept of Kari [31], as the ability to use information or information resources is directly connected to the feasibility of searching for and accessing information,

which makes these concerns important for designing internet-based spaces. Persistence (ie, "the extent to which a platform affords the continued availability of content over time" [77]) and searchability (ie, the extent to which a platform affords users the ability to search for content using search terms) together afforded timely access to information.

Challenge 1: Ability to Find Information Shaped by Persistence and Searchability

Persistence and searchability often went hand in hand. Easy access to and almost real-time return on information was important. Posting a question on an online forum or support group and waiting for responses was not an appropriate method to meet some needs.

For example, P7 used search engines to quickly find information from old forum posts:

> *For me at that stage, googling for info went infinitely to the top...I didn't necessarily wanna talk to a human about what I was experiencing...I didn't wanna wait for a human to respond. I wanted in that minute to be like, "How much blood loss is too much? When should I call my doctor?" I need this immediately.*

Participants appreciated the ability to search for information on the internet, find it quickly, and be able to access it without posting about their own experiences, which can be difficult during moments of distress. The benefit of finding and reading available posts and answers rather than posting oneself is seen in P1's response:

> *I had lots of questions. The cool thing about the Facebook group is not only do you have everything that people are posting right now, but you can go to the top and you can type in a specific thing. And then all the posts that have to do with that come up.*

P7 described the importance of the interfaces in supporting search, evidence-based information, and archived information:

> *Medically informed information with citations...in terms of the actual interface it has to be super-duper searchable, with a very good search. That's one of the downsides to app-based stuff is that you can't go into the Ovia pregnancy app for example, and search 12 weeks or something...Also...making sure that it's archived, so that...I can see here's something someone posted three years ago that was similar to my situation, so I don't have to wait for answers in the moment...there was quite a while that the searchability of Facebook was really poor, especially on mobile...that's really unfortunate.*

Participants found value in archived information, collective experiences, and searchability. Being able to search for relevant information required an effective search functionality and permanent storage that allowed participants to draw from the vast amount of experience-based and evidence-based information shared over time. Internet-based spaces can provide swift access, in contrast to contacting, scheduling an appointment, and then conversing with health care providers. If an internet-based space maintains truly usable search

functionality and stores information in a persistent manner, it can be a resource for information needed at particular moments. As seen in P7's comment on the difficulties of searching in apps, when persistence and searchability are not maintained, information seekers turn to other spaces to meet their information needs.

Challenge 2: Determining Information Credibility

Facing misinformation or information perceived as less credible or difficult to assess was another challenge. Participants often turned to internet-based forums for information about specific conditions related to loss. There, they encountered the challenge of assessing what information was credible and what was not.

P1 described this problem as follows:

> *As far as Baby Center, I used that a ton right after the ectopic pregnancy because I didn't know who else to ask...I found a lot of helpful things...but...you also find things like things that don't seem to be helpful...oh, I heard my neighbor's friend's sister had this response. Like well, is it that really...fact?*

As another example, P4 said, "[That was] really helpful in getting educated, but there's also a lot of garbage in there, which I found out once I moved over to the Ava group." Although P4 was able to gain some useful information in a Facebook group, she also found misinformation, which became apparent to her once she moved to a space that she thought included less misinformation.

The amount of misinformation led some to leave internet-based forums altogether: "I did look at the forum but they drove me nuts and I stopped looking at them. They're a lot of misinformation..." [P6]. This is problematic as people come to these spaces to find information and social support; leaving means that they will not be able to access other types of support either. Ideally, people who join these spaces would stay for some time, both to find support and information for themselves and contribute to support others.

Participants found it difficult to find medically approved information about pregnancy loss in general pregnancy forums. This was particularly challenging and a cause for confusion because of advice that was contested. To this point, P7 said the following:

> *But medically informed information that...I could trust...is hard to find in general forums. Those infertility forums are pretty exceptional in how knowledgeable those people are about medical stuff, but in general pregnancy forums, people are dumb as rocks.*

When participants sought information on Google or forums, they noticed a prevalence of what they considered nonscientific information. P3 reflected on a way of assessing the credibility of evidence-based information shared in digital spaces:

> *I could imagine, in a way, an information center, where it's not so much about feelings but the questions are more fact-based and the discussion is more fact-based. I guess you can't really have medical advice because it's always lawsuits. But where people*

are encouraged to give answers that are fact-based, like studies and what they read.

Finding credible information that one can trust could have helped P7 and P3 make sense of their experiences, plan for the next steps, and regain control that was lost through the loss experience.

A main motivator for turning to internet-based spaces was a need to gain knowledge quickly; however, that benefit can be negated when one is unable to determine the credibility of information, when the information is deemed to be not credible, or when digital spaces do not afford effective searching. In the next section, we address the outcomes of looking for and finding information on pregnancy loss in internet-based spaces.

Information Outcomes: Applying Information, Information Production, and Effects of Information

Overview

Accessing information in internet-based spaces has implications for participants' future behaviors. We found that after new knowledge construction, participants (1) used information to advocate for themselves with medical professionals and (2) had their concerns and ideas validated. These outcomes align with the following information use concepts identified by Kari [31]: applying information, which occurs when one uses new knowledge, such as raising concerns to a medical professional; information production, which involves using learned knowledge to produce information for others, such as writing a post on an internet-based space; and the effects of information, where the information influences one's future choices. In these internet-based information spaces, participants developed tools for clinical encounters, such as learning what to ask and how to advocate for themselves. Newly obtained knowledge can also provide insights into options that are not presented or even discouraged by health care providers, in turn influencing one's decisions.

Applying Information: Learning What to Ask

For some, internet-based spaces were places where participants learned what questions to ask. P9 said the following:

It's only with finding an online community that I also found the language I needed to ask, should we be doing the following things? Should we be considering this kind of doctor? This kind of testing?

This is important, as the stigma surrounding loss contributes to less discourse and education about the topic [26,63].

Learning without asking was also a benefit, described by P5 as follows:

At the beginning of my pregnancy, there was a lot of warning signs that I wasn't aware of: the heartbeat was low, I had low progesterone. There's so many different things that I didn't pick up on, because I just wasn't aware. And being part of this group...helped me become aware, because these women had similar stories.

This is noteworthy, as lurking is often associated with negative connotations [78]; however, we suggest that it can serve as an effective learning strategy.

Overall, internet-based spaces and tools not only provided answers but also inspired participants with questions they could ask health care providers. Knowing what to ask and what to look for can make an individual more informed and lead to changed behavior. Participants expressed that they had used or would use knowledge found in digital spaces to obtain the needed information in conversations with medical professionals and prepare an outline of warning signs to try to avoid a future pregnancy loss; these examples align with the Kari [31] concept of applying information.

Information Production and Effects of Information: Changed Behavior

Internet-based spaces also become spaces for sharing one's own experience to inform others. P3 used an internet-based space to share information that she thought was needed and unavailable from other sources:

The other thing I'll post about is with my third miscarriage, I had the choice of getting...a different procedure...that most women...don't realize is an option...So that's kind of my soapbox...I'll often post about it...if I feel like I can offer relevant, helpful information.

In this case, P3 produced information to help others advocate for themselves by contributing experience-based information that she knew would otherwise be unavailable to others. This is an example of the information production concept of information use by Kari [31].

Another example is found in P2's choice to remain in an infertility group as a source of information for others:

I debated...whether or not to stay, but I feel like if anyone was going through what I went through, it took so long for my doctors to diagnose the problem that...I'd want to help somebody, because it was a simple blood test that nobody bothered to run for a year.

P2's role in the infertility group changed from information seeker to information producer, a source of experience-based information.

As noted in earlier sections, internet-based spaces such as Facebook groups or forums fill an informational gap that can occur when health care professionals are not available or refuse to meet information needs and when other internet-based resources (eg, Google) are unavailable or inaccessible (eg, information related to fertility clinics deleted from Google by clinic businesses). Here, we see how the knowledge gained in these spaces can lead to more informed decisions. As an example, P9 shared a story about finding instructions about in vitro fertilization injections, which led to behavior change; this content comprised questions that she did not get answers to from her provider but instead from other patients, including how to advocate for herself with her provider:

> *But in that group...especially once we started IVF...people share tips about how to make injections less painful, how to get the right angle...I know it can sound...ill-advised to get medical advice from people who aren't doctors, but a lot of the advice is more about how to advocate for yourself as a patient...something that I have learned almost exclusively through being in these groups.*

P5 offered another example of learning to advocate for oneself:

> *I had to be put on progesterone and I had to advocate for myself with my doctor...to put me on whatever progesterone they could...to maintain this pregnancy, which I carried to full term...That was, again, something I learned from the women in those groups...You definitely want to be your own advocate, and self-advocate for yourself...*

The above examples align with the concept of *effects of information* by Kari [31], where the information participants found in these internet-based spaces influenced their future choices, including how to navigate advocacy with a physician.

Discussion

Principal Findings

Our findings highlighted the following three novel themes associated with information behavior after pregnancy loss as mediated through internet-based spaces: (1) needed information type, (2) information-related concerns, and (3) information outcomes. These findings are significant as a first step in designing internet-based spaces to account for pregnancy loss information behavior. We found that participants shrank the knowledge gap regarding what to ask by learning what information others found worth knowing. They bridged language barriers by using information from internet-based spaces to supplement suggestions from medical providers, and the barriers of social stigma, cultural taboo, and lack of social and economic capital were to some extent offset by participants' ability to advocate for themselves, stemming from the confidence gained from interactions in internet-based spaces.

We showed how internet-based information spaces help alleviate some information gaps for individuals experiencing pregnancy losses and supplement information gained in clinical encounters. Nevertheless, digital health resources pose their own obstacles: people need to be able to find the information, understand and determine its credibility, and know how to use it. In addition, primary barriers to health care for women from stigmatized groups include knowledge gaps such as not knowing where to find information and what resources are available or what information to ask for, and a lack of understanding between patients and providers [79], which we also saw examples of in the case of pregnancy loss.

Information Behavior, Health, Pregnancy, and Pregnancy Loss on the Internet

In our dedication to fully engage with information theories beyond search and need, we outlined our analysis in connection with the information use concepts by Kari [31]; however, our

participants' responses also related to other information models. The Wilson [1] model remains relevant, as seen in participant responses first in their expression of unmet information needs (ie, information types), which led to information seeking on the internet, and in their insight into how the environment in which they sought information can influence their behavior (ie, information-related concerns), and finally in how they used information (ie, information outcomes). However, participants often learned what questions they *should* ask related to pregnancy loss in these internet-based spaces, which is a form of information encountering [34]. The internet, as an information-rich environment, is a source for both active information seeking and information encountering, which can occur through browsing or as a part of active seeking.

Pregnancy loss–related information seekers were similar to other health information seekers [40,41] in sharing high regard for information from medical professionals but needing additional information as well. Medical professionals are unable to meet certain personal needs that only knowledge gained from lived experiences can provide [80,81]. The main types of health information sought in prior literature in other health contexts [32,33] align with our participants' expressed need for evidence- and experience-based information. Participants did not expect peers to act as pseudo–medical professionals providing medical expertise or interpreting medical advice but instead to offer suggestions on topics such as how to improve communication with clinicians or insight into experiences with a recommended treatment or procedure [80,81]. We note that in contrast to the documented lack of trust between individuals who are socially marginalized or stigmatized and health care providers [12,14,15], participants expressed trust in medical professionals; their concerns centered on not receiving enough information on this particular topic and possibly not knowing how to broach it with medical professionals. Nevertheless, this expression of trust in medical professionals could be because of our sample limitations as most participants were White and of higher socioeconomic status.

Even so, we extend the scholarship on pregnancy-related information behavior. Participants expressed a desire for information on pregnancy loss *early on* in the pregnancy to prepare for the possibility of complications arising, which resonates with earlier research demonstrating that individuals with pregnancies begin their search for information at the outset of the process [53]; however, research on information needs after pregnancy loss suggests that most seek this information after the loss, not before it [28]. Similar to prior research on the information-seeking (not accounting for loss) [53,82] of individuals with pregnancies, participants in our study showed a propensity for changing behavior in response to the information they discovered on internet-based spaces. Participants also demonstrated a tendency to use this information to advocate for themselves in clinical encounters, which has not been heavily reported on in expectant parents whose pregnancies do not lead to a loss [54].

Some barriers for participants were similar to those faced by other pregnancy-related information seekers: not having instruction on or assistance in conveying information to a partner and lacking targeted information for individual experiences

[76]. Gold et al [61] were one of the first to examine support seeking for pregnancy loss on the internet; our findings reiterate the important role that internet-based support and resources can play. Participants in the study by Gold et al [61] also expressed a need for additional evidence-based information, feeling validated in internet-based spaces, appreciating the ready information access that internet-based spaces can provide, and the value of seeing others move on after pregnancy loss or related medical issues. However, Gold et al [61] focused on the benefits of these internet-based spaces and did not address the barriers to acquiring pregnancy loss–related information or their associated outcomes. Our findings on others' experiences and medical providers as sources of information also resonate with the study by Kresnye et al [28]. Although Kresnye et al [28] explored challenges in accessing information, such as locating resources and self-blame, we identified other challenges with respect to accessing, understanding, and applying information related to the technical features required for effective search and assessing information credibility.

We discuss internet-based health literacy concerns and considerations for design in the following section. Pregnancy-related apps generally do not account for pregnancy loss [17], including information behavior–related needs. We suggest that future pregnancy-related and pregnancy loss–related information spaces should address the needs and challenges that we identify herein [28].

Designing for Assessability, Searchability, and Persistence

Overview

An important aspect of the internet-based health literacy process is assessing data quality within an information environment to determine its usefulness [83,84]. Our participants described internet-based health literacy and data quality as concerns in connection to credibility challenges when seeking information.

The themes we identified resonated with the need to design for populations based on their specific information needs and barriers to meeting those needs, as emphasized in current scholarship on health information behavior in internet-based spaces. Individuals who have experienced pregnancy loss have information needs that, although specific to them, also share the concerns over determining credibility with others [21,85]. Our themes also resonated with current HCI literature on the needs of patients managing chronic disease in internet-based health and support groups [80,81], including consideration of the user as a whole, personal and clinical information, clear organization and the ability to search archived information, and safeguards against misinformation. The remainder of this section addresses these concerns.

Designing for Assessability

Our findings speak to the need to extend the *assessable design* framework [86] to the internet-based health context. Designing for assessability was first introduced by Forte et al [86], fusing information literacy concepts in various disciplines toward developing a framework for the *assessable design* of participatory information sources (eg, Wikipedia, forums, and support groups). The authors established two concepts critical

for assessability by reviewing the information credibility literature: (1) information provenance, concerned with determining where information comes from, and (2) information stewardship, which refers to how an information space is maintained [86]. Assessable designs should facilitate the understanding of how the information in internet-based participatory environments is produced, how an environment is sustained, and how to contribute to the space [86]. In fact, prior research investigating the processes individuals use to determine credibility found that users are likely to refer to the source; sources are deemed more credible if the poster is a professional expert or an expert according to community status or past engagement [87-89].

Applying the assessable design framework to our results, internet-based spaces could provide users with affordances that allow them to identify and assess information sources and contributors and their credibility; for example, internet-based groups may consider adding identity tags to content producers that would enable others to assess their contributions. These recommendations resonate with prior suggestions for formal patient–provider internet-based spaces for patients with chronic diseases [80,81]; our findings extend these design needs into informal digital spaces and beyond chronic disease management to individuals managing experiences such as pregnancy loss that can be acute or chronic.

Participants expressed the need for information in two categories: others' stories and experiences (experience-based) and scientifically oriented information (evidence-based). Individuals want to know that their information source is a knowledgeable expert, whether because of training or lived experience. Therefore, designing for the clear identification of the source can assist users in determining the credibility and usefulness of the information, as people are more likely to adjust their attitudes or behaviors in response to a message from someone deemed an expert [89]. These design directions could assist in users' effectiveness and confidence in doing what we found they already try to do: advocate for themselves with medical professionals.

Although identity attributes should be developed together with relevant stakeholders in future work, examples could include determining whether a person has relevant professional expertise. Encouraging or enforcing the citation of sources for the information shared in internet-based spaces as part of the community guidelines is another consideration; individuals could be prompted to add references to the content they share so that others can assess those sources and the information's credibility.

Similar to Forte et al [86], internet-based spaces could also provide users with aggregate information (eg, through simple visualizations) that show what sources contributors draw from. For example, one may go to a Facebook pregnancy loss group and see that 70% of posts link to outside sources, and out of those, 30% are academic peer-reviewed articles about pregnancy loss. This would likely provide the user with an assessment of the group as a whole. We advocate for including assessability in design considerations.

Designing for Searchability and Persistence

Our analysis led to identifying searchability and persistence as desired affordances for participants. For example, some participants shared successful experiences with a Facebook group's search feature and less successful experiences with some pregnancy-related apps and forums. The point here is not to compare platforms (which requires other methods and is an area for future work) but to learn from participants' experiences. Our findings show that people experiencing pregnancy loss need both evidence-based and experience-based information. There is a wide range of adjacent medical conditions (eg, polycystic ovary syndrome) that shape people's loss experiences; finding information about those conditions was also important to participants. Taken together, future designs could experiment with features that allow people to tag the content they contribute as *evidence-based* or *experience-based* or with adjacent health condition labels to streamline searching for others. Although this needs further exploration, this design application would likely be well-suited for an integrated patient–provider application, as described in the study by Huh et al [81], where peers can share and discuss content with one another and consult a medical professional as needed. A possible added benefit of such a design could be the ability for the expert medical professional to share insights without compromising peer-to-peer sharing, which was an issue observed by Huh et al [81].

Such an approach could also be used to provide aggregate information about what experiences and information types are represented within an internet-based space (eg, 79% experience-based). This design approach could be combined with the approach suggested by Huh et al [81], which calls for designing systems that can suggest prior threads relevant to a user's post, or with the suggestion of Hartzler et al [80] for profile features that detail topics a user typically discusses or posts information about.

In summary, our findings show that when there is a dire need for information, access to relevant experiences and information and the ability to assess the credibility of such information are key. The first can be supported by designing for easy retrieval and organized storage of older content through searchability and persistence. The second could be supported by an assessable design. That said, privacy considerations are crucial; for example, if contributors want their data to expire after a certain point, they should be able to easily achieve that goal. Privacy concerns are especially important when designing for information retrieval in the context of well-being in internet-based communities, which are not regulated at the same level as formal, traditional health information (eg, electronic health records). Altogether, we argue that designing for assessability, persistence, and searchability is needed to achieve dimensions of health literacy (ie, access, understand, appraise, and apply) [84]. Without these aspects of design, individuals are less equipped to find information, make informed decisions about how the information could assist in maintaining their health, and effectively communicate this information to others. Researchers and technologists could consider these recommendations when designing pregnancy-related internet-based spaces, which tend to grossly neglect pregnancy loss [17], as well as spaces dedicated to pregnancy loss. Accounting for pregnancy loss in designing internet-based information spaces will help counter the stigma many endure and make space for diverse pregnancy narratives.

Limitations

The larger context within which survivors experience pregnancy loss shapes their experiences. Therefore, we focused primarily on the United States to examine pregnancy loss experiences in this study. We encourage researchers to explore similar topics in other countries. We hoped to include a wide range of experiences (eg, technology use and pregnancy history) and demographics such as age, race, and income level to the extent possible. We were not entirely successful in achieving diversity on all these levels. Although our sample represents a range of technology experience and pregnancy history, it was primarily White, cisgender, heterosexual, married, educated, and urban and had an income >US $75,000. Our sample's demographics are a limitation; however, the findings advance our knowledge about information behavior after pregnancy loss. In the future, we hope to build on this work by reaching more diverse populations, for example, by partnering with community organizations serving marginalized groups and including partners or caretakers. Although an accepted recruitment practice for engaging hard to reach populations in research [68-70], the social media recruitment strategy has its limitations (eg, not everyone who would have been eligible saw our study call).

Our findings are not generalizable; however, they still hold value and contribute to our knowledge about social technologies' roles in information behavior after pregnancy loss. In addition, rather than achieving validity through quantity, in-depth long interview studies with small sample sizes support interpretive claims achieved through the careful selection of participants who share experiences related to research questions [90]. As such, our findings are not intended to be generalizable; rather, they are presented as generative points to provide a conceptual vocabulary for describing information behavior processes. Future work may use representative samples and surveys to assess the prevalence of the identified themes in this paper.

Abstract

Background: The coronavirus pandemic has increased reliance on the internet as a tool for disseminating information; however, information is useful only when it can be understood. Prior research has shown that web-based health information is not always easy to understand. It is not yet known whether the Korean-language COVID-19 information from the internet is easy for the general public to understand.

Objective: We aimed to evaluate the readability of Korean-language COVID-19 information intended for the general public from the national COVID-19 portal of South Korea.

Methods: A total of 122 publicly available COVID-19 information documents written in Korean were obtained from the South Korean national COVID-19 portal. We determined the level of readability (at or below ninth grade, 10th to 12th grade, college, or professional) of each document using a readability tool for Korean-language text. We measured the reading time, character count, word count, sentence count, and paragraph count for each document. We also evaluated the characteristics of difficult-to-read documents to modify the readability from difficult to easy.

Results: The median readability level was at a professional level; 90.2% (110/122) of the information was difficult to read. In all 4 topics, few documents were easy to read (overview: 5/12, 41.7%; prevention: 6/97, 6.2%; test: 0/5, 0%; treatment: 1/8, 12.5%; P=.006), with a median 11th-grade readability level for overview, a median professional readability level for prevention, and median college readability levels for test and treatment. Difficult-to-read information had the following characteristics in common: literacy style, medical jargon, and unnecessary detail.

Conclusions: In all 4 topics, most of the Korean-language COVID-19 web-based information intended for the general public provided by the national COVID-19 portal of South Korea was difficult to read; the median readability levels exceeded the recommended ninth-grade level. Readability should be a key consideration in developing public health documents, which play an important role in disease prevention and health promotion.

Introduction

Digital health literacy is the ability to seek, find, understand, and appraise health information from electronic sources, and the subsequent ability to apply the knowledge to address a health problem [1]. Many people have difficulty understanding written information worldwide, including approximately 9.6 million Koreans [2] and approximately 75 million Americans [3]. Therefore, providing health information without considering

the population's literacy level does not guarantee people's ability to understand and apply the information [4].

Society should ensure that vulnerable individuals are not left behind. Health literacy is a social determinant of health—people with lower literacy skills are less likely to access information or health care services at the same level as those with higher literacy skills [5]. This may contribute to poor health outcomes, such as lower adherence to infection control and prevention measures, ineffective use of health care, and high mortality rates [5-7]. In this context, public health researchers and policy makers have recently extended the concept of health literacy from personal reading skills to organizational health literacy [5,8,9]. The US Department of Health and Human Services' health strategy [10] emphasized that it is the responsibility of health care organizations to design and deliver health care services and information relating to health in an accessible and understandable format. The South Korean government also includes developing easy-to-read health information in its action plan to reduce health inequity [11]. These public health efforts to achieve health equity will reduce the risk of increasing health disparities within and between countries [10-13].

Readability refers to how easy a text is to read and understand, and it is commonly measured by school grade level (kindergarten to postgraduate school) [14]. Generally, a text is considered easy to read when written below the average reading level of an adult [14]. Health care authorities have encouraged enhancing the readability of health care information, recommending that health information intended for the public be written below a sixth-grade reading level [15-17]. The South Korean government did not establish a standard for the readability of health information despite doing so for other information documents, with the Easy-to-Understand Legislation Project in 2006, which recommended that documents for the general public be written at or below a ninth-grade reading level [18]. This standard was based on the average reading level of Korean adults and the 9 years of free compulsory education that South Koreans receive [19]. The ninth-grade level was also used as a standard for sufficient literacy skills required for daily life in the 2017 Second Korean Adult Literacy Survey conducted by the Ministry of Education and the National Institute for Continuing Education [2]; thus, similarly, this study considers public health information adequately readable when written at or below that of a ninth-grade reading level.

The COVID-19 pandemic has changed the way we communicate, with more people relying on the internet as their primary source of information [20]. COVID-19–related searches have surged and been predominant in 2020 [21,22]. Consequently, web-based communication regarding the risks of the virus has become increasingly important [23,24]. According to a UN report [25], governments have used websites to provide accurate information for the public since the early days of the COVID-19 pandemic. Although health care's digital transformation has increased the accessibility of information [26], many people may not understand the COVID-19 information shared by health care authorities. Prior research [15,27-34] has shown that most available health information is difficult for the general public to understand. For example, a systematic review [15] of 157 cross-sectional studies concluded

that the US and Canada's web-based health information is written above the average reading level of the population that it aims to inform. Patient information leaflets written in Korean were also found to be written above the average reading level of South Korean adults [27-30], and recently, studies [31-34] have reported that web-based COVID-19 information (written in English) is considered too difficult to understand by the public. However, no studies have been conducted on Korean-language web-based COVID-19 information. We aimed to address this literature gap by evaluating the readability of Korean-language COVID-19 resources. We investigated three research questions: (1) Is Korean-language COVID-19 information provided for the general public on the national COVID-19 portal of South Korea written at or below the recommended ninth-grade level? (2) Does readability differ across topics? (3) What are the characteristics of difficult-to-read information, and how can we improve readability?

Methods

Search Strategy

Information posted between February 3, 2020 and February 10, 2021 was downloaded from the national COVID-19 portal of South Korea [35] on February 10, 2021. Any subsidiary webpages or subdirectories that had information accessible by the public were also assessed using software (Sitechecker, version February 2021; Boosta Inc). All documents were initially screened by title and the main text was reviewed by 2 authors (HM and GHL) independently, using inclusion and exclusion criteria. Any discrepancies were resolved through discussion with the third author (YJC). Information that contained (1) COVID-19 information intended for the general public, (2) was written in Korean-language, and (3) provided by the South Korean government was included. Information that was (1) in other languages, (2) noneducational (such as press releases or daily case updates), (3) not in a written format (ie, videos and images), or (4) intended for public health and health care professionals was excluded. We also excluded duplicate documents.

Ethics

In this study, there were no human participants or assigned interventions; therefore, we did not seek specific ethical approval from an institution review board.

Topic Classification

Included documents were classified by topic—overview, prevention, test, or treatment—by 2 of the authors (HM and GHL) independently, and any disagreement was resolved via discussion with the third author (YJC). The *overview* category included documents about COVID-19 risk factors, transmission, and the natural course of the disease. The *prevention* category included documents discussing cleaning, disinfection, physical distancing, personal protective equipment, and vaccination. The *test* category included documents discussing indications, screening and confirmation tests, or the interpretation of test results. The *treatment* category included documents about self-care and patient care.

XSL•FO
RenderX

Text Preparation

Documents were formatted as raw text files using Notepad (Microsoft Inc). Any text not directly related to public education was deleted, such as date, author information, titles, figures, tables, legends, references, and copyright information [31,33,36].

Readability Assessment

We assessed text readability using a tool for Korean text (Natmal, version 2019; Lexical data-processing research institute) that determines the readability level based on sentence length and word difficulty [37]. The Natmal database contains 500,000 words classified into 9 difficulty levels by grade [38]. The frequency of words used in the text is measured for each grade and then weighted according to the number of words listed in the database [37]. We grouped text into 4 levels: professional, college, 10th to 12th grade, and at or below ninth grade. Difficult-to-read information was defined as information with a readability level exceeding the ninth-grade level (professional, college, 10th to 12th grade), and easy-to-read information was defined as information with a readability level at or below the ninth-grade level [2].

Enhancing Readability

We analyzed the characteristics of difficult-to-read information to determine common characteristics. Out of the documents that were written at a professional level, 3 documents, each representing a characteristic, were selected after discussion among the authors. To modify the readability level, we addressed each problem characteristic. The readability of each revised document was reassessed with the tool.

Statistical Analysis

All analyses were conducted with the R statistical software (version 3.6.3; R Foundation for Statistical Computing). Results were considered significant with $P<.05$. Shapiro-Wilk tests were used to assess the data normality. The categorical variable (readability level) was presented as frequency and percentage, and continuous variables (reading time, character count, word count, sentence count, and paragraph count) were presented as median and interquartile range. Chi-square tests or Fisher exact tests were used to calculate P values for categorical variables. Kruskal-Wallis tests were used to calculate P values for continuous variables.

Results

Readability of the Documents

A total of 122 educational documents were included in this study (Figure 1). The median readability level was *professional*; 9.8% (12/122) of documents were classified as easy to read, and 90.2% (110/122) were classified as difficult to read (Table 1).

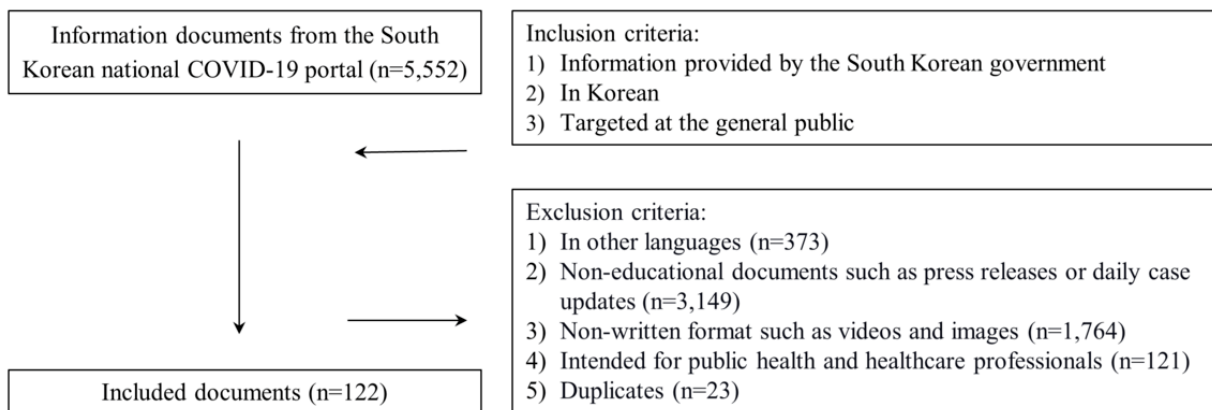
Figure 1. Data collection flowchart.


Table 1. Readability characteristics by level.

Characteristic	All (n=122)	Level				P value
		Professional (n=66)	College (n=33)	10th to 12th grade (n=11)	At or below ninth grade (n=12)	
Reading time (seconds), median (IQR)	78.4 (43.0, 161.3)	129.4 (57.2, 191.6)	64.4 (43.9, 107.7)	38.9 (33.4, 93.9)	32.8 (24.9, 48.8)	<.001
Character count, median (IQR)	1350.5 (703.0, 2418.0)	2003.0 (945.0, 2926.0)	1242.0 (739.0, 1837.0)	701.0 (620.5, 1609.0)	632.5 (475.5, 878.0)	<.001
Word count, median (IQR)	264.5 (145.0, 544.0)	436.5 (193.0, 646.0)	217.0 (148.0, 363.0)	131.0 (112.5, 316.5)	110.5 (84.0, 164.5)	<.001
Sentence count, median (IQR)	31.5 (18.0, 60.0)	47.0 (24.0, 68.0)	26.0 (14.0, 36.0)	21.0 (17.5, 36.0)	17.0 (10.0, 21.5)	<.001
Paragraph count, median (IQR)	35.5 (20.0, 84.0)	75.5 (35.0, 121.0)	27.0 (17.0, 41.0)	23.0 (19.5, 33.0)	13.5 (9.5, 17.0)	<.001

Readability Among the Documents of Different Topics

Included documents did not evenly cover the 4 topics (Table 2), with most (97/122, 79.5%) covering the topic *prevention*. For all topics, median readability was classified as difficult (overview: 11th-grade level; prevention: professional level; test: college level; treatment: college level), and there were few (all cases: *P*=.006) easy-to-read documents (overview: 5/12, 41.7%; prevention: 6/97, 6.2%; test: 0/5, 0%; treatment: 1/8, 12.5%).

Table 2. Readability among the documents of different topics.

Characteristic	All (n=122)	Topic				P value
		Overview (n=12)	Prevention (n=97)	Test (n=5)	Treatment (n=8)	
Readability level, median	Professional	11th grade	Professional	College	College	—[a]
Readability level, n (%)						.006
Professional	66 (54.1)	3 (25.0)	59 (60.8)	2 (40.0)	2 (25.0)	
College	33 (27.0)	3 (25.0)	23 (23.7)	3 (60.0)	4 (50.0)	
10th to 12th grade	11 (9.0)	1 (8.3)	9 (9.3)	0 (0.0)	1 (12.5)	
At or below ninth grade	12 (9.8)	5 (41.7)	6 (6.2)	0 (0.0)	1 (12.5)	
Reading time (seconds), median (IQR)	78.4 (43.0, 161.3)	35.4 (27.4, 57.4)	97.6 (49.8, 170.5)	56.9 (32.0, 64.4)	42.1 (29.9, 93.8)	<.001
Character count, median (IQR)	1350.5 (703.0, 2418.0)	663.0 (565.5, 1176.0)	1559.0 (830.0, 2544.0)	1049.0 (609.0, 1331.0)	763.5 (571.5, 1556.5)	.01
Word count, median (IQR)	264.5 (145.0, 544.0)	119.5 (92.5, 193.5)	329.0 (168.0, 575.0)	192.0 (108.0, 217.0)	142.0 (101.0, 316.5)	<.001
Sentence count, median (IQR)	31.5 (18.0, 60.0)	16.0 (10.0, 27.0)	37.0 (20.0, 63.0)	19.0 (11.0, 29.0)	15.0 (11.0, 29.0)	<.001
Paragraph count, median (IQR)	35.5 (20.0, 84.0)	14.0 (10.5, 30.0)	44.0 (23.0, 97.0)	26.0 (16.0, 31.0)	18.5 (11.5, 36.5)	<.001

[a]This comparison was not made.

Enhancing Readability

Difficult-to-read information had 3 characteristics in common. They were written in literacy style, with medical jargon, and with unnecessary detail (Table 3).

Document A was the answer to the question, "Will I catch COVID-19 if I travel on a bus or subway train previously used by a confirmed patient?" It was written in literacy style, making it difficult to read. It was changed from literacy style to colloquial to improve its readability.

Document B was the answer to the question, "What are the symptoms of COVID-19?" The original version described the symptoms at length, making it difficult to identify important information. To make the document easier to understand, we included only typical symptoms for each organ rather than all possible symptoms. The medical jargon used in document B was replaced with common words to improve its readability. Medical terms, such as dyspnea, hemoptysis, emesis, anosmia, and ageusia, were replaced with commonly used words, such as shortness of breath, coughing up blood, vomiting, and loss of smell or taste.

Document C was the answer to the question, "How is the test for COVID-19 done?" The original version used medical jargon and included excessive detail in the explanation. To improve its readability, the content was summarized, and the unnecessarily detailed information included in document C was replaced with information tailored to the general public.

Table 3. Original text [35] and text with revisions to enhance readability.

Document	Original version	Suggested revision
A, literacy style	When riding on public transportation such as buses or subways, if you touch a handle that has been contaminated by the coronavirus, you could become infected with the virus through your eyes, nose, and mouth. However, proper wearing of a mask and hand sanitization can lower the risk of COVID-19 infection.	You can catch the virus through your eyes, nose, or mouth after touching a handle that has the virus on it. However, if you wear a mask and wash your hands, you can lower your chances of contracting COVID-19.
B, medical jargon	Symptoms such as a fever of 37.5 ℃ or higher, cough, dyspnea, chills, muscle pain, headache, sore throat, anosmia, ageusia, pneumonia, fatigue, decreased appetite, phlegm, confusion, dizziness, and a runny or stuffy nose can indicate COVID-19. Hemoptysis, chest pain, conjunctivitis, skin symptoms, or digestive system symptoms such as nausea, emesis, and diarrhea may also indicate COVID-19.	Fever and cough are common. Having COVID-19 can make you feel cold and tired, and you may have difficulty in breathing. You may lose your appetite and have a sore throat, body aches, nausea, or diarrhea. You may not have any sense of smell or taste. Some people may not have any symptoms and feel normal, but they can still spread the virus.
C, unnecessary detail	Samples are collected by physicians, nurses, and medical technicians at designated locations. Upper respiratory tract sampling is mandatory, while lower respiratory tract sampling is optional for patients with sputum. You may experience discomfort or pain while the sample is being collected. The upper respiratory tract sample is a combination of a nasopharyngeal and oropharyngeal swab in one tube. A nasopharyngeal swab involves inserting a cotton swab into the nostril until it reaches the posterior nares. An oropharyngeal swab includes inserting a cotton swab to scrape the inside of the throat. A lower respiratory tract sample is collected by spitting sputum into a container, ensuring that it is not contaminated by other liquids.	You can get tested at screening centers or drive-through facilities. There is a swab and a spit test. In the swab test, a doctor or nurse inserts a cotton swab into your nose or throat. You may feel some discomfort. For the spit test, you are asked to spit thick mucus from your throat into a tube. You will receive your test results through text message.

Discussion

Principal Results and Study Strengths

This study shows that 90.2% of the information available to the public was difficult to read. Of the documents discussing the prevention of COVID-19, only 6.2% (6/97) could be rated as easy to read. This is noteworthy as it shows that very few documents would effectively be able to spread prevention knowledge to the general population. To encourage people to adopt personal protective measures, such as wearing masks and washing hands during the pandemic, the government should prioritize making information on prevention easier to understand. Moreover, easy-to-read documents that were available did not cover all relevant topics equally, such as overview (n=5), prevention (n=6), test (n=0), and treatment (n=1). To make sure that those with lower literacy skills have access to information on public health and safety topics at the same level as people with higher literacy skills.

To the best of our knowledge, this is the first study to evaluate the readability of web-based COVID-19 information written in Korean. Korean is the 20th most spoken language globally, with approximately 82 million speakers [39]. Moreover, South Korea has a large population of older individuals; in 2020, adults aged 65 years and older accounted for 15.7% of the population [40], and it is estimated that South Korea will become a super-aged society in 2025, when the proportion of older adults is expected to reach 20.3% [40]. The proportion is likely to increase to 43.9% by 2060 [40]. Older adults are an important target group when assembling easy-to-understand COVID-19 information because they are at high risk for developing serious complications from COVID-19 [41]. In addition, many older

adults have low literacy skills [42]. For example, 71% of Americans older than 60 years were reported to have difficulties understanding written information [3]. Nearly one-third (31.27%) of Korean adults aged 55 to 65 years could read the words but could not understand sentences or long texts [19]. Older adults with lower literacy skills are more likely to be marginalized by the government's health care or welfare system because they cannot follow instructions for filling out forms.

The documents used in this study, from the national COVID-19 portal run by the government, which is an integrated communication channel that compiles all the COVID-19 information created by various government agencies [35], are likely an accurate reflection of the information currently accessible to the public. The Korean government's message was amplified through social media platforms (such as Twitter and Facebook) and traditional media (TV and newspapers), thus reaching every corner of the country [43].

Advantages and Disadvantages of the National COVID-19 Portal of South Korea for Distributing Information

The national COVID-19 portal of South Korea has several advantages for disseminating information. First, the website is highly accessible; it appears at the top of the first search results page when searching for COVID-19 on 3 major local search platforms: Naver, which has a 68.9% search engine market share in South Korea; Google, which has a 21.4% market share; and Daum, which has a 7.5% market share [44]. This national COVID-19 portal ranked first in web traffic among South Korean government websites [45], and the website ranked 10th in global rankings for health conditions and concerns [46]. Most

health information seekers begin their search activities with search engines [47]; therefore, it is highly likely that Koreans who searched for COVID-19 information on the internet visited the national COVID-19 portal of South Korea. Furthermore, the information on the national COVID-19 portal are convenient for users because they can access any page without logging in, the documents can be downloaded in various formats, and anyone may freely use these documents for public purposes without any copyright restrictions.

Although the national South Korean COVID-19 portal may serve as a key communication platform between health care authorities and the public, it does not have a user-friendly interface. The web pages of the portal are not divided according to the target audience. As a result, medical professionals visiting this website may waste time reading superficial information, and users who are not medical experts may be overwhelmed with unnecessarily detailed explanations. By separating the pages or sections according to audience type (health care workers, the general public, people with low literacy skills), users may then have a more convenient way to access user-friendly information.

Readability of Web-Based COVID-19 Information Generated by Other Public Health Agencies

The websites of the US Centers for Disease Control and Prevention and the National Health Service England have distinct sections for health care workers, the general public, and people with low literacy skills [48-51]. The web page for health care professionals provides COVID-19 training, such as clinical guides for managing cancer patients and patients requiring endoscopy during the COVID-19 pandemic [50]. Their easy-to-read sections provide information on COVID-19 basics, such as advice surrounding staying at home, COVID-19 vaccine during pregnancy, and what to expect after receiving a COVID-19 vaccine [51].

However, recent studies [34,52,53] have shown that some public health agencies have also failed to provide information in an easy-to-read form. Valizadeh-Haghi et al [52] examined the readability of English-language COVID-19 information based on website categories (ie, news, governmental, commercial, organization, educational) and concluded that that the readability levels in all categories exceeded the recommended level and that commercial websites had better readability than governmental websites. Mishra et al [34] reported that the readability of English-language COVID-19 information on 18 government and international public health agency websites did not meet the recommended readability level. Halboub et al [53] investigated 36 Arabic-language websites on COVID-19 and reported that 66.7% of the included websites were easy for the general public to read. Kruse et al [33] conducted a study of COVID-19 information provided by 8 US academic medical centers and reported that 0.7% of information was written at or below the sixth-grade level.

Comparison With Literature on Readability of Outbreak-Related Information

Reading outbreak-related information poses extra challenges to a layperson because of the use of medical jargon [54-56].

Unfamiliar terms, such as *waterborne*, *vertical*, *zoonotic infection*, *herd immunity*, *incubation period*, *cohort isolation*, *outbreak*, *epidemic*, and *pandemic*, are frequently used. Previous studies [57,58] have shown that information on infectious diseases had poor readability; for example, Ebola virus–related information provided by public health agencies was written at readability levels higher than recommended [57], and Basch et al [58] reported that 93% of web-based Zika virus–related information was difficult to read.

Moreover, understanding COVID-19 information is more challenging because of the use of new words and phrases, such as *social distancing*, *un-tact* (noncontact), *new normal*, and *covideo party*. COVID-19 search results are also difficult for the public to understand—only 17.2% of COVID-19–related web pages were at a readable level [32], and Google-searched information regarding COVID-19 (0/150 articles) did not meet recommended readability levels.

Recent readability studies on English texts have been conducted on various types of texts on specific topics such as those used with vaccine clinical trials, privacy policies, and tests. For example, Emanuel and Boyle [59] reported that informed consent texts for COVID-19 vaccine trials were long and difficult to read. Zhang et al [60] reported that explanations of privacy policies of COVID-19 contact-tracing apps were written at readability levels higher than those recommended. Garcia et al [61] investigated the readability of web-based information on COVID-19 testing and reported that only 6 of 50 websites had appropriate readability.

Interestingly, Mishra et al [34] included information written in English posted on the South Korean government website and reported that it was written above the 11th-grade level; however, these results may not truly represent COVID-19 information commonly shared by Koreans, as South Korea is not an English-speaking country. Korean is the only official language of South Korea; paperwork and internet activities in this region are mainly in Korean. Therefore, information in Korean, rather than information in English, should be analyzed to yield results that represent COVID-19 information commonly shared by Korean.

Implications for Practice

To improve the readability of COVID-19 information aimed at the general public, we urge the South Korean government to introduce the following measures. First, the national COVID-19 portal should be organized according to audience type (ie, health care workers, the general public, and those with a low level of education) to optimize the user experience of each type of audience. Second, guidelines on how to draft easy-to-understand health information for Korean speakers should be developed using plain-writing guidelines that include the principles and skills for easy-to-read writing—the target audience should be identified, important points should be prioritized, information should be provided step by step, foreign words should be reduced, short sentences should be used, important topics should be summarized at the end [62],and synonyms should be used to replace medical jargon with everyday words [63,64].

XSL·FO

RenderX

Limitations

Our study has several limitations. First, the results might be biased since only one tool was used to assess readability. Second, our results are representative only of the search time frame. Numerous COVID-19 studies have been conducted, and web-based information related to it is constantly changing [65]. Third, there is no verifiable information regarding who has accessed or read what information in the study because collecting or using any personal information was not allowed. Fourth, we only used the readability tool and did not test any information with actual reader. Fifth, we only analyzed text and did not consider other factors that could affect readers' understanding, such as layout, figures, or videos.

Future Directions

Future research should investigate the impact of nontext elements (ie, figures, infographics, videos) on information comprehension. In regions where two or more languages are spoken, it is also necessary to assess the readability of COVID-19 information in other languages. and differences in readability between languages should be assessed.

Conclusions

Readability levels of COVID-19 web-based information provided by the national COVID-19 portal of South Korea exceeded the recommended ninth-grade level. Efforts are needed to provide easy-to-read information to reach more people during a public health crisis. We hope that this study serves as a call to action for health care authorities to develop better guidelines that encourage an easy-to-read format so that information is provided at a level that most readers can understand and apply.

Authors' Contributions

HM and GHL designed the study and collected data. HM and YJC conducted statistical analyses. HM wrote the manuscript. All authors reviewed the final manuscript.

Abstract

Background: Anxiety and mood problems in adolescents often go unnoticed and may therefore remain untreated. Identifying and preventing the development of emotional problems requires monitoring and effective tools to strengthen adolescents' resilience, for example, by enhancing coping skills.

Objective: This study describes the developmental process, feasibility, and acceptance of Grow It!, a multiplayer serious game app for adolescents aged 12-25 years. The app consists of the experience sampling method (ESM) to monitor thoughts, behaviors, and emotions in daily life to enhance self-insight and daily cognitive behavioral therapy–based challenges to promote adaptive coping.

Methods: Our approach entails an iterative game design process combined with an agile method to develop the smartphone app. The incorporated game features (ie, challenges, chat functionality, and visual representation) in the Grow It! app were co-designed with adolescent end users to increase participant engagement and adherence.

Results: The Grow It! app was delivered for Android and iOS in May 2020. Grow It! was offered to adolescents during the COVID-19 crisis between May and December 2020. Participants of the Grow It! COVID-19 study (sample 1: N=685; mean age 16.19, SD 3.11 years; 193/685, 28.2% boys; sample 2: N=1035; mean age 18.78, SD 3.51 years; 193/1035, 18.64% boys) completed 31.5% (13.2/42) to 49.5% (10.4/21) of challenges. Compliance of ESM was suboptimal (35.1/210, 16.7% to 32.5/105, 30.9%). Follow-up questionnaires indicated an overall score of the app of 7.1 out of 10. Moreover, 72.6% (278/383) to 75.6% (487/644) would recommend the app to friends.

Conclusions: To our knowledge, Grow It! is the first gamified ESM app that both measures individual differences in emotional dynamics and offers an integrated cognitive behavioral therapy–based intervention. Our findings support the feasibility and acceptance, and therefore applicability, of the Grow It! app in adolescents. Further iterations of this serious game app will focus on the increase of compliance and on providing participants feedback through their personal mood profiles.

Introduction

Background

Internalizing problems, such as anxiety and mood problems, have a substantial impact on young people's lives. These internalizing problems are often associated with school dropout, reduced social functioning, loneliness, unemployment, and reduced quality of life [1-3]. Anxiety and mood disorders usually begin in adolescence [4,5], and unfortunately, they often go unnoticed or untreated [6]. When persistent, internalizing problems often result in emerging psychiatric disorders affecting young people's daily lives, their future, and society [1-3,6]. Therefore, early identification and timely intervention are crucial to prevent further deterioration, improve prognosis, and reduce the burden on health care systems and society in general [1,7,8].

Mobile health (mHealth) can play an important role in accurate recognition of symptoms and timely treatment [9-11]. mHealth is defined as wireless technologies, such as smartphone apps, to support or achieve health objectives. In terms of its advantages, first of all, mHealth is scalable, accessible, and maybe less stigmatizing than traditional treatment for youths because of the level of anonymity and privacy [12]. Furthermore, mHealth offers the possibility of incorporating motivational elements such as playfulness and gamification, which is advantageous because humans supposedly learn best by playing [13-17]. Finally, mHealth offered in an attractive and fun way through adolescents' own devices fits very well with their daily life and activities [18,19]. Use is flexible, as it is independent of time and place and can be at a self-determined pace, which is thought to enhance self-efficacy [12]. Indeed, most adolescents indicated that they would use an app to screen for emotional problems and treatment if available [20]. Even though there are already several mHealth apps [21], preventive mHealth apps that integrate novel methods for early identification and preventive intervention are still lacking.

A promising method for the early identification of emotional problems is the experience sampling method (ESM). The ESM is a structured diary method in which participants obtain multiple random notifications on their phone during the day. When a notification pops up, they fill out a microquestionnaire in which they report on their behaviors, thoughts, and feelings in real time (eg, how are you doing right now?). The strength of the ESM is the high ecological validity. Moment-to-moment assessments in real-world settings address the problem of recall bias [22,23]. The promise of ESM data for early identification of adolescents at risk for the development of psychopathology has been demonstrated in a research setting with adults [24] and adolescents [25]. Moreover, self-management may be enhanced by obtaining insights into everyday functioning dynamics, based on ESM data [22,26,27].

The first choice of treatment of anxiety and mood problems in adolescents is psychological therapy, especially cognitive behavioral therapy (CBT) [28-30]. It is known that the way adolescents cope with stress or handle negative emotions in daily life may increase or buffer against the development of anxiety and depressive symptoms [31-33]. That is why CBT is one of the effective interventions aimed at improving coping. Recently, results of an internet-based CBT intervention revealed that positive effects occur already after 4 weeks of CBT [34]. CBT is mostly used in clinical practice but increasingly also applied for preventive purposes [28,29].

Therefore, we cocreated the Grow It! app (Android and iOS) for adolescents aged 12 to 25 years. Grow It! is a multiplayer serious game, a game that is designed for a primary purpose other than entertainment [30]. Incorporated in the Grow It! app are ESM, to enhance self-management and identify mood problems earlier on, and gamified CBT-based challenges, to increase coping. Initially, the app was developed for high-risk adolescent populations, such as adolescents with chronic somatic conditions, offspring of parents with psychiatric disorders, or adolescents experiencing extreme stressful societal circumstances, for example, the COVID-19 pandemic. However, the app may also serve a broader purpose of prevention for adolescents from a general population.

Objectives

The first aim of this study is to give an elaborate description of the developmental process of the multiplayer serious game app Grow It! Second, we aim to study the feasibility and acceptance of Grow It! among end users.

Methods

Developmental Process

Overview

The Grow It! app was developed, with intermittent periods, from March 2016 to February 2020 (Figure 1). During its development, we cocreated the app with a large multidisciplinary team of child and adolescent psychiatrists, developmental and clinical psychologists, data analysts, game designers, and multiple test panels (adolescents aged 12-25 years) [35,36]. The initial concept was developed with University of the Arts Utrecht (test 1a-1b). With IJsfontein BV and consultancy company Game Architect Studio, an agile process (defined as a software development methodology including iterative development, where requirements and solutions evolve in multidisciplinary teams [37]) then was used to develop and evaluate the minimal viable product (MVP; test 2a-2e). For all tests, informed consent was obtained.

Figure 1. The developmental process of the Grow It! app. ESM: experience sampling method; VAS: visual analog scale.

Initial Concept

In March 2016, the developmental process of Grow It! started with a prepilot (test 1a, N=10), which resulted in a paper-based prototype and wireframes. Later on, in the pilot (test 1b), adolescents from the general population (N=21) tested the app's beta version during a 6-week trial. Weeks 1 and 6 of the test consisted of an ESM-only study with 8 mood assessments per day. During weeks 2 to 5, the mood assessments were given twice a day and combined with CBT-based challenges. In all weeks, users received feedback through push messages complimenting them. Lessons learned were that adolescents were motivated by the game mechanics of Grow It! and liked completing the ESM questionnaires and daily challenges.

Minimal Viable Product

In June 2019, an MVP was built. We aimed to improve the app's content, visual design, interaction design, and reliability of assessments and ran a technical test. The app was developed using agile development and user-centered design methods, including different tests and collaboration with focus groups. Different groups of adolescents (n=6 and n=9) received instructions and were invited to design CBT-based challenges aiming at adaptive coping [36]. Thereafter, all ideas were formulated into specific challenges and were rated in terms of their clinical appropriateness and coping effectiveness by 11 child and youth psychologists and psychiatrists. As a result of these focus groups (test 2a), 126 challenges were formulated, which were later used as the challenges in the Grow It! app. Furthermore, a survey among 107 adolescents (test 2b) resulted in the choice for a visual design that (1) was accepted by a broad range of ages and by both boys and girls and (2) was low cost in maintenance. In interviews (N=4, test 2c) with regard to the navigation of the app, special attention was given to the answer-scale development (Likert and visual analog scale) to increase the assessments' reliability. In empirical studies on ESM data [22], visual analog scales had demonstrated the anchor-influenced results, and therefore, different approaches

were tested (eg, add a cursor above the anchor line). Interviews with adolescents indicated that Likert scales are more intuitive if they run from high to low on the screen instead of low to high. In December 2019 and February 2020, user experience tests of the Grow It! app were run (test 2d). Adolescents (N=23) played the Grow It! app for 1 week. On the basis of interviews, we improved and extended the content of the app by (1) adding a limited chat function with predesigned stickers to motivate team members, (2) allowing users to choose from 3 challenges a day for 6 weeks, and (3) adding a tour in which game mechanics are explained. Finally, a handbook for errors arose from our technical test and quality assessment, which was performed by the research team (N=10, test 2e).

Feasibility and Acceptance Test

In May 2020 and in December 2020, at the first 2 peaks of the COVID-19 pandemic, the Grow It! app was launched to assess the game mechanics and user acceptance of the MVP. Owing to government restrictions, all adolescents had to follow social distancing measures (eg, staying at home because schools were closed). Through (social) media, the app was made available to Dutch-speaking adolescents living in the Netherlands, aged 12-25 years, who owned a smartphone. Participants were consecutively enrolled in a Grow It! team after completion of the baseline questionnaire that was linked to the web-based informed consent procedure on a secure website. This way, participants started with the app as soon as possible.

In total, 685 adolescents (sample 1: mean age 16.19, SD 3.11 years; 193/685, 28.2% boys) played the Grow It! app for 6 weeks, and in the second sample, another 1035 adolescents (sample 2: mean age 18.78, SD 3.51 years; 193/1035, 18.64% boys) played the Grow It! app for 3 weeks. A follow-up questionnaire was filled out by 383 and 644 adolescents for samples 1 and 2, respectively (see Table 1 for demographics). In the Grow It! app, participants were given 5 ESM notifications per day and daily challenges. Users who did not show activity in the app (0 or 1 activity in ESM or challenges) were excluded

from the sample, because to evaluate the user experience of the Grow It! app we were interested in participants who were involved in playing the app.

A complete overview of all (ESM) instruments and questionnaires is provided in our internet-based codebook [38].

The outcomes of our feasibility and acceptance test can be found in the *Results* section. Statistical analyses are descriptive (means, SDs, and frequencies) and performed using SPSS (version 25; IBM Corp) [39].

Table 1. Sample characteristics and demographics.

	Sample 1		Sample 2	
	App engagement (Grow It! activity; N=685)	Follow-up questionnaire (n=383; 55.9% retention)	App engagement (Grow It! activity; N=1035)	Follow-up questionnaire (n=644; 62.2% retention)
Age (years), mean (SD)	16.19 (3.11)	16.26 (3.07)	18.78 (3.51)	18.48 (3.43)

End Product of Developmental Process: The Grow It! App

User Journey

The user journey first entails a phase of enrollment, during which participants can personalize their account. After receiving a 6-digit code (letters and numbers) from the research team via SMS text messaging, they log in to Grow It! and choose their nickname based on 2 turntables. The first turntable shows an adjective (eg, Adorable, Dangerous, Lucky, Creative, and Romantic), and the second turntable shows an animal name (eg, Alpaca, Snake, Iguana, Rabbit, and Crocodile). Participants can rotate the turntables as often as they want to personalize their nickname. For example, one participant nickname could be *Lucky Rabbit* or *Adorable Alpaca* (Figure 2). The game mechanics (ie, personalization, collaboration, competition, and feedback) are explained in the mandatory tour of the Grow It! app.

Figure 2. Nickname.
Collaboration

As adolescents are sensitive to peer influence and can be motivated by interactions with peers [40-42], each participant collaborates anonymously in a team with 3 to 7 other players.

Adolescents are allocated to a team by the researchers. To support team members, participants can chat by sending and receiving positive stickers (Figure 3). Via this chat system, participants can motivate each other, while the system minimizes the possibilities of bullying and negative peer pressure.

Figure 3. Chat function with positive stickers.
Competition

Competition is encouraged at the team level, where teams play versus each other. Each team has a virtual tree with a name (eg, Oaks, Pines, and Palms), which allows participants to compare their team performance with that of other teams (Figure 4). At the start of the game, the tree is empty. Teams *grow* their tree when participants receive points by reporting their feelings and behaviors (ESM) and doing daily challenges. These reports are personal and shielded. Team members only see the amount of points their teammates have collected. After a team collects a specified amount of points, they achieve a *spurt* (ie, level-up), which means that the tree grows in height, and every team member receives a gift to embellish the tree (Figures 5 and 6). As game mechanics, these provide a positive feedback loop and a progress update and establish the reward scheme or the

behavioral conditioning that increases retention. Upon earning a gift (ie, loot box) from a growth spurt, a participant can then select his or her choice from 3 gifts. The gifts are wrapped so that there is no indication of what is inside. As a game mechanic, selecting a random gift creates surprise and moments of anticipation essential to maintaining a state of play [43]. When teams have just started using the app, it does not take many points to achieve the first *spurt* and earn a gift. As the game progresses, however, and teams move to higher levels, more and more points are needed to earn a *spurt* and gifts. In this way, adolescents are stimulated to keep playing and remain engaged with the app. The difficulty level is scaffolded by incrementally increasing difficulty, which supports retention by continuously challenging the participants as they progress through the game.

Figure 4. Comparing own tree with trees of other teams.
Figure 5. Receiving a gift.

Figure 6. Tree decorated with gifts.

Feedback

The game mechanics of Grow It! provide feedback at different levels. Whereas users can see their own and their team members' scores in the score overview screen (Figure 7), on their profile page, they obtain an overview of how many times they reported their feelings, behaviors, and challenges that day (Figure 8). Finally, the Grow It! app has a contact button in case of technical issues or urgent psychological problems. Whenever a participant pushes the contact button, a phone number is displayed through which the research team can be reached by telephone or texting on working days during office hours. On the study website, information can be found on how to reach help in acute situations or outside working hours, referring to professional and free services.

Figure 7. Overview of earned points.
Figure 8. Profile page with the number of completed questionnaires.
Daily Emotions

The ESM is an integral part of the app, which can be used for early identification of emotional problems and enhancing self-management in adolescents [22]. To prompt adolescents to report on their feelings, they receive several notifications per day, which are randomized to prevent structural answering patterns (eg, always in math class at 11 AM) [22]. In the first studies, adolescents answered 5 microquestionnaires per day (taking approximately 1-2 minutes) regarding their sleep, activity, affective well-being (eg, I feel happy or sad), coping strategies, pain, fatigue, social behavior, loneliness, stress, and coping (Figure 9).

Figure 9. Examples of daily experience sampling method questions.

Our ESM approach's novelty is that it is gamified to increase motivation, which intends to result in a higher rate of compliance (percentage completed self-evaluations) as well as improved data quality [15]. Compliance is one of the critical quality markers for ESM studies [22].

Daily Challenges

To teach adolescents how to cope with setbacks and to promote emotional resilience, the Grow It! app contains daily challenges aimed at strengthening adaptive coping, supporting physical activation, and preventing emotional problems. Coping styles incorporated in the challenges promote distraction, problem solving, social support, and acceptance [44,45]. Participants can choose 1 out of 3 challenges per day (Figure 10). Challenges are divided into three categories: photo challenges, quizzes, and assignments. Examples of challenges are as follows: make a picture of something you hold dear (photo challenge; aimed at distraction), ask someone what they like about you and write it down (assignment; aimed at social support), or answer a multiple-choice question such as *What is sushi usually rolled in?* (quiz; aimed at problem solving). An additional randomly available assignment is the photo check. Participants are shown a matrix of 9 photos and assess which photos fit a particular theme. In this way, they act as the photo challenge jury and can award points to participants and earn extra points themselves for this task.

Figure 10. Daily challenges.

Ethical Considerations and Privacy

Risks related to privacy were mitigated by making all participants pseudonymous and only identifiable in the app by participation codes and pseudonyms. Participants determine their pseudonym (ie, nickname) from a preselected set of words provided by the app. Participants cannot be identified, and only the research team has insight into the private data of the participants. Data collected with the app pertain to the user's game data (eg, game-specific actions) and responses to the ESM. The app also accesses the mobile device's camera, but only when a participant takes a photo for a challenge (not at other times), and the app does not access other functionalities (eg, Google, GPS, or health apps). All user data are encrypted and sent directly to a secure server at the researcher's institute. The privacy and security of the Grow It! app is approved by the privacy and security office of Erasmus Medical Center, and the app complies with the Dutch General Data Protection Regulation (Algemene Verordening Gegevensbescherming) and NEN-norm 7510:2017 (Dutch standard of information security management systems in health care). The app is available for research purposes in the Google Play store [46] and Apple store [47]. This study has been approved by the Medical Ethics Committee of the Erasmus Medical Center (MEC-2020-0287).

Results

Overview

As shown in Table 1, participants of sample 1 (N=685; mean age 16.2, SD 3.1 years) were somewhat younger than adolescents in sample 2 (N=1035; mean age 18.8, SD 3.5 years). In general, participants of both samples were relatively highly educated and mostly of Dutch ethnicity. The follow-up questionnaire was filled out by 55.9% (383/685) and 62.2% (644/1035) of the users in sample 1 and sample 2, respectively.

Feasibility and Acceptance

An overview of app engagement (ESM compliance and challenges) and answers of the user evaluation questionnaire carried out in the follow-up can be found in Tables 2 and 3.

Regarding the ESM component, overall compliance was 16.7% (35.1/210 notifications, sample 1) and 30.9% (32.5/105 notifications, sample 2). About 56.77% (583/1027) of the participants indicated that they thought the number of questions per day was too high, whereas about 40.7% (418/1027) indicated the number of questions as sufficient. Some participants also reported that they did not understand why the same questions were asked repeatedly (sample 1: N=20, sample 2: N=16; ie, at each notification, the same ESM questions were asked to monitor their feelings and behavior over the study weeks). Moreover, 15% (97/644) to 22.9% (88/383) reported no effect of the ESM. However, 66.8% (256/383) to 72.4% (466/644) reported reflecting more on their feelings as a result of the ESM.

With regard to the daily CBT-based challenges, participants completed 31.5% (216/685) to 49.47% (512/1035) of all challenges. Whereas in sample 1, a total of 1.2% (8/685) participants completed all 42 challenges (100%), 6.57% (68/1035) participants completed all 21 challenges (21/21, 100%) in sample 2. The self-reported effect of the challenges showed that 20.6% (79/383) to 44.2% (285/644) of the participants became more active as a result of the Grow It! challenges.

The overall user evaluation of Grow It! was positive. The average app evaluation score was 7.1 of 10 (SD 1.5) in sample 1 and 7.2 of 10 (SD 1.3) in sample 2. Moreover, the app's design was evaluated with a score of 7.7 to 8.0 of 10. Finally, 72.6% (278/383) to 75.6% (487/644) would recommend the app to their friends.

Results for Adolescents Compared With Emerging Adults

Given the broad age range in which adolescents participated (12-25 years), we also reported outcomes separately for adolescents (12-17 years) and emerging adults (18-25 years) in Tables 2 and 3. Higher user evaluations of the Grow It! app were found in the adolescent group in comparison with the emerging adult group (ie, samples 1 and 2: adolescents rated the design of the app higher, and more adolescents would recommend the app to their friends in samples 1 and 2; sample 1: adolescents' evaluation of the app was higher, and number of ESM notifications per day was evaluated better; sample 2: evaluation of the chat function was better in adolescents). Moreover, no differences between age groups were found with regard to app engagement with the exception of slightly higher

compliance of ESM in emerging adults than in adolescents (only in sample 1).

Discussion

Principal Findings

The Grow It! app emerged from a lack of and need for preventive interventions for emotional problems and promoting adaptive coping for adolescents; in addition, these interventions need to be low key, nonstigmatizing, fun, attractive, private, and secure. On the basis of the developmental process and acceptance and feasibility of Grow It!, key lessons learned and directions for future research are formulated and shared. Our approach entails an iterative game design process combined with an agile method to develop the smartphone app. The incorporated game features in the Grow It! app were co-designed with adolescent end users to increase participant engagement and adherence. With regard to the app engagement and user evaluation filled out at follow-up, we indicated that we have some evidence that supports the feasibility and acceptance, and therefore applicability, of Grow It! in adolescents.

Earlier studies suggest that adolescents are open to using mHealth [48]. Indeed, the large interest as well as the positive user evaluation provide reason to believe that adolescents, at least a large group, are positive and open to using mHealth. Grow It was co-designed with youths, which was reflected in age-adequate daily challenges and an overall positive rating of the Grow It! app. Moreover, 66.8% (256/383) to 72.4% (466/644) of the participants felt they reflected more on their emotions.

Limitations

Although the results of the developmental process, acceptance, and feasibility are informative and promising for mHealth, several limitations should be mentioned. First, the majority of the study sample consisted of girls. The design of the app seems more appealing to girls, despite the long process of cocreation with both boys and girls. One of the explanations might be that girls are more inclined to seek help [49] and therefore are also more inclined to participate in our study.

Second, the COVID-19 pandemic and related governmental restrictions might have influenced the results. Owing to remote working during the COVID-19 pandemic, participants had no or minimal personal contact and received minimal instructions on how to participate in an ESM study, although this is stated as an important factor to obtain reliable data [22]. Third, concerning self-monitoring, it is notoriously difficult to motivate adolescents. In this study, compliance of ESM was lower than in a typical research design [22]; however, participants received no financial incentive and were entirely motivated by the game structure to answer questionnaires. We, therefore, expect that with more targeted use (eg, in blended care when the app is explained by a professional), the compliance and user satisfaction might be more favorable. Furthermore, the dropout rates were comparable with other web-based studies [50]. In order to increase app engagement, improvements are needed; for instance, designs may need to be tailored to the individual (personalization) and (in-person) feedback is needed.

Future Directions

With regard to the early identification of emotional problems, ESM data of the Grow It! app provides an opportunity to develop algorithms in future research for the early detection of emotional problems, which often go unnoticed in adolescents [6]. Identifying emotional problems early on would require capitalizing on novel developments in clinical psychology [51] combined with the motivational game architecture codeveloped with youths [36]. The ESM has already shown to be a reliable method to investigate variation in thoughts, feelings, and symptoms over time and context in research settings [22,23]. Dietvorst et al [25] have demonstrated that ESM data helps to identify the onset of depressive feelings among adolescents 3 months ahead. Specifically, this was done by differentiating typical adolescents (eg, grumpy at home), from early depressive feelings. In future work, analyzing highly rich ESM data with more powerful analytical techniques, such as machine learning, could potentially improve this early identification.

In clinical practice, self-management and self-insight may be enhanced by obtaining insights into one's emotion dynamics [22,26,27]. A feature such as providing participants with feedback through a daily life emotion chart (eg, mood profile) could provide participants with better insight and feedback into their well-being [52,53]. It may also serve as a therapeutic function, as integrating real time mood profiles in the app could encourage adolescents to reflect more on their emotions, coping, and behavior in different contexts [26] and could also be used as a routine outcome measure during therapy. To test the effects of the app upon adolescent well-being and resilience, an additional in-depth evaluation is required. Research questions and hypotheses that are beyond the scope of the developmental process focusing on the main effect of the app are preregistered [54,55] and will be executed in the future accordingly, including a randomized controlled trial study to test the effectiveness of the Grow It! app.

Conclusions

The Grow It! app has been developed and improved through iterations in collaboration with a large multidisciplinary team. It is innovative, age-attuned, easily accessible, fun, and visually appealing and, most importantly, serves the needs of adolescents. The app was well received by adolescents, and the first findings presented here indicate that adolescents were motivated by the game mechanics of Grow It! and liked completing the ESM questionnaires and daily challenges. Initially, the app was developed for high-risk adolescent populations, such as adolescents with chronic somatic conditions, offspring of parents with psychiatric disorders, or adolescents experiencing extreme stressful societal circumstances, for example, the COVID-19 pandemic. However, the app may also serve a broader purpose of prevention for adolescents from a general population. Our findings support the feasibility and acceptance, and therefore applicability, of the Grow It! app in adolescents.

The ambition is to further improve the app after each research study by including new features and resolving usability issues. The next step will be to focus on the increase of compliance and providing participants feedback through their personal mood profiles.

Abstract

Background: There is growing interest in digital platforms as a means of implementing scalable, accessible, and cost-effective mental health interventions in the workplace. However, little is known about the efficacy of such interventions when delivered to employee groups.

Objective: This study aims to evaluate the feasibility and preliminary efficacy of a digital mental health platform for the workplace, which incorporates evidence-based practices such as cognitive behavioral therapy and acceptance and commitment therapy. A total of 3 brief, unguided interventions designed to address stress, anxiety, and resilience, respectively, are evaluated. The primary aim is to determine the feasibility of the study methods and interventions in preparation for a definitive randomized controlled trial.

Methods: The study used a fully remote, parallel, multi-arm, external pilot randomized controlled trial, with 3 intervention arms and a no-intervention control group. Participants were working adults representative of the general UK population with respect to age, sex, and ethnicity who were recruited from a web-based participant platform. Primary outcomes included objective and self-report measures of feasibility, acceptability, engagement, transferability, relevance, and negative effects. Secondary outcomes included 4 self-report measures of mental health and well-being, completed at baseline (time point 0 [t0]), postintervention (time point 1 [t1]), and the 1-month follow-up (time point 2 [t2]). Secondary outcomes were analyzed via linear mixed-effects models using intention-to-treat principles. Preregistered criteria for progression to a definitive trial were evaluated.

Results: Data were collected between January and March of 2021. A total of 383 working adult participants meeting trial eligibility were randomized, of whom 356 (93%) were retained at t2. Objective engagement data showed that 67.8% (196/289) of participants randomized to an intervention arm completed their intervention. Overall, 87.1% (203/233) of participants reported being *satisfied* or *very satisfied* with their intervention and rated the quality of their intervention as *good* or *excellent*. All intervention groups reported significantly greater improvements than the control group on at least one secondary outcome at t1, with between-group Hedges g effect sizes for the pooled interventions ranging from 0.25 (95% CI 0.05-0.46) to 0.43 (95% CI 0.23-0.64). All the improvements were maintained at t2.

Conclusions: The study methods were feasible, and all preregistered criteria for progression to a definitive trial were met. Several minor protocol amendments were noted. Preliminary efficacy findings suggest that the study interventions may result in improved mental health outcomes when offered to working adults.

Trial Registration: ISRCTN Registry 80309011; http://www.isrctn.com/ISRCTN80309011

Introduction

Background and Rationale

Mental illness affects hundreds of millions of people worldwide, resulting in decreased quality of life, family and community disruption, increased health care costs, and a significant economic burden for employers [1,2]. Employee performance, rates of illness, absenteeism, and staff turnover are all affected by employees' mental health status. In the United Kingdom, workplace mental health problems result in an estimated 70 million lost workdays and a total cost of up to £45 billion (US $61 billion) each year for businesses [3]. This is compounded by an estimated global treatment gap of >50% for people with mental health disorders [4,5].

There is growing interest in web and smartphone apps as a means of increasing the reach of mental health and well-being interventions [6,7]. Digital platforms can offer a broad range of content within a standardized environment that is interactive and dynamic while also being widely accessible, cost-efficient, and nonstigmatizing. With fewer access barriers, digital platforms also have the potential to offer a preventative solution to common mental health problems by facilitating sustained, proactive engagement [8,9]. Such platforms can vary widely in their means of delivery (web vs mobile app), the core therapeutic approach they use (with cognitive behavioral therapy [CBT], mindfulness meditation [MM], and positive psychology being common), and the duration and format of their content.

There is now convincing evidence for the effectiveness of digital interventions when delivered in health and community settings [10], as well as emerging evidence that they may be effective when delivered in occupational settings [11,12]. Previous meta-analyses have found small positive effects on psychological well-being (Hedges g=0.37) and work effectiveness (Hedges g=0.25) [11] and small to moderate effects on common mental health outcomes, such as stress (Hedges g=0.54), anxiety (Hedges g=0.34), and symptoms of depression (Hedges g=0.30) [12]. However, the current evidence base is limited by considerable heterogeneity across studies and an insufficient number of high-quality trials. Moreover, only a fraction of for-profit mental health apps (MHapps) are supported by empirical evidence [13], with added concerns that such platforms are frequently characterized by low adherence [14-16]. Together, these suggest the need for further research.

In this study, we conduct an external pilot randomized controlled trial (RCT) as part of the initial testing of *Unmind*—a novel digital mental health platform for the workplace. *Unmind* provides employees with tools to help them track, maintain, and improve their mental health and well-being. It features a broad range of content that draws on multiple evidence-based approaches such as CBT [17], MM [18], behavioral activation [19], acceptance and commitment therapy (ACT [20]), and positive psychology [21]. Central to the platform are individual learning and development courses (known as *Series*) designed to address specific topics of mental health and well-being. *Series*

are short, standalone interventions, typically ranging between 5 and 7 sessions, each of approximately 10 minutes in duration, and can feature a mix of audio and video content, infographics, and interactions with a chatbot.

Study Objective

Consistent with recent guidelines on pilot trials [22,23], the primary aim of this study is to evaluate the feasibility of the study methods, and 3 separate *Unmind Series* that address the topics of stress, anxiety, and resilience, respectively, in preparation for a future definitive RCT. We chose to evaluate content relating to stress and anxiety as these are highly prevalent in the workplace [3] and have been extensively studied in previous evaluations of MHapps [24-26], allowing for a comparison of the current findings to previous evidence. In addition, we chose to evaluate content relating to resilience, as evidence suggests that it plays an important role in the prevention of mental health problems [27] and thus may be integral to the effectiveness of a preventative platform. A secondary aim is to establish the preliminary efficacy of each intervention with respect to self-report measures of stress, anxiety, symptoms of depression, and resilience, including establishing between-group effect sizes and 95% CIs (for each intervention compared with the control group). Although depression was not a specific target of any of the study interventions, we chose to include it as an outcome as it is highly comorbid with stress and anxiety [28,29] and a common problem in workplace settings [3]. Finally, we also aim to report on the combined effects of all interventions compared with the control group.

As the *Unmind* app comprises an extensive library of standalone interventions, it is important that each component of the app is evaluated. We chose to include 3 intervention arms in this study as this is more efficient than performing sequential 2-arm trials and increases the proportion of participants randomized to an intervention arm [30]. In addition, if a definitive RCT is warranted, an aim might be to evaluate whether each intervention arm has a greater effect on the specific outcome targeted by that intervention relative to the other intervention arms. Thus, this study uses a parallel, multi-arm, external pilot RCT design and recruited UK-based, community-dwelling, working adult participants who are randomly allocated to 1 of 3 intervention arms or to a no-intervention control group. We chose to implement a no-intervention control as (1) participants were not selected on the basis of poor mental health or seeking help for a problem, (2) recent evidence suggests that wait-list groups may introduce nocebo effects in psychotherapy trials [31], and (3) participants received monetary compensation for taking part.

The feasibility of each intervention arm is assessed via objective and self-reported outcomes capturing recruitment, retention, intervention uptake and adherence, acceptability, transferability, relevance, and negative effects. The preliminary efficacy of each intervention arm is assessed via self-report outcome measures delivered before (time point 0 [t0]) and after the

interventions (time point 1 [t1]; 2 weeks after t0) and at the 1-month follow-up (time point 2 [t2]). The results of this study are intended to inform whether a definitive RCT to evaluate the efficacy of each intervention arm is warranted and provide estimates of the parameters required for its design and implementation.

Methods

The authors followed the CONSORT (Consolidated Standards of Reporting Trials) 2010 guidelines [32] when preparing this study, including recent extensions to pilot trials [22] and multi-arm trials [33].

Trial Design

This study was a parallel, multi-arm, external pilot RCT with pre- (t0) and postintervention (t1; 2 weeks after t0) assessments and a 1-month follow-up (t2). Participants were randomly allocated to 1 of 3 brief, self-guided psychological interventions (*Series*) featured on the *Unmind* platform or to a no-intervention control group in a 1:1:1:1 allocation ratio. Participants were working adults recruited from the Prolific web-based recruitment platform [34], and the entire study was conducted on the web between January and March 2021. Of note, the study commenced several weeks after the start of a third national UK lockdown (in response to the SARS-CoV-2 pandemic), and t2 data were collected after the commencement of a phased easing of lockdown restrictions. The trial was preregistered at ISRCTN 80309011, and a full study protocol was preregistered at Open Science Framework in December 2020.

Ethics Approval

The trial received ethical approval from the University of Sussex sciences and technology research ethics committee (ER/KC226/2).

Participants

Participants were recruited via the Prolific web-based recruitment platform, which has been empirically tested across attributes such as participant response rates and data quality [35]. Inclusion criteria were (1) aged at least 18 years, (2) currently residing in the United Kingdom, (3) self-identifying as being in full- or part-time employment, (4) having an active account on Prolific, (5) having access to an internet connection via a smartphone or desktop device, and (6) being fluent in English. Prolific indicated that there were 50,978 eligible individuals at the time of conducting the study.

Prolific implements a prescreening system that allows researchers to screen for eligibility without implementing a screening questionnaire. Prolific also supports the recruitment of study samples representative of the national UK population with respect to age, sex, and ethnicity based on guidelines from the UK Office of National Statistics. This study drew upon this feature to maximize the generalizability of the findings.

Procedures

All study assessments were hosted on the Qualtrics survey platform [36], and participants were required to provide informed consent via a form built into each study assessment alongside a digital information sheet. All participants who completed the t0 assessment were invited to complete the t1 and t2 assessments via the Prolific recruitment platform. Participants were offered a £7 (US $9.50) incentive for completing each of the 3 study assessments (baseline, postintervention, and 1-month follow-up), delivered via Prolific. Participants randomized to one of the intervention arms received reminder messages on days 5 and 10 of the intervention (delivered via Prolific's anonymous inbox system), encouraging them to complete all intervention sessions. However, participant reimbursement was not contingent on intervention adherence.

Randomization

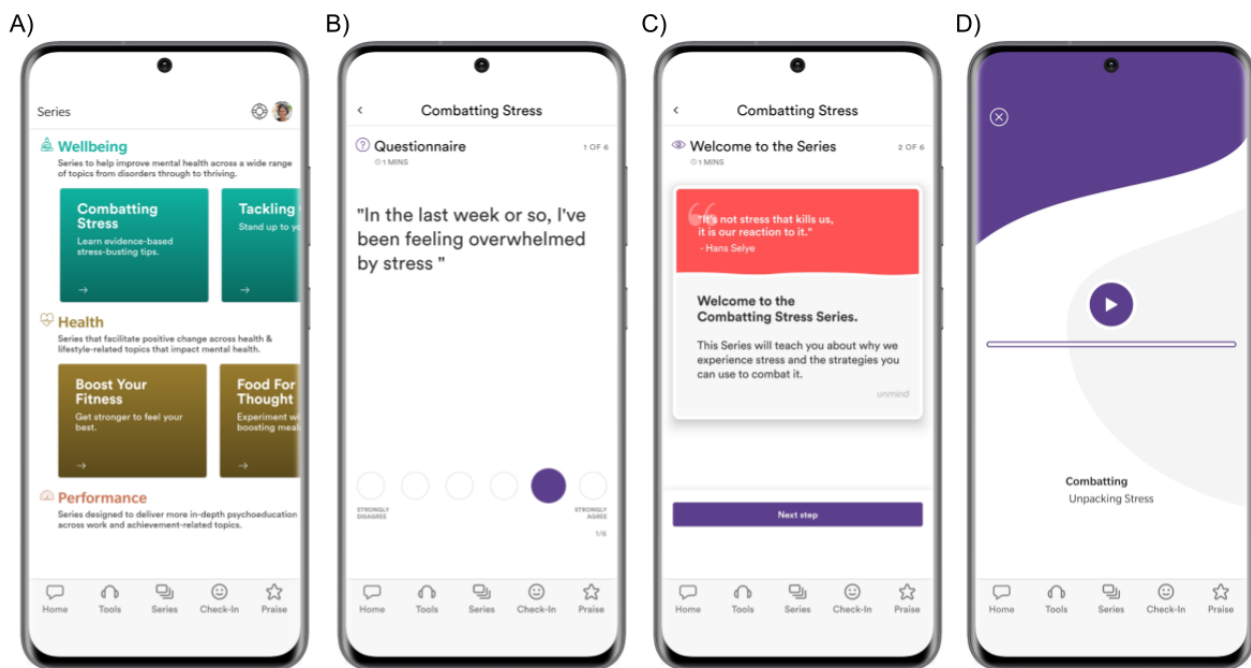
Randomization occurred at the end of t0 and was implemented via the Qualtrics *randomizer* feature, which uses block randomization to ensure balanced groups. It was not possible to blind the participants to group assignments. After randomization, participants assigned to one of the intervention arms were sent a message via Prolific's anonymous inbox system with instructions on how to access their intervention, including using a unique voucher code to sign up to the *Unmind* platform. The research team remained blind to group assignment for the duration of data collection but was unblinded during data analysis.

Interventions

Overview

Unmind is a digital platform designed to be used by working adults to measure, manage, and improve their mental health and well-being. It can be accessed via the web, mobile, or tablet (Android or iOS), and the *Unmind* smartphone app can be downloaded via the Apple or Google Play stores. The platform features a wide range of resources and content created by academics and clinicians with expertise in adult mental health, which are rooted in evidence-based practices such as CBT [17], MM [18], behavioral activation [19], ACT [20], and positive psychology [21].

Although *Unmind* includes a wide range of content and features, this study focused on evaluating *Series*. *Series* are brief, unguided learning and development courses, typically comprising between 5 and 7 sessions, each of approximately 10 minutes in duration, that are designed to be completed sequentially, and include a mix of audio and video content, infographics, and interaction with a chatbot (see Figure 1 for example screenshots). Each *Series* focuses on a specific symptom, topic, trait, or behavior related to mental health and typically uses a key therapeutic approach, such as CBT, MM, or ACT. *Series* are designed to provide both reactive support (to manage or address an existing problem) and proactive support (to prevent the onset of a future mental health problem).

Figure 1. Screenshots of the *Unmind* smartphone app showing the *Series* tab (panel A) and examples from the *combatting stress* intervention (panels B-D).


The intervention arms in this study comprised 3 individual *Series* designed to address stress, anxiety, and resilience, respectively. For the purposes of the study, participants were instructed to only engage with their allocated intervention, despite having access to the full *Unmind* platform, and were excluded from standard email campaigns that encourage interaction with content not evaluated in this study. Participants had 2 weeks to complete their allocated intervention and were free to progress through the intervention at their own pace. A description of each intervention arm is provided in the following sections.

Combatting Stress

This intervention draws upon CBT and ACT techniques and is designed to help users better manage their day-to-day stressors. Over the course of 7 sessions, it provides psychoeducation on stress and its physical manifestations, helps users spot personal triggers, and explores different approaches to coping. It also introduces the idea of acceptance. Users are taught stress management techniques and are encouraged to practice between sessions.

Working With Worry

This intervention is underpinned by theoretical models of generalized anxiety disorder (GAD), although it is targeted at users who identify as worriers rather than those meeting any predefined criteria for a diagnosis of GAD. Content spans 7 sessions and covers key elements of CBT, including tolerance of uncertainty, challenging worry beliefs, problem solving, and working with imagery. It also encourages users to apply evidence-based techniques, including relaxation and attentional focus.

Building Resilience

This intervention aims to help users apply evidence-based techniques to aid the cultivation of essential qualities of personal resilience, drawing upon CBT and ACT. Over the course of 7 sessions, learning covers topics such as honing strengths, facing challenges, and tolerating discomfort. It also explores aspects such as coping styles and realistic optimism. The *Series* encourages users to increase their self-awareness and guides them to build a personal resilience plan.

In each *Series*, learning is optimized by the use of a chatbot to allow note-taking and aid reflection, as well as the use of short recap videos at the beginning of each new session. Each *Series* also has its own accompanying brief handbook, which is emailed to participants as a PDF file on starting their first session. Handbooks contain a summary of key learning points and infographics from the *Series* and include space for participants to write any further reflections on their learning from each session.

For the purposes of this study, participants were instructed not to engage with other content and features included in the *Unmind* app (and not described here) so that the feasibility of the study interventions could be assessed in isolation. The app also includes a *Help* page containing information and resources for key well-being topics and signposting to urgent problems. Participants had access to versions 2.56.0 to 2.59.0 of the *Unmind* app, and no major app changes or updates were launched during the 2-week study period.

Outcomes

Overview

Participant demographics and other variables were captured at t0, including whether each participant had engaged with therapy or counseling, and a mental health or well-being app within 6

months before taking part in the study. Participants were also asked to rate the extent to which they agreed with the statement, "Do you agree that it's important for people to look after their mental health and wellbeing?" on a 5-point Likert scale from *strongly agree* to *strongly disagree*.

Primary Outcome Measures

Recent guidelines suggest that complex health interventions should be feasible, acceptable, engaging, transferable to other settings, and relevant [37]. In addition, psychological interventions should be evaluated for negative effects [38]. Therefore, preregistered primary outcomes included the following:

1. Feasibility: recruitment, intervention uptake, and retention (at t1 and t2)
2. Acceptability: intervention adherence and completion rates, participant satisfaction, and reasons for discontinuing the intervention
3. Engagement: average sessions completed and 3 questions adapted from the Mobile App Rating Scale [39]
4. Transferability: 1 question adapted from the Mobile App Rating Scale
5. Relevance: 1 question assessing subjective relevance
6. Negative effects: 1 question adapted from recent guidelines on assessing negative effects [40] and the proportion of participants that reliably deteriorated across all secondary outcome measures.

Outcomes were measured through a combination of objective data (captured by the *Unmind* platform) and self-reported data captured at t1 (Multimedia Appendix 1).

Secondary Outcome Measures

Preregistered secondary outcomes included self-report measures capturing symptoms of common mental health problems.

The Perceived Stress Scale-10

The Perceived Stress Scale (PSS) is a 10-item scale that asks respondents to rate how often they feel or think that their lives are unpredictable, uncontrollable, and overloaded on a 5-point Likert scale from 0 (never) to 4 (very often) [41]. Total scores range from 0 to 40, with higher scores indicating greater perceived stress. The PSS has a Cronbach α >.70 across 12 individual studies (and .91 in this study at t0) and good test–retest reliability across 4 individual studies [42]. The original scale uses a 1-month reporting period; however, this has been shortened in several previous studies [43,44], and this study used a 2-week reporting period.

The GAD-7 Scale

The GAD-7 is a 7-item scale used to screen for the presence and severity of an anxiety disorder [45]. Participants rate each item on a 4-point Likert scale from 0 (not at all) to 3 (nearly every day), with total scores ranging from 0 to 21. A score ≥10 is suggestive of the presence of anxiety, and scores of 5, 10, and 15 are taken as cutoff points for mild, moderate, and severe anxiety, respectively. The GAD-7 has excellent reliability and internal consistency (Cronbach α of .89 in the original validation and .91 in this study at t0) and has been validated in both the general population and primary care settings [45,46].

The Patient Health Questionnaire-8

The Patient Health Questionnaire (PHQ)-8 is an 8-item scale derived from the PHQ-9, which screens for the presence and severity of depression [47]. The PHQ-8 omits an item that assesses suicidal ideation and is more appropriate for use in nonclinical samples and settings [48]. The response options are equivalent to those of the GAD-7, with total scores ranging from 0 to 24. A score ≥10 suggests the presence of depression, and scores of 5, 10, 15, and 20 are taken as cutoff points for mild, moderate, moderately severe, and severe depression, respectively. The PHQ-8 has excellent internal consistency (Cronbach α of .89 in primary care settings and .88 in this study at t0) and excellent test–retest reliability [49].

Brief Resilience Scale

The Brief Resilience Scale (BRS) is a short, 6-item scale designed to assess people's ability to bounce back or recover after stressful events [50]. Participants rate each item on a 5-point Likert scale from 1 (strongly disagree) to 5 (strongly agree) or the reverse for negatively worded items. The BRS is scored by reverse coding items 2, 4, and 6 and computing the mean of the 6 items. The creators of the scale have suggested that scores <3 be interpreted as *low* resilience and scores ≥4.3 be interpreted as *high* resilience [51]. The BRS displays good internal consistency (Cronbach α=.80-.91 and .91 in this study at t0) and test–retest reliability.

Progression Criteria

As per formal guidelines [52], preregistered progression criteria were defined as follows: (1) full study recruitment within 1 month; (2) at least 30% intervention completion rates based on a previous meta-analysis of adherence to unguided psychological interventions [53]; (3) at least 75% adherence to protocol instructions (defined as the proportion of participants who refrain from engaging with ≥1 *Series* session outside of their allocated *Series*); (4) at least 50% of participants reporting being *satisfied* or *very satisfied* with the intervention and rating the quality of the intervention as *good* or *excellent*; and (5) the 95% CI on between-group effect sizes for secondary outcomes including at least a small effect (Hedges g=0.2) for ≥1 outcome measures.

Progression criteria were considered for each intervention arm individually.

Sample Size

This study was powered for CIs on the feasibility outcomes. A sample size calculation indicated that approximately 100 participants were required to estimate feasibility outcomes with a margin of error ≤10% (based on a conservative population proportion of 50% for retention and adherence, and a 95% CI). This is consistent with previous guidelines suggesting that 60 to 100 participants per intervention arm are optimal for estimating binary outcomes in pilot RCTs [54]. Therefore, we aimed to recruit 400 participants in total.

Statistical Methods

The results from all preregistered primary and secondary measures are reported. Minor deviations from the preregistered

data analysis plan are reported in Multimedia Appendix 2 [40,41,55].

Primary Analyses

Descriptive statistics were used to report primary outcomes. Categorical data were reported as proportions in each response category, and Fisher exact test of independence was used to compare responses between intervention arms (with *P* values computed using Monte Carlo simulation and 2000 iterations). Where tests were significant, post hoc pairwise comparisons between study arms were performed (using false discovery rate methods to adjust *P* values).

Objective in-app usage data were provided by *Unmind*. For simplicity, intervention sessions were only characterized as *complete* if all components of the session were played. Descriptive statistics were used to characterize engagement and stratify participants according to whether they completed, started but did not complete, or failed to start their allocated intervention.

We computed the proportion of participants who self-reported reliable deterioration in mental health scores from t0 to t1, and t1 to t2, based on an estimate of the reliable change index for each outcome measure. The reliable change index was computed based on methods provided by Jacobson and Truax [56], using Cronbach α as a measure of reliability and an α level of .05 (Multimedia Appendix 3). Participants with missing data or those who were unable to reliably deteriorate based on t0 scores were excluded from this analysis.

Secondary Analyses

Secondary outcome measures were analyzed using both intention-to-treat (ITT) and per-protocol (PP) approaches. For the ITT analysis, all participants with complete t0 data were included, regardless of intervention adherence and any deviation from instructions. Participants were excluded from the PP analysis if they failed to complete all 7 intervention sessions, if they started an *Unmind Series* outside of their allocated intervention, or if they were lost to follow-up at t1. As findings from the PP analysis were largely equivalent to ITT, we opted to omit these results (although a comparison of effect sizes is reported in Multimedia Appendix 4).

Analyses were performed using linear mixed-effects models (LMMs) with restricted information maximum likelihood estimation (via the *lme4* package in R [57]). Each model included a within-subject factor *time* (with levels: t0, t1, and t2), a between-subject factor *group* (*combatting stress*, *working with worry*, *building resilience*, or control), their interaction as fixed effects, and a separate baseline for each participant. Time was modeled as a categorical factor. Model residuals were checked via Q–Q plots to assess model assumptions and goodness of fit. For each outcome, we reported (1) the estimated marginal means (EMMs) with 95% CIs for each time point and intervention arm, (2) *P* values for within-group contrasts

comparing changes from t0 to t1 and t0 to t2, and (3) between-group contrasts (with 95% CIs) comparing changes from t0 to t1 and t0 to t2 for each intervention arm (and all intervention arms combined) relative to the control group (with both unadjusted and Tukey-adjusted *P* values). *P* values <.05 were considered significant. We also report a standardized effect size (Hedges *g* with 95% CI) for each between-group contrast. Hedges *g* was calculated using EMMs (as opposed to raw data, which require the use of complete cases only) and pooled SDs. The 95% CIs were calculated using equations 15 and 16 from Nakagawa and Cuthill [58]. *P* values were reported to a maximum of 3 decimal places, with values <.001 reported as *P*<.001.

Subgroup Analyses

Subgroup analyses were performed to examine changes in secondary outcome measures for participants who self-reported having at least mild symptoms at t0 or at least moderately low resilience. Thresholds for subgroup analyses were as follows: a score ≥16 on the PSS, ≥5 on the GAD-7, ≥5 on the PHQ-8, and <3 on the BRS. For simplicity, we report a comparison of Hedges *g* effect sizes for these subgroups versus the ITT analysis but omit the full output of each LMM. In addition, we analyzed the intervention feedback ratings for these subgroups separately. As the findings were similar to the ITT sample, these are reported in Multimedia Appendix 5.

Finally, multivariate logistic regression was conducted on the intervention group data only to explore whether any baseline variables were predictive of intervention completion (defined as *1* for randomized participants who completed all sessions of their allocated intervention and *0* for all other randomized participants). Predictor variables included all demographic variables and other baseline characteristics, as well as all self-report secondary outcome measures at t0. For categorical predictors, categories that included <10 observations were dropped from the regression analysis.

Results

Participants

Participant demographics and other baseline variables are presented in Table 1. The mean age of the participants was 44.6 (SD 14.3) years, 52% (199/383) were female, and 81.2% (311/383) were White, suggesting that the study sample was broadly representative of the general UK population [59]. All participants were employed (part-time: 94/383, 24.5%; self-employed: 49/383, 12.8%) across a broad range of industries and most had not used an MHapp (306/383, 79.9%) or not engaged in talking therapy (352/383, 91.9%) in a 6-month period before taking part in the study. Almost all participants (372/383, 97.1%) either *agreed* or *strongly agreed* with the statement, "It's important for people to look after their mental health and wellbeing."

Patient-reported outcome scores suggested that participants were, on average, experiencing mild symptoms of depression and anxiety at t0 (mean PHQ-8 6.9, SD 5.2; mean GAD-7 6.5, SD 5.1). The proportion of participants scoring above the cutoff for mild symptoms was 59.3% (227/383) for anxiety (GAD-7≥5) and 59.8% (229/383) for depression (PHQ-8≥5), whereas the proportion scoring above the cutoff for moderate symptoms was 26.9% (101/383) for anxiety (GAD-7≥10) and 28.2% (108/383) for depression (PHQ-8≥10). Self-reported stress levels were approximately consistent with population norms (mean PSS 17.0, SD 7.7 [55]).

Primary Outcomes

Enrollment and Retention

The study was enrolled in January 2021 within 48 hours of launching the study advert. Figure 2 shows the participant flow through the trial. One of the participants withdrew consent after randomization, and 4% (16/400) of participants reported not being employed at t0 (in contrast to their prescreening responses) and were excluded from all analyses. Of the remaining 383 eligible participants, 367 (95.8%) completed an assessment at t1, and 356 (93%) completed an assessment at t2. Retention rates at t2 significantly differed across the intervention arms (*P*=.02; control 97.9%, *combatting stress* 93.6%, *working with worry* 93.8%, and *building resilience* 86.7%). Pairwise post hoc comparisons suggested significantly lower retention for *building resilience* than the control arm (adjusted *P*=.03); however, no other comparisons were significant. All groups exceeded the prespecified minimum retention for progression to a definitive trial.

Figure 2. CONSORT (Consolidated Standards of Reporting Trials) flow of participants through the study. t0: time point 0; t1: time point 1; t2: time point 2.
Engagement and Adherence

Overview

A summary of the intervention engagement is shown in Table 2. Of the 289 participants randomized to an intervention, 237 (82%) started their allocated intervention, and 196 (67.8%) completed all intervention sessions. Of those who completed at least one session, 82.7% (196/289) proceeded to complete all sessions, which differed across intervention arms (*P*=.02). Pairwise post hoc comparisons suggested significantly higher completion for *combatting stress* (74/81, 91.4%) than for *building resilience* (59/78, 75.6%; adjusted *P*=.03) but not *working with worry* (63/78, 80.8%). Of the 289 participants randomized to an intervention, 47 (16.3%) did not start their intervention, and 5 (1.7%) incorrectly engaged with an intervention outside of the one they were allocated. Participants took an average of 6.38 (SD 4.10, range 0-15) days to complete all 7 intervention sessions, which did not significantly differ

across intervention arms ($F_{2,193}$=1.58; *P*=.21). Those who started but did not complete their allocated intervention completed a median of 3 out of 7 sessions (mean 3.24, SD 1.96, range 1-6). A summary of participants' self-reported reasons for not starting or discontinuing their intervention can be found in Multimedia Appendix 6. The most common reasons for lack of engagement included insufficient time or technical difficulties (although these data were missing for participants who self-reported completing their intervention, regardless of objective adherence).

Overall, participants who objectively completed at least one intervention session self-reported spending a mean of 60.1 (median 60, SD 29.1, minimum 10, maximum 210) minutes on the *Unmind* platform, which differed significantly across groups ($F_{2,231}$=3.12; *P*=.046). Post hoc Tukey tests suggested that participants in the *combatting stress* arm reported spending more time on the platform than participants in the *building resilience* arm (mean difference 11.49, 95% CI 0.64-22.34;

adjusted *P*=.04) but not the *working with worry* arm (adjusted *P*=.40). Of the 274 participants who completed an assessment at t1, 177 (64.6%) reported receiving a handbook via email (*combatting stress* 58/90, 64%, *working with worry* 61/92, 66%, and *building resilience* 58/92, 63%) while completing their intervention. Of these 177 participants, 45 (25.4%) reported reading the entire handbook (*combatting stress* 12/58, 21%,

working with worry 16/61, 26%, and *building resilience* 17/58, 29%), and 84 (47.5%) reported reading some of the handbook (*combatting stress* 27/58, 47%; *working with worry* 31/61, 51%; and *building resilience* 26/58, 45%). Overall, 4.2% (12/289) of participants deviated from the study instructions by engaging with ≥1 session outside their allocated intervention arm.

Table 2. Intervention adherence and engagement across the 3 intervention arms (N=289).

[a]CS: combatting stress.

[b]WW: working with worry.

[c]BR: building resilience.

Satisfaction and Feedback Ratings

Table 3 shows a summary of feedback ratings from participants who were retained at t1 and who also completed at least one intervention session based on objective app use (233/383, 60.8%; see Multimedia Appendix 1 for feedback questions). Importantly, most (203/233, 87.1%) participants were either *satisfied* (99/233, 42.5%) or *very satisfied* (104/233, 44.6%) with their intervention and rated the quality of their intervention as either *good* (96/233, 41.2%) or *excellent* (107/233, 45.9%). Feedback did not significantly differ across the intervention arms, except for the intervention quality (*P*=.02). Post hoc

pairwise comparisons suggested that ratings differed between *working with worry* and *combatting stress* (adjusted *P*=.02) and differed marginally between *combatting stress* and *building resilience* (adjusted *P*=.07). Compared with *building resilience*, participants in the *combatting stress* arm were more likely to rate the intervention as *good* than *okay* or *poor*, and participants in the working with *worry* arm reported the highest ratio of *excellent* to *good ratings*.

Feedback ratings from participants scoring above predefined cutoffs for inclusion in subgroup analyses were largely equivalent to the overall sample and are included in Multimedia Appendix 5.

Table 3. Postintervention feedback ratings from participants who were retained at time point 1 (t1), both overall and for each intervention arm (N=233).

[d]BR: building resilience.

Negative Effects

Of the 76 participants in the *working with worry* arm, 2 (3%) reported experiencing negative effects while completing their intervention. Qualitative feedback suggested that in both instances, this referred to frustration with the intervention (not understanding the content or not finding it useful). Table 4 shows the proportion of participants whose self-reported outcome scores reliably deteriorated from t0 to t1 and t1 to t2 for each study arm and each secondary outcome measure. Across all outcomes, the proportion of participants who self-reported reliable deterioration ranged from 1.1% to 8.9% for t0 to t1 and 2.4% to 12.4% for t1 to t2 (during which participants no longer had access to any interventions). These rates were largely equivalent between the intervention arms and the control group and are consistent with previous estimates that 5% to 10% of participants are expected to deteriorate following in-person psychotherapy [60]. Thus, the interventions in this study did not appear to be associated with symptom deterioration or other unwanted negative effects.

Table 4. Number and percentage of participants per study arm (and overall) that reliably deteriorated from time point 0 (t0) to time point 1 (t1) and t1 to time point 2 (t2) based on reliable change index for each secondary outcome measure.

Secondary Outcomes

ITT Analyses

Overview

The following are based on ITT analyses that include data from all randomized participants (except for those not meeting the eligibility criteria; see Multimedia Appendix 4 for PP results). EMMs for each secondary outcome (grouped by study arm and time point) are shown in Table 5. All study arms reported significant within-group improvements from t0 to t1 on all secondary outcomes (all $P<.05$), except for symptoms of depression (PHQ-8) and resilience (BRS) in the control group.

Table 5. Estimated marginal means (EMMs) from linear mixed-effects models at each of the 3 study time points shown for each intervention arm and each secondary outcome measure.

Outcome	Time point		
	Baseline (t0)	Postintervention (t1)	Follow-up (t2)

Combatting Stress

Participants in the *combatting stress* arm reported a trend toward larger decreases in perceived stress (t1−t0: Hedges *g*=0.24, 95% CI −0.05 to 0.53; t2−t0: Hedges *g*=0.27, 95% CI −0.02 to 0.56) and larger increases in resilience (t1−t0: Hedges *g*=0.24, 95% CI −0.05 to 0.53; t2−t0: Hedges *g*=0.24, 95% CI −0.05 to 0.53) at both time points; however, none reached significance at an α level of .05 in this sample. Participants also reported greater improvement in symptoms of depression at t1 and t2 (t1−t0*:* Hedges *g*=0.37, 95% CI 0.08-0.66, *P*=.01; t2−t0: Hedges *g*=0.38, 95% CI 0.09-0.67, *P*=.009) and in symptoms of anxiety at t2 (Hedges *g*=0.30, 95% CI 0.01-0.59; *P*=.04) than the control group (Table 6).

Working With Worry

Participants in the *working with worry* arm reported greater improvements in symptoms of anxiety at t1 and t2 than the control group (t1 minus t0: Hedges g=0.33, 95% CI 0.04-0.61, P=.02; t2 minus t0: Hedges g=0.36, 95% CI 0.08-0.65, P=.01), as well as greater improvements across all other secondary outcomes (all P<.05; Hedges g range 0.33-0.55; Table 6). All improvements were maintained at t2 (all P<.05; Hedges g range 0.29-0.42). Effect sizes were largest for symptoms of depression at both t1 (Hedges g=0.55, 95% CI 0.26-0.84) and t2 (Hedges g=0.42, 95% CI 0.13-0.71).

Building Resilience

Participants in the *building resilience* arm reported a trend toward larger increases in resilience at t1 than the control group (t1 minus t0: Hedges g=0.26, 95% CI −0.02 to 0.55), which emerged as significant at t2 (t2 minus t0: Hedges g=0.39, 95% CI 0.11-0.68; P=.006). In addition, participants reported significantly greater improvements across all other secondary outcomes at t1 (all P<.05; Hedges g range 0.30-0.45), which were maintained at t2 (all P<.05; Hedges g range 0.35-0.40; Table 6).

A comparison of the overall (pooled) effect of all intervention arms relative to the control group revealed significantly greater improvement for all 4 secondary outcome measures (Hedges g range 0.25–0.43; Table 6). In addition, post hoc contrasts on the LMM estimates suggested that none of the intervention arms were significantly different from one another when comparing t0 to t1 or t2 for any of the secondary outcome measures (all P>.05), although this study was not powered to detect such differences. Finally, when comparing score changes from t1 to t2, there were no significant differences between the control group and any of the intervention arms for any of the secondary outcome measures (all P>.05).

Subgroup Analyses

Subgroup analyses were performed for all secondary outcome measures to explore intervention effects for participants self-reporting at least mild symptoms (or moderately low resilience) at t0 (see Multimedia Appendix 7 for subgroup sample sizes and baseline scores). Findings were largely equivalent to the ITT analysis, although between-group effect sizes were generally larger, ranging from 0.39 (95% CI 0.12-0.65) to 0.54 (95% CI 0.28-0.81) when pooling the intervention arms (Table 6).

Exploratory Analyses

Exploratory multiple logistic regression suggested that participants working in health care (b=−2.11, SE 0.86; P=.01), finance, insurance, or real estate (b=−2.57, SE 0.88; P=.004), and professional services (b=−1.87, SE 0.91; P=.04) were less likely to complete their allocated intervention relative to those working in industrials (the reference category). The completion rate for industrials was 83.3% compared with 51.9% for health

care, 41.2% for finance, insurance, or real estate, and 55.6% for professional services.

In addition, participants with higher PHQ-8 scores at baseline were less likely to complete their intervention (b=−0.17, SE 0.05; $P<.001$). None of the demographic variables collected in this study predicted completion (all $P>.05$). These analyses also confirmed that participants allocated to *combatting stress* were more likely to complete their intervention than those allocated to *building resilience* (b=−1.05, SE 0.37; $P=.005$) while controlling for all other baseline variables.

Discussion

Principal Findings

Intervention research can be undermined by problems with intervention delivery, acceptability, participant retention, and smaller than anticipated effect sizes. Therefore, guidelines suggest conducting pilot studies to test trial feasibility and estimate important trial parameters before running a definitive trial [61]. This study reports on the feasibility and preliminary efficacy of 3 interventions featured on the *Unmind* MHapp when delivered to working adults in the United Kingdom. The study methods and interventions were found to be feasible, and all preregistered progression criteria were met. This suggests that a definitive trial is warranted, although several minor proposed protocol amendments are discussed.

Participant retention and intervention adherence were largely consistent with or higher than those in comparable studies. For instance, only 7% (27/383) of participants were lost to attrition at follow-up, which compares favorably with recent meta-analyses reporting average attrition rates of 23% to 48% for MHapp trials [11,16,62]. This may be because of the use of the Prolific recruitment platform, which is associated with high participant response rates [35], and reimbursing participants at each study assessment. It may also suggest that participants, on average, perceived the *Unmind* platform as helpful and engaging and were thus motivated to complete the study.

Objective engagement data suggested that 67.8% (196/289) of randomized participants (and 196/237, 82.7% of those starting their intervention) completed all intervention sessions, which is similar to or higher than average completion rates ranging between 30% and 65% for other MHapp interventions [11,16,53,63]. These engagement rates are particularly encouraging, considering that participants were not recruited on the basis of seeking help for a mental health problem and were not randomized to an intervention based on scoring poorly on the target outcome at baseline.

Despite these high levels of engagement, the study interventions were brief, comprising approximately 60 to 80 minutes of learning over 7 sessions. In addition, the study used a nonclinical sample, and regression analyses suggested that participants with higher symptom severity at baseline were less likely to complete their allocated intervention. Thus, these findings may not be generalizable to other interventions featured on the *Unmind* app or to other study populations. Future studies designed to evaluate the use of the *Unmind* app in subclinical populations are currently being planned. Interestingly, although participants

with higher baseline symptoms were less likely to complete their intervention, feedback ratings at postintervention were largely equivalent across the study sample. For example, 87.1% (203/233) of all participants reported being either *satisfied* or *very satisfied* with their intervention and rated the quality of their intervention as either *good* or *excellent*, and these ratings did not differ for participants with more severe symptoms at baseline.

Although all 3 interventions met progression criteria, participants randomized to the *building resilience* arm were marginally less likely to start their allocated intervention and complete all intervention sessions after starting. A potential explanation is that participants may have felt less motivated by the theme of resilience as compared with stress and anxiety. In addition, participants in the *building resilience* arm reported marginally worse mental health scores at baseline, which may have negatively affected engagement. Although participant feedback was largely equivalent across the 3 interventions, there were several marginal (not statistically significant) differences that may be a contributing factor. For example, compared with *combatting stress*, participants in the *building resilience* arm were slightly less likely to rate the intervention as *good* relative to *okay* or *poor*. Although it is difficult to draw firm conclusions from these data, it will be important to test whether such differences persist in a definitive trial and the extent to which any changes or improvements to the *building resilience* intervention are warranted.

The findings from this pilot study revealed several opportunities for minor protocol improvements before running a definitive trial. First, of the 383 participants, 11 (2.9%) reported not fully understanding the study instructions, and 1.7% (5/289) of participants randomized to an intervention engaged with the wrong intervention. This could be addressed by providing participants with detailed video instructions and implementing a brief quiz to ensure that all participants understand how to access their allocated intervention. If feasible, participants could be given access to a modified, study-specific version of the *Unmind* platform that only includes the interventions being tested. Second, discrepancies between self-reported and objective in-app engagement meant that 48% (45/93) of participants who stopped using the *Unmind* app did not provide feedback on their reasons for discontinuing their intervention. This could be addressed by restructuring the feedback questionnaire to capture data from all participants, regardless of self-reported engagement. Third, 0.9% (2/233) of participants reported experiencing negative effects while completing their intervention; however, qualitative feedback suggested that both instances referred to frustration with the intervention (not understanding the content or not finding it useful). This question could be modified to capture *lasting* bad effects (refer to the study by Crawford et al [64]) with more specific clarifying questions to better differentiate harmful effects from frustration and/or lack of intervention enjoyment. Finally, 4% (16/400) of participants were excluded from the analysis as they reported being unemployed at baseline, which was in contrast to their prescreening responses. Although the Prolific platform precludes the use of additional screening questions at baseline, the sample

size calculation for a definitive trial could be adjusted to account for this potential discrepancy.

Although the study was not powered for formal hypothesis testing, preliminary efficacy findings suggested that the study interventions were associated with small to moderate between-group improvements in ≥1 mental health outcomes, which were maintained at the 1-month follow-up. This is consistent with findings from meta-analyses of previous MHapp trials [11,12,26]. All 3 interventions resulted in larger improvements in symptoms of depression, anxiety, perceived stress, and resilience than the control group, although smaller effects (Hedges g<0.3) did not reach statistical significance. An appropriately powered definitive trial may be more likely to capture such small effects with greater precision and, where possible, should aim to report on the clinical importance of these findings (eg, with regard to minimal important difference thresholds). These efficacy findings were consistent across both PP and ITT analyses and are particularly promising, given the brevity of the interventions. In addition, the findings were robust across subgroup analyses that only included participants with at least mild problems at baseline. However, 2 further patterns emerged that merit discussion.

First, relative to baseline, participants in the control group reported statistically significant improvements in stress and anxiety at both study time points and improvements in resilience at the 1-month follow-up, despite not having access to any study interventions. Although this may reflect phenomena such as practice effects or regression to the mean, it is worth noting that baseline data were collected several weeks after the commencement of a third national UK lockdown (in response to rising cases of SARS-CoV-2), whereas follow-up data were collected after the start of a phased easing of restrictions. A longitudinal survey conducted in England suggests that symptoms of anxiety and depression tend to rise rapidly during the early stages of a lockdown but decline quickly thereafter [65], which may partly explain the changes in mental health scores reported by the control group. Thus, the present efficacy findings may not be directly generalizable to other contexts. Importantly, the intervention groups reported larger improvements in mental health despite significant changes in the control group, and MHapps such as *Unmind* may be an effective way of delivering accessible mental health support to workforces working remotely or during times of national crisis.

Second, although all 3 interventions resulted in significant improvements for at least one mental health outcome, the study interventions did not appear to be sensitive or specific to their target outcome. For example, the *combatting stress* arm resulted in small between-group (intervention vs control) improvements in perceived stress (not statistically significant), as well as significant reductions in symptoms of depression. Similarly, participants in the *working with worry* arm reported significant improvements across all outcomes, despite the intervention specifically targeting anxiety. A potential explanation for this is that different facets of mental health tend to strongly covary with one another [66], and transdiagnostic research suggests that symptoms of different mental health problems often respond to the same treatments [67]. The present findings lend credence to this, as the study interventions all primarily involve similar CBT-based techniques (identifying and challenging negative thinking patterns, problem solving, and breaking negative cycles of thinking or behaviors). As this study was not powered to detect differences between intervention arms (or to test whether effect sizes for some outcomes were significantly different from others), it is not possible to draw meaningful conclusions from these data. Future studies should aim to test for any such differences so that users of the *Unmind* app can access interventions that are most likely to benefit their individual problem areas.

Strengths and Limitations

This study had several strengths. First, intervention adherence and engagement were objectively captured via *Unmind* (the intervention platform). This is important, given the recent evidence of substantial discrepancies between self-reported and objective adherence in digital interventions [68]. Second, participant retention was very high, which is extremely important as missing data can reduce statistical power and lead to biased intervention effects. Second, all study outcomes and analyses were prospectively registered, precluding any selective reporting of outcomes or nonpublication of findings [69]. Third, the study recruited a sample representative of the general UK population with respect to age, sex, and ethnicity, and participants were employed across a variety of industries. This is important as *Unmind* is designed for use across a broad range of demographics, and a lack of diversity within study samples can limit the generalizability of the study findings.

A limitation of this study is the use of a passive no-intervention control group, as opposed to an active control group in which participants engage with activities matched for duration, attention, and interest. Passive controls do not allow true intervention effects to be differentiated from nonspecific placebo effects and may introduce nocebo effects [31]. Although it is useful in practical terms to estimate this combined effect of the *Unmind* app, active controls are needed to fully understand the mechanisms underlying its effects. In addition, despite being randomly assigned, participants in the control group had slightly higher levels of self-reported resilience at baseline, and it is unknown whether this may have affected between-group differences in resilience scores over time. In addition, as with most web-based trials, participants were not blinded to group allocation. Finally, although the Prolific recruitment platform has several strengths, the participant pool was entirely self-selected, and it remains unknown to what extent the present findings are generalizable to working adults nationwide.

Conclusions

This study assessed the feasibility of conducting a future definitive RCT to evaluate the efficacy of 3 brief interventions featured on the *Unmind* MHapp. The study methods and interventions were found to be feasible, and all preregistered criteria for progression to a definitive trial were met. Several minor protocol amendments have been suggested. Preliminary efficacy findings indicate that the study interventions may result in improved mental health outcomes when offered to working adults.

Abstract

Background: For patients with multiple myeloma receiving high-dose chemotherapy followed by autologous stem cell transplantation (SCT), acute life disruptions and symptom burden may lead to worsened quality of life (QOL) and increased emotional distress. Digital life coaching (DLC), whereby trained coaches deliver personalized well-being–related support via phone calls and SMS text messaging, has been shown to improve QOL among SCT survivors. However, DLC has not been investigated during the acute peri-SCT period, which is generally characterized by symptomatic exacerbations and 2-week hospitalizations.

Objective: We launched a single-arm pilot study to investigate the feasibility of patient engagement with DLC during this intensive period.

Methods: We approached English-speaking adult patients with multiple myeloma undergoing autologous SCT at our center. Enrolled patients received 16 weeks of virtual access to a life coach beginning on day −5 before SCT. Coaches used structured frameworks to help patients identify and overcome personal barriers to well-being. Patients chose the coaching topics and preferred communication styles. Our primary endpoint was ongoing DLC engagement, defined as bidirectional conversations occurring at least once every 4 weeks during the study period. Secondary endpoints were electronic patient-reported outcome assessments of QOL, distress, and sleep disturbances.

Results: Of the 20 patients who were screened, 17 (85%) chose to enroll and 15 (75%) underwent SCT as planned. Of these 15 patients (median age 65 years, range 50-81 years), 11 (73%) demonstrated ongoing DLC engagement. The median frequency of bidirectional conversations during the 3-month study period was once every 6.2 days (range 3.9-28 days). During index hospitalizations with median lengths of stay of 16 days (range 14-31 days), the median frequency of conversations was once every 5.3 days (range 2.7-15 days). Electronic patient-reported outcome assessments (94% adherence) demonstrated an expected QOL nadir during the second week after SCT. The prevalence of elevated distress was highest immediately before and after SCT, with 69% of patients exhibiting elevated distress on day −5 and on day +2.

Conclusions: DLC may be feasible for older patients during intensive hospital-based cancer treatments such as autologous SCT for multiple myeloma. The limitations of our study include small sample size, selection bias among enrolled patients, and heterogeneity in DLC use. Based on the positive results of this pilot study, a larger phase 2 randomized study of DLC during SCT is underway to investigate the efficacy of DLC with regard to patient well-being.

Introduction

Multiple myeloma (MM) is an incurable hematologic malignancy in older adults. Unlike in many other malignancies, upfront use of myeloablative chemotherapy followed by autologous stem cell transplantation (SCT) remains the standard of care for MM in eligible patients [1,2]. Autologous SCT is marked by acute symptomatic toxicities during the first 100 days after transplantation, such as fatigue, pain, and anorexia [3-6]. Sudden functional limitations, increased isolation, and nonrestful inpatient environments may also contribute to emotional distress. Patients must be monitored closely for other post-SCT toxicities and may, on average, spend over 30% of their days during this 3-month period either hospitalized or at clinic appointments [7,8]. Furthermore, most patients with MM who are employed prior to undergoing SCT are unable to return to work thereafter [9]. These factors, in turn, may lead to significant personal costs from transportation-related expenses and missed workplace productivity.

Specific manifestations of peri-SCT life disruptions may include worsened quality of life (QOL), elevated anxiety or emotional distress, and worsened sleep disturbances. These symptoms are particularly relevant for patients with MM who tend to be older and may have poorer baseline QOL than patients with other malignancies [10]. Previous studies, while limited by substantial heterogeneity in patient populations and survey-based inventories, suggest that well-being reaches its nadir 1-2 weeks after SCT before recovering in subsequent months [5,11-16]. Even so, long-term consequences of these short-term exacerbations may include persistent decreases in QOL, lowered posttransplant medication adherence, psychological comorbidities, reliance on potentially inappropriate medications such as benzodiazepines, and increased risk of hospital readmissions [17-23]. Several hospital-based interventions have thus been studied to target well-being during SCT, such as scheduled palliative care consultations, structured exercise programs, acupuncture, music therapy, and programmed room lighting [24-29]. However, these strategies may be limited by in-person provider availability in the inpatient setting or the need for "extra" clinic appointments in the outpatient setting.

Digital life coaching (DLC), whereby patients receive well-being–related support from trained coaches via bidirectional phone calls and SMS text messaging on their personal phones, may be able to address these limitations because of its virtual and location-agnostic nature. Life coaching, whereby trained coaches provide support and longitudinal accountability to empower patients to set and accomplish personal goals, has been effective in several ambulatory cancer populations [30-39]. DLC can reach patients both during and after their index SCT hospitalizations, which is a priority for patient-facing digital tools in this population [40]. While feasible among SCT survivors [41,42], DLC-type interventions have not been studied during the acute 100-day period immediately preceding and following SCT. Given the paucity of studies on the use of communication-based digital technologies among older adults [43], it is similarly unclear how acceptable DLC can be for patients with MM. We thus launched a pilot study to assess the feasibility of a DLC program for patients with MM actively undergoing SCT.

Methods

Study Design and Intervention

We launched a single-arm, pilot feasibility study of DLC among adult patients with MM undergoing nontandem autologous SCT at our center. English proficiency and mobile phone ownership were required for study participation; however, neither smartphone ownership nor mobile app installation were needed. There were no restrictions on time frames for pre-SCT stem cell collection or on agents used for stem cell mobilization. Based on a 68% rate of engagement in a prior study of DLC among SCT survivors and an assumption that DLC engagement below 33% would not merit further study [41], we enrolled 15 patients to exclude the possibility (with 1-sided α .05 and 90% power) of DLC engagement falling below this threshold. Patients who enrolled in the study but did not ultimately undergo autologous SCT were replaced. All patients provided informed consent prior to study enrollment. This study was approved by the University of California San Francisco Institutional Review Board (ClinicalTrials.gov NCT04432818).

Regarding the DLC platform itself, 2 life coaches employed by Pack Health [44] were paired with all patients enrolled in this study. Both coaches were certified by the National Board for Health and Wellness Coaching [45]. Coaches reached out to patients to coordinate their first coaching call beginning no earlier than day −5 before SCT. Patients then received 16 weeks of free unlimited access to their life coach by phone, SMS text messaging, or email. Coaches used structured frameworks longitudinally, including the Transtheoretical Model, Fogg Behavior Model, SMART (Specific, Measurable, Achievable, Relevant, and Time-based) Framework, and Pathways Thinking, to help patients identify and overcome personal barriers to well-being [46-53]. The content of the coaching curriculum was highly personalized to each patient at any given time and was not standardized per the study protocol. However, coaches did attempt to discuss several components of wellness (physical health, mental health, nutrition, exercise, sleep, and financial health) at least once during the study period. Coaches were not medical providers and were not licensed to address medical or psychiatric issues; as such, coaches were instructed to refer patients back to their SCT providers with any clinical concerns.

Patients could communicate bidirectionally with their coach by SMS text messaging, phone call, or email. This contact information was standardized for each coach; in other words, patients could add their coach to their list of phone contacts and communicate with them as they would communicate with loved ones. While coaches encouraged the use of weekly check-in phone calls, the actual cadence and communication methods of coaching were personalized to each patient based on their individual goals and preferences. Caregivers were allowed to join or participate in coaching as well, although all content was specifically geared toward patients themselves. Coaches organized phone calls and responded to messages during business hours for the DLC vendor (8 AM to 5 PM CST, corresponding to GMT −6); all enrolled patients were on PST (GMT −8). If patients did not respond to messages from their coaches, follow-up messages were sent no more frequently than 3 times per week. Patients were not contacted by coaches after the conclusion of the study period.

Data Collection

The primary objective of this study was to assess the rate of ongoing patient engagement with the DLC program using an intent-to-treat approach during the 16-week study period. We adopted the definition of feasibility used in a previous study of DLC among SCT survivors—patient-initiated engagement at least once with the DLC platform in at least 68% of patients over a 3-month period [41]—with 2 a priori modifications. First, we focused on bidirectional conversations (including phone calls lasting at least 1 minute) as examples of meaningful engagement even if initiated by the coach. Second, we adopted a stricter definition of feasibility as at least one bidirectional conversation every 4 weeks during the 16-week period rather than at least once over 3 months. Our rationale for this second modification was to assess the practicality of *ongoing* patient-coach conversations across a dynamic 100-day period including index hospitalizations as well as the initiation of post-SCT maintenance therapy.

The secondary objectives of this study were to explore the results of email-based electronic patient-reported outcome (ePRO) assessments measuring QOL, emotional distress, and sleep disturbances. ePROs were assessed in accordance with the Checklist for Reporting Results of Internet E-Surveys [54]. To measure QOL, we administered the 10-item Patient-Reported Outcome Measurement Information System (PROMIS) Global Health Scale instrument v1.2. To measure emotional distress, we administered the single-item National Comprehensive Cancer Network (NCCN) Distress Thermometer excluding the problem list. To measure sleep disturbances, we administered the 4-item PROMIS Sleep Disturbance Short Form 4a. These inventories, comprising 15 questions across 4 pages including a welcome page, were assessed through a secure web-based Research Electronic Data Capture (REDCap; Vanderbilt University) platform hosted on the study site's server. Patients received unique weblinks to complete ePRO assessments through emails sent from REDCap to their personal email addresses. These emails were sent at 12 discrete timepoints: weekly for the first

8 weeks of the study (day −5 to day +50) and then biweekly thereafter (day +51 to day +106). No ePRO questions were mandatory, no incentives were provided for ePRO assessment completion, and responses were not editable or rewritable after completion of each timepoint. The results of ePRO assessments were not shared with patients' coaches or clinical teams at any time.

Data Analysis and Statistical Considerations

For our primary endpoint of ongoing DLC engagement, we calculated SCT-relative dates for each bidirectional conversation within each of four 4-week study subperiods: day −5 to +22, day +23 to +50, day +51 to +78, and day +79 to +106. Based on our sample size of 15 patients, we defined feasibility as the presence of ongoing engagement in 10 or more patients (ie, at least 68% of patients) based on a previous study of DLC among SCT survivors [41].

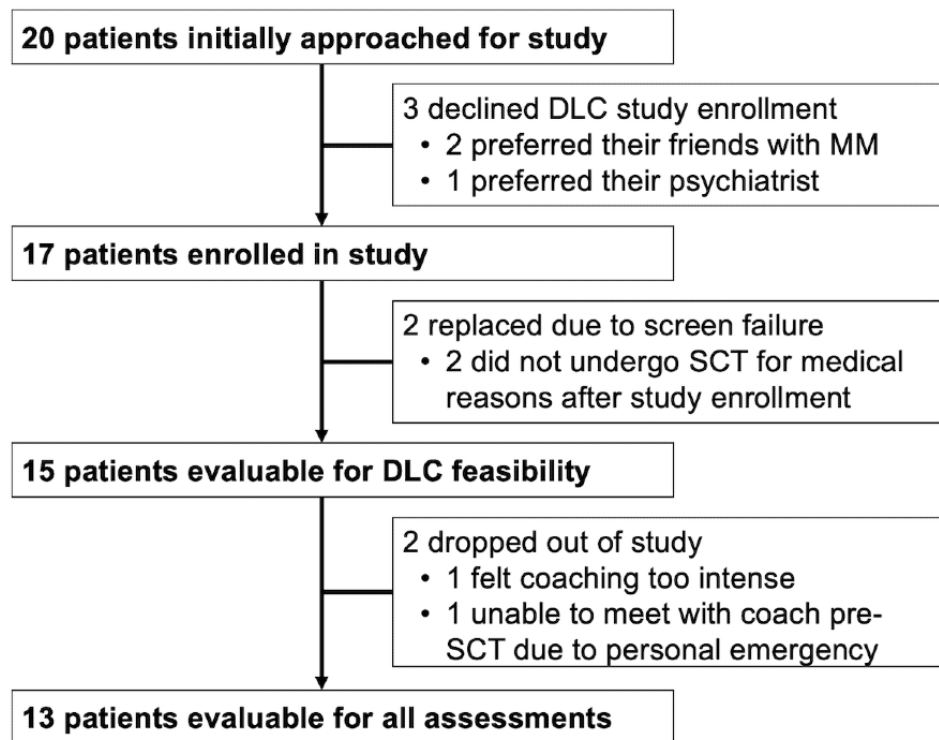
For our secondary objectives involving ePRO assessments, we converted raw PROMIS inventory scores into T-scores to reflect a reference population with a mean score of 50 and SD of 10 as per their respective scoring manuals. We analyzed PROMIS inventory scores and Distress Thermometer scores at each timepoint descriptively using medians and ranges. Based on previous studies of patients with cancer, we defined clinically meaningful changes in PROMIS instruments as an increase or decrease of 5 or more points [55-57]. Specifically, we compared median T-scores at each timepoint to their baseline values. We defined worsened physical or mental QOL as a decrease of 5 or more points and worsened sleep as an increase of 5 or more points. We separately calculated the percentages of patients at each ePRO timepoint with elevated distress, defined as a Distress Thermometer score of 4 or higher [58].

Given our small sample size, we did not perform any longitudinal modeling of ePRO data. All analyses were performed using Stata (StataCorp) and R version 4.0.2 (R Foundation for Statistical Computing).

Results

Enrollment and Baseline Characteristics

Of the 20 patients approached between June 2020 and November 2020, 17 (85%) enrolled as outlined in Figure 1. However, 2 of these 17 (12%) patients did not undergo planned SCT for medical reasons and thus were replaced before DLC initiation. Of the 15/20 (75%) remaining patients, 2 (13%) dropped out of the study before coaching was initiated: one because she felt that the planned frequency of coaching would become too intense during SCT hospitalization and another because of a personal emergency (wildfire-related evacuations) that prevented her from coordinating a time to speak with her coach before arriving to the hospital to undergo SCT. Thus, 13/15 (87%) patients completed ePRO assessments beyond the baseline assessment and were evaluable for our secondary endpoints of QOL, emotional distress, and sleep disturbances.

Figure 1. Flow diagram of enrolled patients. Abbreviations: DLC, digital life coaching; MM, multiple myeloma; SCT, stem cell transplantation.


Baseline characteristics of the 15 patients evaluable for DLC feasibility are summarized in Table 1. The median age of the enrolled patients was 65 years (range 50-81 years); 4/15 (27%) patients were 70 years or older at the time of SCT. The median time between MM diagnosis and SCT was 7 months (range 4-108 months). A total of 4/15 patients (27%) had an Eastern Cooperative Oncology Group performance status of 1; the remainder had a performance status of 0. Most patients (12/15, 80%) received full-dose melphalan conditioning (200 mg/m^2) prior to SCT. All patients were hospitalized for SCT, with a median length of stay of 16 days (range 14-31 days).

[c]Other caregivers included an ex-spouse for one patient and a sibling for another patient.

Feasibility of the DLC Platform

Bidirectional conversations during the 16-week study period are depicted in Figure 2. Of the 15 enrolled patients who underwent SCT, 11 (73%) met our primary endpoint of ongoing engagement. Of the remaining 4/15 (27%) patients, 2 (50%) dropped out of the study prior to DLC initiation while an additional 2 (50%) demonstrated ongoing engagement only for the first 3 of the 4 study subperiods. For the 13/15 (87%) patients who received any coaching, the median number of conversation-days (defined as discrete days with at least one bidirectional conversation) during the 16-week study period was 18 (range 4-29). This corresponded to a median engagement frequency of 1 conversation every 6.2 days (range 3.9-28 days). During inpatient hospitalizations, this corresponding frequency was 1 conversation every 5.3 days (range 2.7-15 days). Of 240 conversation-days across 13 patients, 120 (50%) occurred via SMS text messaging while 109 (45%) occurred exclusively via phone calls. Of note, 69% (9/13) of patients never used emails to engage with their coaches.

We did not formally request feedback from patients about the DLC curriculum with respect to its feasibility or overlap with existing clinical resources. However, 2/13 (15%) patients did opt to reply at least once to automated ePRO assessment emails (correspondences that were then forwarded to the study team nonurgently). One patient wrote that her coach was "fantastic for answering questions, hearing and airing concerns…and mostly boosting hope, which is so very necessary in the MM world." A second patient's caregiver responded to an automated ePRO prompt inquiring about any additional medications for the management of neuropathy; however, whether this question had been redirected to the study team by the patient's coach was not specified.

Figure 2. Timeplot of bidirectional conversations. Days relative to SCT during which at least one bidirectional conversation took place are marked either by unboxed X icons (for outpatient) or boxed X icons (for inpatient). The 16-week study subperiod is divided into four 28-day subperiods as shown. *These patients underwent SCT but dropped out of the study prior to digital life coaching initiation. SCT: stem cell transplantation.
Longitudinal Patient-Reported Outcomes

The results of ePRO assessments for the 13/15 (87%) patients who received any coaching are depicted in Figure 3. A total of 94% (147/156) of ePRO assessments were completed, with a mean time of 3.3 minutes (range 1.1-17.9 minutes) spent per 15-question assessment. The results of these assessments were not shared with patients' coaches or clinical teams at any point. Compared to baseline values assessed at a median of day −5,

both the physical and mental components of QOL nadired during the second week after SCT (median day +9). There were no clinically meaningful exacerbations in sleep disturbances during the study period when compared to baseline. A total of 69% (9/13) of patients exhibited elevated distress at baseline (median day −5) and at the second timepoint (median day +2); this percentage decreased steadily in subsequent weeks to a nadir of 31% (4/13) in the eleventh week (median day +72).

Figure 3. Repeated ePRO assessments over time. For QOL (physical), QOL (mental), and sleep disturbances, values represent population-adjusted T-scores with a mean of 50 and SD of 10. Higher values represent better physical/mental QOL and worsened sleep, respectively. For % elevated distress, values represent the percentage of patients at each timepoint who reported elevated distress (defined as a Distress Thermometer score of 4 or higher) [58]. ePRO: electronic patient-reported outcome; PROMIS: Patient-Reported Outcome Measurement Information System; QOL: quality of life; SCT: stem cell transplantation.
Discussion

Main Findings

In our single-arm pilot study, we found that DLC can be feasible for selected patients with MM during the intensive 100-day period encompassing autologous SCT. Although our study enrolled patients immediately prior to 2-week hospitalizations for myeloablative chemotherapy, the rate of ongoing patient engagement of 73% over a 3-month period was similar to or approached that of DLC-type interventions designed for ambulatory survivors beyond day +100 after SCT [41,42]. Hospitalized patients who underwent SCT in our study engaged bidirectionally with their coaches approximately once per week on average, a frequency comparable to that of unidirectional mobile health apps for patient education or ePRO completion [59,60]. Based on the positive results of this pilot study, a randomized phase 2 study of DLC versus usual care in this population is underway to investigate the efficacy of DLC (ClinicalTrials.gov NCT04589286).

One lesson learned from our study was the optimal timing of supportive interventions during intensive cancer-directed treatments. Our DLC intervention began on day −5 of SCT, which preceded hospital admission for high-dose chemotherapy by 2-3 days. Our rationale for this time frame was to focus on the acute posttransplant period itself, a time during which QOL is known to decrease because of increased symptom burden and acute life disruptions [11-15]. However, in contrast to 2 prior studies that demonstrated that distress peaked at count nadir or hospital discharge [3,15], this study found that elevated distress was highest at pre-SCT baseline. As a second observation of note, our narrow pre-SCT window also precluded participation for 1 of our 15 enrolled patients who was unable to connect with her coach before hospitalization. Earlier initiation of DLC, as we have implemented in our ongoing phase 2 study, may allow coaches to intervene during emotional distress when this symptom is at its peak while also improving the logistical adoptability of DLC for patients.

A second lesson learned from our study was the importance of flexibility and bidirectionality regarding how patients can engage with coaches. Our DLC platform allowed patients to call, text, or email their coaches in the same ways in which they might communicate with loved ones. All communications sent by coaches were intentionally worded to encourage subsequent responses from patients. Prior research has suggested that the promotion of interactivity may improve patients' perceptions of and patient engagement with digital platforms [61,62]. Although we did not formally test this hypothesis, these characteristics may have enhanced the "stickiness" of DLC (defined as the ease of continued use of a patient-facing platform over time) [63] during the peri-SCT period. As a counterexample within digital oncology, the randomized Southwest Oncology Group S1105 study of automated twice-weekly unidirectional SMS text messaging for women with breast cancer did not show a benefit in its primary endpoint of medication adherence [64]. The authors posited that their approach may not have sufficiently engaged patients to promote behavioral change.

Limitations and Future Directions

Our study nevertheless had several limitations; the most important one was the limited external validity from our small cohort of English-speaking patients who owned personal mobile phones. Although our intervention was deemed acceptable by patients who were planning to undergo SCT (with 85% of approached patients enrolling in the study), our patient population was relatively homogenous with regard to race, ethnicity, and marital status. Because racial and socioeconomic barriers affect SCT access and post-SCT outcomes in patients with MM [65,66], further investigation of this platform in a broader population of patients is needed. Two active areas of expansion for the DLC vendor include translation of content into other languages and development of an entirely landline-based curriculum (eg, using hospital-based phones and house-based phones) for patients who do not personally own mobile phones.

Other limitations of our study include our inability to isolate the specific coaching frameworks or themes that were most useful for patients. While patients communicated with their coaches approximately once per week on average, we did not directly gauge patient rationales for DLC engagement at each timepoint. As such, it is possible that patients may have maintained interactions with their coaches out of politeness rather than firm beliefs that the coaching was of value. Elucidating the specific impact of DLC on ePRO assessments of QOL is thus a key goal of our ongoing randomized phase 2 study. Furthermore, our ePRO results must be interpreted with caution given the small sample size and the presence of DLC itself as a potential confounder. Our finding that elevated distress was most prevalent in the days immediately before and after SCT was predicated on scores of 4 or higher on the single-question NCCN Distress Thermometer, a definition used previously in the SCT population [67,68]. It is unclear whether the use of longer survey-based instruments to assess distress, such as the Brief Symptom Inventory or Impact of Event Scale, would have yielded different results.

While DLC-type interventions have already been investigated in ambulatory cancer survivors [32,33,36-39,41,42], this is the first study to our knowledge to investigate DLC during a hospital-based cancer therapy such as SCT. DLC offers 3 possible benefits over traditional face-to-face tools during such intensive treatment modalities. First, although interventions with substantial in-person components may be more likely to improve distress in patients with cancer [69], additional in-person visits may be impractical for patients to attend in the setting of acute symptomatic toxicities. In contrast, DLC allows patients to access a centralized team of life coaches from the convenience of their phones regardless of their current location. Second, for patients who interact frequently with their coaches, "micro-learning" (a key functionality of mobile health tools) [70] may enhance the staying power of the coaching curriculum. Third, as discussed previously, DLC can readily accommodate individual patient preferences with regard to specific communication modalities and cadences.

However, whether DLC can truly improve the quality of supportive care during SCT requires further investigation in our

ongoing randomized phase 2 trial and subsequent investigations. Similarly, given a plethora of ePRO instruments used to assess QOL and distress in the hematopoietic stem cell transplant population [71], the PROMIS Global Health Scale and NCCN Distress Thermometer—both of which are relatively newer in this patient population—require further validation against longer survey-based instruments such as the Functional Assessment of Cancer Therapy Bone Marrow Transplantation or Brief Symptom Inventory assessments. Expansion of DLC into other transplantation settings, particularly for patients with acute leukemia undergoing allogeneic SCT, is warranted given that patients who undergo allogeneic SCT have a higher symptom burden than those who undergo autologous SCT [11,72]. This is an active area of investigation for our group.

Conclusions

Selected patients receiving high-dose chemotherapy followed by autologous SCT can engage meaningfully with life coaches using their phones, even during 2-week hospitalizations. A randomized phase 2 study to assess the efficacy of DLC in this population is underway. If future studies demonstrate the effectiveness of DLC in improving QOL and symptom burden during SCT, this type of intervention may eventually become a routine tool for supporting patient well-being during intensive cancer-directed therapies.

Abstract

Background: Hospital bed management is an important resource allocation task in hospital management, but currently, it is a challenging task. However, acquiring an optimal solution is also difficult because intraorganizational information asymmetry exists. Signaling, as defined in the fields of economics, can be used to mitigate this problem.

Objective: We aimed to develop an assignment process that is based on a token economy as signaling intermediary.

Methods: We implemented a game-like simulation, representing token economy–based bed assignments, in which 3 players act as ward managers of 3 inpatient wards (1 each). As a preliminary evaluation, we recruited 9 nurse managers to play and then participate in a survey about qualitative perceptions for current and proposed methods (7-point Likert scale). We also asked them about preferred rewards for collected tokens. In addition, we quantitatively recorded participant pricing behavior.

Results: Participants scored the token economy–method positively in staff satisfaction (3.89 points vs 2.67 points) and patient safety (4.38 points vs 3.50 points) compared to the current method, but they scored the proposed method negatively for managerial rivalry, staff employee development, and benefit for patients. The majority of participants (7 out of 9) listed human resources as the preferred reward for tokens. There were slight associations between workload information and pricing.

Conclusions: Survey results indicate that the proposed method can improve staff satisfaction and patient safety by increasing the decision-making autonomy of staff but may also increase managerial rivalry, as expected from existing criticism for decentralized decision-making. Participant behavior indicated that token-based pricing can act as a signaling intermediary. Given responses related to rewards, a token system that is designed to incorporate human resource allocation is a promising method. Based on aforementioned discussion, we concluded that a token economy–based bed allocation system has the potential to be an optimal method by mitigating information asymmetry.

Introduction

Hospital bed management is an important resource allocation task for better patient care and sustainable hospital management [1]. In particular, efficient bed utilization is a key driver for hospital revenue [2] and health care system management [3,4]. The management of hospital finances has become difficult in Japan [5,6] and worldwide [7-9]; thus, to cope, effective resource management is essential.

Poor bed management wastes time, resulting in longer wait times for patients, the reduction of employee (especially ward nurses) satisfaction [10], and adverse effects on patient safety [11,12].

The current bed control process begins when physicians admit patients to the hospital and asked bed allocation managers to find adequate beds [13]. Allocation managers search the wards to find the best fit for the patient. Then, either the *negotiation-based method*, wherein allocation managers negotiate with frontline ward managers, who sometimes decline the request, to form consensus and make a final decision [14], or the *command-based method*, wherein allocation managers have the authority to force wards to accept the request [15], emerges. The negotiation-based method takes more time [14], while the command-based method hinders employee satisfaction by involuntarily increasing the patient-to-nurse ratio, which has been reported to increase staff dissatisfaction [16]. In fact, these methods are not discrete but form a continuum, as procedures, in reality, both have negotiation-based as well as command-based aspects.

Conflict is defined as the struggle that arises when the goal-directed behavior of a person or group blocks that of another [17]. Both bed allocation methods include a systemic structure that can cause intraorganizational conflict between allocation managers and frontline ward workers. Previous reports mentioned that mediation of information asymmetry is an effective form of conflict management [18], and often, information asymmetry is observed in real practice between allocation managers, who have broad but superficial views of the bed occupancy situation for the whole hospital, and managers of individual wards, who tend to only see their situation but perfectly know their capacity.

Previous studies [19,20] in operational research have tried to solve the bed assignment problem with mathematical modeling, which is based on the assumption that computers can calculate optimal solutions for command-based bed allocation to satisfy any stakeholder requirements; despite this, no real-world solutions are in wide use, because of the implementation difficulties arising from inputting data from a variety of sources and convincing users to accept computed suggestions [19]. This situation indicates that collecting sufficient information is difficult, which can lead to information asymmetry, resulting in intraorganizational conflict.

In the field of economics and management, *signaling*, whereby one party credibly conveys some information about itself to another [21], is a solution for information asymmetry [22]. However, requiring too much information from frontline staff is not feasible in practice; therefore, simple information to be expressed is needed. Herein, we propose the implementation of a token economy–based operation for bed allocation, in which the allocation process is regarded as a virtual currency transaction. Token economy was originally developed for behavior modification in psychology [23] and education [24] and is now also used by businesses [25] that intend to manage user behavior. We hypothesize that this system has the advantages of both negotiation-based and command-based allocation systems.

We developed a token economy–based system for bed allocation and conducted a preliminary evaluation of the system with a game-like simulation followed by a brief survey about its effectiveness.

Methods

Token Economy–Based Bed Assignment System

Overview

The current bed assignment process begins when physicians decide to admit a patient to the hospital and the allocation manager negotiates with ward staff to find an available bed (Figure 1).

However, we propose that the bed allocation process can be considered as transactions of nursing contributions between physicians and nursing staff. Each ward in the hospital is asked to set a *price* (ie, define the value for their nursing service) using a virtual currency (ie, token) in advance. When physicians admit patients, the hospital allocates a certain number of tokens to the physicians as consideration for admission. Then, using *prices* and their preferences, such as ward specialty, physicians decide where patients will be assigned. Once the deal is finalized, the bed allocation process is completed (Figure 1). In this process, allocation managers do not have a role. By repeating this procedure, each stakeholder can accumulate tokens, to be exchanged for something that has value to them, and ward *price* setting acts as a signaling of availability, which removes information asymmetry to result in optimal bed allocation.

Figure 1. Operation flowchart of current (upper) and proposed (lower) bed allocation methods.
Implementation of Simulation System

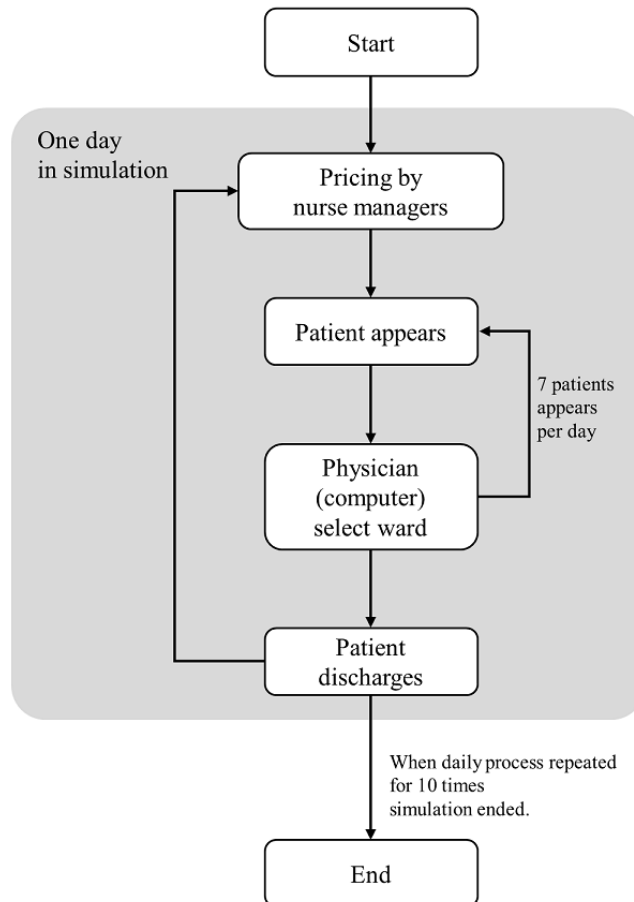
To evaluate the token economy–based bed allocation system, we developed a game-like simulation. We developed a web-based simulation for nurse managers (who represent the nursing staff on the wards). The behavior of physicians was emulated by computer agents.

The scenario consisted of a small hospital with 3 wards, each having 40 beds. For simplicity, we used the assumption that there are 3 illnesses (ie, gastric ulcer, pneumonia, and heart failure) with 3 severities (ie, mild, moderate, and severe). To represent the real-world allocation of specialties, we also defined the assumption that each virtual ward was used to manage a single type of illness: ward A, gastric ulcer; ward B, pneumonia; and ward C, heart failure (Figure 2).

Each virtual ward had a *workload* parameter, that reflected nursing staff workloads. This information was only seen by the relevant ward, thus representing information asymmetry. The workload increased in response to bed occupancy, weighted by patient illness and severity: *workload* increased by 1.0, 1.25, and 1.5 points when the ward received a patient with mild, moderate, and severe, respectively, corresponding illness; however, when the patient's illness was not aligned with the ward's specialty, *workload* increased by an additional 50%—1.5, 1.8, and 2.25 points for mild, moderate, and severe illnesses, respectively, not corresponding to that of the ward specialty (Table S1 in Multimedia Appendix 1).

Figure 2. Game scenario: the hospital consisted of 3 wards, with 40 beds each, and patients with 3 diseases with 3 levels of severity.
User Interface

The simulation consisted of day-level repetition (Figure 3). At the beginning of a day, nurse managers (players) were asked to set a *price* for each illness and severity. They could see the current bed occupancy and staff workload of their ward, but they could only see the number of patients admitted to other wards (Figure S1 in Multimedia Appendix 1). Players were then asked asked to set *prices* for 9 patterns of patients (Figure S2 in Multimedia Appendix 1). Each day, 7 patients appeared, with random illnesses and severities (Figure S3 in Multimedia Appendix 1) and were allocated to the ward selected by physicians—a computer agent programmed to select the ward that proposed the lowest *price* unless the ward specializing in the patient's illness was available, in which case, a certain additional *price* was acceptable. The additional rate was set as a uniform random number between 1.0 (no additional fee) and 2.0 for every admission decision. Patients were randomly discharged from wards at a rate equivalent to a mean of 14 days, so that vacant beds appeared in wards. We repeated the simulation 10 times, representing 10 real-world days. All simulations were implemented with Python (version 3.4.5) and Django (version 2.0.13).

Figure 3. Flowchart illustrating the game. The gray area indicates 1 day in the simulation, with the game consisted of 10 virtual days.


Evaluation

Participants

We recruited 9 nurse managers from a single university-affiliated hospital in Japan. We split them into 3 groups with 3 participants each. After receiving informed consent, we asked the nurse managers to participate in 2 sessions of the game-like simulation. During the first session, participants were told that the player who earned the most tokens would be the winner. For the second session, participants were instructed to assume they can receive the form of compensation they wish and that they are required to make decisions as nurse managers, by considering aspects such as staff satisfaction, patient safety, and equality, as they did in their daily practice.

We conducted 3 surveys with the participants: before, between, and after sessions (Figure 4). Using a similar question format about perceptions relating to manager satisfaction, staff satisfaction, benefit for patients, patient safety, timeliness of decision making, extent of managerial rivalry, extent of managerial control from hospital administrators, effect on revenues, employee development, consistency with

organizational mission (which is equal to the whole hospital's mission), and consistency with the goal of each ward as independent division (Table 1), the before-session survey asked participants about their perceptions of the current bed assignment practices, whereas the after-session survey asked participants about their perceptions of the token economy–based assignment method. Each response used a 7-point Likert scale (1, strongly disagree, to 7, strongly agree). We developed the questionnaire to examine the system's effect on hospital management through resource allocation decision-making, given the advantages and disadvantages that have been identified by previous researchers [26], of decentralized decision-making in an organization. In addition, we considered Balanced scorecard, which is well-known organizational performance assessment tool [27]. In particular, questionnaire about employee development was set to evaluate this method could develop ward staffs' managerial ability. We did not perform statistical testing, due to the limited number of participants.

For the interim survey, we asked participants about desired compensation regarding the token—"Please enumerate what you want to get as a consideration of tokens. List at least two, and at most five, items with giving priority."

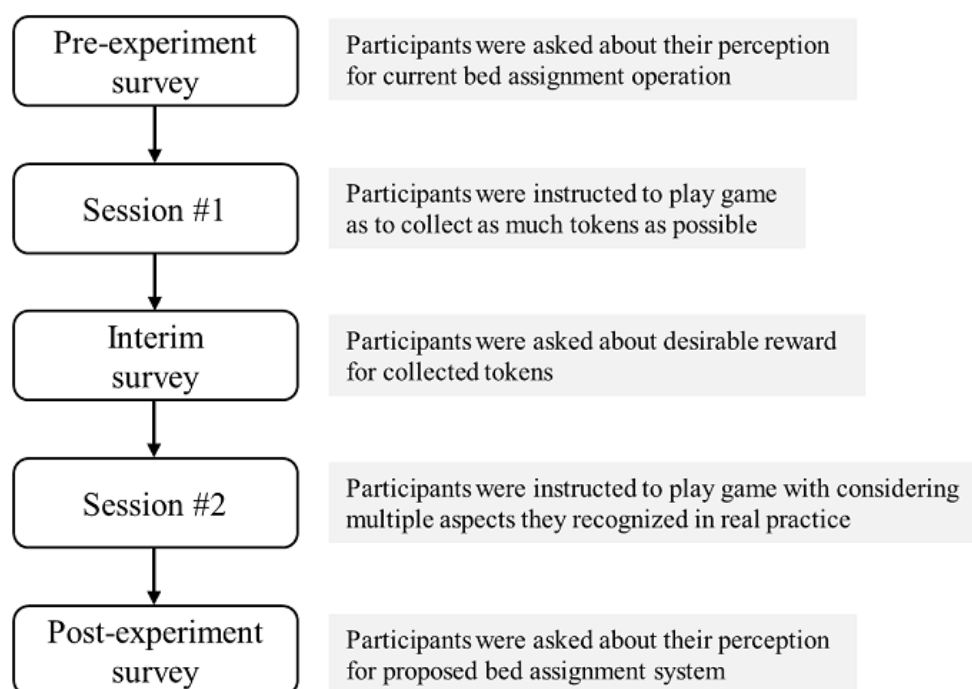
Figure 4. Evaluation flowchart.


Table 1. Before- and after-session survey questions.

Topic	Current bed management practices	Proposed token economy–based system
Managers' satisfaction	Are you satisfied with it?	Will you be satisfied with it?
Staff satisfaction	Do you think your staff is satisfied with it?	Do you think your staff will be satisfied with it?
Benefit for patients	Do you think it is beneficial for patients?	Do you think it will be beneficial for patients?
Patient safety	Do you think it has problems from the patient safety point of view?	Do you think it will have problems from the patient safety point of view?
Timeliness	Do you think it offers prompt decision-making?	Do you think it will offer prompt decision-making?
Managerial rivalry	Do you think it evokes managerial rivalry?	Do you think it will evoke managerial rivalry?
Control	Do you think managerial governance is maintained though it?	Do you think managerial governance will be maintained though it?
Revenue	Do you think it is optimized for hospital revenue?	Do you think it will be optimized for hospital revenue?
Employee development	Do you think it helps your staffs' employee development?	Do you think it will help your staffs' employee development?
Hospital mission	Do you think it is consistent with the hospital mission?	Do you think it will be consistent with the hospital mission?
Goal of divisions	Do you think it considers the goal of each ward?	Do you think it will consider the goal of each ward?

Analysis of Participants' Price Setting

We recorded *price* list input by participants and *workload* fluctuations. We collected data from 6 sessions (3 groups, each playing 2 sessions). To evaluate this token economy–based method as a signaling mediator, we plotted the associations between *workload* and *price* setting.

Ethics Approval

These experiments were conducted with the approval of the Ethics Committee of Kyoto University Graduate School and Faculty of Medicine (R1972).

Results

Participants

Participants had more than 25 years (mean 31.1 years) of experience as nurses and more than 3 years (mean 11.6 years) as nurse managers at the time of experiment (Table 2).

Table 2. Demographic backgrounds of participants.

Characteristics	Value
Gender (n=9), n (%)	
Male	1 (11)
Female	8 (89)
Experience (years), mean (range)	
Nurse	31.1 (26-34)
Nurse manager	11.6 (4-18)

Survey Results

Staff satisfaction for current operation practices and for the proposed method were at 2.67 and 3.89 points on average, respectively. Conversely, they scored benefit for patients in current practices and for the proposed method at 4.44 and 3.56 points, respectively. Participants gave favorable responses for the proposed method when compared with those for current practices for manager satisfaction, patient safety, timely decision-making, and consistency with goal of divisions; however, they gave unfavorable responses for the proposed method compared with those of current practices for the extent of managerial rivalry, the extent of control from hospital administration, employee development, and consistency with hospital mission (Table 3 and Figure 5).

Most participants (7 out of 9) listed additional human resources as preferred compensation for tokens. Financial compensation, such as salary increases or bonuses, ranked in the top 3 for some participants (4 out of 9). Only 1 participant did not list items related to human resources; this participant listed commendation from the hospital as the top priority (Table 4).

Table 3. Before- (current) and after-session (proposed) survey scores; items were rated on a 7-point Likert scale (1, strongly disagree, to 7, strongly agree).

	Current bed management practices, mean	Proposed token economy–based system, mean	Difference
Manager satisfaction	3.44	3.78	0.33
Staff satisfaction	2.67	3.89	1.22
Benefit for patients	4.44	3.56	−0.89
Patient safety[a]	3.50	4.38	0.88
Timeliness	3.67	4.00	0.33
Managerial rivalry[b]	2.78	3.67	0.89
Control	4.44	3.44	−1.00
Revenue	3.78	3.78	0.00
Employee development	4.11	3.44	−0.67
Hospital mission	4.56	4.11	−0.44
Goal of divisions	3.00	3.67	0.67

[a]There was a missing response; therefore, n=8 for this item.

[b]Only for this item, a higher score means a negative response.

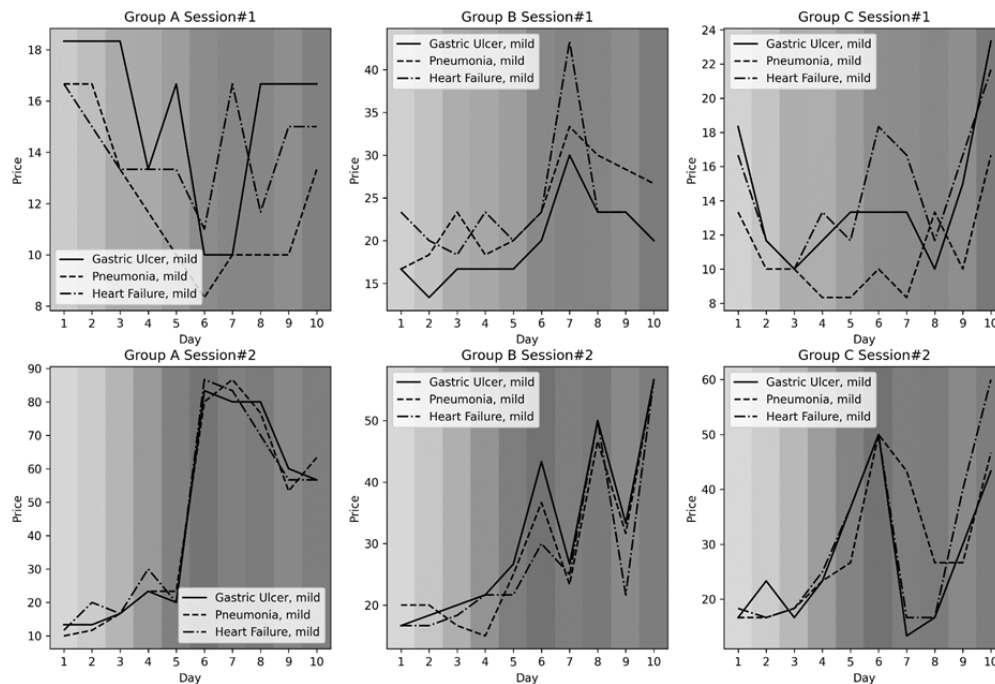
Figure 5. Differences between perceptions in current bed management practices and those for the proposed bed management method. Since a higher score for managerial rivalry indicates a negative response, we inverted the raw data. There was 1 missing response for patient safety.
Table 4. Participants' response to the question asking the desirable rewards for collected token.

Participant	Priority				
	First	Second	Third	Fourth	Fifth
1	Human resources (nurses)	Travel fee for workshop	Travel fee for conference	Spare time or bonus	Improved work environment
2	Human resources (nurses)	Travel fee for conference	Improved work environment	Human resources (nurse assistants)	Equipment
3	Human resources (nurses)	Vacation	Bonus	Reduction of overtime	Support for mental condition
4	Human resources (nurses)	Bonus	Office supplies	Equipment	Human resources (doctors)
5	Allowance	Human resources (nurses)	Vacation	Spare time	Recreation fee
6	Human resources (nurse)	Human resources (nurse assistants)	Improved work environment	Education materials	__a
7	Human resources (nurses)	Salary	Human resources (doctors)	Improved work environment	—
8	Commendation	Equipment	Recreation fee	—	—
9	Human resources (nurses)	Spare time	Equipment	—	—

[a]Participants were asked to list between 2 and 5 items; therefore, some entries are blank.

Workloads and Price Setting

When average *workload* increased, participants typically set higher prices for each illness; however, this did not occur every time (Figure 6). Every group, especially Group A, showed a more apparent association between price and workload during the second session than that in first session (Figures S4 and S5 in Multimedia Appendix 1). There was a similar tendency for mild illnesses; however, we could not evaluate quantitative association due to limited data.

Figure 6. Association between price and workload. The upper graphs show the first session, in which players were asked to collect as many tokens as possible, and the lower graphs show the second session, in which players were asked to make decisions as nurse managers in real practice. A darker gray indicates a higher workload.


Discussion

General

A preliminarily examination of practicing nurse managers' perception on the feasibility of using a token economy–based bed allocation system to mitigate information asymmetry indicated that the system may enhance staff satisfaction and patient safety but may worsen managerial rivalry and inhibit staff development. There is also potential that hospital administrators can utilize our system as a strategy development tool for human resource allocation.

In mathematical modeling studies of bed assignment processes, patient flow, and bed availability [19,20], there is the implicit assumption that there is no information asymmetry, which allows an optimized solution to be found; however, as those studies [19,20] indicated, communication problems between planners and frontline workers remained. That is, information asymmetry diminished the efficacy of such methods in practice. The impossibility of the planner being able to collect complete information has been widely acknowledged in economics (ie, calculation controversy [28]) and by military strategists (fog of war [29]). Likewise, in real practice at hospitals, there is too much apparent or latent information that can be considered in bed assignment process; thus, solving the bed assignment operation problem with mathematical calculation is fundamentally unfeasible.

To the best of our knowledge, no previous research has focused on information asymmetry in bed allocation or hospital management. We identified optimized bed assignment as the target behavior and designed our token economy with transactions occurring between physicians and impatient wards. Unlike token economy designs, in which psychiatrists or

teachers define target behavior unilaterally, our design made both stakeholder parties represent desirable behaviors with tokens. Even though the sample size was limited, associations between the information that participants had (*workload*) and the information that participants broadcast (*price*) demonstrated that our token economy–based has potential to mitigate information asymmetry in bed allocation management.

Participants positively rated staff satisfaction, patient safety, and consistency with divisional goals. Autonomy is said to be one of the important factors in improving employee satisfaction in hospitals [30], and characteristics of the proposed method—each frontline division can broadcast their status in a 1-dimensional simplified manner, in the form of pricing—may enhance the autonomy of divisions, resulting in positive effects, which may explain our survey results. Employee satisfaction increases organizational loyalty and employee retention [31], which is critical for human resource management generally and specifically in the nursing filed [32,33]. In addition, patient safety improves when employees are satisfied with their workplace [34] and vice versa [35].

Participants negatively rated the effect on the intensity of managerial rivalry, employee development, and the benefits for patients. Managerial rivalry is said to be a disadvantage of decentralized decision-making;. However, a decentralized method is also said to have positive effects on employee development, by allowing autonomous decision-making [26].

Participants were nurse managers in a teaching hospital, where many employees have limited experience as nurses to make adequate decisions independently; therefore, participants, as managers, might be afraid that their staff would make selfish choices [36]. Given this, prior to being implementing this token economy–based systems in practice, staff decision-making

capabilities should be evaluated. Regarding benefit for patients, our method did not take ward specialty into consideration when selecting admission for the sake of simplicity; therefore, participants thought patients had higher possibilities of being assigned to nonspecialized wards than the current method. To address this problem, rule-based restrictions can be considered in future system designs.

When asked about desirable rewards for tokens, most participants indicated human resources (in particular, additional nursing staff). Rewards for tokens are called "back-up reinforcer(s)" [37] when used in behavior modification fields, and are key factors in the method's design [38]. Hospitals in Japan are suffering from nurse shortages [39], and efficient human resource allocation is needed. Wards (or divisions) that collect more tokens can be regarded as creating more value for the hospital. Therefore, allocating more resources to those wards is reasonable, especially given that hospitals are a labor-intensive industry [40], in nurses play central role [41]. Through such implementation design, a token economy–based system may be able to optimize resource allocation and improve staff motivation.

Although we chose bed allocation as the target problem, hospitals have many other resource allocation problems to be solved. The proposed token economy–based method may be applied to other resource allocation problems in hospitals in the future, with appropriate token economy design.

Limitations

The study had some limitations because this research showed only preliminary implications for efficiency in applying a token economy–based system to bed assignment processes. First, the assumptions used in our simulation were too simple compared with those in real practice. That is, we only considered emergency admissions, whereas in reality, hospitals also receive elective admissions. The proposed token economy–based system may cause confusion for nurse managers whether emergency and elective cases should be prioritized at first, but they will be able to adjust pricing behavior by referring elective admission lists. We can, theoretically, expect that the adjustment may result in convergence to adequate allocation via market mechanism. Second, participants were recruited from a single university-affiliated teaching hospital, thus the perceptions of the participants may be different from the perceptions of staff in general hospital fields. Third, we only recruited 9 participants, due to limited resources, and the limited sample size may result in impaired external validity.

Based on these limitations, immediate implementation of our method into real practice is probably unfeasible. However, by showing the constraints of previous studies [19,20] and proposing an innovative method, we make an important contribution.

Conclusion

A token economy–based bed allocation system has the potential to be an effective method to innovatively solve bed allocation problems in hospitals, by mitigating intraorganizational information asymmetry, and improve staff satisfaction, by allowing the autonomy of frontline professionals.

Authors' Contributions

SH provided the research idea, wrote the manuscript, and led the preparation of figures and tables. JH designed and conducted experiments. OS supervised programming of the simulation game. KS helped with data analysis and preparation of the manuscript, figures, and tables. MN and TK led the discussion and the team.

Abstract

Background: Singapore's national digital contact-tracing (DCT) tool—TraceTogether—attained an above 70% uptake by December 2020 after a slew of measures. Sentiment analysis can help policymakers to assess public sentiments on the implementation of new policy measures in a short time, but there is a paucity of sentiment analysis studies on the usage of DCT tools.

Objective: We sought to understand the public's knowledge of, concerns with, and sentiments on the use of TraceTogether over time and their preferences for the type of TraceTogether tool.

Methods: We conducted a cross-sectional survey at a large public hospital in Singapore after the COVID-19 lockdown, from July 2020 through February 2021. In total, 4097 respondents aged 21-80 years were sampled proportionately by sex and 4 age groups. The open-ended responses were processed and analyzed using natural language processing tools. We manually corrected the language and logic errors and replaced phrases with words available in the syuzhet sentiment library without altering the original meaning of the phrases. The sentiment scores were computed by summing the scores of all the tokens (phrases split into smaller units) in the phrase. Stopwords (prepositions and connectors) were removed, followed by implementing the bag-of-words model to calculate the bigram and trigram occurrence in the data set. Demographic and time filters were applied to segment the responses.

Results: Respondents' knowledge of and concerns with TraceTogether changed from a focus on contact tracing and Bluetooth activation in July-August 2020 to QR code scanning and location check-ins in January-February 2021. Younger males had the highest TraceTogether uptake (24/40, 60%), while older females had the lowest uptake (8/34, 24%) in the first half of July 2020. This trend was reversed in mid-October after the announcement on mandatory TraceTogether check-ins at public venues. Although their TraceTogether uptake increased over time, older females continued to have lower sentiment scores. The mean sentiment scores were the lowest in January 2021 when the media reported that data collected by TraceTogether were used for criminal investigations. Smartphone apps were initially preferred over tokens, but the preference for the type of TraceTogether tool equalized over time as tokens became accessible to the whole population. The sentiments on token-related comments became more positive as the preference for tokens increased.

Conclusions: The public's knowledge of and concerns with the use of a mandatory DCT tool varied with the national regulations and public communications over time with the evolution of the COVID-19 pandemic. Effective communications tailored to subpopulations and greater transparency in data handling will help allay public concerns with data misuse and improve trust in the authorities. Having alternative forms of the DCT tool can increase the uptake of and positive sentiments on DCT.

Introduction

COVID-19, declared a pandemic by the World Health Organization in March 2020, is highly transmissible, with infections leading to deaths and severe illnesses [1]. Contact tracing has been a critical measure in curbing infectious disease transmissions [2]. However, conventional methods are time-consuming, labor-intensive, subject to recall biases, and unscalable during large-scale outbreaks, such as COVID-19 [3].

Digital contact-tracing (DCT) tools can potentially address the problem of scale during the COVID-19 pandemic by capturing device encounters via Bluetooth-enabled smartphone apps or wearable devices [4,5]. Studies have suggested that DCT tools can help to increase the detection of cases and reduce the time taken for contact tracing by 2.5 times [6-8]. However, a minimum population adoption rate of 60% is required for contact tracing to be effective with DCT tools [9]. At present, Singapore is the only country that has achieved a nationwide DCT adoption rate of more than 70% [10].

Singapore developed a national DCT tool—TraceTogether—in March 2020 and promoted its use after exiting a lockdown in June 2020. Since then, mandatory use of the TraceTogether smartphone app or wearable token for check-ins to enter public venues (such as shopping centers, grocery stores, restaurants, cinemas, schools, and hospitals) has been introduced to increase its adoption [11]. Although the adoption rate of TraceTogether increased from 40% in July to more than 70% in December 2020 [10], the adoption of TraceTogether may have been involuntary under mandatory conditions.

Privacy concerns, lack of trust in the government, and pessimistic views on the effectiveness of DCT tools were barriers against its adoption [12-14]. The plethora of reasons for the hesitancy to adopt DCT tools suggests complex sentiments among users, which may have been deep seated under mandatory conditions. Since the large-scale adoption of DCT tools is unprecedented, understanding the complex sentiments associated with its use would help policymakers to adjust implementation approaches. Traditional qualitative analyses can identify in-depth user perspectives on a topic but are usually confined to smaller samples of text due to their resource-intensive requirements. Natural language processing (NLP) tools are less sensitive in identifying nuances in text data but are able to process a large number of texts in a shorter time frame. Therefore, the use of NLP tools would be most suitable for the analysis of a large number of short texts without in-depth meanings [15].

Opinion mining and sentiment analysis have been performed widely to understand the public's reaction and challenges faced during the COVID-19 pandemic [16,17]. These methods are useful for consolidating a large amount of information in a short period. For example, policymakers can study public sentiments on new events or COVID-19 measures and tailor public health communications to mitigate negative emotions arising from the event or measure [17]. An increasing number of studies have utilized short social media texts, such as Tweeter posts, to understand public sentiments on the COVID-19 pandemic [18,19]. Despite the benefits of opinion mining and sentiment analysis in rapidly garnering the public's opinion, the data collected from online platforms, such as microblogs, social media, app store reviews, and online surveys, were biased toward the more privileged and technologically savvy individuals [20,21]. Overrelying on data collected from social media sites would omit the views of social groups that do not use these sites [22,23].

There is also a paucity of sentiment analysis studies on the usage of DCT tools. An Irish study analyzed the sentiments of DCT app reviews and found predominantly positive sentiments; however, the review focused on voluntary app users who may be more accepting of DCT tools [20]. Given the lack of studies on user perspectives on DCT tools and biases of the data sources used for opinion mining, we sought to understand the public's knowledge of, concerns with, and sentiments on the use of DCT tools over time, as mandated by the authorities for pandemic control, across an extensive demographic and age distribution.

Methods

Study Design

We conducted a cross-sectional survey in the 2 busiest ambulatory clinics at the second-largest public hospital in Singapore, starting from 1 month after the nationwide COVID-19 lockdown in 2020. Data collection occurred over 8 months from July 2020 through February 2021 during patients' or their caregivers' visit to the clinic. Respondents from ages 21 to 80 years were sampled proportionally by sex and four 15-year age groups to cover the perspectives of digital natives and digital immigrants. We included only citizens and permanent residents of Singapore as this population would best fit the context of our study.

Timeline of TraceTogether Events in Singapore

The use of TraceTogether was widely promoted after the COVID-19 lockdown in Singapore. The smartphone app was initially promoted to trace encounters with users in close proximity but was updated in June 2020 to collect personal identifiers for more effective contact tracing. The app is available in multiple languages, including Bengali, Burmese, Chinese, English, Hindi, Melayu, Tamil, and Thai. In July 2020, the token form of TraceTogether was made available to seniors who do not own smartphones. Each token weighs 15 g, with dimensions that are 62 mm long, 15 mm thick, and 45mm wide. From September to November 2020, the government made a series of announcements to promote the uptake of TraceTogether. All Singapore citizens were eligible to collect a free TraceTogether token to facilitate mandatory safe entry check-ins at all public venues [11], and social restrictions would

be eased further if at least 70% of the population adopted TraceTogether [24]. In early January 2021, the Singapore police force used the TraceTogether data for criminal investigations under the Criminal Procedure Code (CPC) [25]. Clarifications were made when the act evoked a public outcry on personal data protection.

Survey Instrument

We designed a 14-item survey questionnaire based on literature review and included questions on the status of digital device usage and willingness to use TraceTogether (pre- and postsharing on DCT tools). Three open-ended questions were used to determine respondents' knowledge of TraceTogether, top three concerns with any DCT technology, and the reasons for their preference for the form factor of TraceTogether (refer to Multimedia Appendix 1 for the questionnaire).

Data Collection

We trained all data collectors to ensure that the questionnaire was appropriately administered by the interviewer. Information on respondents' perceptions of a DCT tool was collected using TraceTogether as an example. We then provided a 2-minute explanation on the purpose of DCT tools at the end of the survey and asked respondents again whether they would be willing to use a DCT tool and, if so, whether they preferred an app or a token and the reason for their choice. Demographic information was collected to perform segmented analyses.

This study focused on the open-ended responses from respondents, which included asking the respondents their thoughts on the purpose, data security, and usage of TraceTogether and their concerns with TraceTogether. The reasons for the choice of a smartphone app or token were also analyzed.

Descriptive Statistics

We classified respondents into 4 age and sex categories (younger females, older females, younger males, and older males) and classified those who were above the age of 50 years as older adults and those 50 or under 50 years as younger adults. Mean and SDs were computed for age, while proportions were computed for other categorical variables, such as demographics, smartphone ownership, awareness of TraceTogether, willingness to use TraceTogether, and preference for its form factor. We also presented the bimonthly uptake rate of TraceTogether by age and sex to show the impact of the policy measures to boost uptake rates.

Data Processing

The open-ended responses were manually processed to correct language and spelling errors. Abbreviations were written in full, and the informal and colloquial form of the English language was rephrased to the formal form. For example, "don't like" was rephrased as "dislike" as "don't" would likely be removed as a stop word, while "like" would be detected as a positive sentiment, although the phrase implies a negative sentiment. Important phrases on "knowledge of TraceTogether" were standardized 3-word phrases and analyzed as trigrams (refer to Table S1 in Multimedia Appendix 1), while other sections were analyzed as bigrams. The processed trigrams were subsequently replaced with a phrase that was closer to their original meaning before it was presented graphically (eg, the pre-processed phrase "Location unknown uncollected" was replaced with "Location data NOT collected" when presented graphically).

The preprocessed responses were then processed with NLP tools. All phrases were tokenized (split into smaller units), and the sentiment score of each phrase was computed by summing the sentiment scores of all the tokens in the phrase. Stopwords, such as prepositions and connectors, were removed according to the *stopwords* package in R, followed by implementation of the bag-of-words model (simplifying the representation of words) to calculate the occurrence of bigrams and trigrams in the data set. Demographic and time filters were applied to segment the responses, as required (Figure 1).

Sentiment Analysis

We used the *syuzhet* package for sentiment analysis as it incorporates 3 other lexicons developed by other groups [26]. The *bing* lexicon contains a list of words classified into positive and negative sentiments, while the *nrc* lexicon classifies words into 8 other emotions on top of the positive and negative sentiments. The *afinn* and *syuzhet* lexicons contain a database of words with a sentiment score. We compared the sentiment scores derived from the *syuzhet* and *afinn* lexicon and did not find substantial differences in sentiment patterns [26,27]. Hence, we used the *syuzhet* lexicon for our analyses as the database contains a wider range of vocabulary compared to the *afinn* database. Each word in the *syuzhet* library has a value of between –1 and 1. Words with positive connotations are scored positively, while those with negative connotations are scored negatively. The sentiment score of a response statement was computed by summing the values of all the words in the

statement that could be found in the *syuzhet* library. All analyses were performed using RStudio version 1.2.5033.

Some of the respondents would comment on the disadvantages of the TraceTogether token when asked why they preferred the smartphone app or vice versa. Hence, the reasons for respondents' preference for either the TraceTogether tool (smartphone app or portable token) were split into token- or smartphone-related comments before sentiment analysis.

Ethical Considerations

This study was approved by the National Healthcare Group (NHG) Domain Specific Review Board (DSRB) in Singapore (NHG DSRB ref. 2020/00775). A waiver of written informed consent was granted, and implied consent was assumed if the individual agreed to respond to the survey.

Results

Recruitment Rate and Demographics of Respondents

We approached 6260 potential respondents and excluded 744 (11.88%) who did not meet the inclusion criteria. Of 5229 eligible participants, we interviewed 4097 (78.35%) respondents in total. Approximately a quarter of the respondents who were interviewed declined to respond to the open-ended questions.

Table 1 shows the demographics of respondents. Age and sex were proportionately sampled during data collection. Hence, respondents were divided into 4 age and sex categories. The Chinese race was slightly oversampled in older adults as the Chinese race constitutes about 76% of the Singapore population. A higher proportion of younger adults were tertiary educated compared with older adults, but the overall education level of respondents was representative of the general population. A smaller proportion of older adults were employed, as 796 (38.81%) of 2051 older adult respondents were retirees.

Table 1. Baseline characteristics of respondents (N=4097).

Characteristics	Total respondents	Younger males	Younger females	Older males	Older females
Age (years), mean (SD)	50.2 (16.8)	35.4 (8.7)	35.7 (8.5)	64.8 (7.9)	64.7 (7.9)
Ethnicity, n/N (%)					
Chinese	3330/4097 (81.27)	802/1024 (78.32)	756/1022 (73.97)	867/1027 (84.42)	905/1024 (88.38)
Malay	315/4097 (7.69)	107/1024 (10.45)	148/1022 (14.48)	49/1027 (4.77)	50/1024 (4.88)
Indian	354/4097 (8.64)	84/1024 (8.20)	84/1022 (8.22)	91/1027 (8.86)	56/1024 (5.47)
Others	98/4097 (2.39)	31/1024 (3.03)	34/1022 (3.33)	20/1027 (1.95)	13/1024 (1.27)
Education level, n/N (%)					
Tertiary	1296/4097 (31.63)	488/1024 (47.66)	489/1022 (47.85)	214/1027 (20.84)	105/1024 (10.25)
Employment status[a], n/N (%)					
Employed	2728/4097 (66.59)	870/1024 (84.96)	872/1022 (85.32)	548/1027 (53.36)	438/1024 (42.77)
Digital device usage[b], n/N (%)					
Owns a smartphone	3712/4097 (90.60)	1022/1024 (99.80)	1019/1022 (99.71)	871/1027 (84.81)	800/1024 (78.13)
Heard of TraceTogether	3818/4097 (93.19)	987/1024 (96.39)	972/1022 (95.11)	934/1027 (90.94)	925/1024 (90.33)
Willing to use TraceTogether (presharing)	3143/4097 (76.71)	739/1024 (72.17)	767/1022 (75.05)	806/1027 (78.48)	831/1024 (81.15)
Willing to use TraceTogether (postsharing; 36 [0.9%] missing)	3674/4061 (90.47)	908/1021 (88.93)	924/1018 (90.77)	903/1010 (89.41)	939/1012 (92.79)
Form factor preference (willing to use TraceTogether postsharing; 127 [3.5%] missing), n/N (%)					
Smartphone app	1900/3547 (53.56)	604/872 (69.27)	602/887 (67.87)	399/872 (45.76)	295/916 (32.21)
Token	1647/3547 (46.43)	268/872 (30.73)	285/887 (32.13)	473/872 (54.24)	621/916 (67.79)

[a]Full-time, part-time, self-, or temporary employment.

[b]Uptake of TraceTogether was not presented in this table, as uptake rates changed over time with the policy measures. Refer to Figure 2 for bimonthly uptake rates.

Figure 2. The proportion of TraceTogether uptake and mean (syuzhet) sentiment score of concerns with TraceTogether over time.
The overall smartphone ownership was 3712 (90.60%) of 4097 people. However, the proportion of older adults who owned a smartphone was lower than that of younger adults. Older females had the lowest smartphone ownership compared with other groups. The majority of respondents (3818/4097, 93.19%) had heard of TraceTogether at the time of the survey. The willingness to use TraceTogether increased across all age and sex categories after the study team explained the rationale and benefits of TraceTogether to the respondent.

Knowledge of TraceTogether

We counted the occurrence of unique trigrams and further collapsed trigrams with similar meanings to reduce the number of statements. Figure 3 shows the proportion of top trigrams classified into 2-month periods. All but 1 period had trigrams covering at least 70% of responses. Overall, the proportion of trigrams, representing respondents' knowledge and perceptions of TraceTogether, changed over time.

The top 6 trigrams from respondents' opinion on the purpose of TraceTogether ("What do you think TraceTogether is for?") were "Contact-tracing purpose/trace close-proximity contacts," "Location-tracing purpose," "Location-tracking purpose,"

"COVID-19-positive patient," "Receive alert notification," and "Scan QR code/location check-ins." The proportion of mentions on contact tracing decreased (from 414/1806 [22.92%] to 365/2755 [13.25%]), while mentions on QR code scanning and location check-ins increased (from 19/588 [3.23%] to 133/1362 [9.77%]) over time.

The top 6 trigrams from respondents' opinion on the usage of TraceTogether ("What do you think users need to do?") were "Activate Bluetooth setting," "Activate GPS tracker," "Activate mobile data," "Activate/download phone app," "Carry token alongside," and "Scan QR code/scan NRIC/location check-ins" (where NRIC stands for National Registration Identity Card). Initially, respondents thought they had to download the app (41/292, 14.04%) and activate Bluetooth on their smartphones (174/292, 59.59%) to use TraceTogether. Over time, the proportion of mentions on Bluetooth activation decreased from 174 (59.59%) of 292 to 284 (29.71%) of 956, while the proportion of mentions on scanning QR codes/location check-ins increased from 9 (3.08%) of 292 to 301 (31.49%) of 956. The proportion of mentions on the need to carry the TraceTogether token also increased from 0 in August 2020 to 81 (8.47%) of 956 in December 2020.

Figure 3. Participants' responses on their knowledge of TraceTogether changed over time. The occurrence of trigrams and their proportions relative to all trigrams in a time category were computed. GPS: Global Positioning System; NRIC: National Registration Identity Card. *Trigrams were rephrased for clarity.
When respondents were asked their opinion on the data security of TraceTogether, three-quarters of the responses from July to October 2020 were mentions of "location data collected" or "users' location traced/tracked." By December 2020, the proportion of mentions related to location tracking/tracing/data collection decreased to 263 (61%) of 428 and subsequently to 25 (6.44%) of 388 by February 2021. The proportion of mentions on "secured data collection" doubled from 18 (5.96%) of 302 in July-August 2020 to 49 (12.63%) of 388 in November-December 2020. However, 64 (16.49%) of the 388 trigrams in January-February 2021 were mentions of the use of data collected by TraceTogether for the "Criminal Procedure Code."

Concerns With the Use of TraceTogether

We present the proportion of TraceTogether uptake (question item on "Are you currently using the TraceTogether app or Token?") and the mean *syuzhet* sentiment score of concerns with TraceTogether (open-ended question on "Please list your top three [3] main concerns with any DCT technology [not limited to TraceTogether]") at 2-week intervals in Figure 2. The plots were segmented into 4 categories: older males, older females, younger males, and younger females. Older adults were aged between 51 years and 80 years, while younger adults were between 21 years and 50 years of age. Uptake rates increased rapidly after the announcement of mandatory TraceTogether check-ins at public venues in mid-October 2020 and reached 70% by December 2020. The magnitude of the sentiment scores was used to compare sentiment changes over

time, and the concerns with TraceTogether were negative overall.

Younger males had the highest TraceTogether uptake (24/40, 60%), while older females had the lowest uptake (8/34, 24%) in the first half of July 2020. This trend was reversed in mid-October after the announcement on mandatory TraceTogether check-ins at public venues. In mid-February 2021, the TraceTogether uptake of older adults surpassed 90% (93/99), while that of younger adults was 80%-90% (100/116).

The mean sentiment scores were the lowest in January 2021 when the media reported that the data collected by TraceTogether were used for criminal investigations. Older females also had decreased sentiment scores as their TraceTogether uptake increased over time. This group of respondents were mainly concerned about data breaches, privacy violation, and the pressure to adopt a new technology that they were unfamiliar with. Four respondents had misconceptions about the Bluetooth technology and cited health concerns about possible radiation emitted by TraceTogether. Younger adults had similar concerns with privacy violation but were also concerned about Bluetooth battery consumption on their smartphones.

We present the occurrence of bigrams on respondents' concerns with the usage of TraceTogether in Table 2. The bigrams were classified into 5 categories. Each bigram was presented with a corresponding example of a response statement and the sentiment score of the statement.

Table 2. Top bigrams (N=3995) of respondents' concerns with TraceTogether.

Bigram	Occurrence, n (%)	Example of response statement	Sentiment score of example statement
TraceTogether app inconvenience			
Battery drainage	489 (12.24)	*Bluetooth needs to be activated, which causes battery drainage and slows down the app.* [Male, 57 years, September 2020]	–0.25
Technical glitch	83 (2.08)	*Technical glitch. It malfunctions on my phone all the time and does not seem to capture any interactions that I made with the people around me. That is why I stopped utilizing it.* [Female, 41 years, August 2020]	–1.5
Phone battery	77 (1.93)	*Inconvenient. If [my] phone battery [goes] flat, it [TraceTogether] would not work anymore.* [Female, 57 years, November 2020]	–0.25
User unfriendly	22 (0.55)	*App is user unfriendly.* [Female, 49 years, October 2020]	–0.5
Bluetooth battery	22 (0.55)	*Bluetooth battery drainage.* [Respondents aged 21-71 years, both sexes, all months]	–0.25
Memory space	10 (0.25)	*Lack of phone memory storage space.* [Female, 27 years, July 2020]	–0.75
Phone memory	9 (0.23)	*Lack of phone memory storage space.* [Female, 27 years, July 2020]	–0.75
Language barrier	5 (0.13)	*Language barrier. [The] Interface is in English. The first page should especially be in mandarin as 70% of the population is Chinese and some may not understand [English].* [Male, 68 years, July 2020]	–0.5
TraceTogether app and token data security			
Privacy violation	386 (9.66)	*Data privacy violation. Even though they [the authorities] say they collect minimal data, you would not know if they changed it down the road since nobody reads the terms and conditions.* [Male, 46 years, November 2020]	–0.5
Data privacy	238 (5.96)	*Location data privacy violation. You do not want others to know some places you go to.* [Female, 68 years, January 2021]	–0.5
Dislike location	139 (3.48)	*Linked with location tracking and location tracing*	__a
Location tracking	96 (2.40)	*Dislike location tracking. The app will track my location like an ankle collar on criminals.* [Male, 54 years, December 2020]	–1.5
Location tracing	53 (1.33)	*Dislike location tracing. Mistrust the government on data safety.* [Female, 57 years, November 2020]	–1.2
Data insecurity	81 (2.03)	*Lack of transparency on data usage, concerned about data insecurity.* [Male, 29 years, July 2020]	–2.1
Data leak	66 (1.65)	*Afraid of [data] being hacked and having data leak.* [Male, 27 years, September 2020]	–2.1
Data unprotected	9 (0.23)	*Data [are] unprotected. Dislike having to input IC [identification] number. Phone number should suffice.* [Male, 68 years, September 2020]	–1.8
TraceTogether app and token data misuse			
PDPA[b] violation	152 (3.80)	*PDPA violation. Dislike that personal details have to be entered before you can utilize it.* [Female, 42 years, December 2020]	–1.5
Data breach	148 (3.70)	*Who is responsible if there is a data breach and how is the breach being handled?* [Female, 50 years, July 2020]	–0.5
Privacy invasion	41 (1.03)	*Privacy invasion. A sense that you are being stalked.* [Male, 67 years, July 2020]	–1.4
Jeopardize bank details	17 (0.43)	*Jeopardize bank and credit card details.* [Respondents aged 26-67 years, both sexes, September 2020-February 2021]	–0.5
Credit card details	16 (0.40)	*Jeopardize bank and credit card details.* [Respondents aged 26-67 years, both sexes, September 2020-February 2021]	–0.5
Personal information	18 (0.45)	*Privacy violation as there may be a personal information leak.* [Female, 47 years, January 2021]	–0.85
Information leak	12 (0.30)	*Privacy violation as there may be a personal information leak.* [Female, 47 years, January 2021]	–0.85

Bigram	Occurrence, n (%)	Example of response statement	Sentiment score of example statement
TraceTogether app and token efficiency and efficacy of contact tracing			
Contact tracing	58 (1.45)	*Even with contact tracing we are unable to immediately know who is infected or if I met them, so it is inefficient.* [Female, 40 years, February 2021]	–1.35
TraceTogether inaccurate	6 (0.15)	*TraceTogether [is] inaccurate. It is pointless if I utilize and others do not.* [Male, 50 years, October 2020]	–1.5
Delayed notification	6 (0.15)	*The app notified me of possible exposure on the 14th, but I received delayed notification only on the 30th.* [Male, 30 years, December 2020]	–0.15
TraceTogether token design			
Size cumbersome	35 (0.88)	*The token is badly designed, has a limited lifespan and its large size [is] cumbersome.* [Male, 74 years, December 2020]	–2
Token size	12 (0.30)	*Cumbersome token size and it is unaccepted at some stores.* [Female, 51 years, December 2020]	–0.5

[a]Not applicable.

[b]PDPA: Personal Data Protection Act.

Inconvenience Created by the TraceTogether App

In this study, 717 (17.95%) of 3995 bigrams were concerns with the inconvenience created by the TraceTogether app. The concerns included smartphone battery drainage due to Bluetooth activation, frustration with technical glitches, and the app taking up phone memory space. Older individuals may have language barriers with using the app, and individuals with dependents may find the process of checking into locations troublesome.

> *Bluetooth needs to be activated, which causes battery drainage and slows down the app.*

> *Inconvenient. If [my] phone battery [goes] flat, it [TraceTogether] would not work anymore.*

> *User unfriendly. Will appreciate [it] if you can include your child in the parents' app as well so can save time on scanning as the child's details are inside the parents' app.*

> *Language barrier. [The] interface is in English. The first page should especially be in [M]andarin as 70% of the population is Chinese and some may not understand [English].*

Concerns With Data Security in the TraceTogether App and Token

In this study, 1068 (26.73%) of 3995 bigrams were concerns with the data security of TraceTogether. Respondents disliked location tracking or tracing and felt that their (data) privacy was/will be violated with the use of TraceTogether. Respondents also felt that data transparency was insufficient, and they were insecure about data leaks should they lose their token.

> *Data privacy violation. Even though they [the authorities] say they collect minimal data, you would not know if they changed it down the road since nobody reads the terms and conditions.*

> *Location data privacy violation. You do not want others to know some places you go to.*

> *Dislike location tracking. The app will track my location like an ankle collar on criminals.*

> *Dislike location tracing. Mistrust the government on data safety.*

> *Lack of transparency on data usage, concerned about data insecurity.*

Concerns With Data Misuse by the TraceTogether App and Token

In this study, 404 (10.11%) of 3995 bigrams were concerns with data misuse, such as violation of the Personal Data Protection Act (PDPA), data breaches, and leakage of personal information and credit card details. Respondents also felt that tagging the TraceTogether device provided a sense of privacy invasion and insecurity about possible data breaches.

> *PDPA violation. Dislike that personal details have to be entered before you can utilize it.*

> *Who is responsible if there is a data breach and how is the breach being handled.*

> *Privacy invasion. A sense that you are being stalked.*

Concerns With the Efficiency and Efficacy of Contact Tracing

In this study, 70 (1.75%) of 3995 bigrams were mentions of the accuracy of TraceTogether and delayed notifications. Respondents were concerned that TraceTogether would be inaccurate if most of the population does not utilize TraceTogether appropriately. Some respondents mentioned that they did not receive timely app notifications of possible exposures.

> *Inefficiency of the tool. The success of contact tracing depends on the cooperation of citizens.*

> *The app notified me of possible exposure on the 14th (of the month), but I received delayed notification only on the 30th (of the month).*

Dissatisfaction With the TraceTogether Token Design

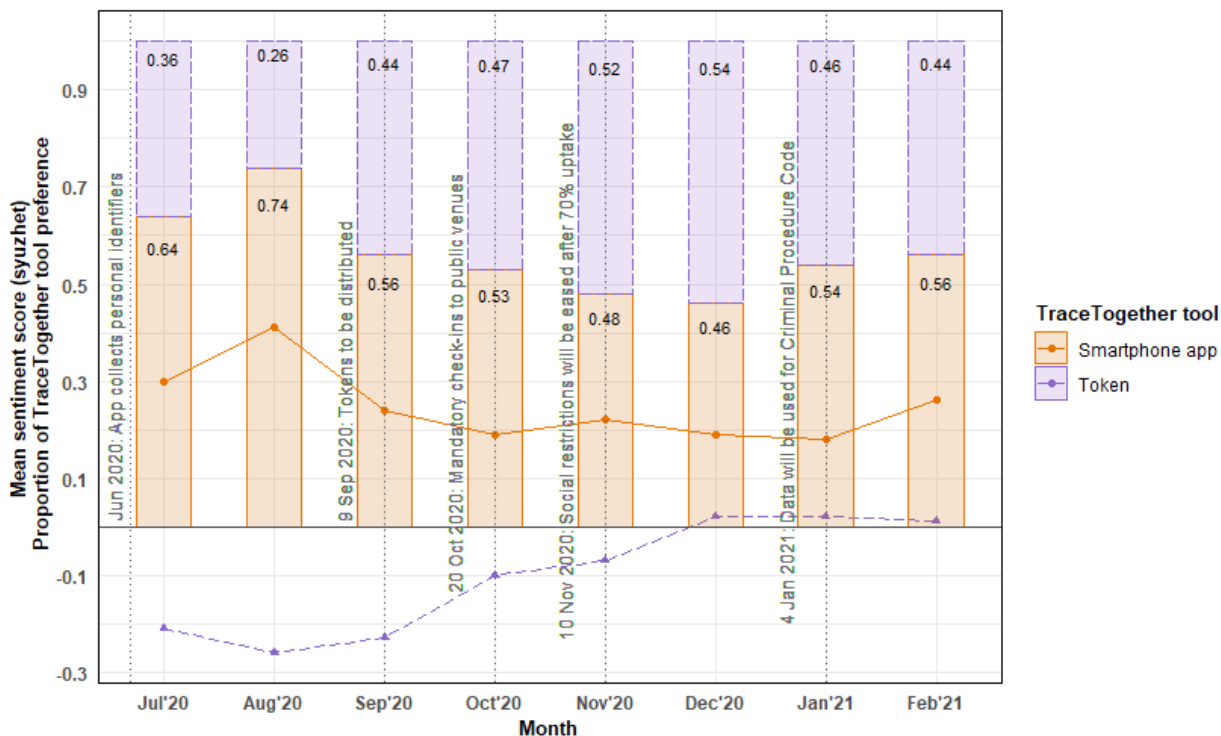
In this study, 47 (1.18%) of 3995 bigrams were mentions of dissatisfactions with the TraceTogether token form factor. Respondents felt that the large token size makes it cumbersome

to carry around. Other issues related to the token include its limited battery span, unsightly aesthetics, and inability to check in at smaller stores without token scanners.

> *The token is badly designed, has a limited lifespan, and its large size [is] cumbersome.*
>
> *Cumbersome token size and it is unaccepted at some stores.*

Preference for the TraceTogether Tool

Respondents' preference for the type of the TraceTogether tool (smartphone app or portable token) and sentiment scores of the reason for their preferred type over time are shown in Figure 4. In the first 2 months of data collection, in July and August 2020, two-thirds (96/150, 64%) and three-quarters (161/217, 74.2%) of respondents preferred the smartphone app over the token. Over time, the preference for the type of TraceTogether tool equalized among respondents as tokens became accessible to the whole population.

Figure 4. The proportion of respondents' preference for the TraceTogether tool (smartphone app or token) and the sentiment scores of the reason for their choice over time. Note: The proportion of TraceTogether preferences are based on cross-sectional time series data.


The sentiment scores of the reason for the preferred type of TraceTogether tool moved in tandem with the proportion of respondents' indicating preference for that particular type. The sentiments on token-related comments became more positive as the preference for tokens increased. Similarly, the sentiments on smartphone app–related comments became less positive as the preference for the smartphone app decreased. Overall, respondents had more positive sentiments on the use of the TraceTogether app compared with the token.

Respondents preferring the smartphone app felt that the app was a convenient option since they would always have their phones with them. Respondents preferring the app also felt burdensome to have to remember to bring the token when going out and were worried that the token, if misplaced, would be misused by the finder. In addition, some respondents commented that the plastic used to manufacture the tokens was environmentally unfriendly and that the tokens were unsightly and bulky to carry. There were also smaller shops that did not allow the checking-in of tokens.

Respondents preferring the token felt that the tokens were suitable for the elderly with difficulty using smartphone apps.

They liked that the token does not consume the smartphone's battery and mobile data and that there is no need to charge the token or worry about their smartphone battery going flat.

Discussion

Principal Findings

We found differences in the sentiments of respondents across age, sex, and time under voluntary and mandatory use of TraceTogether. The application of NLP techniques on unstructured free-text responses to open-ended questions in an interviewer-administered questionnaire implemented consistently over 8 months enabled us to quantify and examine the changes in public sentiments as the COVID-19 pandemic evolved. Such analyses will provide useful and timely feedback to policymakers on the impact of public health policies and measures imposed on the population and enable them to fine-tune them for greater public acceptance and compliance.

The knowledge of TraceTogether did not differ across age groups. Respondents' knowledge of the purpose of TraceTogether did not change substantially over time, except for a slight shift from its use for contact tracing to scanning of

QR codes for location check-ins. A small proportion of respondents (450/5206, 8.64%) had the misconception that TraceTogether tracks their location. Polls have shown that 1 reason for the hesitancy in TraceTogether uptake is the misconception that TraceTogether tracks the user's location [28]. More could be done by the authorities to address such misconceptions in public education.

Respondents' perception of the security of the data collected by TraceTogether shifted from being location focused from July to December 2020 to a focus on the Criminal Procedure Code and loss of freedom and privacy in January-February 2021. The overall sentiments on the concerns with TraceTogether were most negative in January 2021. Despite the negative sentiments on the usage of TraceTogether data for the CPC, there was also a higher proportion of mentions of secured data collection in January-February 2021, implying improved knowledge of and confidence in TraceTogether's data handling among some respondents. The media is powerful in eliciting knee-jerk reactions among the public. Although such reactions may be short lived, it is imperative to promptly address any public concern to prevent long-term repercussions [29].

The sentiments on concerns with TraceTogether became more negative after the government's announcement on the mandatory use of TraceTogether for check-ins to enter public venues, although the reported uptake rate of TraceTogether increased. This observation suggests involuntary uptake of TraceTogether required for social interactions to resume. In another study, we assessed the trade-offs of social interactions and incentives on the use of DCT tools and found that most people would prefer to use a DCT tool in exchange for more social interactions under conditions of social restrictions during the COVID-19 pandemic.

The involuntary uptake of TraceTogether may lead to negative sentiments due to a lack of understanding of the data transparency and the need for users to tag their identifiers with the tool. Although the negative sentiments could be transient and existent only during the COVID-19 pandemic, prolonged negative population sentiments may lead to future political repercussions if the benefits of the mandatory measures are unappreciated [30].

The sentiments and preference for TraceTogether tokens improved after mass token distributions to the public. Although smartphone apps were preferred, having an alternative type of TraceTogether tool could have improved the overall uptake of TraceTogether. Reducing barriers to accessibility may have helped to increase the TraceTogether uptake rate as no other country has nationally distributed alternative forms of the DCT tool or achieved more than 70% uptake [31].

Limitations

There are various limitations to this study. First, the observations were cross-sectional, as we did not assess opinion changes of the same respondents over time. Nonetheless, the serial cross-sectional surveys on proportionately sampled respondents with a good representation of age and sex at every period provided invaluable insights into the changes in the population's opinions over time. Second, the *stopwords* package removed too many words, while the existing sentiment libraries did not have sentiment scorings for colloquial phrases such as "don't like," "don't want," and "not friendly." We had to manually replace these words with words found in the sentiment library to apply a sentiment score to the phrase. Regardless, the meaning of the words was retained. Third, manual data cleaning is time-consuming and may not be feasible for analyzing a large data set in a short amount of time. Lastly, respondents were patients and visitors of a public hospital and may not be representative of the Singapore population. However, a good representation of sex and age groups were sampled.

Future studies could explore crowdsourcing to develop a sentiment library that better suits the local context to reduce the time spent on data preprocessing. A stop word library that excludes (does not remove) words used in colloquial phrases will also reduce efforts on data preprocessing. Timely awareness of the public's sentiments on a new policy will allow policymakers to adjust their approach to public communication [32]. The insights gained from subpopulations, such as the elderly and adults who are not technologically astute, provide opportunities to tailor interventions that can help them to better adapt to the new technology.

Conclusion

In conclusion, the public's knowledge of and concerns with using a mandatory DCT tool varied with the national regulations and public communications over time with the evolution of the COVID-19 pandemic. Effective communications tailored to subpopulations and greater transparency in data handling will help allay public concerns with data misuse and improve trust in the authorities. Having alternative forms of the DCT tool can increase the uptake of and positive sentiments on DCT tools.

Authors' Contributions

ZH conceived the manuscript, analyzed the data, and drafted the manuscript. ET and DW assisted in analyzing the data. HYFL and AC provided support for the study and study planning. All authors critically reviewed the manuscript and approved the final version of the manuscript prior to submission.

Abstract

Background: Digital health is efficacious for the management and prevention of mental health (MH) problems. It is particularly helpful for the young adult population, who appreciate the autonomy digital health provides, and in low-income countries, where the prevalence of MH problems is high but the supply of professionals trained in MH is low.

Objective: The objectives of this study are 2-fold: to determine whether university students in Bangladesh find using digital health for MH promotion acceptable and to examine motivational factors for using digital health for MH.

Methods: This study used a cross-sectional survey to examine the likelihood that university students in Bangladesh (n=311) would use different forms of digital health platforms for MH promotion and assessed drivers of intention to use and actual use of digital health generally and digital health for MH through the lens of the Technology Acceptance Model. The results provided evidence that the university student population in Bangladesh is likely to use digital health to promote their MH.

Results: Social influence (adjusted odds ratio [aOR] 1.68, 95% CI 1.40-2.01; $P<.001$), ease of use (aOR 1.85, 95% CI 1.35-2.53; $P<.001$), and perceived usefulness (aOR 4.12, 95% CI 1.79-9.51; $P=.001$) of digital health were found to be significant drivers of the intention to use general digital health, and having an intention to use digital health (aOR 2.10, 95% CI 1.17-3.78; $P=.01$) had the greatest influence on actual use of digital health. Social influence (aOR 1.71, 95% CI 1.43-2.04; $P<.001$), perceived usefulness (aOR 8.92, 95% CI 4.18-19.04; $P<.001$), and use of general digital health (aOR 2.16, 95% CI 1.18-3.97; $P=.01$) were associated with higher intention to use digital health for MH. The use of general digital health (aOR 4.19, 95% CI 2.37-7.41; $P<.001$) was associated with the actual use of digital health for MH, as were greater non–stigma-related barriers to using traditional clinical MH services (aOR 2.05, 95% CI 1.10-3.80; $P=.02$).

Conclusions: Overall, we see that the use of digital health for MH is acceptable in this population and can be helpful for students who perceive barriers to receiving traditional care. We also gain insight into how to promote the intention to use digital health, which in turn promotes the actual use of digital health.

KEYWORDS

Introduction

Background

Digital health interventions have become widespread to fulfill the need for mental health (MH) services that are low in supply and high in demand [1]. Mobile health (mHealth) is a category within digital health defined as the use of mobile computing and communication technologies in health care and public health [1]. The most common uses of mHealth are apps for monitoring and treating chronic conditions as well as in prevention efforts [2]. mHealth interventions have been found to be beneficial for smoking cessation, adherence to care, health behavior changes, disease management, increasing physical activity [3], and attendance rates of care [4,5]. Marcolino et al [2] examined 23 systematic reviews encompassing >10,000 articles published from 2009 to 2016 and concluded that there is strong evidence to suggest that mHealth is effective in disease management, symptom improvement, and increasing the quality of life of populations.

MH is another domain in which the use of apps has shown promising results. Apps are defined as discrete and independent software that runs on a mobile device [6,7]. Mobile apps have more benefits than SMS text messaging as they can be more deeply personalized [8], visually engage the user, track progress, and be self-paced [9,10]. These features make apps an invaluable platform for the dissemination of interventions. A systematic review evaluated 5646 abstracts published between 2008 and 2013 and found 8 papers describing 5 apps targeting depression, anxiety, and substance abuse that met their inclusion criteria [11]. The review only included evidence-based MH apps that could be downloaded from app stores. The results showed significant reductions in depression, stress, and substance use [11]. Other meta-analyses support that psychological intervention content delivered through a web or mobile app can be as efficacious as face-to-face treatment for depression [12-14].

Digital health can increase the likelihood that health interventions will be delivered to otherwise hard-to-reach populations, particularly in low- and middle-income settings [2]. A systematic review assessed 6 interventions that were specific to low- and middle-income countries and found that 5 out of 6 showed benefits to participants [15]. Other advantages of digital health are convenience, ease, cost-effectiveness, scalability, personalization, and "the ability to send time-sensitive messages with an 'always on' device" [16]. Furthermore, it can reach populations who would otherwise not engage with traditional health services [17].

There are particular benefits for governments of low-income countries that need additional support for patient management [18] because digital health is potentially highly accessible in low-income countries, with 60% of low-income populations having access to a mobile phone [19]. Furthermore, internet and smartphone use are rising worldwide in high- and low-income countries alike [20]. Bangladesh is one such low-income country that has shown positive results in the use of digital health for promoting health care in Bangladesh for various health-related issues [21,22]. The Bangladesh government fosters digital development, and the United Nations recognized its efforts toward building a digital health infrastructure in 2011 [23]; as of the beginning of 2020, >99 million people use the internet in Bangladesh [24], and most of them own smartphones [25]. Although the focus of most interventions in Bangladesh has been on the use of SMS text messaging and landlines [21,22], a handful of studies have examined using apps on smartphones for health [22]. In Bangladesh, apps have been used to link village physicians to formal physicians [26] and for diabetes management [27], nutrition services [28], and maternal and child health [29]. A systematic review examined all health-related apps in Bangladesh (N=234), and a total of nine categories of apps were mentioned in the report: general health information apps, physician information apps, institutional apps, fitness apps, mother and child apps, disease-specific care apps, herbal apps, and food and nutrition apps [20]. As such, we see a large number of mobile phone apps being used for health promotion in Bangladesh; yet, none are focused on MH promotion.

Although apps show promise in Bangladesh for other health outcomes, there is a lack of literature examining the use of mHealth for MH in this population or rates of mHealth use in general. This is particularly important given the high rates of MH problems in the population and the current lack of infrastructure in Bangladesh to deal with these problems [30]. According to the World Health Organization, there is <1 (0.001%) psychiatrist available for every 100,000 people in Bangladesh [31,32]. Although there is no national surveillance system that indicates a nationally representative prevalence rate of MH disorders in Bangladesh, a systematic review estimated the prevalence of MH disorders to be between 6.5% and 31% among adults [33]. Another systematic review examining rates of suicide estimated the rate to be 39.6 per 100,000, which is triple the global rate (10.7 per 100,000) [30].

The onset of depression typically occurs from adolescence to early adulthood [34,35]. In particular, early adulthood is deemed the "most vulnerable time" for the onset of depressive symptoms in Bangladesh [30]. This time frame, along with the multiple stressors (academic pressure and new social and physical environments) that college students face, makes the university student population particularly prone to depressive symptoms [36]. Recent studies examined MH outcomes in Bangladesh university students and found high rates of depression, ranging from 47.5% [37] to 69.5% [25]. Evidence supports that, the earlier one can manage stress and depressive symptoms, the better the overall health outcomes they will have [38]. MH apps are particularly well-suited for young adults seeking help for their symptoms because this population reports a high need for autonomy [39,40]. Young adults prefer using self-help materials if they are familiar with the medium that delivers them, such as smartphones [41].

Although the rates of MH problems may be high, there is low MH literacy [33] and high stigma surrounding the topic [28]. Hossain et al [33] found that there was low awareness of MH disorders and that attitudes toward seeking help for MH were negative. They found that even those who had an MH disorder did not prioritize MH care. This is not uncommon in low-income countries in Asia [31,42], where it is believed that MH problems

are caused by religious or cultural abnormalities [43], which in turn is associated with low use of clinical services. As mHealth has been used successfully in Bangladesh for chronic disease management [20], it is possible that it can also be used to improve MH. At a minimum, the acceptability of using digital health for MH should be determined. Developing MH messaging for in-app delivery for college students in Bangladesh has the potential to reduce, manage, and prevent depression symptomatology.

The Technology Acceptance Model (TAM) is an information technology framework for understanding users' adoption and use of emerging technologies [44]. The model proposes that a user's perception of the usefulness (ie, perceived benefits) and ease of use lead to their intent to use the technology and that intention is directly related to actual use. The TAM also posits that perceptions of usefulness and ease of use are influenced by external factors such as social influences [44]. This study uses this framework to assess where a Bangladeshi population falls on the scale of accepting digital health for MH and describing their current digital health use.

Objectives

This paper aims to (1) describe the likelihood that students will use different forms of digital health platforms for MH promotion; (2) assess the relationship between the perceived ease of use, usefulness, and social influence on the use of digital health and the intention to use and actual use of digital health; and (3) assess the relationship between the perceived ease of use, usefulness, and social influence on the use of digital health for MH and the intention to use and actual use of digital health for MH.

Methods

Study Sample

Adult university students across Bangladesh were invited to take an anonymous web-based survey. Students were emailed a flyer invitation by faculty to participate in the study and offered a 1-in-4 chance to win 422 Bangladeshi taka (US $5) for participating in the survey. In addition to faculty recruitment, flyers were posted on university social media pages. The total sample size was 311 complete responses.

Survey Creation

A total of 5 cognitive interviews were conducted with Bangladeshi university students to develop the survey. As part of the creation of the survey instruments, first, native Bangla speakers reviewed and translated the English survey items (most items were part of previously validated scales, which is explained further in the *Measures* section of this paper) into Bangla. Items with complex translations or items with cultural meanings that differed in Bangla were noted and compiled into a guide for the cognitive interviews. The cognitive interviews asked the participants to explain how they defined MH and their interpretation of the survey items. Items that were culturally inappropriate or that students did not understand were adapted to make it easier for them to understand. For example, the phrase *feeling down* to denote feeling sad or depressed in the question *How often in the past two weeks did you feel down, depressed,*

or hopeless? is not used in Bangladesh and was removed from the question. On the basis of the cognitive interviews, the questionnaire was adapted and pilot-tested with 10 participants. The pilot test participants reported no difficulties with the items, and the survey was completed.

Measures

Dependent Variables

Overview

Intention to use general digital health (Cronbach α=.88) was assessed by creating a mean score of three items: (1) *I intend to use a digital health service in the future*, (2) *I will always try to use digital health services in my daily life*, and (3) *I plan to continue to use digital health services frequently* [45]. Intention to use digital health for MH (Cronbach α=.89) was assessed similarly using the mean of three items: (1) *I intend to use digital mental health services in the future*, (2) *I will always try to use digital mental healthcare in my daily life*, and (3) *I plan to continue to use digital mental health services frequently*. Items were scored from 1 (do not agree) to 7 (totally agree) and then dichotomized into no or low (1-4.44) and moderate or high (4.45-7) intention. The cutoff was 4.45 because 4 was considered *neither agree nor disagree* and 5 was considered *slightly agree* on the scale.

Current Use

The use of digital health for general health was assessed by asking if the following statement—*I use digital health services to better my health (excluding use for mental health) currently*—was true or false. An example was given in the question stem *For example, using an app to track steps, for weight loss, to increase physical activity*. Similarly, digital health for MH was a binary variable as to whether participants used digital health: *I use digital health for mental health currently (for example, following meditation videos)*. These questions have been used in previous studies assessing use of digital health for MH in populations in low-income countries [46].

Independent Variables

Barriers to Using Clinical MH Services

Barriers to seeking MH services were measured using the Barriers to Access to Care Evaluation scale [47]. The scale consists of both stigma-related and nonstigma-related items. The participants responded using a Likert-scale of 1=not at all (indicating this was not a barrier to care) to 4=a lot (indicating a great barrier to care) to the following question: *Have any of these issues ever stopped, delayed or discouraged you from getting, or continuing with, professional care for a mental health problem?* The respondents rated how much of a barrier the provided scenarios were to receiving MH care, example barriers being *Thinking that professional care probably would not help* or *Concern about what people at work might think, say, or do*. Responses to the items were averaged to create the final score (1-4). The nonstigma (attitudinal and instrumental) barriers subscale of the Barriers to Access to Care Evaluation scale included 22 items and had adequate reliability, with a Cronbach

α of .76. The stigma subscale consisted of 12 items and had a Cronbach α of .89.

Variables in relation to general digital health and digital health specifically for MH promotion were included.

Likelihood of Using Digital Health

This variable was assessed by asking how likely the participants were to (1) text a helpline or crisis center, (2) text a professional (ie, therapist or physician), (3) use a smartphone app for self-paced meditation or nonclinical practices, (4) use a smartphone app to look up information and symptoms about MH, (5) use internet-based self-paced programs for meditation or nonclinical practices, and (6) use internet-based programs to video chat with a professional on a scale of 1 (extremely unlikely) to 5 (extremely likely).

Ease of Use of Digital Health

This variable was assessed by averaging the scores of 6 items measured on a 7-point scale (1=do not agree, 7=strongly agree). Example items included *Learning how to use digital health services is easy for me*, *My interaction with digital health service is clear and understandable*, and *I find digital health services easy to use* [45]. The Cronbach α for these items was .89.

Social Influence on Digital Health Use

This variable was assessed using the mean of the following three items on a 7-point scale (1=do not agree, 7=strongly agree): (1) *People who are important to me think that I should use a digital health service*, (2) *People who influence my behavior think that I should use a digital health service*, and (3) *People whose opinions that I value prefer that I use digital health service* [45]. The Cronbach α for these items was .94. Social influence regarding the use of digital health for MH was assessed using the mean of 3 items measured on a scale of 1 (do not agree) to 7 (strongly agree); for example, *People who are important to me think that I should use digital mental health services*. The Cronbach α for these items was .95.

Perceived Usefulness of General Digital Health

This variable was assessed by taking the mean of two items: *I find digital health services useful in my daily life* and *Using digital health services helps me accomplish things more quickly* [45]. Both were measured on a scale of 1 (do not agree) to 7 (totally agree). Perceived usefulness of digital health for MH was assessed by taking the mean of 3 items and dichotomizing the measure into a scale of 0 (low perceived usefulness; *do not agree* to *neither agree nor disagree*) to 1 (high perceived usefulness; *slightly agree* to *totally agree*). The construct was dichotomized as a method of addressing collinearity between this construct and the ease of use construct. The following is an example item: *I find that digital mental health services are or could be useful in my daily life*. The Cronbach α for these items was .88.

Covariates

Wellness

This variable was measured using the 5-item HERO Wellness Scale by Yaklin et al [48]. The scale assesses happiness, enthusiasm, resilience, and optimism, and had high-reliability

scores in the study sample (Cronbach α=.87). An example item—*On average, during the last seven days, how optimistic have you felt?*—was scored on a scale of 0 (not at all) to 10 (extremely). Final scores were created by summing the answers to all items and ranged from 0 to 50, with higher scores indicating higher wellness.

Perceived Stress

This variable was measured using the 4-item Perceived Stress Scale [49] and had an acceptable reliability score in the study sample (Cronbach α=.70). Questions such as *In the last month, how often have you felt that you were unable to control the important things in your life?* were answered on a scale of 0 (never) to 4 (very often) and were summed, with final scores ranging from 0 to 16 and higher scores indicating higher stress.

Depression

This variable was assessed using the 2-item ($r=0.53$; $P<.001$) Patient Health Questionnaire [50]. Questions such as *In the past two weeks, how often have you felt depressed or hopeless?* were answered on a scale of 0 (never) to 3 (almost every day). Scores were dichotomized into whether one was likely to have a major depressive disorder based on a cutoff point of 3 from the sum of the scale items.

Lifetime Suicidal Ideation

This was assessed as a binary variable (yes or no) as to whether they had ever had thoughts that they would rather be dead.

Physical Health

This variable was assessed using one item: *How would you rate your overall health?* (1=poor, 5=excellent).

Demographics

Socioeconomic status (SES) while growing up was assessed by asking *How often did your family have enough money to make ends meet?* Respondents answered on a scale of 0 (never) to 5 (always), and the answers were dichotomized into low versus high SES. Gender was measured in three categories: male, female, and gender minority. Age was measured as a continuous variable. Relationship status was assessed categorically; the participants selected if they were single, partnered (in a relationship or married), or other. Semester or year in school was categorized as first to third or first year, fourth to sixth or second year, seventh to ninth or third year, 10th to 12th or fourth year, and 13th or fourth year or higher. The degree of study was dichotomized as pursuing either a bachelor's or master's degree. Geographic location was assessed by asking if the participants lived in a rural or urban setting.

Specific digital health indicators of interest were payment methods, where responses indicated if the participants had monthly plans, pay as you go, or something else. The participants were also asked about their language preference for digital health and if they preferred their native language (Bangla), English, or something else.

Analysis

Analyses were conducted using complete case analysis with a final sample size of 311. Means, SDs, and frequencies were used to describe the data. Group differences between the primary

outcome of interest—use of digital health for MH—and demographic variables were assessed using analysis of variance and chi-square tests. Logistic regression analysis was used to examine the unadjusted relationships between individual predictors and outcomes of interest. If the unadjusted association was found to be associated at $P \le .20$, the variable was included in a final, adjusted logistic regression model. Models were shown to predict the intention to use and actual use of general digital health and digital health for MH. The models predicting actual use included hierarchical regression, with the first step showing unadjusted associations, the second step showing the model without including intention to use, and the final step (step 3) including the intention to use. Model fit statistics were reported.

Ethics Approval

The study was approved by the University of Maryland College Park (UMCP) Institutional Review Board (IRB number: 1656046-3)

Results

Overview

Descriptive statistics were used to describe the sample demographics in Table 1. Differences between those who used the primary outcome of digital MH and those who did not were examined within demographic variables. The sample was predominantly male (184/311, 59.2%), identified as heterosexual (276/311, 93.9%), not in a relationship (239/311, 76.8%), and sought a bachelor's degree (258/311, 83%). Growing up, the participants were mostly from families with a high SES (223/311, 71.7%) and from urban areas (167/311, 53.7%). The only significant differences among the variables of interest between those who used digital health for MH and those who did not were gender and whether they used general digital health. The participants who reported using digital health for MH (82/311, 26.4%) used general digital health at nearly twice the rate (57/82, 70%) of those who did not use digital health for MH (25/82, 30%), a significant difference ($P<.001$). Men were less likely to use digital health for MH than women and gender minorities—of those who did not use digital health for MH, 62.4% (143/229) were men and 37.6% (86/229) were women or gender minorities ($P=.049$).

Students had moderate levels of wellness (mean 26.58, SD 9.94), self-reported health status (mean 2.69, SD 0.87), and perceived stress (mean 8.46, SD 0.87). Approximately 43.4% (135/311) of the sample were likely to have depression, and 28% (78/311) reported lifetime suicidal ideation. Most students used a monthly plan to pay for their phones (223/311, 71.7%), owned their phones (308/311, 99%), and used a smartphone (310/311, 99.7%). In the sample, 43.4% (135/311) reported using digital health for general health, and 26.4% (82/311) used digital health for MH. Although half of the sample (115/311, 49.8%) did not have a preference between their native language (Bangla) and English, 31.5% (98/311) preferred Bangla and 18.6% (58/311) preferred English.

Respondents reported their likelihood of using different forms of digital health for MH promotion (Figure 1). Overall, a large percentage (227/302, 75.3% to 246/297, 82.9%) of the sample reported likelihood of using apps and internet-based programs. Most respondents said they would be likely to text a helpline or crisis center (170/290, 58.8%) or a professional (ie, therapist or physician; 220/292, 75.3%), use an app on a smartphone for self-paced meditation or nonclinical practices (227/302, 75.3%), look up information and symptoms about MH (229/301, 76.2%), use internet-based self-paced programs for meditation or nonclinical practices (242/302, 80.2%), or talk with a professional (250/301, 82.9%).

A correlation matrix of the independent variables used in all models is shown in Table 2. When examining the main constructs of the TAM related to general digital health, we found significant correlations between social influence and ease of use of general digital health ($r=0.316$; $P<.001$) and perceived usefulness ($r=0.241$; $P<.001$). For the variables related to digital health for MH, there were significant correlations among the ease of use of digital health construct, social influence ($r=0.256$; $P<.001$), and perceived usefulness ($r=0.366$; $P<.001$). There were also significant correlations among the control variables of interest—wellness was negatively correlated with stress ($r=-0.560$; $P<.001$) and depression ($r=0.338$; $P<.001$). Geography and SES were correlated ($r=0.190$; $P<.001$) in that those who lived in urban areas had higher SES. Perceived general health was positively correlated with wellness ($r=0.382$; $P<.001$) and negatively correlated with stress ($r=-0.292$; $P<.001$). Perceived stigma as a barrier to MH care and instrumental and attitudinal barriers to care were highly correlated ($r=0.765$; $P<.001$).

Table 1. Participant demographics (N=311).

Demographics	Overall	Did not use digital health for MH[a] (n=229)	Used digital health for MH (n=82)	Chi-square *P* value or ANOVA[b] *P* value
Age (18-41 years), mean (SD)	22.7 (1.86)	22.8 (1.74)	22.6 (2.18)	.59

Regression Analysis Results

The outcomes of intention to use and actual use of digital health in general and digital health for MH were examined using logistic regression analysis. Table 3 shows the results for the outcome of intention to use general digital health. In the unadjusted results, all the main constructs of the TAM (ease of use, social influence, and perceived usefulness of digital health) were positively associated with intention to use digital health, as was perceived wellness. In the adjusted model, these constructs remained statistically significantly associated. Those who perceived digital health to be easy to use (adjusted odds ratio [aOR] 1.85; $P<.001$), had higher approval from their social networks to use digital health (aOR 1.68; $P<.001$), and perceived higher usefulness of digital health (aOR 4.12; $P=.001$) had higher adjusted odds of intending to use digital health. The R^2 for this final adjusted model was 0.445 ($P<.001$).

[d]OR: odds ratio.

[e]aOR: adjusted odds ratio.

[f]Higher scores equal greater amounts.

[g]N/A: not applicable.

[h]SES: socioeconomic status.

When examining the outcome of use of digital health, the only TAM construct significantly associated was social influence, as seen in Table 4. However, when the intention to use digital health construct was added to the model (step 3 of the hierarchical regression), social influence was no longer significantly associated with the use of digital health. In the unadjusted analyses shown in step 1 of Table 4, the controls of better health, wellness, and higher SES were associated with actual use; in the adjusted model, only SES remained associated. In the final step of the model, we saw that those with higher intention to use digital health had higher adjusted odds of actual use (aOR 2.10; *P*=.01). The R^2 for this final adjusted model was 0.108 (*P*<.001).

In Table 5, for the analysis looking at predictors of intention to use digital health for MH, we found that social influence, perceived usefulness, and use of general digital health were positively associated with the intention to use digital health for MH in the unadjusted model. In the adjusted model, these constructs remained significantly associated. Higher social

influence (aOR 1.73; *P*<.001), perceived usefulness (aOR 8.70; *P*<.001), and use of general digital health (aOR 2.16; *P*=.01) were associated with higher adjusted odds of intention to use digital health for MH. The R^2 for this final adjusted model was 0.492 (*P*<.001).

The results in Table 6 show that social influence, intention to use, use of general digital health, instrumental and attitudinal barriers, and gender were positively associated with using digital health for MH. There were no significant changes when comparing step 2 of the model (without intention to use) and step 3. In the final adjusted model, we see that those who used digital health for their general health had higher odds (aOR 4.19; *P*<.001) of using digital health for MH. Those who perceived higher instrumental and attitudinal barriers to receiving clinical MH care had higher adjusted odds of using digital health for MH (aOR 2.05; *P*=.02), and women had almost twice higher adjusted odds of use when compared with men (aOR 1.88; *P*=.03). These model statistics show that the model is statistically significant (*P*<.001), with an R^2 of 0.204.

Discussion

Principal Findings

This study explored the acceptability of using digital health to promote MH among university students in Bangladesh. Although the MH of the sample was comparable with other Bangladeshi university student samples [37,51], with 43.4% (135/311) of the sample experiencing symptoms of depression, we cannot compare the percentage of students who use smartphones with other studies as other studies included smartphone use as an eligibility criterion in research pertaining to the digital field [52,53]. In this sample, nearly all the students owned a personal smartphone (308/311, 99.7%). We found a similar percentage of students (135/311, 43.4%) who self-reported use of digital health, defined as answering *I use digital health services to better my health (excluding use for mental health) currently* in the affirmative, to that of Waldman et al [54], who found that 45% of their Bangladeshi student sample reported looking up health-related information on the internet. To our knowledge, no other studies have examined digital health for MH promotion in Bangladesh; however, our findings show that most students would be likely to use digital health for MH. Our findings also support previous research that shows that those who are more cognizant of their health—in this case, those who already use digital health for general health—are more likely to also be attuned to their psychological health [55]. Specifically, we found that people who use digital health in general have 4 times the odds of also using digital health for MH compared with those who do not use digital health at all.

Overall, the findings partially confirm the hypotheses that the constructs of the TAM (perceived ease of use, usefulness, and social influence) are essential precursors of intention to use and actual use of digital health in general and digital health for MH. We found that the TAM constructs were particularly useful in predicting the intention to use digital health both generally and for MH, as can be seen by the model fit statistics, which included control variables (Nagelkerke R^2=0.445-0.492).

Interestingly, the TAM constructs were predictive of the intention to use both general digital health and digital health for MH but not for the actual use of either (in the adjusted models); this may be because university students in Bangladesh are unaware of or do not have the type of digital health that they would prefer to use. This aligns somewhat with the TAM as the model posits that intention mediates the connection between these constructs and actual use [44]. Therefore, theoretically, ease of use, social influence, and perceived usefulness should be stronger predictors of intention. We also found intention to be a strong predictor of actual use in the unadjusted analysis. These findings suggest that it is necessary for people to think that the use of a product (in this case, a digital health platform) is approved by their social network, easy to use, and valuable for them to form an intent to use the product and that intention is an important precursor to action. This research found that Bangladeshi students would like to use digital health for MH. However, future research should examine whether user-friendly digital health products that promote MH exist for this population to use as previous research shows that usability issues are a barrier to using digital health in general [20].

The results suggest that increasing the use of digital health in general would promote the use of digital health for MH as well. According to our results, one way to do this is to increase the acceptability of digital health products among peer groups as social influence is predictive for general and MH-specific digital health use (and intention toward use). Using user-centered design to ensure that the product is easy to use and meets the users' needs is also imperative as ease of use and perceived usefulness of an app are associated with intention to use and actual use of general digital health and the intention to use digital health for MH. From an implementation science perspective, this information is critical when developing health communication strategies around health promotion [56]. University administrations can use these findings to encourage transparency regarding health promotion directly, which may indirectly affect the use of digital health for MH.

The results show that university students are open to the use of digital health for MH in Bangladesh and that digital health may be particularly useful for those who may not otherwise seek clinical care as those with higher instrumental and attitudinal barriers are twice as likely to use digital health for MH. We also found that women had higher odds of using digital health for MH, although previous research in rural Bangladesh found that women were less aware of mHealth services than men even though intentions to use mHealth were high regardless of gender [57]. This difference in findings may be because, in this sample, university students had access to mobile phones across genders, unlike in the rural sample, where women had lower rates of phone ownership than men [57]; as such, our findings may show that, when given access, women translate their intention to use mHealth into actual use of such platforms. Previous research in Bangladesh found that women are also less likely to seek physical health care than men [58], although gender differences in MH service use have not been assessed in this population. In other populations where gender differences in MH service use have been researched, it has been found that women seek traditional MH care more than men [59]. In any case, these study results indicate that an MH promotion program on a digital platform may benefit this subgroup of people who may face attitudinal or instrumental barriers to seeking clinical care. This information can be key in marketing as the app can be framed so that it can be used autonomously. To our knowledge, no current app exists that was developed with empirical evidence for a Bangladeshi student population; as such, next steps would entail developing and pilot-testing such an app.

Limitations

The limitations of this study stem from its cross-sectional design and convenience sample. Owing to the study design, the results were not able to determine causality, nor are they generalizable to the Bangladeshi university student populations at large. As the study's topic was MH promotion, it is possible that respondents were inclined toward this approach, and those who were not interested in MH promotion did not participate. We cannot conclude that a digital MH promotion program would be of interest to all university students in Bangladesh; however, we can say that this type of program shows promise for students who may not be inclined to receive clinical MH care.

Conclusions and Future Directions

This study is the first of its kind to examine the acceptability of digital health for MH in Bangladesh. The results show that students are quite open to using digital health as a tool to improve their MH and highlight the influence that social networks might have on this decision-making. As these findings provide evidence of the acceptability of using digital health for MH, future research should pilot-test messaging for a self-paced MH app, such as a meditation app or a web-based intervention, in Bangla. Universities should promote these mental wellness programs to their students.

Authors' Contributions

MSS developed the research question, study instrument, research design, and data analysis, and wrote the manuscript. SLS consulted on data analysis and the theoretical underpinnings of the research. NT assisted with translation of the survey. KMG consulted on the research design and data analysis and edited the paper.

Abstract

Background: On May 8, 2021, Elon Musk, a well-recognized entrepreneur and business magnate, revealed on a popular television show that he has Asperger syndrome. Research has shown that people's perceptions of a condition are modified when influential individuals in society publicly disclose their diagnoses. It was anticipated that Musk's disclosure would contribute to discussions on the internet about the syndrome, and also to a potential change in the perception of this condition.

Objective: The objective of this study was to compare the types of information contained in popular tweets about Asperger syndrome as well as their engagement and sentiment before and after Musk's disclosure.

Methods: We extracted tweets that were published 1 week before and after Musk's disclosure that had received >30 likes and included the terms "Aspergers" or "Aspie." The content of each post was classified by 2 independent coders as to whether the information provided was valid, contained misinformation, or was neutral. Furthermore, we analyzed the engagement on these posts and the expressed sentiment by using the AFINN sentiment analysis tool.

Results: We extracted a total of 227 popular tweets (34 posted the week before Musk's announcement and 193 posted the week after). We classified 210 (92.5%) of the tweets as neutral, 13 (5.7%) tweets as informative, and 4 (1.8%) as containing misinformation. Both informative and misinformative tweets were posted after Musk's disclosure. Popular tweets posted before Musk's disclosure were significantly more engaging (received more comments, retweets, and likes) than the tweets posted the week after. We did not find a significant difference in the sentiment expressed in the tweets posted before and after the announcement.

Conclusions: The use of social media platforms by health authorities, autism associations, and other stakeholders has the potential to increase the awareness and acceptance of knowledge about autism and Asperger syndrome. When prominent figures disclose their diagnoses, the number of posts about their particular condition tends to increase and thus promote a potential opportunity for greater outreach to the general public about that condition.

Introduction

Background

Asperger syndrome (hereafter referred to as Asperger), which was removed from the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) as a formal diagnosis, is currently merged with autism and pervasive developmental disorders that are otherwise not specified within "autism spectrum disorder" (hereafter referred to as autism). Although the International Classification of Diseases framework in its current 10th edition has not yet formally removed Asperger as a diagnosis; it will do so within the 11th version that is forthcoming [1]. However, those that have been diagnosed with Asperger may choose to use this as their formal diagnosis. The removal of Asperger from the DSM-5 has been controversial as many individuals took, and continue to take, pride in their Asperger identity [2]; however, many people with Asperger were also in favor of subsuming Asperger into the broader category of autism as a spectrum of conditions [3] on the grounds of, for instance, equality of service provision and legal protection. Although still a term used by many, Asperger is becoming more and more known as an integrated part of the broader autism spectrum and thus also a part of the blooming autistic neurodiversity movement [4]. Although less focus has been given to the term Asperger in recent years, public figures who are open about their diagnosis contribute to increased media attention. Examples of highly prominent people with Asperger who have been publicly open about their diagnosis include Elon Musk (who revealed his condition on Saturday Night Live on May 8, 2021) and Greta Thunberg (who refers to her Asperger diagnosis as her "superpower"). The media attention given to such disclosures typically leads to subsequent social media discussions that can inform but also misinform public perception [5]. Asperger and autism have become a part of pop culture [6,7], and research indicates there are advantages and disadvantages to this from a public health perspective but also, more importantly, an impact on individuals with the diagnosis. Asperger and autism are misunderstood and often "hidden." They are hidden because there are no facial or bodily features that readily indicate a person has these conditions or not. Misunderstandings of the diagnoses relate directly to media representations (eg, films such as Rain Man [8] that are so influential that they can be perceived by the public as definitions for a whole diagnosis). For instance, savant syndrome is widely misconceived as very common in the population of individuals with autism and because of this and the intriguing features of the syndrome, it is a common part of media representation [9] of individuals with autism. However, the prevalence of savant syndrome in people with autism is rare [10]. Another widely held misconception of autism and Asperger is that people with autism, in general, are asocial [11]. Media attention is a double-edged sword in that public awareness and acceptance can increase, but it can also oversimplify highly complex heterogeneous conditions such as autism and Asperger. Oversimplifications and misconceptions can lead to stereotype thinking [12] and can maintain stigmas [13], but this could be reduced with the increase in societal awareness and understanding of the conditions [14]. This knowledge could be acquired or promoted through social media, where millions of people are exposed daily to all varieties of information, whether they explicitly seek it or find it unintentionally. Research on different conditions shows that health promotion through social media is mostly linked to positive effects [15-20].

Previous research has shown that the combination of key figures in society and their disclosures of personal diagnoses can affect the public's perception of their conditions [21,22]. As with Musk's disclosure and in the age of social media, the expectation was that the number of web-based discussions about Asperger and autism would increase, which could contribute further to spreading knowledge and awareness and thus potentially alter people's perceptions of the condition.

Objectives

The objective of this study was to compare the types of content used in (informative, misinformative, or neutral), the engagement with, and the sentiment of popular tweets about Asperger before and after Musk's disclosure.

Methods

Study Design and Sample

We designed a cross-sectional study to analyze the type of content, engagement, and perception of popular tweets related to Asperger. We defined popular tweets as those with more than 30 likes as this is slightly higher than the average of 25 likes reported in previous research [23]. We focused on popular tweets because of their potential to reach more users.

Eligibility Criteria for Tweets

We used the Twitter advanced search engine to find popular tweets (>30 likes) that were posted in English and included the terms "Aspergers" or "Aspie." The term "Aspie" was included because it is a common slang term used by the autism community to refer to Asperger [5]. We extracted tweets that were published between May 1, 2021, and May 14, 2021, (1 week before and after Musk disclosed his Asperger diagnosis on May 8, 2021). As commonly used on other social media platforms, the "like" function on Twitter was chosen because of the quickness and ease (one click) with which it allows users to show their agreement with a posted tweet compared to the retweet function, which requires at least 2 clicks and potentially, the addition of accompanying text from the media user [24].

Data Extraction and Classification

From the selected popular tweets, we extracted the post message and the number of comments, retweets, and likes. We extracted only the original tweets and no personal or identifiable data were collected.

We created a coding guideline, which was used to classify the tweets (the coding guideline is available in the data repository) [25]. Each post was classified by 2 independent coders who are experts in autism (IS and ANH) as to whether the post contained correct information (eg, "people with Asperger have difficulties in social interaction"), misinformation (eg, "people with Asperger have an IQ below average"), or neutral information (eg, "my son has Asperger"). Classification disagreements were

discussed with the rest of the coauthors until a consensus was reached. We analyzed the number of posts and engagement from other media users with those posts. The engagement was assessed using the number of comments, retweets, and likes.

Sentiment Analysis

We analyzed the perceptions or sentiments of each post using the AFINN sentiment analysis tool [26]. AFINN is a lexicon that assigns scores to each word ranging from –5 (very negative) to 5 (very positive) [25]. The text-mining tool considers scores higher than 0 as positive words, and scores lower than 0 as negative words [26]. The AFINN tool has been used to analyze the sentiment included in tweets about Asperger [5], and to compare the sentiment towards different COVID-19 vaccines expressed in social media posts [27]. The AFINN tool has also been used to analyze free short text, such as answers given in surveys [28,29], web-based reviews [30], self-reported notes [31], or descriptions of public health campaigns [32].

Data Analysis

All statistical analyses were performed using SPSS (version 25.0; IBM Corp). Both the data set and data analysis, including scripts, were made available in the data repository [25]. The treatment of data for this study was approved by the data

protection officer at the University Hospital of North Norway (Nr.02489).

Results

We extracted a total of 227 popular tweets. A total of 34 (14.9%) tweets were posted the week before the Musk announcement and 193 (85%) were posted the following week.

Engagement and Sentiment of Tweets Before and After Musk's Announcement

When we compared the engagement and sentiment of tweets before and after Musk's announcement, we found that tweets posted before the disclosure received significantly more engagement; they received more comments (254.15, 95% CI 87.1 to 331.5 compared to 44.88, 95% CI –74.6 to 493.2; $P<.001$), more retweets (494.47, 95% CI 28.3 to 635.6 compared to 190.80, 95% CI –321.6 to 928.9; $P=.001$), and more likes (7058.00, 95% CI 1734.9 to 10,443.6 compared to 969.44, 95% CI –4483.2 to 16,661.8; $P<.001$) than after the announcement (See Table 1). We did not find any statistically significant differences regarding the sentiment of tweets posted before and after Musk's disclosure. Finally, the Kruskal-Wallis test did not show significant differences regarding engagement or sentiment according to the type of content provided by the tweet.

Table 1. Engagement with and sentiment of popular tweets about Asperger according to the time points when they were posted and the type of information provided.

Category of engagement	Time point when the tweet was posted		t test[a]	P value	Type of information provided			P value[b]
	Before Musk's disclosure (n=34), mean (95% CI)	After Musk's disclosure (n=193), mean (95% CI)			Provides information (n=13)[c], mean (95% CI)	Neutral tweets (n=210)[d], mean (95% CI)	Contains misinformation (n=4), mean (95% CI)	
Comments	254.15 (87.08 to 331.46)	44.88 (–74.63 to 493.16)	3.375	<.001	68.77 (–43.36 to 180.93)	77.96 (30.12 to 125.79)	9.50 (–0.77 to 19.77)	.81

[a]df=225.

[b]P value obtained from the Kruskal-Wallis test.

[c]Example of a tweet that provides information: "Not all autistic people (including people with Asperger's diagnoses) are white, male techie types. Some of us are poets. Some of us are even women."

[d]Example of a neutral tweet: "Elon Musk reveals he has Asperger's syndrome during SNL monologue."

Informative, Neutral, and Misinformative Tweets Following Musk's Announcement

The interrater agreement for the classification of the tweets and respective tweet data provided was κ=0.469 (moderate agreement). We classified 210 (92.5%) of the 227 tweets as being neutral, 13 (5.7%) tweets as informative, and 4 (1.8%) as containing misinformation. Both informative and misinformative tweets were posted after Musk's disclosure. Tweets identified as misinformative included the following examples: tweets suggesting that Musk's Asperger was deeply problematic, a

tweet suggesting that autism and Asperger are the results of asymmetrical brain stem injuries, and a joke related to Musk's development of the SpaceX Starship and the need of people with autism to travel into space.

Discussion

Summary of Findings

We found that after Musk's disclosure, the number of popular tweets about Asperger increased by almost 6-fold. This increase

XSL•FO
RenderX

in tweeting has the potential to promote awareness of the Asperger condition to more social media users. However, these "after" tweets seemed to receive less engagement than the ones posted before the disclosure.

Impact of a Celebrity Disclosure

As this was an observational study, the association between Musk´s disclosure and the increase in the number of tweets about Asperger receiving less engagement warrants further research to assess other possible factors affecting these results. It is nevertheless noteworthy that after Musk's disclosure, discussions about Asperger on Twitter increased. On May 9, 2021, Asperger became the 19th top trending topic on Twitter [33]. The interest in Asperger syndrome was also reflected in Google searches, when on May 11, 2021, Asperger ranked as the top 28th trending search [34]. This is remarkable since neither of the terms "Aspergers" or "Autism" ranked in the top 50 trending search topics during World Autism Awareness Day (April 2, 2021).

With the increase of popular posts about Asperger, both informative and misinformative tweets also appeared. Although nonsignificant, the few popular tweets that did contain misinformation tended to receive less engagement than posts that provided neutral or informative content. The lower engagement with tweets containing misinformation could suggest a kind of collective intelligence among Twitter users [35] that could contribute to increasing social knowledge by reducing the spread of misinformation as seen with the autism tweets.

Considering the impact that celebrity culture has on directing the public's attention to matters of health, it is worthwhile to investigate the types of information displayed on social media [36]. Within the field of autism research, very few studies assessing the informative and misinformative content posted on social media platforms have been conducted. This is slightly surprising since one of the more infamous studies, that resulted in a vast amount of misinformation on early childhood vaccination, was published (and later retracted) within this field. Misinformation about vaccines causing autism remains a problem today and is even propagated by some celebrities. Investigating the influence that celebrities, such as Musk, have on the public is underscored in our findings with the increase in attention that Asperger and autism received after Musk's disclosure.

Promoting the Awareness of Asperger and Autism Through Social Media

Promoting the awareness and acceptance of Asperger and autism by posting informative and factual content on social media platforms such as Twitter could assist in increasing social media users' knowledge about and understanding of the condition. Research on the use of social media for health promotion has shown its positive effects related to different conditions [15-20]. However, in our sample, we found that the tweets on Asperger that stimulated higher engagement tended to be neutral. These neutral posts did not misinform, but they did not provide any type of information that could increase one's knowledge or awareness about autism, either. Social media is ubiquitous and has become for most people a standard part of their everyday routine and habits. The ubiquitous use of social media platforms could provide an opportunity to expand the reach of trustworthy information about Asperger and autism in order to increase users' knowledge about and awareness of the conditions and reduce the associated stigmas [5,14,21].

Limitations

Our study had several limitations. We focused on a short period of time. We collected popular tweets about Asperger that were posted only in English. Furthermore, we only analyzed tweets posted the week after Musk's announcement, which may not be enough to form a conclusion on the effect of the disclosure. Also, Twitter users may not be representative of a random sample of the population, as the platform's users tend to range in age from 25 to 34 years [37]. Our findings may not apply to other social media platforms, to posts on autism that did not include our search terms, to posts in other languages, or to posts with less than 30 likes. We did not extract any identifiable information regarding the users that posted the popular tweets. Therefore, we cannot know if these tweets were posted by individuals or institutions. If posted by an institution, this could introduce a bias in terms of potential engagement impact (as institutions or organizations usually have more followers than individual accounts). Finally, due to the presence and sophistication of bot accounts, we cannot know if our sample size included tweets coming from any bot accounts [38].

Conclusions

The use of social media platforms by health authorities, autism associations, and other stakeholders has the potential to increase awareness of and knowledge about both Asperger and autism. When prominent figures disclose their conditions, such as autism, posts about their condition tend to increase, which provides an opportunity for trustworthy information about the condition to reach more social media users. Future research on autism and celebrity engagement with media should deploy in-depth data collection and longitudinal designs to detect possible changes in sentiment, as well as different methodological approaches (eg, qualitative, quantitative, and mixed designs) to elucidate underlying mechanisms at play related to the spread of both information and misinformation.

Abstract

Background: Musculoskeletal conditions such as joint pain are a growing problem, affecting 18.8 million people in the United Kingdom. Digital health interventions (DHIs) are a potentially effective way of delivering information and supporting self-management. It is vital that the development of such interventions is transparent and can illustrate how individual components work, how they link back to the theoretical constructs they are attempting to change, and how this might influence outcomes. getUBetter is a DHI developed to address the lack of personalized, supported self-management tools available to patients with musculoskeletal conditions by providing knowledge, skills, and confidence to navigate through a self-management journey.

Objective: The aim of this study was to map a logic model of behavior change for getUBetter to illustrate how the content and functionality of the DHI are aligned with recognized behavioral theory, effective behavior change techniques, and clinical guidelines.

Methods: A range of behavior change models and frameworks were used, including the behavior change wheel and persuasive systems design framework, to map the logic model of behavior change underpinning getUBetter. The three main stages included understanding the behavior the intervention is attempting to change, identifying which elements of the intervention might bring about the desired change in behavior, and describing intervention content and how this can be optimally implemented.

Results: The content was mapped to 25 behavior change techniques, including information about health consequences, instruction on how to perform a behavior, reducing negative emotions, and verbal persuasion about capability. Mapping to the persuasive system design framework illustrated the use of a number of persuasive design principles, including tailoring, personalization, simulation, and reminders.

Conclusions: This process enabled the proposed mechanisms of action and theoretical foundations of getUBetter to be comprehensively described, highlighting the key techniques used to support patients to self-manage their condition. These findings provide guidance for the ongoing evaluation of the effectiveness (including quality of engagement) of the intervention and highlight areas that might be strengthened in future iterations.

Introduction

Background

Musculoskeletal conditions such as joint pain are a growing problem, affecting 18.8 million people in the United Kingdom, which equates to 22% of the total burden of ill health across the population [1]. The importance of supporting people with musculoskeletal conditions in self-managing their own condition is increasingly acknowledged as a valuable tool for improving symptoms and facilitating healthy behaviors [2].

Self-management includes all the actions taken by people to recognize, treat, and manage their own health care independently of, or in partnership with, the health care system [3]. Supported self-management requires a whole systems approach that should be fully integrated into clinical care pathways, providing information and encouragement to help people gain more control over symptoms by understanding their condition through monitoring and taking appropriate action [4].

Adopting digital methods to support the self-management of a number of health conditions has become increasingly popular, gaining further traction during the COVID-19 pandemic with a rise in the number of digital health consultations [5]. Recent literature has highlighted the benefit of using digital technology in general practice, suggesting that the National Health Service (NHS) continues to invest in digital-first primary care [6].

Despite the rise in popularity, it is recognized that most digital health interventions (DHIs) are not well-described [7]. It is vital that the development of DHIs is transparent and can illustrate how individual components work, how they link back to the theoretical constructs they are attempting to change, and how this might influence outcomes [8]. During DHI development, it is important to clearly document techniques used by mapping content against recognized behavior change taxonomies [7]. This approach can allow for better implementation into practice, producing more effective and longer term engagement with healthy behaviors [9]. The National Institute for Health and Care Excellence (NICE) Evidence Standards Framework for digital health technology (DHT) also highlights the importance of using recognized effective behavior change techniques (BCTs), recommending that evidence is available to illustrate how BCTs within an intervention are consistent with recognized behavior change theory and recommended practice (aligned with guidance from NICE or relevant professional organizations) and appropriate for the target population [10].

As part of the Small Business Research Initiative Health Care and an NHS England program to bring new technologies to the NHS, getUBetter was contracted to develop, deploy, evaluate, and optimize its DHT to scale into the NHS. The contract was titled *Integrated Self-management and Prevention for Multiple Musculoskeletal Conditions and Pathways*. getUBetter worked with teams from the Wandsworth NHS Clinical Commissioning Group, St Georges University Hospitals NHS Foundation Trust, the Digital Evaluation Unit at the Health Innovation Network in South London, and the University of the West of England in Bristol to evaluate the DHI in a real-world setting. Part of this evaluation focused on evidencing the underpinning logic model of behavior change in the DHI; this element of the project is reported in this paper.

getUBetter [11] was developed to address the recognized problem within the health system of a lack of personalized, supported self-management tools available to patients with musculoskeletal conditions that provide the knowledge required to trust in, and successfully navigate through, a self-management journey.

The aim of the getUBetter self-management app is to empower individuals to self-manage from the start of an acute phase of an injury or episode to recovery and long-term condition management. It intends to do this by providing knowledge, developing skills, identifying and developing support strategies, and using persuasive language to develop positive beliefs about one's self-management capability. Patients are prescribed getUBetter by a clinician (or practice staff) face to face, virtually, or via an SMS text message as part of routine care. Patients can also self-refer from a health care provider's website. Musculoskeletal conditions include back, back and leg, neck, shoulder, knee, ankle, and lower limb soft injury, and patients can be linked to ≥1 local injury or condition pathway simultaneously, such as lower back pain and new ankle injury.

getUBetter was designed for both new and recurrent conditions and is specifically tailored to local care pathways, supporting triage, day-to-day recovery, referral when needed, connection to local rehabilitation programs, and prevention and well-being when a patient is back to their normal.

The getUBetter platform *houses* standardized national care pathways for the range of conditions based on evidence and national clinical treatment guidelines. Before the getUBetter platform and app are integrated into a health care system (eg, into general practitioner practices), urgent care centers, or physiotherapy departments, getUBetter works with the local clinical teams to configure each element of the local care pathway. There are three pillars of configurability: the day-by-day condition (lived experience of the patient), the end-to-end clinical condition pathways, and the local health system (health care and social care and public health). Patients are then connected to their specifically tailored local care pathways via either prescriptions or self-referrals.

getUBetter adopts a whole pathway approach that includes a symptoms checker, use of stratification tools, and automated referrals. Targeted and personalized content aims to help patients understand their stage of recovery, providing knowledge to strengthen confidence; reduce negative behaviors; and include a recovery plan around medication, effective treatment options, and the ability to self-monitor recovery. Evidence-based advice is provided on a range of topics such as what to expect at different stages of recovery; information about pain relief; guidance on referral options; information about driving, work, and other everyday activities; a symptom checker; information about red flags; and a variety of exercises demonstrated by physiotherapists are available to guide patients through their recovery journey (for more examples, see Multimedia Appendix 1 [12]).

The co-design process included patient and public involvement groups from the local clinical commissioning group, general practitioners, physiotherapists of all grades, consultant or advanced practice physiotherapists for most conditions, carers, charities such as Age UK, and patients. Patients from the patient and public involvement group were a broad group with differing technical capabilities, and the focus groups comprised patients of all ages. Importantly, ongoing user experience was captured on a regular basis during development.

getUBetter is suitable for all patients aged ≥18 years. The platform and app have been co-designed with all stakeholder groups to minimize digital exclusion; for example, easy-to-use buttons, text size to 200%, and an easy-to-access web version. getUBetter works closely with organizations, patients, and all stakeholders to minimize digital exclusion and support *care as usual* and actively seeks to support patients who may be having difficulties accessing the solution.

Aim of Study

The aim of this study was to develop a logic model of behavior change for getUBetter, illustrating how the content and functionality of the app are aligned with recognized behavioral theory, effective techniques, and recommended clinical practice. This paper describes the development of a behavior change model for getUBetter using widely used models and frameworks described in more detail in the following sections.

Methods

Overview

The behavior change wheel (BCW) [13], Capability Opportunity Motivation-Behavior (COM-B) model [14], and BCT Taxonomy (BCTT) Version 1 (BCTTv1) [7] were used to map the BCTs present and the behavior change model for getUBetter. The persuasive systems design (PSD) framework [15] was used to describe the functionality and delivery of content.

To replicate and implement behavior change interventions in practice, we need an agreed-upon language to report their content or *active ingredients*. There are a range of tools that can be used to do this, and one that is widely used is the BCW, which provides a systematic way of characterizing interventions. It is often used in conjunction with the COM-B framework [14], a theoretical framework that incorporates key components (capability, opportunity, and motivation) considered to affect behavior. The COM-B model is a starting point for understanding behavior in the context in which it occurs. The central tenet of the model is that for any behavior to occur (1) there must be the *capability* to do it (ie, physical strength, knowledge, skills, and stamina), (2) there must be the *opportunity* for the behaviors (ie, physically accessible, affordable, socially acceptable, and sufficient time), and (3) there must be sufficiently strong *motivation* [12]. BCTTv1 was developed to specify content in terms of BCTs, the smallest components of behavior change interventions that can bring about change [7]. BCTTv1 is a hierarchically structured

taxonomy of 93 distinct BCTs, including labels, definitions, and examples.

Although the BCTT enables the illustration of BCTs adopted within an intervention, the additional inclusion of the PSD framework was important to demonstrate how BCTs were translated into practice and ensure that important aspects of functionality were adequately described. The PSD framework was developed to guide the process of designing and evaluating persuasive systems, which highlights 28 design principles for persuasive system content and functionality, categorized into four areas: primary task, dialog, system credibility, and social support categories [15].

The following sections describe the 3 stages that were conducted to illustrate the behavior change model for getUBetter. It is important to highlight that this process was nonlinear, and *mapping* procedures moved between stages iteratively to link BCTs with theory, intended outcomes, functions, and categories of the BCW, as well as persuasive system design elements.

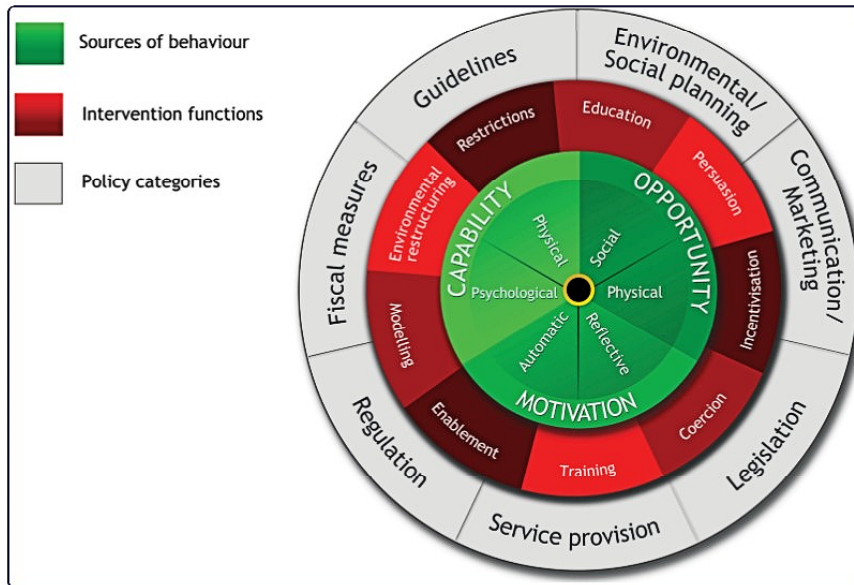
Stage 1: Understanding the Target Behavior

Several team meetings comprised clinicians, developers, user experience and user interface designers, project managers, and product owners from getUBetter alongside other clinicians from the stakeholder groups and researchers with experience in developing self-management and behavior change interventions from the University of the West of England. The clinicians included an advanced physiotherapy practitioner in primary care and emergency care and a consultant musculoskeletal physiotherapist. The meetings were held to understand the health problems that getUBetter aims to address and the behavior(s) that it attempts to change and describe what needs to change to achieve the intended outcome(s). This process enabled the aims and objectives of getUBetter to be comprehensively described and illustrated in a logic model of the problem.

Next, the COM-B model and the Theory and Technique tool [16] were used to link the BCTs present in getUBetter to relevant theoretical domains. The Theory and Technique tool links the theoretical domains framework [17] to the COM-B model to provide a more granular understanding of how constructs are associated with capability, opportunity, and motivation (eg, the theoretical domain *beliefs about capabilities* is linked to *reflective motivation* within the COM-B model). This step highlighted to the team the potential areas where getUBetter might be strengthened by adding in BCTs commonly reported in similar published literature but which were not currently present in getUBetter.

Stage 2: Mapping Intervention Options

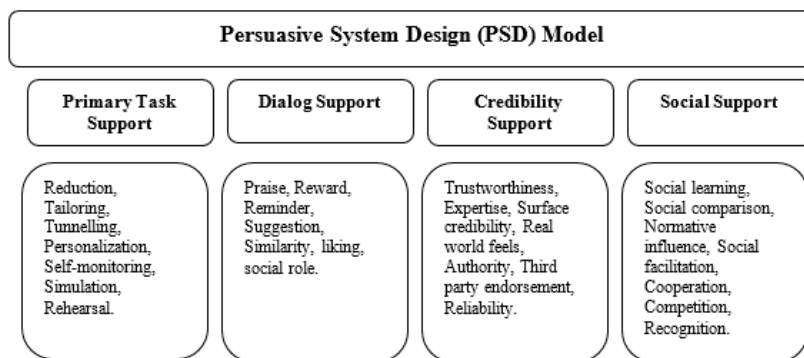
This stage involved linking information gathered previously in stage 1 (the *behavioral diagnosis*) to the intervention functions (Figure 1) and policy categories (Figure 1) through which getUBetter is currently being implemented. Team meetings were held to agree on the links between the BCTs present in getUBetter and relevant implementation functions and policy categories. Once again, this was an opportunity to explore the areas that could be strengthened in future iterations.

Figure 1. Behavior change wheel [13].


Stage 3: Mapping Content and Implementation Options

This final stage involved using the BCTT [7] to identify and map BCTs present within getUBetter and the PSD model to illustrate how the BCTs were being delivered (Figure 2).

Figure 2. Persuasive systems design model.

The results from the abovementioned stages described were then consolidated into a logic model of behavior change for getUBetter.


Results

Overview

An initial mapping exercise was completed during November 2019 and April 2020 by the lead author (AB), who discussed and agreed on the mapping with team members. The mapping process was nonlinear and iterative, moving between the stages described earlier and guided by team discussions. This initial mapping exercise enabled the team to identify particular areas of the app that could be strengthened by adding specific BCTs commonly used in other interventions [12] but which were not currently present in getUBetter. Following ongoing iterative design and development of getUBetter throughout 2020, a second mapping exercise took place between January 2021 and March 2021 to highlight additional techniques and functionalities.

The following sections describe each stage of *mapping round 1* in more detail and the additional techniques and changes in functionality highlighted during *mappinground 2*.

Stage 1: Understanding the Target Behavior

Overview

The aim of getUBetter is to empower individuals to self-manage their musculoskeletal condition by providing support and advice throughout their recovery journey and prevent future episodes. Objectives were clustered into three subgroups: knowledge and skills, supportive environment, and motivation and self-efficacy. The aims and objectives are described in more detail in the following sections.

Behavioral Aims and Objectives of getUBetter (version 2.0)

Knowledge and Skills

These objectives aim to provide the patient with sufficient knowledge about their musculoskeletal condition, enabling them to develop sufficient skills to conduct positive self-management behaviors.

The objectives were as follows:

1. Educate about normal physiological responses (ie, symptoms and time frames)
2. Train the patient in personally relevant skills (such as reducing sedentary behavior, introducing graded tasks, and relevant exercises) to enable them to manage symptoms and implement positive self-management behaviors

Supportive Environment

These objectives aim to train the patient to identify and develop supportive aspects of physical and social environments.

The objectives were as follows:

1. Guide understanding of the interpersonal influences on self-managing their musculoskeletal condition and how the environment can be restructured to provide optimal support
2. Promote reflection on environmental and emotional aspects affecting self-management (time, resource use, and place and well-being)
3. Highlight opportunities for restructuring the physical and social environments to best support self-management behaviors
4. Enable patient to navigate the health system and understand treatment pathways and referral options

Motivation and Self-efficacy

These objectives aim to enable the patient to form positive beliefs and feelings toward self-managing their musculoskeletal condition and support the formation of a personally relevant action plan for self-management behaviors

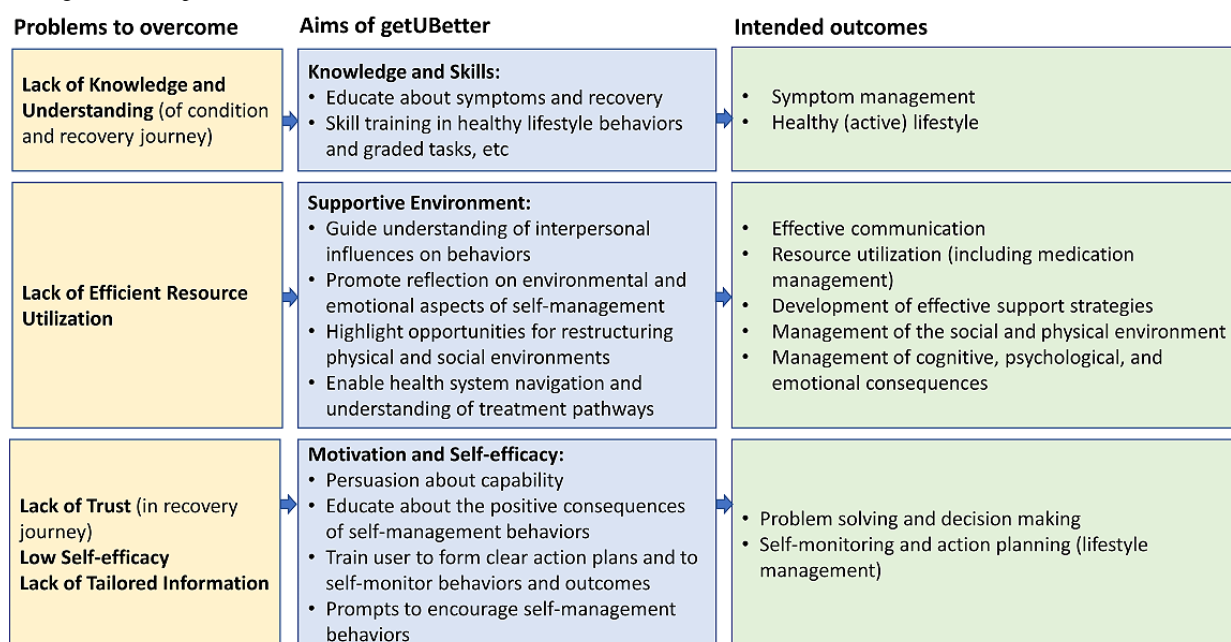
The objectives were as follows:

1. Persuade the patient about their capability and enable them to perform self-management behaviors such as action planning or healthy lifestyles
2. Educate (to strengthen beliefs) about the positive consequences (outcomes) of the directed self-management behaviors
3. Train the patient to form clear action plans for conducting self-management behaviors and self-monitor behaviors and outcomes
4. Provide prompts and cues to encourage self-management behaviors.

Specific self-management behaviors were also identified (intended outcomes; Figure 3). Figure 3 shows the logic model of the problem(s) that getUBetter aims to address, how it aims to engage patients with positive self-management behaviors, and the intended outcomes.

The next step was to identify how BCTs present in getUBetter were linked back to the theoretical constructs they were attempting to change (using the BCW guidance and the Technique and Theory Tool see *Methods* section). Textbox 1 illustrates these links.

This stage highlighted a number of BCTs that could be beneficial to include in future iterations of getUBetter. More specifically, BCW guidance highlighted that BCTs related to social comparison (5.2) and goal setting and monitoring (ie, 1.1, 1.5, and 2.3) were reported to have been used in previous behavior change interventions [12].

Figure 3. Logic model of problem.


Textbox 1. Capability, Opportunity, and Motivation–Behavior analysis (coded to Behavior Change Technique Taxonomy version 1).

Capability

- Knowledge and skills

  - 4.1 Instruction on how to perform a behavior

  - 5.1 Information about health consequences

  - 8.1 Behavioral practice and rehearsal

  - 8.7 Graded tasks

- Memory, attention, and decision processes

  - 7.1 Prompts and cues

- Behavioral regulation

  - 1.2 Problem solving

  - 8.2 Behavior substitution

  - 11.2 Reduce negative emotions

Opportunity

- Environmental context and resources

  - 7.1 Prompts and cues

  - 12.1 Restructuring the physical environment

  - 12.2 Restructuring the social environment

- Social influences and identity

  - 3.1 Social support (unspecified)

  - 6.2 Social comparison

  - 9.1 Credible source

Motivation

- Beliefs about capabilities

  - 1.2 Problem solving

  - 4.1 Instruction on how to perform a behavior

  - 6.1 Demonstration of the behavior

  - 8.1 Behavioral practice and rehearsal

  - 8.7 Graded tasks

  - 15.1 Verbal persuasion about capability

- Beliefs about consequences

  - 5.1 Information about health consequences

  - 5.6 Information about emotional consequences

- Intentions

  - 5.1 Information about health consequences

- Reinforcement

  - 7.1 Prompts and cues

- Emotion

  - 11.2 Reduce negative emotions

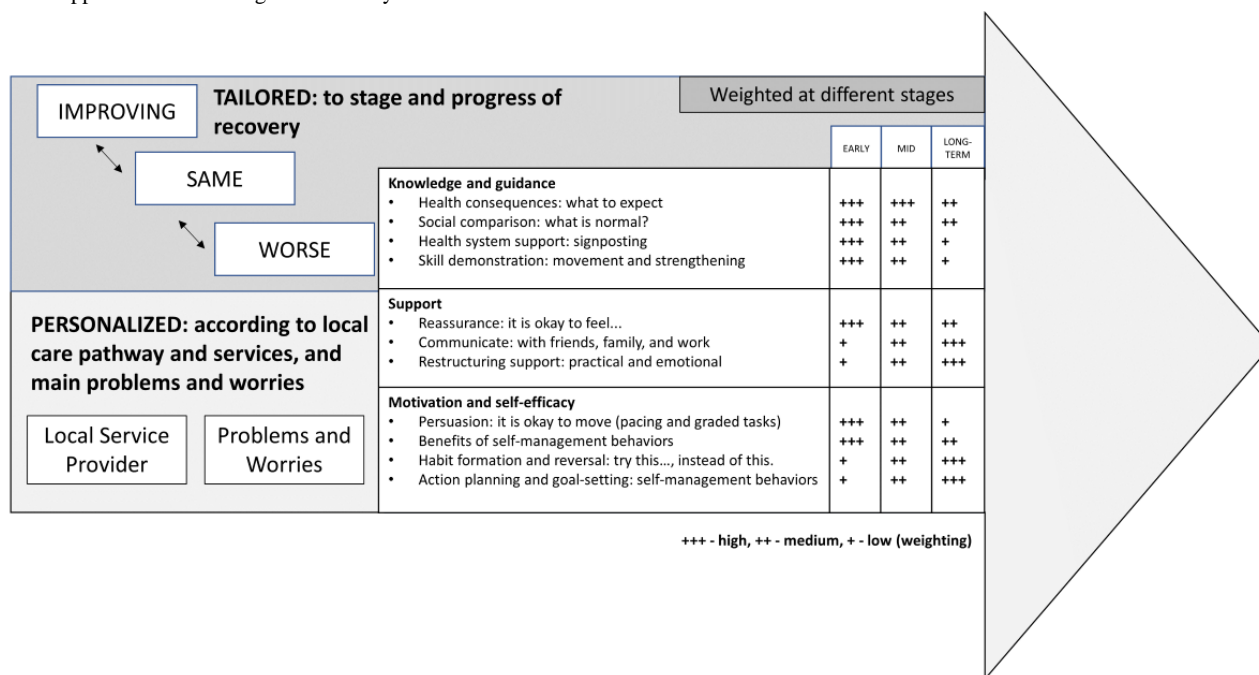
Behavioral Support at Different Stages of Recovery

The mapping process described in this paper provided an opportunity for the team to highlight that a key aim of getUBetter is to empower individuals to self-manage their condition wherever they may be on their recovery journey. This issue was not governed by the mapping process; however, the team agreed that it was important to describe this during the mapping process to illustrate the nuance of delivering BCTs in both a personalized and tailored way. The team also consulted with clinicians at this point to gather opinions on the potential weighting of BCTs at different stages of recovery. Although there were some differing opinions, there was general agreement in line with the weighting shown in Figure 4.

Figure 4 illustrates how, within getUBetter, content is tailored to two main variables: (1) timeline of the recovery journey, moving through early-term, mid-term, and long-term stages of recovery, and (2) status—how the patient is progressing at any given time point (ie, getting better, staying the same, or getting worse). Content is also personalized to two main variables: (1) an individual's local care pathway, local services, and health care provider and (2) patients identifying their main problems and worries to receive personalized advice. Content automatically adjusts to the stage of the recovery journey and individual progress, and this targeted content helps the patient to understand their stage of recovery while providing personalized support. Figure 4 illustrates how content is both tailored and personalized.

The full range of BCTs is present across all stages of recovery, although weighted differently according to individual progress and stage of recovery. For example, in the earlier stages of recovery, the key focus is on reassurance and providing knowledge about what to expect, what is normal, and having the confidence to seek help if needed. Later on, the focus might shift to making an action plan and considering healthy lifestyle changes to support effective self-management (Figure 4 also illustrates how content is weighted at different stages of recovery). The main concerns and problems can also be identified to further personalize content to strengthen confidence, reduce negative behaviors, and provide ongoing reassurance and persuasion about conducting self-management behaviors.

Figure 4. Support at different stages of recovery.


Stage 2: Mapping Intervention Options

BCTs present in getUBetter were then mapped to the intervention functions and policy categories of the BCW. This was another opportunity to evaluate how well the existing BCTs in getUBetter represented each intervention function.

Relevant intervention functions included education, persuasion, training, environmental restructuring, modeling, and enablement. Policy categories relevant to support the delivery of getUBetter included communication and marketing, guidelines, fiscal measures, regulation, service provision, and environmental and social planning. Multimedia Appendix 2 provides a detailed description of the links between the COM-B components and the intervention functions.

Stage 3: Mapping Content and Implementation Options

Mapping: Round 1

BCT Mapping

During the first round of mapping, getUBetter was mapped to 22 BCTs in the BCTTv1 (Textbox 2).

Textbox 2. Mapping of behavior change techniques in getUBetter.

Behavior change technique (coded to Behavior Change Technique Taxonomy version 1)

- 1.1 Goal setting (behavior; *added in round 2*)

- 1.2 Problem solving

- 1.5 Review behavior goal(s) (*added in round 2*)

- 2.3 Self-monitoring of behavior (*added in round 2*)

- 2.5 Monitoring of outcome(s) of behavior without feedback

- 3.1 Social support (unspecified)

- 3.3 Social support (emotional)

- 4.1 Instruction on how to perform a behavior

- 5.1 Information about health consequences

- 5.6 Information about emotional consequences

- 6.1 Demonstration of the behavior

- 6.2 Social comparison

- 7.1 Prompts and cues

- 8.1 Behavioral practice and rehearsal

- 8.2 Behavior substitution

- 8.3 Habit formation

- 8.4 Habit reversal

- 8.7 Graded tasks

- 9.1 Credible source

- 11.1 Pharmacological support

- 11.2 Reduce negative emotions

- 12.1 Restructuring the physical environment

- 12.2 Restructuring the social environment

- 12.6 Body changes

- 15.6 Verbal persuasion about capability

PSD Elements

Mapping to the PSD model illustrated the use of a number of persuasive design principles, including tailoring, personalization, simulation, and reminders, which were used to deliver the content of getUBetter.

Table 1 below shows how getUBetter incorporates key persuasive design principles from the PSD model into its functionality and content. In addition, it was recognized that some of these might be adapted and strengthened in future iterations.

Table 1. Persuasive system design elements in getUBetter.

Elements and descriptions	Existing content in getUBetter
Primary task support	
Reduction	
A system that reduces complex behavior into simple tasks helps patients perform the target behavior, and it may increase the benefit–cost ratio of a behavior.	• Simplification of national guidelines and musculoskeletal pathway • Simplifies the journey through local pathway and access to local services • Automates referrals and promotes self-choice • Writing style—translates complex messages into simple language • Simplifies tasks—related to time point
Tunneling	
Using the system to guide patients through a process or experience provides opportunities to persuade along the way.	• Tunneled by timeline—content provided depending on choice: improving, staying the same, or getting worse • Full autonomy for which order to visit app pages • Symptom checker—red flags directing the patient to a health professional (lock screen)
Tailoring	
Information provided by the system will be more persuasive if it is tailored to the potential needs, interests, personality, use context, or other factors relevant to a patient group.	• All content tailored to the day of recovery and recovery status (getting better, staying the same, or getting worse) • Feedback zone—tailored information around main worries and problems
Personalization	
A system that offers personalized content or services has a greater capability for persuasion.	• My main problems • My main worries (provides tailored information) • Personalized information to local services (local trust specific)
Self-monitoring	
A system that keeps track of one's own performance or status supports the patient in achieving goals.	• Diary, calendar, and goal-setting functions are available in the app, which are linked to prompts and reminders
Simulation	
Systems that provide simulations can persuade by enabling patients to observe the link between cause and effect immediately.	• Videos about simple exercises and activities of daily living
Rehearsal	
A system providing means with which to rehearse a behavior can enable people to change their attitudes or behavior in the real world.	• Videos and instructions on how to perform a behavior—exercising specific and general day-to-day activities
Dialogue support	
Praise	
The system should use praise via words, images, symbols, or sounds as a way of providing patient feedback information based on their behaviors.	• Persuasive messaging throughout (including information about health consequences, reducing negative emotions, and verbal persuasion about the capability to perform self-management behaviors—covered in BCTTv1[a] mapping)
Reminders	
If a system reminds patients of their target behavior, the patients will more likely achieve their goals. The system should remind patients of their target behavior during the use of the system.	• Automated reminders to log back into the app
Suggestion	
The system should suggest that patients conduct behaviors during the system use process.	• Covered in BCTTv1 mapping
Liking	
A system that is visually attractive for its patients is likely to be more persuasive.	• Ongoing design updates

XSL•FO
RenderX

Elements and descriptions	Existing content in getUBetter
System credibility support	
Trustworthiness	
The system should provide information that is truthful, fair, and unbiased.	• Follows national guidelines, NHS[b] guidelines, and NICE[c] digital health guidelines and is validated by CCG[d]—linked to the musculoskeletal pathway • Local GP[e] logo
Expertise	
The system should provide information showing knowledge, experience, and competence.	• Developed by experts
Surface credibility	
The system should have a competent look and feel.	• P-mat—tested with patients—high level of usability and acceptability • No advertisements
Real-world feel	
The system should provide information about the organization and actual people behind its content and services.	• NHS badge, local services, local CCG—credible source • In GP practices
Authority	
The system should refer to people in the role of authority.	• Links back to GP and other NHS services
Third-party endorsements	
The system should provide endorsements from respected sources.	• Links back to GP and other NHS services
Verifiability	
The system should provide means of verifying the accuracy of the site content via outside sources.	• Links back to GP and other NHS services
Social support	
Social learning	
The system should provide means of observing other patients who are performing their target behaviors and seeing the outcomes of their behavior.	• Some target behaviors were displayed in videos but not all • No illustrations of outcomes of behavior (eg, positive stories of improvement)

Mapping: Round 2

The first round of mapping highlighted the potential value of adding specific BCTs to strengthen it in future iterations. Following a number of changes during ongoing development, a second round of mapping was conducted, resulting in the identification of 3 additional BCTs (Textbox 2). This was translated to a number of areas within the app that were strengthened; for example, the addition of a goal-setting section linked to a calendar function where patients can log progress and self-monitor their recovery journey.

A number of PSD elements were also strengthened, including more direct links between sections, production of additional guidance and instruction videos, development of video strings to guide patients through videos, and addition of a traffic light system to guide the patient to the most appropriate exercises.

Logic Model of Behavior Change for getUBetter

Figure 5 illustrates the full behavior change model for getUBetter. It provides details of the target COM-B elements that getUBetter intends to change (target behaviors) and describes the intervention functions and BCT groups that are used to make this change (description of intervention), the PSD elements present that deliver the BCTs (mode of delivery) via the app, and how the intervention as a whole affects the intended outcomes (outputs).

Figure 5. Logic model of behavior.
Discussion

Principal Findings

The aim of this project was to evidence the behavior change model underpinning getUBetter. A range of models and frameworks were adopted to demonstrate how the content and functionality of the intervention aligns with the recognized behavioral theory, effective BCTs, and recommended clinical practice.

This study offers a method for illustrating a behavior change model for a complex DHI and is in line with Medical Research Council complex intervention development guidelines [18], NICE evidence standards framework for DHT [10], and literature that has adopted similar methods to illustrate the development of behavior change interventions in musculoskeletal health [19]. It recognizes the value of using overlapping frameworks to capture recognized BCTs (using the BCTTv1) while highlighting the novel functionality of the intervention (using the PSD model), which importantly enables transparency and replicability.

The behavior change model can be seen as a blueprint for behavior change that can be used to guide future iterations of the intervention and the development of content for other musculoskeletal conditions, which are currently in development. The process also enabled the team to identify potential areas of the intervention that could be strengthened and highlighted the potential value of adding BCTs not present in the initial mapping round.

The mapping exercise opened up an opportunity for team discussion about the relative importance of different BCTs at different time points of recovery. getUBetter was developed so that content is tailored depending on where each individual is within their own recovery journey and whether symptoms are improving, staying the same, or getting worse. Future research should explore with patients the relative importance of different behavioral support at different stages of recovery to help identify if and how behavioral support can be more tailored and personalized in future iterations of the DHI. This is a novel area

that is yet to be explored in the literature and requires further investigation.

Limitations

Mapping and coding of BCTs are often open to interpretation, and we recognize the potential bias from the project team. However, a number of team meetings (which included clinicians with extensive experience in treating musculoskeletal conditions and academics with experience in developing behavior change interventions) were held to discuss the content and reach consensus when linking content to BCTs.

Coproduction and engagement with patients (a planned next step) would add value and help to learn more about potential areas that could be better represented and additional BCTs relevant and acceptable to the musculoskeletal population.

Next Steps

Throughout this process, the importance of exploring acceptability (of intervention content) and usability (of the digital intervention) was recognized as a key factor in understanding how the intervention will be adopted and used by patients, and work in this area is being planned in future studies. The behavior change model described in this paper will act as a useful foundation for exploring these topics further with patients, and we recognize the important need to understand the characteristics and strategies that are most effective in promoting both the engagement with digital technologies [20] and the healthy behaviors that they intend to promote. Future work will also explore the effectiveness of this DHI on a larger scale.

Conclusions

This process enabled the proposed mechanisms of action and theoretical foundations of a DHI to be comprehensively described, highlighting the key BCTs used to empower patients to self-manage their condition. These findings provide guidance for the ongoing evaluation of the effectiveness of the intervention.

The new standard framework for DHT includes the evaluation of behavior change [10]. There is limited evidence about how people engage with and act upon information delivered via digital behavior change interventions, especially in tools that

span acute to long-term conditions. We have demonstrated that it is possible to evaluate the behavioral mechanisms of this DHT using a range of models and frameworks to illustrate a behavior change model for getUBetter.

Abstract

Background: The COVID-19 pandemic has drastically changed the physical activity (PA) landscape through the closures of gymnasiums, schools, and many outdoor spaces. Physical distancing guidelines have also reduced opportunity for PA. The popularity of free web-based home fitness videos on video hosting platforms (eg, YouTube and Instagram) has spiked during the pandemic. Many web-based fitness videos offer a convenient, accessible, and cost-effective means of engaging in PA through regularly posted videos or discrete programs. Notably, traditional PA programs often suffer from poor adherence and high dropout rates, despite many advantages over web-based workout programs (eg, equipment, feedback, and in-person engagement). Thus, notwithstanding clear advantages of these web-based fitness videos, their ability to maintain long-term engagement and adherence is unknown.

Objective: We explored patterns of engagement (ie, views, likes, and comments) for channels posting daily or program-based web-based fitness videos since the declaration of COVID-19 as a pandemic, over 4 months. Our secondary objective was to examine potential moderators of engagement metrics.

Methods: An environmental scan was used to identify eligible channels. Eligible channels were (1) freely available on YouTube or Instagram and (2) posted daily or weekday series workouts or offered quarantine-specific workout programs. Searches for eligible channels were conducted on June 1 and 4, 2020. Engagement metrics of views, likes, and comments were then collected from channels' videos posted between March 11 and June 26 or 30, 2020, inclusive, on June 26 or July 8, 2020. A series of multilevel modeling analyses were conducted to examine longitudinal changes in each of the 3 outcome variables.

Results: Ten channels were deemed eligible and included in analyses; 6 posted regularly, while the other 4 posted discrete workout programs. Multilevel models revealed that both views and likes significantly decreased across days. Visually, channels display the sharpest drop in engagement within the first week. Linear change estimate indicates that the number of views initially declined by 24,700 per day (95% CI –44,400 to –11,300, P=.01) on average across all the channels. Channels with more subscribers declined in their views, likes, and comments at a significantly higher rate than those with fewer subscribers ($P\leq.04$). The day of the week a video is posted, "virality," and content of a video appear to influence engagement. Integrating behavior change techniques and posting new and varied videos often may help garner further engagement with these videos. Future research should examine common elements of videos, which drive engagement.

Conclusions: Despite raw engagement metrics, each channel demonstrated peak engagement with the initial video followed by decreased engagement with subsequent videos. As many countries maintain restrictions on traditional PA facilities owing to the COVID-19 pandemic, determining methods to improve engagement and adherence with web-based fitness videos becomes increasingly important.

Introduction

The COVID-19 pandemic has scaled up to over 38 million cases and over 1 million deaths worldwide as of this writing [1]. When COVID-19 was declared a pandemic on March 11, 2020 [2], this led to considerable changes in daily life including social distancing, elimination of community gatherings, restricted travel, and general instruction to "stay home" [3]. The consequences have affected how people engage in recreation, as many parks and recreation facilities were closed [4,5]. Commercial gyms, group exercise classes, and sporting activities ceased to operate over safety concerns and many have failed to reopen owing to bankruptcy or continued restrictions [6,7].

As a result of these drastic shifts in opportunity for physical activity (PA), the population has altered daily PA behaviors [8]. Fitbit's blog presentation of its users noted a 5% to 20% reduction in total steps across the globe during the early stages of the pandemic [9]. Early research has replicated this general finding in China [10], the United States [11,12], the United Kingdom [13], Canada [14], and Europe [15]. Furthermore, higher-intensity PA, such as regular exercise, appears to be particularly compromised [12,14,15]. For example, a recent survey of 3052 US adults found a clinically meaningful drop in PA among active participants (pre–COVID-19) who were socially isolating [12]. These findings are concerning because regular moderate to vigorous intensity PA was already low in prevalence among high-income countries before the COVID-19 pandemic [16], despite how essential this behavior is for mental and physical health [17]. An increased burden that this wave of inactivity will cause leaves the population and the health care system weakened and at higher risk as COVID-19 continues to plague many countries [18].

Despite general trends in physical inactivity, some people have reported increasing their PA or remaining stable [14,15]. For example, work by Rhodes et al [14] found that minutes spent in PA during the pandemic were moderately positively associated with personality traits (eg, activity-extraversion, habit, and identity) and weakly positively associated with demographic factors (eg, income, education, and dog ownership). Notably, one of the key predictors of this stability has been opportunities to engage in home exercise [14,19]. Early research examining home exercise delivered through videos or videoconferencing software has demonstrated effectiveness in both improving levels of PA [20,21] and in increasing motivation to be physically active [22]. Further, affordances for PA (equipment and media) in the home environment have always been a reliable correlate of behavior [23]; yet, the COVID-19 pandemic restrictions on recreation facilities and gymnasiums have likely resulted in a dramatic shift in its importance. In concert with this demand, some commercial fitness businesses have transitioned to web-based fitness programs as an alternative to traditional exercise options [24]. Many web-based workout providers are offering quarantine specific workouts in an attempt to serve a new group of viewers, or prior patrons who are looking for a way to maintain their

activity. Web-based fitness programs, on platforms such as YouTube and Instagram channels offer many advantages over traditional fitness options such as cost-effectiveness (free with an internet connection and no or minimal equipment), convenience (autonomy of when to watch and many different options), accessibility (vast catalogue of home fitness workouts and routines suited for different populations, skill levels, modes of exercise, etc), and community (comments, likes or dislikes, and live streaming allow for a level of interactivity that can mimic the social aspects of other traditional workout programs). In fact, YouTube reported a quadrupling of daily views for exercise videos with "no equipment" or "home" in the title since declaration of the pandemic [25].

There are clear advantages of these web-based exercise programs in these unprecedented times; yet, there remain several unanswered questions about long-term effectiveness and engagement. These programs cannot emulate several elements of traditional exercise options, such as movements that require equipment (resistance training machines, bikes, rowing, etc), true in-person feedback, and individualization of training. It may be that dropout from these programs is high. Indeed, fast dropout of approximately 50% from traditional gymnasiums and recreation centers is a well-established phenomenon [26]. More information on the patterns and potential moderators of engagement of these pandemic home exercise workouts will assist in tailoring future workouts toward the more successful approaches (eg, challenges vs daily workouts and population-focused approaches) as well as a general understanding of long-term engagement.

Thus, the purpose of this study was to explore the pattern of engagement levels of 10 web-based freely available exercise channels that posted either daily or program-based fitness videos since the beginning of the COVID-19 pandemic. We explored total engagement and changes in engagement through views, comments, and likes across a period of 4 months during the pandemic. We further explored potential moderators of engagement metrics, such as viewership across a week and engagement across specific video posting formats and video content. Given the exploratory nature of this study, no formal confirmatory hypothesis was proposed. However, based on prior exercise adherence research, we expected to see that engagement with these web-based videos—via higher engagement metrics—would occur for the initial videos posted by channels; however, a sharp drop-off in engagement was also hypothesized to follow in subsequent videos, paralleling retention and adherence patterns in existing PA efforts [26].

Methods

Eligibility Criteria

Eligible media met the following criteria: (1) freely available on YouTube or Instagram and (2) posting daily or weekday series workouts or offering quarantine-specific workout programs, as these criteria were rationalized to parallel closest with regular gymnasium-going or exercise or PA guidelines

[27]. As such, websites that offered free workout series or programs but were not hosted on YouTube or Instagram (eg, CrossFit [28]) were excluded, as comparable metrics of engagement (eg, views, likes, and comments) were not consistently available. Similarly, series or programs that were accessed through a proprietary app (eg, Gymshark conditioning workout app [29]) were also not included. Further, channels that posted regular videos but were not as part of a regular series or program (eg, vlogs, testimonials, and diet advice) were not included, as these unstructured or unrelated videos were thought to receive variable hits depending on their individual popularity (eg, trending or viral videos).

Search Strategy

The following keywords were used (in combination) within search engines: "Daily," "Online," "Workout," "Exercise," "Program," "Streaming," "Fitness," "At-Home," "Of the day," "Today's date" (ie, date of the search), "Class," "Session," "quarantine," "lockdown," and "COVID-19." For example, "Daily online workout program" was a permutation of search strategy used.

Information Sources

Search term keywords and combinations therein were searched directly into a Google search engine, as well as YouTube and Instagram platform search engines. For Google searches specifically, webpages that contained lists of available web-based workouts (eg, "The best places to go for free online workouts" [30]) were parsed for eligible channels.

Procedure

An environmental scan was initially employed to determine the media sources (ie, YouTube and Instagram channels) for longitudinal data extraction. According to Graham [31], environmental scans leverage diverse sources and amounts of data, so decision-makers can be informed of "current social, economic, technological, and political contexts, and to identify any potential short- and long-term shifts." Importantly, the flexibility and diversity of potential data sources within an environmental scan can reveal preliminary trends or current relationships that may warrant further, more robust investigation. As such, two initial searches to identify eligible channels were conducted: one on June 1 and one on June 4, 2020.

Upon selection of appropriate YouTube and Instagram channels, overall engagement metrics were collected for videos posted between March 11 and June 26 or 30, 2020, inclusive. Specifically, these overall engagement metrics were collected on June 26 or July 8, 2020. While this extraction method does infer that older videos have more time to accumulate engagement, the regular or programmed nature of the videos posted by the observed channels is likely still sensitive enough to reflect changes in engagement over time.

Primary Outcome: Engagement Metrics

Engagement metrics from videos of eligible channels were collected; specifically, number of views, number of likes (if available), and number of comments. Further, to explicate trends in video engagement, channels that posted a regular series of workout videos (ie, regularly) were charted differently than channels that released a discrete workout program (ie, program). Further, number of channel subscribers was collected as a potential moderator of channel engagement.

Statistical Analyses

A series of multilevel modeling analyses were conducted to examine longitudinal changes in the engagement metrics. Separate models were carried out for each of the three outcome variables (ie, views, likes, and comments) and were predicted by a linear and quadratic time variable, coded as days since COVID-19 was declared as a global pandemic (March 11, 2020) [2]. Number of channel subscribers (grand-mean centered) and video start date were included as between-channel covariates to statistically adjust for initial differences in channel exposure and time elapsed between the first video and the onset of the pandemic. Subscribers and start date were also included as moderators on both linear and quadratic slopes to determine if the rate of change differed depending on channel size or video onset. All models were estimated in Mplus (version 8.4) using the Bayes estimator to facilitate model convergence. Statistical significance was set at $P<.05$.

Results

Channel Descriptives

Overall, 10 channels were observed in this environmental scan: Fit Factory [32], One Workout A Day [33], The Body Coach [34], Orange Theory Fitness [35], Planet Fitness [36], Holly Dolke [37], Six-Pack Factory [38], Leansquad [39], Amanda Bisk [40], and Gaby Pimental [41]. The majority of these channels were identified through websites found through Google searches that posted curated lists of web-based exercise videos or channels. Descriptive characteristics and statistics for each channel are presented in Tables 1 and 2, respectively. Of the 10 channels observed, 9/10 (90%) were based on YouTube and 1/10 (10%) was based on Instagram. The channels were almost evenly split between regularly posting videos (6/10, 60%) and posting discrete programs (4/10, 40%). Of the channels that posted regularly, post frequency ranged from daily videos (4/6, 67%) to weekdays only (2/6, 33%). Of the channels that posted programs, program length ranged from 7 days (2/4, 50%) to 30 days (1/4, 25%). With respect to posting date, the majority of channels observed began posting in March 2020 (8/10, 80%), with 1 (10%) channel starting in mid-May [32] and 1 (10%) channel starting in June [36]. Subscriber count varied drastically among channels, ranging from 766 [41] to 2,500,000 [34], with a median value of 74,100 (based on the date of data collection).

Table 1. Descriptive characteristics for each channel.

Channel	Channel characteristics			Subscribers, N	Videos posted, N	Video start date
	Platform	Posting format	Target audience			
Fit Factory	Instagram	Regularly (daily)	Adults	30,100	38	May 15, 2020
One Workout a Day	YouTube	Regularly (daily)	Women	77,100	100	March 23, 2020
The Body Coach	YouTube	Regularly (weekdays)	Children and parents	2,500,000	100	March 23, 2020
Orange Theory Fitness	YouTube	Regularly (daily)	Adults	89,300	105	March 18, 2020
Planet Fitness	YouTube	Regularly (weekdays)	Adults and adolescents	71,100	12	June 1, 2020
Holly Dolke	YouTube	Program (30 days)	Women	1,110,000	30	March 23, 2020
Six-Pack Factory	YouTube	Program (7 days)	Adults (men)	1,460,000	7	March 30, 2020
Leansquad	YouTube	Program (7 days)	Adults	21,000	14	March 21, 2020
Amanda Bisk	YouTube	Program (14 days)	Women	24,800	14	March 20, 2020
Gaby Pimental	YouTube	Regularly (daily)	Older adults	766	30	March 18, 2020

Table 2. Descriptive statistics for average video engagement metrics of each channel.

Channel[a]	Views, mean (SD)	Likes, mean (SD)	Comments, mean (SD)
Fit Factory	3396.3 (1679.4)	159.8 (67.4)	17.4 (10.8)
One Workout a Day	4164.4 (8787.1)	209.6 (327.5)	17.0 (15.8)
The Body Coach	1,110,476.1 (1,077,577.6)	23,462.3 (16,401.5)	853.7 (589.8)
Orange Theory Fitness	60,951.4 (37,330.2)	243.8 (244.5)	22.8 (15.9)
Planet Fitness	2652.0 (829.9)	53.3 (29.1)	0.00 (0.00)
Holly Dolke	140,494.2 (120,562.1)	5278.4 (4913.1)	512.0 (421.1)
Six-Pack Factory	9707.3 (7060.8)	299.9 (231.6)	123.7 (63.1)
Leansquad	6811.1 (8272.2)	89.7 (102.9)	8.9 (9.6)
Amanda Bisk	19,175.0 (21,117.2)	266.4 (328.9)	17.6 (10.7)
Gaby Pimental	1071.0 (1337.8)	15.6 (13.3)	6.7 (4.7)

[a]Grand means: 135,889.9 views, 3007.9 likes, and 158 comments.

Engagement Metrics Across the COVID-19 Pandemic

The raw daily engagement metrics are displayed in Figure 1, Multimedia Appendix 1, and Multimedia Appendix 2. Multilevel models were used to formally test for the decline in engagement metrics throughout the pandemic. Our results revealed that both views and likes significantly decreased across days (see linear change estimate in Table 3 and Multimedia Appendix 3, respectively). These linear declines in views and likes were still detectable after adjusting for number of channel subscribers and video start date. Table 3, Multimedia Appendix 3, and Multimedia Appendix 4 also indicate that channels with more subscribers had significantly more views, likes, and comments on average than channels with fewer subscribers. Conversely, channels that began their videos later into the pandemic (ie, had a higher value for their video start date) produced fewer views and likes on average compared to channels that began their videos closer to the onset of the pandemic. Daily views were divided by 10,000 to enable model estimation. Therefore, the intercept value of 82.24 indicates that at the onset of the pandemic (time 0), the estimated number of views would be 822,400. The linear change estimate of –2.47 indicates that the number of views were initially declining by 24,700 per day, on average across all the channels. The positive quadratic change value indicates a slowing of this rapid decline in views. However, the quadratic term was not statistically significantly for any of the engagement metrics. Daily likes and comments were also scaled to enable model estimation (divided by 100 and 10, respectively). Therefore, the initial estimated number of likes would be 12,787 with an initial linear decline of 289 likes per day. Descriptively, visual inspection of Figure 1, Multimedia Appendix 1, and Multimedia Appendix 2 indicate the rapid decline in views, likes, and comments for most of the channels across time. Visual inspection also revealed potential "micro" patterns of engagement. For example, the Orange Theory Fitness channel appears to demonstrate a repeating weekly pattern of engagement, whereby engagement is highest on Monday and dips midweek before rising again during Friday and the weekend. Additionally, uncharacteristic spikes in engagement may indicate the "virality" of some videos.

[a]Views were divided by 10,000 to enable model estimation.

[b]Italicized values are significant at *P*<.05.

[c]Subscribers = number of channel subscribers / 1000.

[d]Start day = number of days from the beginning of the declaration of COVID-19 as a pandemic (March 11, 2020).

[e]N/A: not applicable.

Moderators of Channel Engagement

The interaction between the number of channel subscribers and linear declines was significant for each of the 3 engagement metrics; that is, channels that had more subscribers experienced a decline in their views, likes, and comments at a significantly faster than those with fewer subscribers. Figure 2, Multimedia Appendix 5, and Multimedia Appendix 6 displays the nature of this interaction for a channel with 500,000 subscribers compared to that with 100,000 subscribers for views, likes, and comments, respectively. Inspection of the figures depicts how channels with more subscribers begin with more engagement but decline at a faster rate than those with fewer subscribers.

Figure 2. Estimated trajectories of views for channels with high (500,000) and low (100,000) subscribers.
Discussion

Principal Findings

Our study sought to explore the pattern of engagement levels of web-based freely available exercise channels that posted regular or program-based videos since the beginning of the COVID-19 pandemic. To this end, our environmental scan identified 10 channels that met inclusion criteria. While the study is the first of its kind and thus exploratory, we expected to see a large engagement presence for videos posted closer to the start of the pandemic, followed by a sharp drop-off in engagement in subsequent videos, which mirrored patterns among traditional PA opportunities [26]. Overall, commensurate with our expectations, all the channels observed saw a significant linear decline for posted videos over time in views and likes, with a trending decline for comments. Visual inspection indicated the sharpest decline in these engagement metrics within the first week of when the channel started posting videos, controlling for start date, paralleling previously reported dropout rates among traditional gym use [26].

Specifically, earlier videos posted by a channel garnered more views, likes, or comments than subsequent videos, with a drop-off in engagement in subsequent videos, regardless of channel or posting format. The multilevel models also revealed the role of the video start date (in relation to the declaration of COVID-19 as a pandemic), in that channels that began posting videos closer to March 11, 2020, saw higher engagement than those that began posting later. These findings may be representative of the trend in popularity of web-based fitness videos throughout the course of the COVID-19 pandemic. Lockdowns and stay-at-home messaging in early March drastically increased the number of individuals who were staying at home [42], which coincided with a spike in interest in Google searches for "online fitness videos" and "online exercise videos" [43] and a quadrupling of views for "no equipment" and "home" exercise videos on YouTube [25]. However, return to pre–COVID-19 levels of interest in these search terms by May 2020 also generally coincides with plateaus in engagement metrics among videos posted by the observed fitness channels. It is possible that colder or inclement weather may have contributed to the greater engagement in these videos [44] closer to March and a diminishing of engagement over the next few months (ie, winter or spring transition in the Northern hemisphere), in that indoor opportunities for PA—such as web-based workout videos—may have been preferentially chosen over outdoor opportunities in the early months of the COVID-19 pandemic. However, the dramatic drop-off we observed is notably incongruent from the slower moderation of season on PA [44]. Hence, the overall trend we observed supports the notion that the COVID-19 pandemic has driven a mass of engagement to web-based fitness and exercise videos on YouTube and Instagram.

Notably, while our multilevel models revealed a significant negative linear relationship between the video posting date and engagement metrics, when examining our data descriptively, the sharpest decline in all engagement metrics was evident within a week of a channel posting its first video, regardless of the start date. This initial drop-off in channel engagement parallels the poor adherence rates to traditional PA programs, whereby 50% of adults drop out within a few months of beginning a PA program [26]. However, use of YouTube and Instagram as the sole means of delivering a PA program presents several disadvantages to a traditional PA program, which may explain the sharper decrease in engagement. By virtue of the medium of delivery (ie, posting a video on the internet), the web-based fitness videos examined do not incorporate many of the strategies that have been shown to improve adherence to PA. For example, viewers of web-based fitness videos do not inherently have a way to receive feedback on the basis of their participation, which can lead to overexertion or improper form or injury, both of which have been shown to deter future participation in PA [45]. Further, capacity for elements such as goal-setting and social participation with other viewers is limited with web-based fitness videos given the asynchronous "delivery" of the workout.

Descriptively, several potential moderators for engagement were identified within the data. Specifically, while the larger trend of engagement demonstrated was a negative linear relationship, smaller patterns within the data were also observed through visual inspection. For example, some "regularly" posting channels appeared to demonstrate weekly patterns in video views; specifically, video views were higher at the beginning of the week (ie, Monday) and tended to decline throughout the week. This weekly—or circaseptan—cycle has been previously documented for smoking cessation efforts [46] and other health-related behaviors [47], whereby the healthiest contemplations occur during Monday. The Orange Theory Fitness channel [35], in particular, appeared to demonstrate an M-shaped circaseptan cycle, with relatively higher engagement at the start and end of the week. Other notable patterns include large spikes in engagement metrics, which are may be attributable to the "virality" of some videos, or videos that become popular through sharing and resharing [48]. These viral videos do not usually deviate from the creator's typical content, but rather feature some characteristic or characteristics that facilitate traction on social media very soon after publication. Smaller spikes in engagement were also present in regularly posting channels and may be reflective of the specific content of the PA that day. In other words, the specific content of that day's workout may elicit more engagement from viewers than typical or expected.

In general, patterns of engagement metrics were related to other engagement metrics. For example, views of a video were consistently several magnitudes higher than likes on a video; similarly, the number of likes was generally an order of magnitude higher than comments on a video. These findings are unsurprising given that these metrics likely represent an increasing level of engagement of a video, respectively. Views of a video represent a spectrum of viewers: from those who watch the full video (and presumably participate in the PA) to those who may only have a passing curiosity in the video and disengage after 30 seconds of watching the video (ie, minimum watch time to be considered a view [49]). On the other hand, likes and comments are intentionally performed by the viewer, which may be indicative of higher engagement with the video.

Of the channels observed, adults were the primary audience for these videos, followed by women, children and adolescents, and then older adults. Despite insufficient observations to statistically compare channels examining these groups, descriptively, channels demonstrate fairly consistent patterns of engagement. Perhaps a notable exception to this is the channel focused on older adults [41]; Gaby Pimental's channel, despite a subscriber count of <1000, had some of the highest views, likes, and comments per subscriber. Whether this is owing to the low subscriber count (ie, less engagement is needed to achieve higher ratio of engagement) or potentially inherent differences to how older adults engage with these videos (eg, more likely to like and comment compared to other demographics) is worthy of future investigation.

Practical Implications

This work holds several potential practical implications for both future digital exercise research and viewers or creators of digital exercise content. Our data suggest that COVID-19 has generated interest and engagement with web-based fitness and exercise videos. Furthermore, as reports of resurgences of COVID-19 cases emerge globally and many countries revert to lockdowns and stay-at-home orders—and consequently, limitations to traditional PA opportunities—interest in these web-based fitness and exercise videos is likely to rise again. Given the similar drop-off in adherence between the web-based exercise videos observed and traditional PA opportunities (eg, gymnasiums and recreation centers), research investigating means by which these videos can retain engagement with new viewers may be able to draw from existing exercise adherence research; for example, for content creators, posting videos often and regularly, encouraging habit formation [50], posting a variety of exercises [51], responding to viewers' comments as a means of social support and feedback [52], and offering incentives or prizes for regular engagement [53] may all assist content creators in improving and retaining their subscriber base. Similarly, for viewers and subscribers to these channels, goal-setting and creating an action plan on the basis of the posting schedule of a channel may improve adherence [54], and more distally, habit formation [54]. Further, liking and commenting on videos and engaging with the content creator may improve engagement and adherence through fostering social identity [55]. Additionally, exploring avenues by which these videos can be made more accessible or available to digitally disadvantaged populations (eg, low-income households and those with poor digital literacy) is worthy of pursuit, as currently, engagement with these videos—and any benefits imparted from PA derived from these videos—is limited by digital inequities [56].

By extension, research investigating how engagement with these types of videos is linked to actual exercise behavior is also crucial for understanding their effectiveness. Further, building on previous work examining engagement with YouTube videos [57], content analyses examining common elements of more popular exercise videos can reveal potentially unique factors driving engagement in this medium of PA promotion, such as branding, targeting emotions or affective states, and authenticity [58,59]. Similarly, determining demographics for the audiences of these videos can reveal which type of channel or video may be more effective for promoting PA among different populations [58].

Limitations

There are limitations to our work and its interpretation. The primary limitation is that we cannot ascertain the extent to which any individual engagement metric, or combination thereof, translates to actual PA. YouTube only requires 30 seconds of video watch time to be considered a view [49]; similarly, likes and comments—while necessitating more engagement from the viewer—can also be done without participating in any actual exercise. Notably, likes and comments can also only be left by viewers with a YouTube or Instagram account, which considerably limits the use of solely these metrics as a measure of video engagement. Perhaps the best surrogate measure for actual exercise participation may be average watch duration for a video, since it is unlikely for an individual to watch a 30-45–minute workout video without participating in exercise themselves. Unfortunately, these metrics are only available to

the channel owner, along with other useful metrics, such as audience retention (ie, percentage of video watched), number of shares, demographics, and more specific engagement metric trends (eg, changes in day-to-day engagement). Further, some channels posted their videos "live" initially (eg, The Body Coach [34]), and hence have comments and other engagement metrics that are not archived on the webpage. Engagement metrics from these "live" sessions may also provide a better representation of exercise participation; however, these are also only available to the channel owner. Our work also only examined a narrow criterion of freely available channels on YouTube or Instagram. Our searches uncovered numerous more "popular" channels, based on subscriber count and views or uploads, which did not meet our eligibility criteria. Inclusion of these channels through broader inclusion criteria may reveal additional patterns of engagement not observed in this study. Comparably, other platforms (eg, Twitter, Facebook, and paid platforms) may include features to influence engagement beyond what we observed. However, whether metrics for engagement are as easily extracted from these platforms remains an area for future research. Finally, the mode of delivery for these videos (ie, YouTube and Instagram) presents as another limitation, as these videos are only available to individuals with access to these websites. As the COVID-19 pandemic continues to exacerbate digital inequalities [56] (eg, the ability to receive PA promotion and facilitation via web-based exercise videos) the generalizability of these findings is limited to those with access to said videos.

Conclusions

In summary, the declaration of COVID-19 as a global pandemic has coincided with a surge in engagement (ie, views, likes, and comments) with web-based fitness and exercise videos on YouTube and Instagram, with observed videos posted closer to the start of the pandemic garnering significantly more engagement than subsequent videos. However, compared to earlier posted videos, engagement metrics associated with subsequent videos decline significantly, regardless of posting type, with the sharpest decline in engagement occurring within a week of the initial video and greater decline for channels with higher subscriber counts. Investigating means by which these types of channels can improve and maintain engagement with viewers, elements of current popular videos that garner engagement, as well as how this engagement translates to actual exercise behavior, are all lucrative areas for future research, especially throughout the uncertainty associated with the COVID-19 pandemic.

Abstract

Background: Smartphone app–based ecological momentary assessment (EMA) without face-to-face contact between researcher and participant (*app-based noncontact EMA*) potentially provides a valuable data collection tool when geographic, time, and situational factors (eg, COVID-19 restrictions) place constraints on in-person research. Nevertheless, little is known about the feasibility of this method, particularly in older and naïve EMA participants.

Objective: This study aims to assess the feasibility of app-based noncontact EMA as a function of previous EMA experience, by recruiting and comparing a group of participants who had never participated in EMA before against a group of participants who had been part of an earlier in-person EMA study, and age, by recruiting middle-aged to older adults.

Methods: Overall, 151 potential participants were invited via email; 46.4% (70/151) enrolled in the study by completing the baseline questionnaire set and were emailed instructions for the EMA phase. Of these participants, 67% (47/70) downloaded an EMA app and ran the survey sequence for 1 week. In total, 5 daytime surveys and 1 evening survey, each day, assessed participants' listening environment, social activity, and conversational engagement. A semistructured *exit* telephone interview probed the acceptability of the method. As markers of feasibility, we assessed the enrollment rate, study completion rate, reason for noncompletion, EMA survey response rate, and likelihood of reporting an issue with survey alerts and requested assistance from researchers, family, or friends.

Results: Enrollment rates among invitees (63.3% vs 38.2%; P=.004) and completion rates among enrollees (83.9% vs 53.8%; P<.001) were higher in the experienced than in the naïve EMA group. On average, experienced participants responded to 64.1% (SD 30.2%) of the daytime EMA surveys, and naïve participants responded to 54.3% (SD 29.5%) of the daytime EMA surveys (P=.27). Among participants who retrospectively reported issues with survey alerts, only 19% (3/16) requested researcher assistance during data collection. Older participants were more likely to report not being alerted to EMA surveys (P=.008), but age was unrelated to all other markers of feasibility. Post hoc analyses of the effect of the phone operating system on markers of feasibility revealed that response rates were higher among iOS users (mean 74.8%, SD 20.25%) than among Android users (mean 48.5%, SD 31.35%; P=.002).

Conclusions: Smartphone app–based noncontact EMA appears to be feasible, although participants with previous EMA experience, younger participants, and iOS users performed better on certain markers of feasibility. Measures to increase feasibility may include extensive testing of the app with different phone types, encouraging participants to seek timely assistance for any issues experienced, and recruiting participants who have some previous EMA experience where possible. The limitations of this study include participants' varying levels of existing relationship with the researcher and the implications of collecting data during the COVID-19 social restrictions.

Introduction

Background

Ecological momentary assessment (EMA) refers to a range of methods used for measuring daily life feelings, events, experiences, and behaviors in real-time, real-world settings [1]. These methods include pen-and-paper surveys and diary methods [2,3] and surveys delivered via palmtop computers [4,5], mobile phone SMS text messaging [6,7], and, most recently, smartphone apps [8-10]. In the past decade, smartphone app–based EMA has surged in popularity, coinciding with an exponential growth in smartphone ownership; in the United Kingdom, 87% of the population owned a smartphone in 2020 compared with only 27% in 2010 [11,12]. This presents an opportunity for participants to partake in app-based noncontact EMA, where they can download an app and run EMA schedules from their own smartphone, without the need for in-person interaction with researchers at study invitation, recruitment, initiation, or data collection.

Among its advantages, app-based noncontact EMA allows for the recruitment of large samples, or those drawn from specific or hard-to-reach populations, more easily than in-person EMA. It is convenient and can reduce or remove time and geographic barriers to participation. The participant burden associated with borrowing, becoming familiar with, and carrying around a supplied research smartphone is eliminated. For researchers, equipment costs are reduced, and allowing participants to use their own personal smartphone means that less training is required, thus saving time. When training is provided, it is more feasible to use a blanket approach (eg, distribution of generic written instructions only) with noncontact EMA than in-person EMA. Finally, noncontact EMA presents an alternative when situational factors, such as the COVID-19 restrictions, prevent in-person research.

However, there are also limitations associated with this method, not least that participants must own a smartphone. Furthermore, EMA schedules can be complex and demanding, and therefore require a certain degree of participant investment and a solid understanding among participants of what they are being asked to do, along with technological proficiency with the smartphone and app. This may be difficult to achieve without an in-person initiation. Finally, in allowing participants to run EMA on their own smartphones, researchers have less control over the study, and the wide variety of smartphone devices on the market makes it difficult to provide technical support to participants when required. These factors may have negative implications for the quality and quantity of the EMA data collected.

One may reasonably expect that previous experience of successful participation in EMA studies (in whatever form) would increase the likelihood of being able or willing to complete a subsequent app-based noncontact EMA study, although to the authors' knowledge, this has never been explored. In contrast, participants who are new to the EMA method may be disadvantaged by the lack of in-person initiation and subsequently struggle with the noncontact EMA protocol. Regarding the potential effects of age, the high technological demand of EMA may prove challenging for older adults who tend to have lower rates of smartphone ownership, use [13], and competency [14]. Notably, Duncan et al [15] found that, among a sample of sexual minority men, older participants were less willing to download the EMA app to their smartphone than younger individuals. Hence, the limitations of app-based noncontact EMA may lower its feasibility for older participants and introduce sampling bias. As app-based noncontact EMA has become necessary under the COVID-19 restrictions, it is essential to understand the feasibility of this method.

Existing Evidence of Feasibility

To explore the prevalence of published app-based noncontact EMA research and uncover any evidence relating to the abovementioned effects of age and EMA experience, a literature search of the Scopus database was conducted. The search was conducted in April 2020, using the terms *ecological AND momentary AND assessment AND smartphone.* A total of 404 articles were found, all published from 2011 onward. After removing duplicates and inaccessible or irrelevant articles, 73.3% (296/404) of studies remained. Of the 296 studies, 220 (74.3%) used in-person recruitment or initiation techniques, and the studies described by 47 articles were indeterminable as in-person or noncontact EMA. In total, 29 articles reported noncontact procedures, and all were published since 2015. Of these 29 articles, 3 (10%) were protocol papers and 2 (7%) used SMS text message–based sampling measurements. Therefore, 83% (24/29) of publications described observational app-based noncontact EMA studies, demonstrating that this method has been enjoying minimal (in contrast to in-person EMA) but increasing application in recent years.

A meta-analytic approach was used to determine the characteristics of the 24 studies. The median sample size across the studies was 135 participants (range 17-6675). Among studies which reported mean age and dichotomous male–female gender distribution of the sample, participants tended to be younger (mean 30.9, SD 8.0 years, based on 21 studies) and mostly women (mean 68.7% of the sample, based on 19 studies). The topics of study were smoking [16,17], alcohol consumption [18-22], mental health [23-29], dietary behavior [30-35], drug use [36,37], physical activity [38], and tinnitus management [39].

All studies used noncontact methods of recruitment, initiation, and EMA data collection, although the specific procedures varied across studies. Advertisement was conducted on the web via circulation of study details on social media [28,39] and within Reddit and other web-based communities [27,29], and

offline via mass media [26,28], flyers [30], and networking or word of mouth [18,22,30]. When an existing database of university students was available, email invitations were used to advertise studies and recruit samples [21,35,38]. Recruitment and initiation of participants commonly involved directing participants to a webpage where they could read the study description, provide informed consent, complete baseline measures, and access instructions for downloading and using the EMA app [18,33]. In some studies, written instructions for the EMA phase were supplemented by a telephone call [31] or a prerecorded video demonstration [35], indicating that noncontact initiation is more intensive in some studies than others.

Although the specifics of EMA data collection varied depending on the purpose of the study, all 24 studies required participants to run the app on their own smartphone; some specified that this must be running iOS [19] or Android [24], whereas others allowed both [22]. In most studies, the feasibility of this aspect of the design was unaddressed, although McQuoid et al [37] reported that iOS and Android smartphones collected sensor data at different rates in their EMA study; Schlee et al [39] noted low controllability owing to participants using their own smartphones as a limitation of their study, and Wouters et al [35] concluded that the main cause of participant dropout in their study was related to a technical issue caused by an Android update during data collection. Notably, participant dropout rates were not systematically reported; in 71% (17/24) of the studies, it is implied, but not explicitly stated, that no dropout occurred, whereas some reported dropout rates ranging from 14% to 37% [22,23,32-35,38]. Finally, across the 6 studies that did not exclude participants based on low response rate and reported response rate as a percentage of delivered signal-contingent EMA surveys [18-21,32,39], the mean response rate was 65%.

None of the aforementioned 24 studies directly assessed the feasibility of app-based noncontact EMA in comparison with in-person EMA. To the authors' knowledge, the only study to date to have done so is that of Carr et al [40], which was not published when we conducted the literature search. In their sample of men who have sex with men (N=100; mean age 27 years), participants were enrolled in the study and were initiated either in-person or via a live videoconferencing session. The measured outcomes included response rate, behavioral reactivity, and consistency and reliability of the EMA responses. The in-person and noncontact groups returned similar response rates, similar levels of behavioral reactivity, and equally consistent and reliable EMA responses. This suggests that app-based noncontact EMA is feasible and equivalent to EMA initiated in-person, at least with younger, male participants who are initiated via videoconferencing. The use of videoconferencing by Carr et al [40] to initiate noncontact participants means that their findings may not be generalizable to studies that use written instructions [15-17]. Indeed, videoconferencing might arguably be classified as *in-person* for the purposes of instruction and initiation.

Study Objectives

From the foregoing, it is apparent that much remains unknown regarding the feasibility of app-based noncontact EMA.

Specifically, evidence is lacking regarding the method's feasibility with older adults and with experienced versus naïve EMA participants. Therefore, the research questions are as follows:

1. How does the feasibility of app-based noncontact EMA compare, for participants who have never participated in EMA before versus participants who have previous in-person EMA experience?
2. Does older age have an adverse effect on the feasibility of app-based noncontact EMA?

Given the paucity of previous evidence relating to these questions, this study adopted an exploratory approach rather than testing specific hypotheses.

Methods

Participants and Recruitment

In total, 151 members of our pre-existing participant pool were invited. Recruitment occurred in 2 stages. First, 32.5% (49/151) of people who had participated in an earlier in-person EMA study of listening and daily life fatigue conducted by Burke and Naylor [41] (referred to hereafter as the EMA Fatigue study) were invited. In the study, which ran 12 to 18 months before this study, participants were selected randomly from our participant pool, invited by postal letter, and attended three in-person sessions: an initiation session at baseline, a check-in session midway through the study, and a debriefing and interview session at the end. They used smartphones supplied by the researchers with the EMA app preinstalled (the same app as used in this study) to respond to 6 EMA surveys per day for 2 weeks. In all, 50.3% (76/151) of participants initiated the study, and 44.4% (67/151) completed the study. The participants who initiated but subsequently dropped out of that study were not invited to this study to reduce variation with respect to the level of EMA experience acquired. Of the 67 participants who completed the EMA Fatigue study, 18 (27%) were no longer contactable. Thus, 49 individuals with previous EMA experience of 2 weeks, including in-person initiation, were invited to participate in this study. Of these, 63% (31/49) accepted the invitation and formed the *experienced* EMA group.

Thereafter, an additional sample of 102 participants was invited. They had not participated in the EMA Fatigue study, although 19.6% (20/102) were selected randomly and invited to participate in that study—an overlap that resulted from sampling from the same participant pool for both studies. Recruitment of this *naïve* EMA group was conducted on a rolling basis to recruit a group that was similar in size, age, and gender distribution to the experienced EMA group. Initially, 26 invitations were sent, followed by 30 more, followed by 46 more, at which point the naïve group matched the experienced group to an acceptable extent. Of the 39 who accepted the invitation, all but one reported that they had not previously participated in smartphone-based research; one was unsure.

As the aim of recruitment was to recruit as many *experienced* participants as possible from a finite group of past participants, and subsequently to recruit a similarly sized naïve group, this drove our recruitment approach rather than power analyses,

which would have been redundant. Notably, all members of our participant pool were recruited from the National Health Service Audiology in Glasgow, although not all experience hearing loss; issues of tinnitus, hyperacusis, and balance, for example, are also present within our participant pool. The only inclusion criterion was that participants had to own either an Android or iOS smartphone. Invitees' smartphone ownership status was unknown before recruitment.

Ethical Approval

Ethical approval was received from the West of Scotland Research Ethics Committee (18/WS/0007) and the National Health Service Research and Development (GN18EN094). This study was not preregistered.

Procedure

Data were collected from June to August 2020. Email invitations included a participant information sheet and a link to the web-based consent form and baseline questionnaire set. The participants who provided consent and completed the questionnaires were sent a follow-up email containing *beginning the study* and *finishing the study* instruction guides. These participants were asked to download the EMA app to their smartphone and run our EMA survey sequence, which was launched when participants completed a *start-up* survey. At this point, they received an email confirming their enrollment in the study, start and end dates of the EMA phase, and the date and time to expect a telephone *exit* interview. Participants who provided consent and completed the baseline questionnaire set, but did not run the EMA sequence, were emailed a link to a follow-up web-based survey that asked them why they had failed to complete the study.

The EMA sequence consisted of 7 full days of smartphone surveys. Each day, 5 *daytime* surveys were received randomly between 9 AM and 8 PM, with at least an hour between the surveys. Participants had up to 30 minutes to respond to the daytime surveys before they expired. One *evening* survey was received at 9 PM each night, and participants had up to 3 hours to respond. On the final day of the EMA data collection, participants received a *final* survey at 8:30 PM, instead of an evening survey. This informed participants that they had finished the EMA sequence and advised them to consult the *finishing the study* instruction guide, which instructed them to check their data upload status within the app, upload data if necessary, and uninstall the app. The final survey did not expire, so the response window was unlimited.

Telephone *exit* interviews were conducted with all participants who ran the EMA sequence. Participants were made aware of their invitation email that they would be compensated a fixed amount, a £20 (US $27) Amazon e-voucher, to complete the study. They were not paid on a per-survey basis; therefore, there was no monetary incentive to complete the EMA surveys. Participants who completed the baseline survey, 1-week EMA sequence, and telephone interviews received full compensation. It was decided after the data collection, to compensate participants who only completed the baseline survey with a £10 (US $13.5) Amazon e-voucher.

Materials

The web-based consent forms and baseline questionnaires were created and administered using the JISC Online Surveys [42]. The LifeData EMA platform [43] and its corresponding smartphone app, RealLife Exp [44], were used to create and administer smartphone EMA surveys. All the participants used their own smartphones. A participant information sheet explaining the study in detail, a *beginning the study* instruction guide, explaining how to install and use the app and respond to EMA surveys, and a *finishing the study* instruction guide, containing information about data upload and app uninstallation, were supplied as PDF documents.

Measures

Demographic Information

Invitees' age (years), gender (*male, female, or prefer not to say*), degree of hearing loss (represented as better ear average pure-tone threshold across four frequencies: 500 Hz, 1 kHz, 2 kHz, and 4 kHz), and the number of previous in-person appointments attended at our facility were retrieved from the participant database.

Baseline Questionnaires

In all, 3 questionnaires were administered at baseline and are described further. As the study was conducted during the COVID-19 restrictions, some of the questionnaires were modified to better reflect those circumstances. These questionnaires were not directly related to the research questions being examined in this paper; in this context, they merely serve as a procedural step which is often found in EMA studies, namely acquisition of descriptive variables at baseline. As this is a step at which participants may drop out, its presence is relevant for the current purposes. Its content is not relevant, beyond assessing age associations and whether the naïve and experienced groups were equivalent on the variables collected.

An adapted Hearing Handicap Inventory for Adults/the Elderly [45,46] measured the perceived social and emotional consequences of hearing loss. This comprises 26 items and takes approximately 7 minutes to complete. The social activity log [47] was adapted to measure social activity during the past week and month using 15 items and took approximately 5 minutes to complete. Finally, the 10-item Technology Readiness Index (version 2.0 [TRI 2.0]) [48] measured attitudes toward and adoption of technology in the home. A mean value between 1 and 5 was computed for each participant, with higher values reflecting higher levels of techno-readiness. This questionnaire takes approximately 3 minutes to complete. The TRI 2.0 has been found to be both a valid and reliable measurement tool [48].

EMA Surveys

Start-up Survey

A 1-time start-up survey elicited participants' employment status (collapsed into *full- or part-time employed* or *retired/not working/familial caregiver*) and whether they had participated in smartphone-based research previously (*yes*, *no*, or *unsure*).

XSL•FO

RenderX

Daytime Survey

The daytime survey (occurring 5 times per day) elicited self-reports of the type of location, presence or absence of other people, conversational situation, level of background noise, and length of time spent in the situation.

Evening Survey

The evening survey consisted of 6 questions regarding participation in and avoidance of social activity, conversational engagement, and hearing difficulty during that day.

All EMA surveys logged the make, model, and operating system of the phone used to respond.

Follow-up Survey

Participants who completed the baseline questionnaires, but failed to proceed further, were emailed a short JISC survey exploring the reasons for noncompletion of the study. Prefixed by "I did not download the app because," response options were (1) "I did not receive any instructions to do this," (2) "The instructions looked too complicated," (3) "I tried to download the app but found it too difficult/did not know how," (4) "I did not want to," (5) "I did not have time/I was too busy," (6) "I did not realize this was part of the study," (7) "I do not own a smartphone," (8) "My smartphone would not download the app," (9) "I have not got around to it yet," and (10) "Other". Participants were permitted to select only 1 response option.

Exit Interview

The exit interview explored the acceptability of the set-up process (eg, ease of installing the app and completing the start-up survey), study participation (eg, satisfaction with auditory survey notifications and size of question text), procedure for ending the study (eg, data upload status and uninstallation of the app), and general topics (eg, use and usability of instruction guides and reactions of family and friends). In addition, participants with previous EMA experience were asked if they preferred using their own smartphone, as in this study, or a supplied smartphone, as in the EMA Fatigue study.

Data Analysis

Predictor Variables

There were two primary predictors in this study: previous EMA status and age. Participants were classified as experienced EMA participants if they had taken part in the EMA Fatigue study and as naïve EMA participants if they had not. These classifications were corroborated by participant responses to the question which asked if they had previously taken part in any smartphone-based research. Age (years) was treated as a continuous predictor. Interview responses, specifically the high proportion of Android users reporting issues with survey alerts, prompted the post hoc addition of one secondary predictor: phone operating system (coded as *Android* or *iOS*).

Outcome Variables: Markers of Feasibility

The outcome variables were the markers of the feasibility of the app-based noncontact EMA. These were (1) enrollment rate, represented as the percentage of invitees who enrolled into the study by completing the baseline questionnaire set; (2) completion rate, represented as the percentage of enrollees who ran the EMA sequence for 1 week; (3) reason for noncompletion of the study among enrollees, coded dichotomously as *technical reason* or *personal reason*; and (4) EMA survey response rate, measured as the percentage of delivered signal-contingent (ie, daytime and evening) EMA surveys which were responded to. Interview responses prompted the creation of 1 post hoc outcome variable, that being (5) reported issue with survey alerts (coded as *yes* or *no*). Finally, (6) requested assistance from either the research team or a family member or friend, each coded dichotomously as *yes* or *no*, comprised another marker of feasibility. A final outcome measure that applied only to the experienced EMA group was preference for using personal phone or a supplied phone, coded as *preferred own phone*, *preferred supplied phone*, or *no preference*.

Statistical Techniques

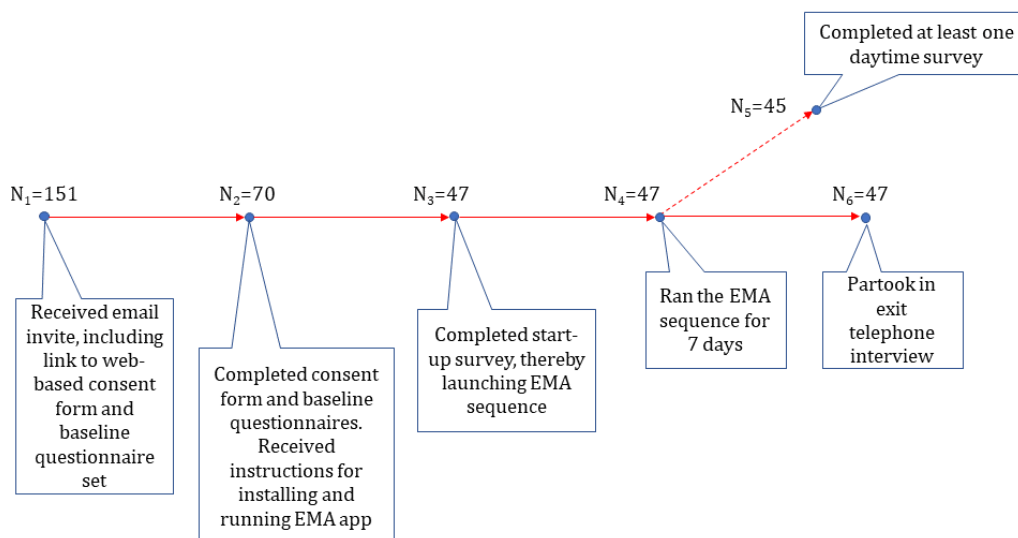
First, the associations between the experience group and baseline factors were examined using independent-samples 2-tailed *t* tests and chi-square tests, and the associations between age and baseline factors were assessed using Pearson correlations and binary logistic regression. For all markers of feasibility, summary statistics (means and SDs for continuous variables and frequencies and percentages for categorical variables) were computed for the experienced and naïve groups, and comparisons were made using independent-samples *t* tests and chi-square tests. The associations between age and all markers of feasibility were examined using Pearson correlations and logistic regression analyses. The phone operating system was assessed as a predictor of marker 4 (response rate), and markers 6a and 6b (requested assistance from the research team and from family or friends, respectively), using independent-samples *t* tests and chi-square tests. Finally, responses regarding smartphone preferences were counted for the EMA group.

Across all analyses, chi-square tests were only conducted when the minimum cell count in each group was 5. The analyses were conducted using the SPSS Statistics (version 25; IBM Corp). The α level was set to .05, for all analyses.

Results

Sequence Completion and Markers of Feasibility

Figure 1 illustrates the flow of participants and the number of participants who reached various stages of the study.

Figure 1. Participation at each stage of the study. EMA: ecological momentary assessment.


Experience Level

Group Characteristics and Differences at Baseline

The baseline characteristics and comparisons between the experienced and naïve EMA groups are presented in Table 1.

The only baseline variable on which the groups differed was the number of previous laboratory appointments attended, with experienced EMA participants having attended more on average.

Table 1. Baseline characteristics and differences by experience group.

Characteristics	Experienced EMA[a] group (n=26)[b]	Naïve EMA group (n=21)[b]	Group comparisons		
			Chi-square (df)	t test (df)	P value
Age (years), mean (SD), range	66.2 (8.6), 45-78	65.1 (8.6), 46-75	N/A[c]	−0.45 (45)	.65
Gender (male), n (%)	12 (46)	8 (38)	0.31 (1)	N/A	.58
Employed, n (%)	6 (23)	7 (33)	0.61(1)	N/A	.44
Degree of hearing loss in dB HL[d], mean (SD)	22.7 (14.2)	22.1 (13.2)	N/A	−0.14 (45)	.89
Hearing aids users, n (%)	9 (35)	9 (43)	0.33 (1)	N/A	.56
Previous laboratory appointments attended, mean (SD)	5.2 (2.0)	3.3 (2.2)	N/A	−3.04 (45)	.004
HHIA/E[e] score (hearing handicap), mean (SD)	32.3 (29.7)	25.0 (17.6)	N/A	−1.04 (39.88)	.30
SAL[f] score (social activity), mean (SD)	1.9 (1.0)	2.0 (0.9)	N/A	0.34 (44)	.74
TRI[g] 2.0 score (techno-readiness), mean (SD)	3.3 (0.7)	3.2 (0.7)	N/A	−0.14 (44)	.89
Android users, n (%)	15 (58)	12 (57)	0 (1)	N/A	.97

Effect of Previous EMA Experience on Markers of Feasibility

As shown in Table 2, the enrollment rate (marker 1) was almost twice as high in the experienced EMA group compared with the naïve EMA group (χ^2_1=8.3; P=.004). Similarly, the completion rate (marker 2) was significantly higher among experienced enrollees compared with their naïve counterparts (χ^2_1=7.1; P=.008). In the experienced group, 60% (3/5) of the participants who enrolled in the study but did not complete it, provided a reason why (marker 3, the only marker not displayed in Table 2); 67% (2/3) cited technical difficulties and 33% (1/3) reported a personal reason. In the naïve EMA group, 44% (8/18) provided a reason why; 25% (2/8) cited technical difficulties and 75% (6/8) cited personal reasons. There were too few responses in each group to analyze group-wise differences in this outcome variable.

Table 2. Markers of feasibility in the overall sample, experienced ecological momentary assessment (EMA) group, and naïve EMA group.

Characteristics	Overall[a]	Experienced[b]	Naïve[c]
N_1 (participants receiving study invitation)	151	49	102
N_2 (participants initiating study)	70	31	39
Marker 1: enrollment rate among invitees (%; N_2/N_1)	46.4	63	38.2
N_3 (participants launching EMA sequence)	47	26	21
N_4 (participants running the 7-day EMA sequence)	47	26	21
Marker 2: completion rate among enrollees (%; N_4/N_2)	67.1	84	53.8
N_5 (participants completing at least one daytime EMA survey)	45	25	20
N_6 (partook in exit interview)	47	26	21
Marker 4: signal-contingent survey response rate (%), mean (SD)	61.4 (30.1)	65.4 (30.7)	56.3 (29.3)
Marker 5: reported survey alert issue (n, yes)	16	7	9
Marker 6a: requested assistance from researcher (n, yes)	3	2	1
Marker 6b: requested assistance from family or friends (n, yes)	6	2	4

[a]Overall sample.

[b]Experienced EMA group.

[c]Naïve EMA group.

The response rate on signal-contingent (ie, daytime and evening) EMA surveys (marker 4) ranged from 0% to 100% in the experienced EMA group and from 0% to 90.9% in the naïve EMA group. The response rate (as shown in Table 2) was not significantly different among the groups (t_{45}=−1.04; P=.31). One participant in each group did not respond to any signal-contingent survey; both reported that they had not been alerted to the incoming surveys. In total, 16 participants reported not being alerted to surveys either some or all the time, as shown in Table 2. There was no effect of previous EMA experience on the likelihood of reporting this issue (χ^2_1=0.0; P=.93). Compared with those who did not report any issue with alerts (marker 5; mean 65.9%, SD 25.6%), those who had attained a lower average response rate (mean 47.7%, SD 34.7%; t_{45}=2.04; P=.047).

In all, 3 participants contacted the researcher for help during the study (marker 6a), all in relation to survey alerts not working, and 6 participants reported asking for help from a family member or friend with some technical aspects of the study (marker 6b). There was too little variation in the responses to assess the effect of past experience on these outcomes.

Age

Relationship of Age to Baseline Variables

Unsurprisingly, older age was related to a greater likelihood of being retired (Wald χ^2_1=10.0; P=.002), more severe hearing loss (r=0.31; P<.001), and a greater likelihood of being a hearing aid user (Wald χ^2_1=5.4; P=.02). Age was also related to gender (Wald χ^2_1=4.5; P=.04), such that older participants were more likely to be men. No association was found between age and the number of previous laboratory appointments attended (r=0.29; P=.05), hearing handicap (r=−0.10; P=.50), social activity (r=0.06; P=.67), techno-readiness (r=0.04; P=.79), or the likelihood of being an Android (vs iPhone) user (Wald χ^2_1=0.0; P=.90).

Effect of Age on Markers of Feasibility

Age was unrelated to both enrollment rate (marker 1; Wald χ^2_1=0.7; P=.39) and completion rate (marker 2; Wald χ^2_1=0; P=.99). The effect of age on the reason for noncompletion (marker 3) was not assessed, as too few responses were obtained. Age was unrelated to response rate (marker 4; r=0.19; P=.21), but older participants were more likely to report not being alerted to surveys (marker 5; Wald χ^2_1=7.0; P=.008). The effect

XSL•FO

RenderX

of age on the likelihood of requesting assistance (markers 6a and 6b) was not examined because of the homogeneity of responses.

Phone Operating System

The phone operating system was related to response rate (marker 4); in comparison with Android users, participants using iOS returned a higher response rate (mean 74.8%, SD 20.3% vs mean 48.5%, SD 31.4%; $t_{45}=-3.28$; $P=.002$). Among iOS users, 25% (5/20) reported not being alerted to surveys (marker 5) compared with 41% (11/27) of Android users; however, this difference was not statistically significant ($\chi^2_1=1.3$; $P=.26$). All 3 participants who sought assistance from the research team (marker 6a) were Android users. Of the 6 who reported asking a family member or friend for help (marker 6b), 4 (67%) were Android users and 2 (33%) were iOS users. The effect of the phone operating system on markers 6a and 6b was not assessed because of the lack of variability of responses on these outcomes.

Although both older age and using an Android operating system were related to reporting issues with survey alerts, the mean age of Android users in this study (mean 65.9, SD 7.9 years) was not significantly different from that of iOS users (mean 65.6, SD 9.4 years; $t_{45}=0.12$; $P=.91$).

Experience of Using Personal Versus Supplied Smartphone

The 26 experienced EMA participants who completed the study were asked if they preferred using their own smartphone, as in this study, or using a supplied smartphone, as in the EMA Fatigue study. Of these 26 participants, 22 (85%) preferred using their own phone, whereas 4 (15%) preferred using the supplied research phone and/or preferred the face-to-face method in general.

Discussion

Principal Findings

This study aimed to assess the feasibility of noncontact EMA. To the authors' knowledge, this is only the second study to do so, after Carr et al [40], and is the first to examine the effects of previous EMA experience, age, and phone operating system on the feasibility of this method. Although the findings suggest that previous in-person EMA experience, younger age, and iOS use may be advantageous, the observed effects were specific to certain markers of feasibility and not systematic across all possible indicators. It is therefore suggested that app-based noncontact EMA is feasible to run with naïve and older EMA participants.

Perhaps the most compelling finding from this study is that naïve participants were less likely to enroll in and complete the study than their experienced counterparts. However, confounding effects could not be ruled out. Specifically, experienced EMA participants had previously attended more in-person laboratory appointments than naïve participants, which may indicate a stronger degree of existing relationship with the researcher or greater willingness to participate in research,

among these participants. Future research would benefit from the measurement and tight control of these factors. The observed higher rate of attrition among naïve participants between the baseline survey and EMA phase is concerning. This may indicate technological difficulties in downloading the app or a lack of understanding of the study demands. A low response to the follow-up survey among dropouts means that little information has been gathered regarding the reasons for attrition; therefore, the feasibility of app-based noncontact EMA in this respect remains unclear. Notably, age was unrelated to both enrollment and completion rates, suggesting that the feasibility of this method is not sensitive to age (within the range studied here; 45-78 years).

Turning to the responses to individual survey alerts, it is notable that the response rate was unrelated to both previous EMA experience and age. At 61.4%, the response rate in this study corresponds closely to the 65% mean of response rates across other noncontact EMA studies [18-21,32,39]. We may have expected a higher response rate, given that this study was conducted at a time when many people were confined to their homes and unable to work, travel, or attend social gatherings owing to the COVID-19 pandemic. Hence, some of the main reasons for nonresponse to EMA surveys, including being in a noisy environment and not hearing the alert, or being in a social situation where it would be inappropriate to respond [41,49], were less likely to occur. However, our participants were not paid per EMA survey completion, as in some other EMA studies [27,29], and it is also possible that participants' motivation to respond about their social interactions was reduced when social activity was restricted. Overall, this study yielded acceptable response rates.

Finally, a sizable number of participants reported that they were not alerted to some or all EMA survey alerts, and their response rates were unsurprisingly lower than those returned by unaffected participants. Whether participants truly experienced a technical issue, or were just unaware of alerts, cannot be determined by the data. However, older participants were disproportionately affected by this issue. These findings undermine the feasibility of app-based noncontact EMA and suggest that supplying participants with a preprogramed smartphone (which would typically involve an in-person initiation session) yields better results in terms of data quantity. However, participants in this study who had experience using both their own smartphone and a supplied research smartphone for EMA overwhelmingly preferred using their own. Future app-based EMA research (both in-person and noncontact) should consider giving participants the option to use either their own smartphone or a supplied smartphone where possible [50], and the chosen app should be tested extensively with different phone makes, models, and operating systems.

Limitations

In addition to caveats mentioned above with respect to specific results, there are several more wide-ranging factors which may limit the reliability and generalizability of this study's results.

First, all participants had working email accounts, possibly indicating some level of technological competence. In support of this, the mean TRI 2.0 score obtained by this sample was

slightly higher than that reported by the Parasuraman and Colby [48] representative sample of US-based adults, reported in the paper in which they introduced the TRI 2.0 (3.33 units vs 3.0 units on a 1-5 Likert scale). Moreover, all participants were recruited from our participant pool, meaning that they had attended at least one in-person appointment at our facility and therefore had some degree of existing relationship with the researchers. This is also a strength of the study, as it indicates some level of homogeneity of participant background, all having come from Glasgow National Health Service Audiology. However, these factors limit the generalizability of our findings. In addition, in the experienced group, the decision not to invite participants who had dropped out of the EMA Fatigue study to recruit a genuinely *experienced* EMA group in this study may have led to the recruitment of an unrepresentatively motivated or conscientious group.

Limited variation and lack of data pertaining to some of the markers of feasibility in this study suggest that they are not useful outcomes. Furthermore, despite attempts to explore the reasons for noncompletion of the study by sending a follow-up survey to the dropouts, only few participants responded. Even less is known about why individuals declined to participate in this study in the first place. Crucially, the smartphone ownership status of this group is not known, a key factor in terms of feasibility.

Finally, our method was noncontact insofar as participants did not attend in-person laboratory sessions; however, they did receive detailed instructions to guide them through the study and were contacted several times by email during recruitment, initiation, and enrollment, as detailed in the *Procedure* section. Consequently, the findings are most relevant to physical noncontact, but nonetheless interactive, EMA research.

Conclusions

This study assessed the feasibility of app-based noncontact EMA as a function of past EMA experience and age. Experienced EMA participants were more likely to enroll in and complete the study than naïve participants, whereas age was unrelated to both enrollment and completion rates. The response rate was acceptable and unrelated to both experience and age, but Android users returned markedly lower response rates than iOS users. Although a sizable number of (mostly older) participants reported in exit interviews that they were not always alerted to surveys, very few informed or sought assistance from the researchers during data collection. In summary, app-based noncontact EMA is feasible, although consideration should be given to how to increase enrollment and completion rates, especially when recruiting participants who are new to EMA.

Abstract

Background: Despite routine review of medication lists during patient encounters, patients' medication lists are often incomplete and not reflective of actual medication use. Contributing to this situation is the challenge of reconciling medication information from existing health records, along with external locations (eg, pharmacies, other provider/hospital records, and care facilities) and patient-reported use. Advances in the interoperability and digital collection of information provides a foundation for integration of these once disparate information sources.

Objective: We aim to evaluate the effectiveness of and satisfaction with an electronic health record (EHR)-integrated web-based medication reconciliation application, MedTrue (MT).

Methods: We conducted a cluster-randomized controlled trial of MT in 6 primary care clinics within an integrated health care delivery system. Our primary outcome was medication list accuracy, as determined by a pharmacist-collected best-possible medication history (BPMH). Patient and staff perspectives were evaluated through surveys and semistructured interviews.

Results: Overall, 224 patients were recruited and underwent a BPMH with the pharmacist (n=118 [52.7%] usual care [UC], n=106 [47.3%] MT). For our primary outcome of medication list accuracy, 8 (7.5%) patients in the MT arm and 9 (7.6%) in the UC arm had 0 discrepancies (odds ratio=1.01, 95% CI 0.38-2.72, P=.98). The most common discrepancy identified was patients reporting no longer taking a medication (UC mean 2.48 vs MT mean 2.58, P=.21). Patients found MT easy to use and on average would highly recommend MT (average net promoter score=8/10). Staff found MT beneficial but difficult to implement.

Conclusions: The use of a web-based application integrated into the EHR which combines EHR, patient-reported data, and pharmacy-dispensed data did not improve medication list accuracy among a population of primary care patients compared to UC but was well received by patients. Future studies should address the limitations of the current application and assess whether improved implementation strategies would impact the effectiveness of the application.

Introduction

Background

Nearly 50% of Americans are on at least 1 prescription medication [1]. Among Medicare patients, these prescriptions are prescribed on average by 7 different physicians [2]. This does not include nonprescription medications, such as over-the-counter medications, herbal medications, vitamins, and other supplements. The prescribing of medications from multiple providers and the prevalence of nonprescription medication use contribute to inaccurate medication lists. Inaccurate medication lists can lead to adverse consequences, including hospitalization and death [3]. This well-recognized problem has been the subject of initiatives from a variety of organizations [4-7] and is designated a National Patient Safety Goal by the Joint Commission [6].

Medication reconciliation has been recognized as problematic across a variety of health care settings, including primary care. Studies in primary care have found that the rate of discrepancies is high [8-10]. For example, we conducted a study within our primary care environment and identified that when asked, 369 (89.1%) of 414 patients requested a change to their medication list in the electronic health record (EHR) and, on average, patients noted 2.4 discrepancies on their medication lists [8]. At the time of this finding, there were few published tools to facilitate medication reconciliation in primary care and those that did had limitations. For example, a tool developed by Schnipper et al [11] was designed to be used after hospital discharge and compared the discharge medication list to the preadmission list held by the ambulatory care site. This tool was limited in that it was not applicable to all primary care patients and did not facilitate the collection of patient-reported medication use. Conversely, a tool by Lesselroth et al [12] collected medication information from patients using a kiosk; however, this technology was limited to Veterans Affairs facilities and may have missed medications not prescribed outside of those facilities.

To address the limitations of existing tools and improve medication reconciliation within our primary care environment, we developed an EHR-integrated web-based reconciliation application, MedTrue (MT), to facilitate the process of reconciling EHR medication lists with other sources, including patient-reported medications within a primary care environment. We designed this tool to have both staff- and patient-facing interfaces.

Objectives

The goal of this paper is to present the results of an evaluation study aimed at assessing the impact of the application MT on medication list accuracy and patient and staff satisfaction. Using mixed methods, we aimed to evaluate the effectiveness of and satisfaction with MT.

Methods

Study Design

We conducted a mixed methods evaluation of MT, including a pragmatic cluster-randomized controlled trial (cRCT), along with patient and provider surveys and semistructured interviews. This study was approved by the Geisinger Institutional Review Board (2018-0174). Patient use of MT was considered not research as this technology was planned to become part of usual care (UC); however, the evaluative components were considered research.

Setting

The trial was conducted at 6 primary care sites, with an even distribution of rural and urban clinics, within a large integrated health care delivery system. Within our system, there are over 40 primary care sites eligible to participate. The specific sites included were chosen collaboratively with input from primary care and clinic site leadership. Leadership was consulted to ensure alignment with ongoing initiatives and recommended sites based on their capacity to participate in the study (eg, adequate staffing). The included clinics had an average staff size (nurses/physicians/physician assistants) of 10. In the sites, nurses or medical assistants would bring the patient to the room, conduct a medication history and reconciliation, and perform a variety of other tasks to prepare the patient for a visit with their clinician. The clinician would then verify and approve any changes to the patient's medication list. All sites used the same EHR, EpicCare® version 2018 (Madison, WI, USA).

Population

Patients were eligible to participate if they were 18 years of age or older, able to speak English, and seen at a participating site by a member of the primary care team.

Intervention

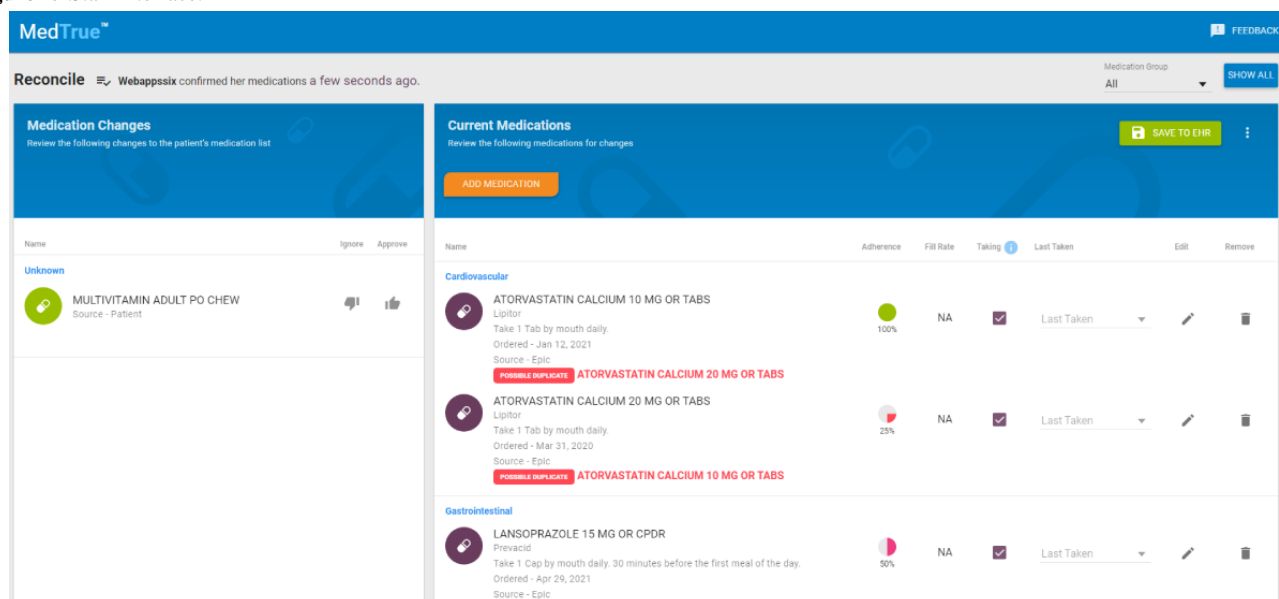
MT is a real-time web-based application that integrates information from the EHR, patients, and pharmacy-dispensed data into a common database that is viewable to patients through an online portal and in-clinic tablets and to clinicians through an EHR interface. The application was developed using an iterative design process. First, meetings were held with key stakeholders (eg, informatics, clinic staff, and pharmacy) to determine the necessary functionalities of the tool. Based on these initial requirements, we created a minimally viable prototype. We then iteratively improved upon this prototype by implementing it in 2 sites not involved in the later evaluation. These sites would use the tool and provide feedback to the study team. Additionally, study team members would observe the use of the tool in those sites to gather additional insight into how the tool was performing and what adjustments needed to be made. From the feedback received, we created a list of potential improvements, which was prioritized based on necessity and feasibility. The tool tested in this study is the result of several rounds of improvements.

The patient interface presents the patient with their active medication list that is located in the EHR, as well as pharmacy-dispensed data available as an additional function

within the EHR (Figure 1). The patient is asked to review their list of medications, remove medications they are not currently taking, and enter additional medications missing from the list, such as medications purchased over the counter or medications they take that belong to a friend or family member. Additionally, patients are asked about their adherence to their medications over the past month using a Likert-type scale (ranging from 0% for "never" to 100% for "always"). This type of scale is similar to other validated scales for adherence [13,14]. Patients with an upcoming visit at 1 of the intervention sites had access to MT through our online patient portal up to 2 weeks prior to their visit. If the patient did not complete MT through the patient portal prior to their visit, they were provided with a tablet computer (iPad®) by patient access representatives upon check-in and were asked to complete MT while waiting for their appointment. Patients were not given any training in the use of the tool, since during prototyping, we found that most patients were able to navigate the tool without assistance. Approximately a third of the patients accessed MT using the online portal, while the remainder used iPads.

Figure 1. Patient interface.

MT was available to staff through a direct link (access tab) within the EHR as a web-based application. During the intake process and normal workflow of rooming a patient, staff (ie, nurses and medical assistants) accessed MT when assessing medication use. The interface was presented in an embedded browser within the EHR. For the staff interface, MT displayed all the medications the patient was presented with as well as those the patient entered (Figure 2). Discrepancies (ie, patient-suggested removals and additions or pharmacy-dispensed differences) were displayed alongside the EHR-listed medications that were not flagged as discrepant. For each medication adherence, calculated as the proportion of days covered from pharmacy-dispensed data [15], patient-reported medication adherence, captured from the patient-completed Likert-type item, was also displayed. Staff were instructed to conduct their medication history normally and use MT to confirm or change medications. All changes made within MT were "pushed" to the EHR upon clicking the "Save to EHR" button in MT. Staff at the intervention sites had access to paper and audiovisual training materials but also attended an in-person meeting where MT was introduced and reviewed by members of the study team. Study team members were available for consultation and guidance throughout the study.

Figure 2. Staff interface.


Usual Care

UC providers accessed the EHR-based medication profile that included the standard EHR list of active and discontinued/cancelled medications, along with a separate tab of medications collected through a feed of pharmacy-dispensed data. Patient-reported discrepancies (additions, changes, etc) were also available if the patient completed a previsit questionnaire through the online patient portal (approximately a third of patients have portal accessibility). Standard medication list patient information collected was similar to the MT intervention but did not include self-reported adherence. Hence, UC clinics also had a degree of patient and pharmacy-dispensed information available to clinicians, along with EHR lists, although this information was not available for all patients and information in the EHR was not available within 1 tab. The EHR system used in both UC and MT clinics was EpicCare® version 2018.

Data Collection

Best-Possible Medication History

Trained pharmacists approached a convenience sample of patients exposed to MT as well as a convenience sample of patients in the UC arm to collect a best-possible medication history (BPMH); feasibility considerations informed our decision to use convenience sampling. All pharmacists were licensed and had experience conducting medication histories. Prior to enrolling patients, pharmacists underwent brief training by study staff reviewing components of a BPMH and a clinical interview guide complete with prompts (Multimedia Appendix 1). This guide was based on the literature related to conducting a BPMH [7,16,17]. Pharmacists identified patients via a custom web-based dashboard listing patients with a documented launch of MT by a clinician (MT arm only) or arrival to an eligible visit for UC. Patients completing an encounter in UC were assumed to have EHR-based medication reconciliation due to routine workflow completion of medication reconciliation in all primary care encounters. Pharmacists were blinded to clinic site use of MT, as dashboards only supplied names, not information about MT use. Only study personnel and clinic staff were aware of study group assignment. Pharmacists approached eligible patients after their visit and asked whether they would be interested in participating in a study. If a patient was agreeable, the pharmacist brought them to a private room for consent and to conduct the BPMH.

Pharmacists documented discrepancies for each medication on the postvisit EHR active medication list and also for any medication not present on the medication list. Each medication was coded with only 1 type of medication discrepancy, which fell into 1 of 4 domains. The first was patient acknowledgement of taking the medication differently than prescribed (eg, allergy medication is prescribed daily, but the patient takes it seasonally). Second was removal of a medication on the medication list. The third domain was a modification to the formulation, strength, dose, frequency, route of medication, or timing of administration. The final discrepancy was adding a medication to a profile that was not on the EHR medication list. Since taking a medication differently than prescribed would not automatically infer an inaccurate medication or description of the medication on the medication profile (eg, the patient reported missing a weekend dose of a medication due to forgetfulness), we did not include this in our composite discrepancy endpoint (see later) but did report on this individually. In addition, after each BPMH, pharmacists provided feedback on their confidence that the list they gathered from the patient was accurate using a 3-point scale (not confident, somewhat confident, and confident).

Following the final BPMH collection, study investigators reviewed the reconciled lists of medications in a blinded manner to ensure consistent coding of discrepancies. Inconsistencies were flagged and recoded for final analysis.

Consent, the BPMH, and pharmacist questions were documented using REDCap (Vanderbilt University, Nashville, TN, USA) [18,19]. The interviews took up to an hour, and patients were compensated US $10 for their time in the form of a gift card.

Surveys

All patients exposed to MT were given an opportunity to complete a survey on the usability of and satisfaction with using MT. The survey was presented to the patient following MT completion. Responses were collected within MT.

Staff participating in the intervention arm of the study were also given a survey on the usability of and satisfaction with using MT near the end of the study. Staff were contacted by email and invited to participate in the survey, with up to 2 reminder emails sent at weekly intervals. Surveys were collected using Microsoft Forms (Microsoft Corporation, Redmond, WA, USA).

Interviews

The interviews were guided by a qualitative descriptive approach [20]. Patients in the intervention arm were invited to participate in interviews about their experience using MT through convenience sampling. After a visit where MT was used, patients were approached by a research assistant, who invited them to participate in a brief interview. Consenting patients were interviewed using a semistructured interview guide (Multimedia Appendix 1). The research assistant underwent brief training in qualitative interviewing from 1 of the investigators with experience in qualitative interviewing. The interviews lasted no more than 30 minutes, and patients were compensated US $10 for their time in the form of a gift card.

Rooming staff who used MT during the study period were also given an opportunity to voluntarily participate in semistructured interviews to discuss their experience using MT. The interviews were conducted by an investigator with experience in qualitative interviewing using a semistructured interview guide (Multimedia Appendix 1). The interviews lasted no more than 30 minutes, and staff were not offered compensation.

Primary Outcome

The primary outcome of the study was the accuracy of the medication list. We defined accuracy by counting discrepancies between the medication list gathered through MT or UC and the list gathered by the pharmacist conducting the BPMH. A perfectly accurate medication list would be a list with 0 identified discrepancies.

Secondary Outcomes

We secondarily measured accuracy using a composite numerical assessment of accuracy, where each medication in a list could contribute either 0 or 1 discrepancy, and all discrepancies were totaled per patient. This endpoint included all of the following medication discrepancies: not taking the listed medication, needing the medication to be modified (eg, change in dose or frequency), or having the medication added to their list. Although taking a medication differently was included in our list of discrepancies, this was not included in the composite accuracy list, since this discrepancy would in of itself not necessitate a change in the actual prescription as written, and if the list needed to be modified by the BPMH, 1 of the other listed discrepancies would have been selected over this discrepancy, as per BPMH instructions. We reported individual types of discrepancies identified per group (ie, adding, modifying, removing, or taking a medication differently) on a

medication level. To determine the rate of medication discrepancies per patient, we calculated the percentage of the patients' medications that had discrepancies. Finally, we conducted a sensitivity analysis based on the pharmacists' confidence in their BPMH, including only those patients where the pharmacist conducting the BPMH was confident in having an accurate medication list. Patient and staff satisfaction with MT, as measured by surveys and qualitative interviews, was also reported.

Sample Size

Assuming a 1% intracluster correlation coefficient and a 19% difference in accuracy rates, our target sample size was 300 patients (n=150 [50%] intervention, n=150 [50%] control; each of the 6 sites was expected to enroll 50 [16.7%] participants) to achieve 80% power. During data collection, we conducted an interim look to verify our sample size assumptions and found that our initial assumptions regarding the proportion of completely accurate medication lists (no discrepancies), which were based upon previous studies [21-23], were overly optimistic (~50% in previous studies vs 4% in our interim analysis). As a result, we were underpowered to detect our primary outcome; however, we were powered to detect a secondary composite outcome based on a count of discrepancies. Later, due to feasibility, namely difficulties in recruitment, the trial was stopped.

Randomization

In total, 6 sites were chosen in collaboration with primary care leadership and randomized to the intervention or the control arm using a random number generator in Microsoft Excel (Microsoft Corporation). Prior to recruitment, due to unforeseen challenges, 1 UC site was substituted for a different clinic with similar baseline characteristics.

Blinding

Neither patients nor clinicians were blinded due to the nature of the intervention; however, there were steps taken to blind the pharmacists conducting the BPMH (as described in the Data Collection section). During the analysis, the statistician was blinded as to which arm was intervention and which was control.

Analysis

Qualitative Analysis

Interviews were transcribed verbatim and analyzed thematically [24]. Patient and staff interviews were separately analyzed. The transcripts were independently read by 2 study team members, who collaboratively developed 2 codebooks (1 for patients and 1 for staff). The transcripts were independently coded by 2 study team members using the appropriate codebook. Discrepancies in coding were discussed and resolved by consensus. The codes were then grouped into themes, which were refined based on discussion.

Statistical Analysis

To understand the representativeness of our sample, we compared the demographics of patients seen at the clinics during the intervention period to those who received a BPMH. We described continuous variables using means and SDs as well as

medians and IQRs. Categorical variables were described using frequencies and percentages. Wilcoxon rank-sum tests were used to compare the differences between 2 groups for skewed continuous outcomes; chi-square tests were used to evaluate the independence of categorical outcomes between MT and UC, where odds ratios (ORs) were presented. A mixed effects model with Poisson regression was performed to model the impact of MT on count data (number of medication discrepancies) after adjusting for age, sex, and Charlson comorbidity index, with the total number of medications as the offset variable. Incidence rate ratios (IRRs) and 95% CIs were estimated from Poisson regression models. Sensitivity analyses were performed with or without considering cluster-level covariates for cRCTs. $P < .05$ was considered statistically significant. Statistical analyses were performed using RStudio version 1.2.1335 (RStudio, PBC, Boston, MA, USA) [25].

Additionally, we conducted sensitivity analyses including only those patients for whom the pharmacist rated that they were confident in the history they gathered from the patients; histories where the pharmacist was either somewhat confident or not confident were excluded.

Results

Patient Characteristics

MT was implemented in 3 clinics from July 10, 2018, through August 1, 2019. Over this time frame, MT was accessed 10,835 times by 7342 distinct patients. The majority of access (6501/10,835, 60%) was by tablet computer. Of the 7342 patients using MT, 4005 (54.55%) removed at least 1 medication (mean 3.6 medications removed), 606 (8.25%) added at least 1 medication (mean 1.6 medications added), and 6061 (82.55%) completed the adherence questions. Staff accessed MT for 8443 distinct patients (staff could access MT even if patients did not), removed at least 1 medication for 3544 (41.98%) patients (mean 2.1 medications removed) and added at least 1 medication for 1643 (19.46%) patients (mean 3.3 medications added).

Clinics allocated to MT and UC had similar baseline characteristics, although patients at MT clinics were slightly younger in age (46 vs 48 years), had fewer African Americans (n=871 [3%] vs n=1255 [5%]), less depression (n=1441 [5%] vs n=1490 [6%]), and took more medications (7.75 vs 6.53 medications per patient); see Table 1.

Overall, 224 patients were recruited and underwent a BPMH with the pharmacist (n=106 [47.3%] MT, n=118 [52.7%] UC). The samples of patients who underwent a BPMH were older; were more likely to be female; had depression, dementia, or mild cognitive impairment; were more likely to be married; and had more medications than the baseline clinic population (similar between groups).

Primary Outcome

For our primary outcome of medication list accuracy (defined as 0 discrepancies), we did not detect a statistically significant difference between MT and UC (OR=1.01, 95% CI 0.38-2.70, P=.98). Pharmacists completing the BPMH reported being confident in the medication history for 200 (89.2%) of 224 patients (91 [85.8%] MT, 109 [92.4%] UC). The primary outcome remained the same upon conducting a sensitivity analysis limited to those BPMHs in which the pharmacist was confident (OR=1.08, 95% CI 0.39-3.02, P=.88).

Secondary Outcomes

The composite secondary outcome of total medication discrepancies, defined as the sum of additions, medications the patient was not taking, and medications that were modified summed per patient, was comparable between MT and UC arms (MT median=4, IQR 2-7 vs UC median=3, IQR 2-6; P=.15). The most common discrepancy was medication the patients' reported not taking, with a median of 2 (IQR 1-3) identified per patient in the UC arm and 1 (IQR 1-3) per patient identified in the MT arm.

The composite outcome was consistent upon sensitivity analysis limited to those patients where a pharmacist was confident in their BPMH (MT median=3, IQR 2-5 vs UC median=4, IQR 2-7; P=.10).

A Poisson regression model indicated that the MT and UC arms were comparable regarding the rate of discrepancies (IRR=1.22, 95% CI 0.97-1.55, P=.09). The rate of discrepancies was significantly affected by age (IRR=1.01, 95% CI 1.00-1.01, P=.03), male sex (IRR=0.81, 95% CI 0.71-0.93, P=.003), and Charlson comorbidity index (IRR=0.95, 95% CI 0.92-0.98, P=.001). Sensitivity analyses with or without considering cluster-level covariates confirmed the robustness of findings of the Poisson regression model (data not shown).

In addition to the composite, we assessed accuracy as the proportion of medications that were discrepant. The proportion of discrepant medications was not significantly affected by MT compared to UC (MT median=40%, IQR 23%-54% vs UC median=34%, IQR 21%-59%; P=.87); this finding was similar on sensitivity analysis (MT median=40%, IQR 22%-55% vs UC median=33%, IQR 21%-56%; P=.66). Further accuracy data can be found in Tables 2-4.

Usability and Satisfaction

Of the 7342 patients who accessed MT, 1450 (19.75% response rate) completed the survey. Patients were satisfied with MT, giving it an average rating of 8 out of 10 for their likelihood to recommend to a friend or family member (Table 5).

Additionally, 1276 (88%) of 1450 patients agreed or strongly agreed that it was easy to use, and 1233 (85%) agreed or strongly agreed that it helped them create a more accurate medication list (Table 6).

Table 5. Patient net promoter score (N=1450).

Patient survey question	Score (1-10)										Mean (SD)
	1, n (%)	2, n (%)	3, n (%)	4, n (%)	5, n (%)	6, n (%)	7, n (%)	8, n (%)	9, n (%)	10, n (%)	
On a scale of 1 (low) to 10 (high), what is the likelihood you would recommend MT[a] to a friend or family member?	41 (2.8)	15 (1)	15 (1)	18 (1.2)	155 (10.7)	112 (7.7)	149 (10.3)	222 (15.3)	156 (10.8)	567 (39.1)	7.95 (2.29)

[a]MT: MedTrue.

Table 6. Patient survey data (N=1450).

Patient survey	Strongly agree, n (%)	Agree, n (%)	Neutral, n (%)	Disagree, n (%)	Strongly disagree, n (%)
I would use MT[a] in the future.	643 (44.3)	568 (39.2)	169 (11.7)	24 (1.7)	46 (3.2)
MT helped me create an accurate medication list.	641 (44.2)	596 (41.1)	124 (8.6)	44 (3.03)	45 (3.1)
MT is easy to use.	724 (49.9)	559 (38.6)	103 (7.1)	17 (1.2)	47 (3.2)
MT reminded me to include all my medications, including those my doctor prescribes and those I purchase over the counter.	721 (49.7)	592 (40.8)	77 (5.3)	21 (1.4)	39 (2.7)

[a]MT: MedTrue.

These findings were echoed in the patients' qualitative interviews and were consistent across sites. Of the 7342 patients who used MT, 14 (0.2%) participated in interviews (1 spouse was also present for 1 of the interviews). Overall, participants had a positive experience with MT. Most found it easy to use and were able to complete the application quickly. The ability to visually see their list of medications rather than be asked about them was noted as an important feature. Seeing the medication names helped patients recognize the medications because they are used to seeing them in print on their medication packaging. Some patients felt it was more efficient than the normal workflow, whereas others disagreed and felt it was creating unnecessary work for them. The patients also noted

that having the indication for the medication would help with recognition and recall. Example quotes from patients illustrating these themes can be found in Table 7.

Of the 22 rooming staff members who accessed MT, 18 (82% response rate) completed the survey. Staff were unsatisfied with MT, giving it an average rating of 0 out of 10 (Table 8).

All staff members disagreed or strongly disagreed that they were satisfied with MT and noted that it did not fit well in their workflow (Table 9).

Interviews provided a more nuanced perspective from staff, with themes and example quotes in Table 10.

Table 7. Patient feedback on MTM[a] (N=14).

MT characteristic	Example quote
Usability	• *. . . It's that simple. I mean, I think somebody from 9 to 90 can use it. I really, I really do, because it's . . . there's nothing confusing about it. It was, and most things are to me, but it truly wasn't. It was quicker than I thought it would be. I thought we'd be there for a while answering questions after. But it wasn't; it was simple.* [Patient T12]
Benefits	• *I think it did help. Because normally, checking in, they would ask what I'm currently taking. This also showed what I was taking 4 months ago but I'm not now. That wouldn't have even crossed my mind if it wasn't right in front of me. I would have never thought to say, "Oh, I'm no longer taking the clobetasol. Oh, I'm not on prednisone anymore." But because it was right in front of me, I thought, oh yeah, I can remove that. I can remove that. I found that to be helpful.* [Patient T13] • *I thought it was easy, and I like that I can delete things off of there if I want. Because I've been asking for 1 medication to be taken off and it hadn't, so I was able to do that.* [Patient P7] • *It's just time-saving. I mean, you're going to sit there and wait for the doctor anyway, so you might as well get it done. And then, it makes it quicker once you're back in the room. You have control over what's in your chart—which I feel like, sometimes, you don't, and, you know, you go to another doctor, and they're like, "Oh, I see you're taking this." And it's like, I haven't taken that in a million years, you know?* [Patient P7]
Necessity	• *. . . It's just an extra thing to do on our part, and I really wonder if it's really necessary to get that information.* [Patient T9]
Suggestions	• *On the meds, the listings of the meds, you'd had both the marketing name and you have the commonly known. The other thing, if you could do it simple, after that say, you know, blood thinner or cholesterol drug for the average person. That's what they think about it. "Oh, that's my blood pressure med. That's my cholesterol med." Because if not, they look at it, you know, hydrochlorothiazide. They're like, "I don't know what that is."* [Patient T8]

I am satisfied with MT[a].	—[b]	—	—	4 (22)	14 (78)
I want to use MT in the future.	—	—	—	3 (17)	15 (83)
I would want to use MT at every visit with every patient.	—	—	—	3 (17)	15 (83)
MT helped me conduct medication reconciliation with my patients.	—	—	—	6 (33)	12 (67)
MT is compatible with my clinic flow.	—	—	—	3 (17)	15 (83)
MT is easy to use.	—	1 (6)	—	3 (17)	14 (78)

[a]MT: MedTrue.

[b]Not applicable.

Table 10. Staff feedback on MT[a] (N=11).

MT characteristic	Example quote
Usability	• *Yeah, like overall, if it wasn't so slow and it didn't refresh after every time you clicked something, there really would've been, like, no, like, huge issue with it; like, it was just the fact that, like, every time you clicked a box, it just spun—which, like, you know, really held you up.* [Nurse P4] • *Oh, it was very usable. It was very easy. Like again minus the slow Wi-Fi once we got it up and running it was like very easy to get through and you know kind of clear, to the point, you can click on things very easily.* [Nurse P1]
Benefits	• *I've been able to say, well, you know, you say you're taking your Lasix, but it looks like you've only been getting it filled, like, 60% of the time. Is there a reason, you know, that you weren't getting it filled? Because I'm concerned that maybe you aren't taking it like you should. So, it opened up that dialogue . . .* [Nurse MT9] • *I think the benefits of MT are we get a more accurate picture of the medications patients are on, which in the long run helps us treat them better.* [Nurse MT9]
Functionality	• *MT was not able to do that. Um, in [the medical record], they have, like, a little Post-It. It looks like a Post-It note next to the medication, and you just click on that, and you can enter in a comment. And I can say [the] patient has not started yet or will start or you know was too expensive.* [Nurse P1]
Patient Concerns	• *They will remove something in the waiting room, and then they get frustrated that we're still going over it with them in the room.* [Nurse MT7]

Discussion

Principal Results

The use of MT, a web-based application facilitating medication reconciliation, did not impact the accuracy of medication lists. The application was well received by patients; however, implementation challenges limited usability and acceptance by staff. The failure to improve medication list accuracy reflects both implementation challenges as well as the challenge of reliance on a technology-only solution to obtaining accurate medication lists.

Comparison With Prior Work

Our application is 1 of many technologies and applications being developed to obtain and maintain accurate medication lists [26-32]. Many applications are focused on hospitalized patients, and not all applications have been pragmatically evaluated or included a methodology to compare accuracy with the gold-standard BPMH. Lesselroth et al [12,33] have developed a medication reconciliation kiosk where patients can review and edit their medication lists. Similar to MT, this information is imported into the EHR and reviewed by clinicians [31]. In their evaluation, they found similar rates of discrepancies (29%-39% vs 34%-40%), and the overall number of patients with discrepancies were similar (91%-99% vs 92%-93%) [33,34]. When evaluating the implementation of their application, they also found that time is a factor in using medication reconciliation technology and that, to be taken up, the technology needs to be well integrated into current workflows [35]. This was also found to be a challenge with our application despite its intent to work within the staff workflow.

Strengths

We implemented several design elements to enhance the validity of our evaluation. We randomized clinics to MT or UC to avoid potential contamination that might have occurred at the patient or clinician level. We controlled for possible confounding factors through an adjusted analysis, the results of which mirrored the unadjusted analysis, increasing our confidence in our results. Throughout the trial, we also attempted blinding, wherever possible, to minimize bias. Other strengths include the use of pharmacists to conduct a BPMH and our application itself, which incorporates patient, clinician, and pharmacy-dispensed data to facilitate medication reconciliation.

Limitations

Despite these strengths, a few limitations should be noted. Due to the nature of the intervention, clinicians and, to an extent, patients could not be blinded to the intervention. Fidelity to the use of MT was not always optimal and was variably used among rooming staff. As indicated in the staff survey and interviews, MT was not favorably viewed by the staff and as such they might have failed to use MT consistently, which would reduce observed effectiveness. Technical challenges, such as loading delays and internet connectivity for tablets, also affected the usability of the application in our clinics. Additionally, although the application was implemented within the EHR, it was outside of the existing workflow and required several additional clicks. Finally, we are underpowered to confidently detect the differences we observed in this trial. This was, in part, due to optimistic initial estimates of the effect of MT, as well as recruitment challenges. Our initial estimates of the effect of MT may have been optimistic as by the time the application was implemented, certain features were also available in the EHR, thereby reducing the difference between MT and UC.

Conclusion

Novel approaches to medication reconciliation are needed to ensure safe and effective medication use. The use of technology, such as MT, a web-based application integrating various data sources, is a promising solution to reduce the rate of

discrepancies. In our study, MT did not affect the rate of discrepancies, which may have been the result of failure to use the tool consistently and with fidelity due to implementation challenges. Thus, technology solutions may need to be paired with additional implementation strategies, and particular attention should be paid to how these technologies and other innovations are integrated into clinical workflows to facilitate fidelity and maximize effectiveness.

Editorial notice: This randomized study was not registered. The authors explained that the trial was intended to be a part of a staged roll-out within usual care to improve the quality of treatment received by patients. Randomization was used to assign which sites received the improvements first. The editor granted an exception from ICMJE rules mandating prospective registration of randomized trials, because the risk of bias appears low and the study was considered formative. However, readers are advised to carefully assess the validity of any potential explicit or implicit claims related to primary outcomes or effectiveness.

Abstract

Background: As global obesity prevalence continues to increase, there is a need for accessible and affordable weight management interventions, such as web-based programs.

Objective: This paper aims to assess the outcomes of healthy weight coaching (HWC), a web-based obesity management program integrated into standard Finnish clinical care.

Methods: HWC is an ongoing, structured digital 12-month program based on acceptance and commitment therapy. It includes weekly training sessions focused on lifestyle, general health, and psychological factors. Participants received remote one-on-one support from a personal coach. In this real-life, single-arm, prospective cohort study, we examined the total weight loss, weight loss profiles, and variables associated with weight loss success and program retention in 1189 adults (963 women) with a BMI >25 kg/m² among participants of the program between October 2016 and March 2019. Absolute (kg) and relative (%) weight loss from the baseline were the primary outcomes. We also examined the weight loss profiles, clustered based on the dynamic time-warping distance, and the possible variables associated with greater weight loss success and program retention. We compared different groups using the Mann-Whitney test or Kruskal-Wallis test for continuous variables and the chi-squared test for categorical variables. We analyzed changes in medication using the McNemar test.

Results: Among those having reached the 12-month time point (n=173), the mean weight loss was 4.6% (SE 0.5%), with 43% (n=75) achieving clinically relevant weight loss (≥5%). Baseline BMI ≥40 kg/m² was associated with a greater weight loss than a lower BMI (mean 6.6%, SE 0.9%, vs mean 3.2%, SE 0.6%; P=.02). In addition, more frequent weight reporting was associated with greater weight loss. No significant differences in weight loss were observed according to sex, age, baseline disease, or medication use. The total dropout rate was 29.1%. Dropouts were slightly younger than continuers (47.2, SE 0.6 years vs 49.2, SE 0.4 years; P=.01) and reported their weight less frequently (3.0, SE 0.1 entries per month vs 3.3, SE 0.1 entries per month; P<.001).

Conclusions: A comprehensive web-based program such as HWC is a potential addition to the repertoire of obesity management in a clinical setting. Heavier patients lost more weight, but weight loss success was otherwise independent of baseline characteristics.

Introduction

Global increases in the prevalence of obesity represent a pressing public health concern. Obesity is closely linked to various physical and mental health impairments, including type 2 diabetes, hypertension, nonalcoholic fatty liver disease, cancer, depression, and a decreased health-related quality of life, to name a few [1]. Among individuals with obesity, a moderate weight loss of 5% carries significant metabolic health benefits [2]. Furthermore, the etiology of obesity is multifactorial and consists of genetic, environmental, and behavioral factors. Behavioral factors, such as appetite control, eating habits, and physical activity, remain central targets in clinical practice and substantially impact treatment outcomes [3].

Treating obesity traditionally relies on lifestyle modifications during individual or group face-to-face sessions [4]. With ever-increasing rates of obesity and limited financial resources within health care systems, we must identify effective weight loss interventions that can be delivered to the wider public at a reasonable cost. Using information technology in obesity treatment may offer a cheaper alternative to relying on employed staff alone. Furthermore, while setting up an internet-based program may be expensive, upkeep can be cost-effective [5,6]. In addition, remote guidance may also reduce the number of necessary in-person consultations and minimize the travel time and costs associated with location-dependent treatment. Financial benefits and technology-based programs can be accessible regardless of the time of day, participants' life situations, places of residence, and potential disabilities or oral communication difficulties [7].

Common successful components of web-based interventions include self-monitoring, professional feedback, goal-setting, social support, and a structured program [5,8-10]. Tailoring programs in this manner may enhance self-efficacy, evoke a feeling of being cared for, improve end results, increase engagement, and decrease attrition [11-14]. Furthermore, web-based programs may enhance the feeling of control over one's own care and facilitate patient–expert and patient–patient interactions [11,15].

The effectiveness of web-based weight loss and weight management programs can diminish because of the poor use of the program and its elements. Reasons for this may include outdated website design, insufficient internet skills, limited internet connection, and patient unfamiliarity with web-based interventions in health care [15-17]. Moreover, users may perceive programs requiring self-monitoring to be burdensome [13]. Additional obstacles in technology-assisted programs may include problems with confidentiality and privacy, a decrease in face-to-face communication, medical errors caused by system malfunctions, technological errors, and data manipulation and misinterpretation, as well as legal, ethical, and administrative barriers [13,17]. Finally, high attrition rates and decreasing engagement over time represent common features of both eHealth innovations and weight loss interventions in general [18-20].

Although obesity treatment remains multidisciplinary, previously published studies typically focused on a limited number of factors important to successful weight loss. Most available studies on web-based programs offered no real-time human support to participants, and only a few studies have been conducted in real-life clinical settings in diverse patient groups. Moreover, previous studies have primarily examined small populations with short intervention and follow-up periods [21,22]. However, there are a few important exceptions. In a previous Danish study conducted in a real-life municipal setting, an eHealth intervention resulted in a significant weight reduction of 4.3% at the mean 7.3-month time point [23]. In patients who remained in the intervention for over 9 months, the mean weight loss was 6.3% [23]. Thus, although eHealth interventions are promising alternatives to conventional interventions, it remains important to assess their benefits in actual clinical care.

In this paper, we report our initial observations from a large cohort of patients taking part in a web-based platform, HealthyWeightHub, through which patients use an interactive program, Healthy Weight Coaching (HWC), for obesity management. The cohort consisted of men and women with a wide age and BMI range. Furthermore, the program relies on a broad spectrum of approaches (eg, diet, physical activity, sleep, health, psychological factors, and coping with stress) in the form of web-based training modules supported by a personal coach. In this real-life, single-arm, prospective cohort study, we assessed the outcomes of the HWC program. In doing so, we focused on the amount of weight loss, interindividual variability in the weight loss response, and possible variables associated with weight loss success and program retention.

Methods

Intervention

HWC is an ongoing 12-month interactive web-based intervention for weight management among patients identified with overweight or obesity. The program is available free of charge to all Finnish citizens as a part of Finnish public health care. In the program, we addressed a broad spectrum of health behaviors related to weight management, including diet, physical activity, sleep, psychological factors, coping with stress, and general health status. The program structure relied on weekly training sessions, and participants can freely choose from 200 available sessions to best meet their individual needs. Participants could submit daily—and were instructed to do so at least weekly—their weight, targets, feelings, diet, and physical activity logs to the program. In addition, each patient was assigned a personal coach (a nurse, nutritionist, physiotherapist, or psychologist) who offered remote one-on-one support and could individually tailor specific sessions to patients.

One-on-one coaching was arranged biweekly during the first month, after which it was arranged monthly. Alongside coaching, participants were able to exchange messages with the coach whenever needed. Participants could also interact with each other using anonymous group chats. The group chats were arranged monthly. To ensure cybersecurity, the program required strong authentication.

The HWC program and its training sessions are based on the framework of acceptance and commitment therapy (ACT) and other theories of behavior change. ACT is a form of cognitive behavioral therapy that supports flexible decision-making in everyday life. Specifically, ACT increases mindfulness, self-regulation, and psychological flexibility [24-27]. In addition, the elements incorporated include self-monitoring, counselor feedback and communication, group support, a structured program, and individual tailoring, all of which appear to support successful weight loss [14,28,29]. The program has been previously described in detail [30].

Participants

Patients entered the program based on a referral from a licensed physician in Finland. Most of the patients were from the Hospital District of Helsinki and Uusimaa. The general inclusion criteria in the referral process for the HWC were as follows: (1) age ≥18 years, (2) BMI ≥25 kg/m², (3) access to a computer or a smartphone with a stable internet connection, and (4) a willingness and motivation to participate in a web-based treatment program. Persons who were pregnant, lactating, or for other reasons required face-to-face treatment modalities were not accepted to the program, as their intervention would be conducted more safely in the clinics rather than via the internet.

Ethical Considerations

Each participant provided written informed consent. The study was approved by the Coordinating Ethics Committee of the Helsinki University Hospital (reference number 327/13/03/00/2015).

Data Collection

The database for this study was created on March 12, 2019, and included data from all consenting participants since the initiation of the HWC in October 2016 [30]. To avoid confounding factors, we excluded participants who were diagnosed with type 1 diabetes; were following a very low-calorie diet; were taking weight loss medication; had undergone a gastric balloon procedure or bariatric surgery; and those who did not complete a 2-week trial period (n=264, 18.2%). All other patients who were initially referred to the HWC were included in the analyses.

We obtained data regarding age and sex from the Finnish national register. During the program, the participants completed several internet-based questionnaires, as previously described in detail [30]. To summarize, height and weight as well as baseline morbidities and medications were reported upon entry into the program. Daily reporting for weight was optional. However, at a minimum, weekly reports were encouraged as part of the training sessions. We used these weekly reports to interpolate the daily weight measurements. We calculated BMI

as weight in kilograms divided by height in meters squared (kg/m²) and dichotomized it into groups with BMI <40 kg/m² (n=557) and BMI ≥40 kg/m² (n=631). This grouping at the morbid obesity cut-off point was used instead of conventional overweight (BMI 25-29.9 kg/m²) and obesity (BMI ≥30 kg/m²) groups, as only 25 individuals were identified in the overweight group. We also calculated the entry rate (entries per month) from the total number of weight entries divided by the time until the last weight entry. We considered participants who were inactive for >90 days as dropouts from the program.

Statistical Analyses

As recruitment to the program remains continuous, the number of participants reaching each time point varied (Multimedia Appendix 1, Table S1). Unless otherwise stated, the figures and statistical analyses were based on the data from all participants. Data are presented as frequencies (%) for categorical variables and mean (SE) and median (IQR) for continuous variables. All continuous variables had skewed distributions (Shapiro-Wilk normality test). All statistical analyses were performed using the R statistical computing environment (version 3.4.1; R Foundation for Statistical Computing) [31]. Group comparisons were conducted using the Mann-Whitney test (2 groups) or Kruskal-Wallis test (>2 groups) for continuous variables and the chi-squared test for categorical variables. Changes in medication between baseline and 12 months were analyzed using the McNemar test. Weight loss patterns were clustered based on the dynamic time-warping distance and agglomerative hierarchical clustering using the R package *dtwclust* [32]. The R package *ggplot2* was used for the visualization of all results [33]. We set the level of significance at $P<.05$.

Results

Baseline Characteristics

Table 1 summarizes the baseline characteristics of the 1189 participants in this study. The mean age of patients was 48.6 (SE 0.3) years. BMI ranged from 26.3 to 78.7 kg/m² (mean 40.6, SE 0.2 kg/m²). There were no statistically significant differences in age or BMI between men and women.

In total, 1044 (87.8%) participants reported comorbidities of some type. The mean number of comorbidities reported per person was 4.8 (SE 0.1; range 0-15). Hypertension was the most prevalent comorbidity (n=598, 57.2%), followed by dyslipidemia (n=368, 35.2%), allergies (n=368, 35.2%), sleep apnea (n=358, 34.2%), depression (n=343, 32.8%), and osteoarthritis or osteoarthrosis (n=318, 30.4%; Multimedia Appendix 1, Table S2). In addition, 18.5% (n=193) of the participants reported type 2 diabetes as a comorbidity.

Altogether, 1000 (84.1%) participants reported using any medication. The reported medications were grouped as shown in Multimedia Appendix 1, Table S3. The mean number of these medication groups per patient was 2.5 (SE 0.1, range 0-10). The most prevalent medication groups were cardiovascular drugs (n=513, 43.1%), followed by dietary supplements (n=434, 36.5%), metabolic and endocrine drugs (n=349, 29.4%), acute pain medication (n=348, 29.3%), and psychopharmacological drugs (n=284, 23.9%; Multimedia Appendix 1, Table S3). At

12 months (n=173), the mean number of medication groups remained the same (2.5, SE 0.03), whereas the use of respiratory and acute pain medication changed significantly (Multimedia Appendix 1, Table S4).

Table 1. Basic characteristics of the study population.

Characteristic	All (N=1189)		Women (n=963)		Men (n=226)	
	Value, mean (SE; range)	Value, median (IQR)	Value, mean (SE; range)	Value, median (IQR)	Value, mean (SE; range)	Value, median (IQR)

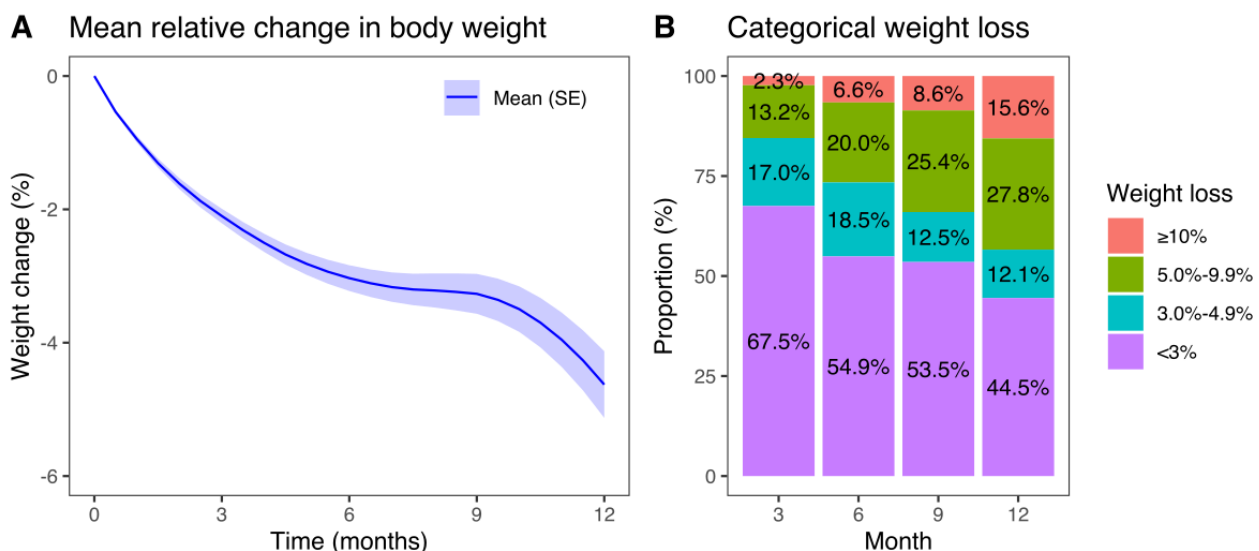
Mean and Categorical Weight Loss

The mean weight loss trajectory throughout the 12-month intervention period is shown in Figure 1A. At 12 months, the mean weight loss reached 4.6% (SE 0.5%) or 5.6 kg (SE 0.7 kg). The mean relative (%) and absolute (kg) weight losses at 3, 6, 9, and 12 months are shown in Multimedia Appendix 1, Table S5. Figure 1B shows the categorical weight loss at each time point. Among all participants who reached the 12-month time point by the data lock (n=173), 12.1% (n=21) lost 3% to 4.9%, 27.7% (n=48) lost 5% to 9.9%, and 15.6% (n=27) lost ≥10% of their baseline body weight. Altogether, 43.3% (n=75) of participants reaching the 12-month time point reported a clinically relevant weight loss of ≥5% of their initial weight.

At 12 months (n=173), the mean weight loss was similar in men (mean 5.4%, SE 1.4%) and women (mean 4.5%, SE 0.6%; Multimedia Appendix 1, Table S6). Participants aged <40 years achieved a weight loss (mean 4.3%, SE 1.2%) comparable with that of older individuals (mean 4.7%, SE 0.6%). Participants with a baseline BMI ≥40 kg/m² exhibited greater weight loss than those with a baseline BMI <40 kg/m² (mean 6.6%, SE 0.9% vs mean 3.2%, SE 0.5%; P=.02). Instead, patients with and without type 2 diabetes achieved similar weight loss rates (mean 5.3%, SE 1.2% vs mean 4.2%, SE 0.6%; P=.45, respectively). By the end of the intervention, patients who reported their body weight ≥4 times per month did not achieve statistically significantly greater weight loss (mean 5.9%, SE 1.1%) than those who reported a body weight <4 times per month (mean 4.2%, SE 0.6%; P=.09). However, at 3-, 6-, and 9-month time points, significantly greater weight loss was observed for patients who reported their body weights more frequently (P<.001).

Figure 1. (A) Mean weight change (percentage from baseline) through the intervention; (B) distribution of weight loss categories at 3 (n=839), 6 (n=563), 9 (n=359), and 12 (n=173) months. The numbers indicate participants who have reached each time point.


Interindividual Variation in Weight Loss Responses

In our attempt to delineate the interindividual variation in weight loss responses, we first plotted the last available observation from each participant, observing a wide range of weight changes, from −34.3% to +14.4% (Figure 2). Similarly, wide variations were observed at 3, 6, 9, and 12 months (Multimedia Appendix 1, Figure S1).

We next analyzed the variation in weight changes using a dynamic time-warping algorithm and hierarchical clustering. In this process, we identified 5 clusters into which participants could be divided based on their weight loss success (Figure 3).

The mean weight changes in each of the 5 weight loss clusters from baseline to 3, 6, 9, and 12 months are shown in Multimedia Appendix 1, Table S7. Those in cluster 1 (superresponders; n=93, 8% of the study population) lost weight rapidly and consistently until the end of the 12-month period. In this group, participants lost an average of 15.7% (SE 1.3%) of their baseline body weight at 12 months.

In cluster 2 (responders; n=208, 17.5% of the study population), participants lost weight rapidly during the first 3 months, after which the weight loss rate slowed down. In this group, the participants had lost an average of 6.1% (SE 0.3%) of their baseline body weight at 12 months.

In cluster 3 (moderate responders; n=332, 27.9% of the study population), participants exhibited a small and steady mean 12-month weight loss of 3.4% (SE 0.3%) of their baseline body weight.

In cluster 4 (nonresponders; n=384, 32.3% of the study population), neither significantly lost nor gained weight. In this group, participants had lost on average 0.1% (SE 0.2%) of their baseline body weight at 12 months.

In cluster 5 (gainers; n=172, 14.5% of the study population), participants slowly gained weight rather than losing it. In this group, participants gained on average 3.5% (SE 0.6%) of their baseline body weight at 12 months.

Across all participants, 53.2% (n=633) fell into the category of responders (clusters 1-3), 32.3% (n=384) represented nonresponders (cluster 4), and 14.5% (n=172) represented gainers (cluster 5).

Figure 2. Individual weight change (percentage from baseline) at the last available time point.
Figure 3. Clusters of study participants (N=1189) based on weight loss success trajectories. Individual weight loss patterns were clustered based on dynamic time-warping distance and agglomerative hierarchical clustering. Each colored line represents the weight change trajectory of a participant. The black line represents the average weight change in said cluster. Cluster 1, superresponders; cluster 2, responders; cluster 3, moderate responders; cluster 4, nonresponders; cluster 5, gainers.
Factors Explaining the Interindividual Variation in Weight Loss Response

To identify factors contributing to weight loss success, we analyzed whether the clusters differed according to age, sex, baseline BMI, concomitant diseases or medication use, or the frequency of weight entries. The clusters exhibited no statistically significant differences in age or sex (Multimedia Appendix 1, Table S8). Instead, a higher baseline BMI was associated with greater mean weight loss success ($P<.001$). Furthermore, greater mean weight loss was associated with more frequent weight entries ($P=.004$). In addition, the clusters differed only in relation to the number of medications ($P=.048$) but not in the medication groups and diseases (Multimedia Appendix 1, Table S9 and Figure S2).

Attrition

Finally, we analyzed the attrition rate and possible associated factors. The total dropout rate at 12 months was 29.1% (n=346; Multimedia Appendix 1, Figure S3). In addition, given the continuous recruitment, 56.6% (n=689) of participants had not yet reached the 12-month time point at the time of the data lock.

We found no significant differences in the baseline BMI (mean 41.0 kg/m^2, SE 0. 4 kg/m^2 vs mean 40.4 kg/m^2, SE 0.2 kg/m^2; $P=.12$) or sex (272, 79% vs 691, 82% women; $P=.21$) between those who prematurely discontinued the program and those who remained continuously active (Multimedia Appendix 1, Table S10). Those discontinuing were younger (mean 47.2 years, SE 0.6 years vs 49.2 years, SE 0.4 years; $P=.01$) and made fewer monthly weight entries (mean 3.0, SE 0.1 entries/month vs mean 3.3, SE 0.1 entries per month; $P<.001$) compared with those who adhered. On the basis of their last reported body weight, most individuals who dropped out, clustered either as nonresponders or gainers (Multimedia Appendix 1, Figure S4).

Discussion

Principal Findings

The data collected in the novel web-based weight management program, HWC, offered a unique perspective of real-time obesity management in a large population of individuals with a wide age and BMI range. They also enabled us to identify subgroups of patients with different weight trajectories and trends in weight loss success. Furthermore, with a large number of included modules (including diet, physical activity, sleep, psychological factors, stress, and general health), the HWC program encompasses the multidisciplinary nature of clinical weight management with a long intervention time. Importantly, our patients, on average, presented with morbid obesity, with several comorbidities and the use of various medications. HWC is embedded into standard Finnish clinical care, and thus represents real-life clinical patient material. However, although the data collection was preplanned alongside the routine delivery of care, one needs to bear in mind that this real-life study has no control group.

We observed a mean weight loss of 4.6% (SE 0.5%) or 5.6 kg (SE 0.7 kg) at the 12-month time point. In a meta-analysis of 15 personalized eHealth studies, Lau et al [21] reported a 2.8

kg (range 2.0 kg-3.5 kg) greater mean weight loss in the eHealth intervention group than in the control group. Similarly, in a systematic review, a 2.4 kg higher weight loss was observed in traditional face-to-face treatments compared with no or minimal interventions [34]. In a previous Finnish randomized controlled trial, patients treated only via a web-based behavioral weight loss program lost on average 1.2% (range 0.3% to 2.2%) of their baseline body weight in 12 months, whereas the group treated via both the program and cognitive behavioral group therapy lost on average 3.5% (range 2.1% to 4.8%) of their baseline body weight [35]. In this real-life study, we did not have a control group, whereby we were unable to assess how a similar patient population to our study would have fared longitudinally without any treatment. On the basis of previous longitudinal studies, the BMI in Finnish cohorts tends to either increase [36] or remain stable [37] over time. Furthermore, in a Swedish Obese Subjects trial, where participants had a similar mean BMI (40.1 kg/m^2) as in our study, there was no weight change in the control group with usual care at the 12-month time point [38]. Thus, it seems likely that the mean 4.6% (SE 0.5%) weight loss we observed was a result of the HWC treatment. However, based on a previous randomized controlled trial [35], it is also possible that combining web-based treatment with face-to-face behavioral therapy would have been more effective than web-based treatment alone.

We identified 5 clusters based on weight loss success, when examining weight change trajectories, allowing us to explore characteristics predicting weight loss outcomes. The clusters were comparable in terms of age and sex. However, a higher baseline BMI was associated with greater weight loss success. We found no statistically significant differences in the number of comorbidities or medication groups among clusters, suggesting that medication use and concomitant diseases did not define features of weight loss success. Of note, cluster 1, which had the best weight loss success, also had the largest variability in the weight loss results, which is most likely because this cluster size was the smallest population. Moreover, this cluster had the highest baseline BMI values. The largest of the formed clusters, cluster 4, comprised individuals with no change in their body weight. Indeed, it is very typical that not all patients undergoing weight loss interventions are successful in losing weight [23,39]. Identifying individuals and the reasons for not responding would be important to better support these individuals in future interventions. Overall, 53.2% (n=633) of the participants fell into clusters 1 to 3, and thus experienced some weight loss. Moreover, the observed mean weight loss was 4.6% (SE 0.5%), which is comparable with or somewhat higher than that previously reported [21,34,35].

No difference in weight loss was observed between individuals with and those without type 2 diabetes. Interestingly, in previous weight loss studies, patients with diabetes exhibited poorer success than those without diabetes [40,41]. One reason might be that diabetes as a comorbidity can render weight loss more difficult and harder to maintain [40,42]. However, diabetes and its related comorbidities may result in greater adherence and motivation for weight loss [43]. Furthermore, these novel interactive approaches may be more engaging and empowering than traditional methods because web-based programs may

enhance a feeling of self-control and accountability regarding one's care [15].

We found that a higher number of weight entries was associated with greater weight loss, in agreement with previous findings [10,44,45]. We also found that those who dropped out made fewer weight entries to the program than did those who adhered. However, whether the number of entries attributes to success itself remains unclear. Success may make the program more rewarding, thus prompting a patient to log weights more frequently and engage more with the program. As for attrition, it is probable that individuals who fail to lose weight or experience any other benefits more readily drop out from the programs. In addition, discontinuing an intervention may also occur because the participants already met their personal goals before the targeted end date [17,46-48]. Understanding the nature of this relationship between success and the weight entry rate requires further investigation.

In the HWC program, we observed an attrition rate of 29.1% (n=346). Patients who dropped out were younger and more often belonged to the group that did not lose weight in the program. Retention and weight loss may be bidirectionally related to each other: patients retained in the program have more support for weight loss attempts, and better weight loss motivates them to remain active in the program. Overall, attrition may bias the outcome and should be considered when interpreting the results of the study. High attrition rates and decreasing engagement over time represent common features of both eHealth innovations and clinical face-to-face weight loss interventions [18-20]. This may be especially true in long-term interventions, such as this program. Similar to our study, the 2 eHealth platforms for weight management reported a 54% attrition rate in a clinical setting [35,46]. This is comparable with a traditional face-to-face clinic-based intervention, which also reported that 54% of patients discontinued [19]. Previous meta-analyses on eHealth-based weight loss interventions primarily focused on randomized controlled trials and determined average attrition rates close to 20% [6,10]. However, these rates might misrepresent attrition in real-life programs given inherent differences in, for example, participant demographics (ie, real clinical patients vs volunteers) and program design (ie, additional assessment sessions, participant retention strategies, and greater accountability).

This study had several strengths and limitations. An important strength of this study lay in its reliance on a large sample of individuals with a broad age and BMI distribution. With a large number of reported comorbidities and medications, our data provided a realistic view of treating patients with obesity-related complications. Although using data from a real-life clinical setting offers a tangible and practical view of the web-based management of obesity, the program was not randomized and was thus lacking a control group. Subsequently, the study has low internal validity, and we are unable to determine the efficacy of the program compared with no treatment, face-to-face treatment, or any other comparison. We were also not able to study those patients who needed treatment for obesity but were not willing to participate in a web-based program and received a referral to HWC in the first place. In addition, as body weight was self-reported, the possibility of misreporting will need to be considered when interpreting the results. It should also be noted that the program comprises several components. On the basis of the current analyses, it is not possible to distinguish between the different treatment effects, dose responses, or mechanisms of change in these components. The current report describes the overall outcomes of this program. Finally, as is the case with most previous studies, our participants consisted predominantly of women and adults of middle age. Therefore, our conclusions are not fully generalizable to younger adults and men.

Future research should focus on younger adults and men, in particular, and attempt to examine the effects and appeal of web-based programs. In addition, further investigation of the factors associated with successful weight loss and reasons for attrition would prove beneficial. For example, future studies should attempt to determine when attrition occurs because of reaching weight loss targets early instead of genuine nonuse. This would advance the development of targeted web-based programs tailored to specific patient subgroups.

Conclusions

In conclusion, HWC is a web-based method for the management of obesity in real-life clinical settings. During the 12-month treatment, the average weight loss was 4.6% (SE 0.5%) but varied widely. Specifically, baseline medication use, baseline health status, age, or sex was not significantly associated with weight loss in the HWC program. Further research is needed to understand the determinants of weight loss success.

Abstract

Background: Participatory research methodologies can provide insight into the use of mobile health (mHealth) apps, cultural preferences and needs, and health literacy issues for racial and ethnic groups, such as African Americans and Hispanics who experience health disparities.

Objective: This methodological paper aims to describe a 1-year multi-method participatory research process that directly engaged English-speaking African American and bilingual or Spanish-speaking Hispanic adults in designing a prevention-focused, personalized mHealth, information-seeking smartphone app. We report design team participants' experiences with the methods to show why our approach is valuable in producing apps that are more aligned with their needs.

Methods: Three design sessions were conducted to inform the iteration of a prevention-focused, personalized mHealth, information-seeking app. The research team led sessions with 2 community member design teams. Design team participants described their goals, motives, and interests regarding prevention information using different approaches, such as collage and card sorting (design session 1), interaction with the app prototype (design session 2), and rating of cultural appropriateness strategies (design session 3).

Results: Each design team had 5 to 6 participants: 2 to 3 male participants and 3 female participants aged between 30 and 76 years. Design team participants shared their likes and dislikes about the sessions and the overall experience of the design sessions. Both African American and Hispanic teams reported positive participation experience. The primary reasons included the opportunity for their views to be heard, collectively working together in the design process, having their apprehension about mHealth reduced, and an opportunity to increase their knowledge of how they could manage their health through mHealth. The feedback from each session informed the following design sessions and a community-engaged process. In addition, the specific findings for each design session informed the design of the app for both communities.

Conclusions: This multi-method participatory research process revealed 4 key lessons learned and recommendations for future research in mHealth app design for African Americans and Hispanics. Lesson 1—community partnerships are key because they provide the *chain of trust* that helps African American and Hispanic participants feel comfortable participating in app research. Lesson 2—community-based participatory research principles continue to yield promising results to engage these populations in mHealth research. Lesson 3—interactive design sessions uncover participants' needs and development opportunities for mHealth tools. Lesson 4—multiple design sessions with different methods provide an in-depth understanding of participants' mHealth

XSL·FO

preferences and needs. Future developers should consider these methods and lessons to ensure health apps in the marketplace contribute to eliminating health disparities and achieving health equity.

KEYWORDS

Introduction

Background

Nationally representative data from the Pew Research Center survey and the Health Information National Trends Survey show that Hispanic and African American adults are more likely than their White counterparts to use smartphones to access health information [1-3]. Hispanic and African American adults use their smartphones to access the internet to search for health information, communicate with health care providers, manage medicines, and use decision support tools, thereby reducing health gaps [1-3]. Despite these new digital options for prevention and management, Hispanic and African American populations are more vulnerable to some of the most common and preventable causes of illness and disease, such as diabetes and heart disease [4,5]. A well-designed, prevention-focused mobile health (mHealth) app that provides credible, culturally appropriate, and easy-to-understand information and recommendations could help better inform these groups, increase information-seeking, and aid decision-making to help prevent or delay chronic diseases. Previous research suggests that intended app users will be more likely to use and benefit from a prevention app if they are informed by their own lived experiences as well as being based on theoretical and methodological approaches that explain health behaviors [6,7]. Such apps can provide examples to mHealth app developers, public health practitioners, and researchers who want to ensure these products help eliminate health disparities, address communication inequities, and achieve health equity which is as follows [8]:

> *Is achieved when every person has the opportunity to 'attain his or her full health potential' and no one is 'disadvantaged from achieving this potential' because of social position or other socially determined circumstances.*

Limited health literacy may be a major barrier to mHealth app use, specifically among certain populations [9,10]. Healthy People 2030, the United States 10-year health objectives, define health literacy in both personal and organizational terms, and encompass not only comprehension of information but also seeking information and using it for decisions and actions [11]. According to the only nationally representative health literacy study of English-speaking adults in the United States, Hispanics and African Americans had lower average adequate health literacy than their White counterparts [11,12]. It is also important to consider how language is associated with health literacy in relation to the Hispanic population that prefers to speak Spanish or has limited English proficiency for health-related concerns. The National Assessment of Adult Literacy study also revealed that individuals who spoke only Spanish or a language other

than English had lower averages of health literacy skills than those whose primary language was English [12]. As the Hispanic population has grown substantially over the past decade, it is imperative that apps are available in Spanish to address their health information needs [13].

Participatory research methods are used in several disciplines, and in mHealth development, these methods have been shown to have positive effects when intended users are part of app development and testing processes [6,14]. This method involves the intended users in the research design and implementation of the intervention, product, or program [15]. Methods to engage intended users in app design and development, such as user-centered design, are known and published in the trade and academic literatures [16-18]. User-centered methods can inform all stages of app development and help refine and update apps as they mature. These methodologies provide insights into the motivations and challenges that users face and can help reveal any special circumstances or requirements that racial and ethnic groups, such as African American and Hispanic adults, may have with mHealth app use when seeking health information to manage their health.

Participatory approaches are imperative to inform and guide research with marginalized communities that have experienced unethical research practices and to engage these communities in research that is not part of their everyday lived experiences. Community-based participatory research (CBPR) has been effective in engaging racial and ethnic groups as well as marginalized communities in the development of mHealth tools. Its success in mHealth is rooted in researchers establishing trust with community partners while collaboratively working on the product development and evaluation processes of the intended product [6,14,19,20]. This is critical when engaging communities who are historically and understandably suspicious of or reluctant to engage in research [21-24].

Objectives

This methodological paper aims to describe a 1-year multi-method participatory research process that directly engaged English-speaking African American and bilingual or Spanish-speaking Hispanic adults in designing a prevention-focused, personalized mHealth, information-seeking smartphone app. The research reported in this paper was phase 1 of a 4-year process to iteratively refine the field test and revise an app. The study is being conducted by a multidisciplinary team of health literacy, communication, health services, public health, and computer science researchers. The process and app are grounded in CBPR, user-centered design principles, and health literacy techniques. This paper describes (1) the participatory approach, (2) the design session process, (3) participant-reported experiences of the design sessions, and (4)

recommendations and lessons learned for future research in mHealth app design for African Americans, Hispanics, and other racial and ethnic groups with a disproportionate burden of health disparities. This paper provides new information about how to combine participatory methods from different intellectual traditions to better discover African American and Hispanic adult health app needs through co-design.

Methods

App Design Session Theoretical Underpinnings and Methodological Approach

CBPR principles, user-centered design, and health literacy techniques were our core methods. Understanding the challenges in finding African American and Hispanic adults who might be interested in a research study on an mHealth app, the research team applied several CBPR principles. These principles included (1) building on strengths and resources within the community, (2) promoting a colearning and empowering process that attends to social inequalities, and (3) disseminating findings and knowledge to the user [25]. The research team collaborated with 2 key community partners, a National Institutes of Health–designated Research Center of Excellence in Race, Ethnicity, and Health Disparities Research, and a Hispanic-serving community-based organization. These partners are part of a *chain of trust* in their local Hispanic and African American communities because of the engagement infrastructures they have built over time. By affiliating with these partners, we became part of the chain. Collaboration with the community partners included routine meetings to seek input in the recruitment and retention strategies, content of marketing materials, and input for the development of the design sessions to ensure an equitable participatory research learning process for the participants. In addition, the participant design sessions supported a *co-learning and empowering process that attended to social inequalities* by establishing a bidirectional communicative process between the participants and research team to learn how the communities' needs can be better served. The research team practiced *disseminating findings and knowledge to the user* by continuously maintaining transparency in the research process and results throughout the study. To put the principles into practice for the app, the team applied user-centered and health literacy techniques.

Not only is a lack of community engagement a weakness in mHealth development but also many tools have been developed without a strong theoretical foundation. Our overall study combined the consumer information process (CIP) model and adult learning theory to inform information-seeking motivation and action [26,27]. The CIP and adult learning theories consider what motivates and engages adults in information-seeking and action. Adult learning theory posits that adults will invest in learning when they perceive a strong *need to know*. The theory's key ideas about the importance of adults' previous experience and their developmental stage were applied to inform app design and content. The CIP model's core concept is *individual processing capacity*, and the model's core assumption is that individuals are limited and intentional or goal-directed when they seek information and how much information they process [26]. These tenets align with health literacy research and its basic insight that people prefer relevant, easy-to-understand information that does not overwhelm them.

The CIP and adult learning theories and health literacy insights informed the choice of user-centered methods and the design session activities so that the team could develop an understanding of the motivations and interests of the participants in relation to health information–seeking through a prevention-focused mHealth app.

Background Work on an App Prototype Before the Design Sessions

Before receiving funding for the 4-year study and implementing the design sessions, the research team conducted a 6-month prefunding phase (year 0) that involved vetting the app concept and developing and programming an early-stage prototype. The core app content is from healthfinder.gov, an award-winning, federal consumer health information website available in English and Spanish that was designed based on health literacy principles [28]. The research team presented this to a community advisory group, the Maryland Community Research Advisory Board (MD-CRAB), to validate the app concept, receive general feedback on the prototype, and determine what amendments should be made before applying for research funding to support the phases shown in Figure 1. The MD-CRAB is a research advisory group established by the Maryland Center for Health Equity (M-CHE) at the University of Maryland School of Public Health. The MD-CRAB includes 22 members, most from the local African American and Hispanic communities, and they provide community insight and guidance to strengthen research and ensure the results of research benefit vulnerable populations, especially in African American and Hispanic populations.

Figure 1. Display of the 4-year smartphone health app research study phases.
The African American and Hispanic MD-CRAB members reported that they believed people such as themselves might be willing to use an app that provided (1) information specific to their medical concern, (2) an array of health information, (3)

bilingual options, and (4) culturally tailored health information. We used this feedback to iterate the prototype and plan the research funding proposal. Once the study was funded in August

2018, we planned and began implementing phase 1 design sessions.

Design Session Participant Recruitment

Between September 2018 and December 2018, the research team worked with 2 community partner organizations in Prince George's and Montgomery Counties, Maryland, United States, to recruit English-speaking African American and bilingual or Spanish-speaking Hispanic adults. The organizations advised us on culturally tailored recruitment fliers. M-CHE led the African American recruitment, and the M-CHE Director asked the local barbers and stylists in the research community network in Prince George's County, Maryland, United States, to share the fliers. Requests to share the fliers with church members were made to local African American churches. An African American research team member presented the project at local church meetings to recruit participants. The research team also tried recruiting at local, free, well-attended health services events by many African American and Hispanic community members. Community health workers at Community Health and Empowerment through Education and Research (CHEER), a nonprofit service provider for Hispanic residents in the Takoma Park, Maryland neighborhood, distributed fliers and asked their clients to volunteer for the study. Interested African American and Hispanic community members called the project telephone number and left a message for a bilingual research assistant who called back and screened callers in English or Spanish to see if they met the study criteria. The goal was to recruit 1 group of African American adults and 1 group of bilingual or Spanish-speaking Hispanic adults who would commit to attending multiple design sessions over several months.

We screened participants based on race and ethnicity, age, sex, education, smartphone access, information-seeking habits, and willingness to participate in multiple sessions. Participants had to self-identify as African American or Hispanic or Latino and aged ≥18 years. We aimed for an equal distribution of self-identified male and female participants. As healthfinder.gov, the app's core content, is designed to be useful for adults with low health literacy, we were interested in working with community members with low health literacy and low health information–seeking habits. We screened participants to identify those who had no more than 2 years of community or technical college, had a smartphone or were willing to learn to use one, and answered questions that indicated they were a low to medium health information seeker and had low health literacy based on questions from the Health Information National Trends Survey [29]. Those who met the recruitment criteria were scheduled for the initial African American or Hispanic design sessions.

Design Session Planning

The research team wrote the moderators' guides in English that the bilingual research assistants translated into Spanish. The guides provided informed consent, followed by open-ended questions and tasks specific to the design sessions. The purpose of the sessions was to confirm the basic structure of the prototype app and solicit intended user ideas and feedback for

a revised app with additional content, features, and functions. We asked the same questions of the African American adults (in English) and Hispanic adults (in Spanish). A sample moderator's guide in English is available for review in the Multimedia Appendix 1. We scheduled the African American Study Director to lead the African American sessions and either a CHEER community health worker or a Hispanic bilingual research assistant to lead the Hispanic sessions in Spanish. We audio recorded each session and scheduled at least one bilingual or English-speaking research assistant to take notes during each session, depending on the session (English or Spanish). The design sessions were held on Saturdays at a local church for African American participants and evenings at the CHEER offices, a Hispanic-serving community-based organization, to make them convenient for participants based on their availability and preferences. Building trust and comfort between ourselves and participants was why we chose to hold the 3 sessions with the same 2 groups of participants. Participants were offered a gift card for US $25 for each session attended and an additional remuneration of US $25 if they completed all 3 sessions.

Ethics Approval

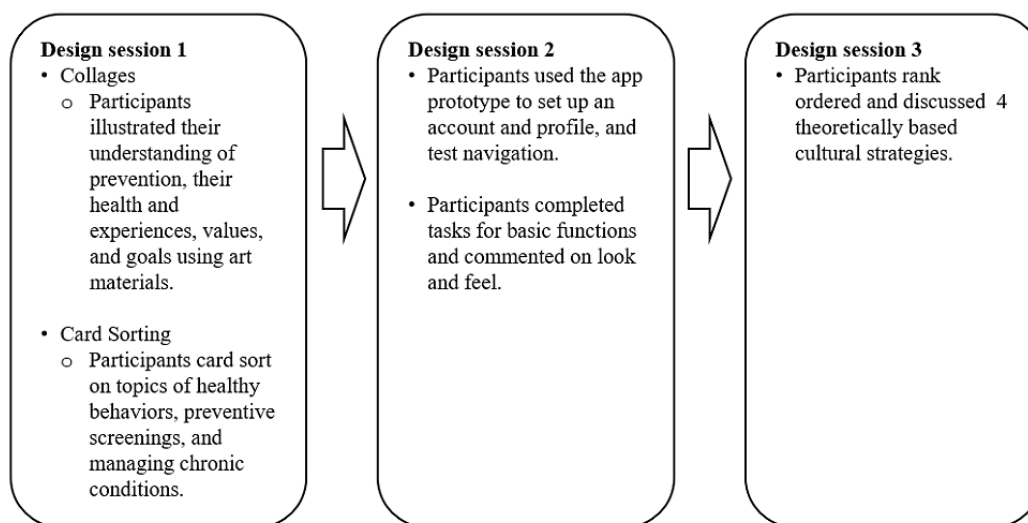
Each design session received approval from the University of Maryland Institutional Review Board (approval numbers 1292902-1, 1388156-1, and 1430335-1), and all project team members completed the Collaborative Institutional Training Initiative training for human subjects research before engaging with participants.

Design Session Procedures

User-center design methods engage the intended users of a product or service at different stages of design and testing processes to ensure maximum usability [30,31]. Our community partner organizations told us that although many community members have smartphones, they might not know much about how to download and use apps. In addition, we did not know how comfortable participants would be sharing information about their health experiences, beliefs, and technology use. As we were also applying CBPR and health literacy principles in how we engaged with participants, we chose methods to allow participants to draw on what was familiar to them and become comfortable talking about health topics and smartphone apps. We used hands-on activities and plain language in our study materials and design discussions to help participants fully understand and share the design process. To minimize any literacy challenges, we read aloud written materials, such as informed consent materials, written directions, or information on screens. During the 3 design sessions, we wanted participants to think broadly about their health and describe their goals, motives, and interests regarding prevention information using different approaches: (1) collage and card sorting (design session 1), (2) interaction with the app prototype (design session 2), and (3) rating of cultural appropriateness strategies (design session 3; Figure 2). In addition, participants could share their likes and dislikes about the sessions and the overall experience of the design sessions. We followed the same process as our separate African American and Hispanic groups for each design session.

XSL·FO

RenderX

Figure 2. Design session activities.


Design Session 1 Process

The goal of design session 1 was to learn participants' meanings and interpretations of health, prevention, and management, and the collage and card sorting activities involved participants creatively expressing their ideas, thoughts, interests, and desires about health generally and their health specifically. Collages are a *make tool* for people to create artifacts and express unspoken feelings and emotional states [32]. Participants were provided with tools such as poster board, colored pencils, markers, and printed images of people and activities that allowed them to create collages to explain what prevention meant to them, describe their present health, express their health values, and what they desired for their health in the future. Each participant had 30 minutes to create their own collage, and then the group spent 30 minutes on a *walking tour* so that each participant could tell the story of their collage to the group. The 1-hour card sorting activity allowed participants to have a tangible task to discuss prevention topics, which can be abstract for many people, and took advantage of in-depth group discussion to learn about participants' thoughts about the cards presented to them [33]. The card sorting activity involved each participant individually receiving a card stack on a group of health topics. The topic groups were healthy behaviors such as physical activity and healthy eating; preventive screenings and vaccinations, such as blood pressure checks or annual flu shots; and managing chronic conditions, such as chronic back pain or diabetes. We asked participants if they had questions about the terms on the cards and to talk aloud for 10 to 15 minutes about what the topics meant to them.

At the end of the discussion, we asked them to choose 2 to 3 cards that were most relevant to them. We repeated this process for round 2 with preventive screenings and vaccinations. For round 3, we asked them to look at 5 chronic disease cards and tell us the first thing they thought of. At the end of the session, we collected the collages and stacks of the sorted cards for analysis. The research assistants summarized the recordings and their session notes and organized responses by discussion

questions in spreadsheets. The research team members who attended the session, which included the principal investigator (PI) and the study director, debriefed, examined the collages for similarities and differences, and reviewed participants' comments by question. The PI and study director discussed the collages and participants' comments and recommended app changes to the full research team, who collectively decided what to revise before design session 2.

Design Session 2 Process

The goal of design session 2 was to learn how participants navigated the app prototype, and the session involved participants interacting with the revised prototype app and providing input on the interface, functions, and overall look and feel. A key step in user-centered design is to provide prototypes to a small number of intended users to try real-world tasks and scenarios [30]. Our participant groups included people with vision or literacy challenges; so, at the session sites we set up full-size computer monitors and connected a smartphone with the app to display the app screens for easier readability. The participant, research team facilitator, and research assistant sat around the monitor, and then the participant held the smartphone to complete the tasks while being observed. We read aloud the directions and information. We video recorded each session, and the research assistant took notes. Participants had 4 tasks to complete: (1) review the introductory content of the app that describes the app purpose, (2) perform a nonpersonalized health information search in the app, (3) perform a basic personalized health information search in the app entering data about their age, sex, and pregnancy status, and (4) create a personalized profile with demographic and health information data. We asked them to talk aloud while they did the tasks and explain what they were doing and thinking. The research assistants summarized the recordings and notes of participants and questions in spreadsheets. The PI and the study director, who were present during the testing, reviewed the responses and recommended app changes to the full research team for discussion and implementation decisions.

Design Session 3 Process

Knowing and including culturally appropriate references is a key tenant of effective health communication practice, which can also be applied to digital health tools [34,35]. The goal of design session 3 was to learn design team participants' cultural preferences and needs in relation to health, and we explored culturally appropriate strategies reported in the literature that are necessary for relevant and useful health information and messages [34,36]. On the basis of comments and suggestions from design sessions 1 and 2 as well as the literature on culturally tailored strategies, the research team developed a packet of activities that asked participants to evaluate the different strategies: (1) cultural appropriateness appearance, (2) evidence of health issues specific to African Americans and Hispanics, (3) specific language and linguistic content, and (4) sociocultural values and characteristics. For the appearance evaluation task, for example, the packet included possible images for the app, and for evidence, examples of health statistics relevant to either African American or Hispanic adults. The research team discussed each strategy with participants. This session also involved participants viewing and ranking their interest in web content and tools, such as a health services locator, nutrition planner, medication information source, and an air quality tracker, that the research team was considering for the final app. These activities provided further understanding of what the participants would like to integrate in the app to increase and motivate engagement.

The research assistants summarized the audio recordings and their written notes on the spreadsheets. The PI and the study director summarized the discussions for the full research team, and the team reviewed participants' app content addition preferences. The research team convened the design groups in a separate final community member report-back meeting. The research team shared the revised app with the design session participants so they could see how their input manifested itself in the app. This was a *report-back* and a user validation session, not data collection, to close the loop with our community co-designers. The authors took notes but did not audio record the final session.

Process for How Design Session Data Informed the App

Each session was audio or video recorded, and sometimes both depending on the type of session, and transcribed and the

Spanish-speaking sessions were translated into English by bilingual research assistants on the team. Data collected from each session were entered into spreadsheets and categorized based on the design session discussion guide questions. The input from each design session informed the app development and was organized according to the (1) changes to the existing prototype to make it more attractive, easier to use, and relevant; (2) missing features that participants felt would motivate their app use and continued engagement; (3) suggestions on how to present and explain the importance of preventing illness and disease; and (4) suggestions on how to explain the personalization features, such as personal and family health history information and goal-setting. The analysis of the data from each design session is not included in this paper, as the intent of this methodological paper is to propose and discuss the multi-method co-design process we used. This paper provides the feedback from the design session team participants' on their experiences participating in the overall design process. Participant feedback was provided informally during each design session.

Results

Design Session Recruitment and Attendance

The M-CHE recruitment efforts at one local African American church resulted in 6 English-speaking African American adults, and the CHEER outreach produced 5 bilingual or Spanish-speaking Hispanic adults participating in the sessions (Table 1). The racial, ethnic, and sex distributions were 3 African American women, 3 African American men, 3 Hispanic women, and 2 Hispanic men. Participants' were aged between 30 and 76 years. Three design sessions and a report-back in English for African American participants and 3 design sessions and a report-back in Spanish for Hispanic participants occurred between December 2018 and May 2019. The groups were conducted separately to allow each group to communicate in their preferred language. Each design session lasted 2 to 3 hours. Although we held the sessions at the local church or CHEER office, participant attendance varied by session, sometimes resulting in 5 to 6 participants attending.

Table 1. Design session participant demographics (n=11).

Demographics	African American participants (n=6)	Hispanic participants (n=5)
Age (years), range	30-76	35-76
Sex, n (%)		
Male	3 (50)	2 (40)
Female	3 (50)	3 (60)
Total number of participants (design session 1), n (%)	6 (100)	5 (100)
Total number of participants (design session 2), n (%)	5 (84)	5 (100)
Total number of participants (design session 3), n (%)	5 (84)	5 (100)

Design Session Participant Experiences

Overview

Both African American and Hispanic design team members reported a positive participation experience. The primary reasons for their experiences included (1) the opportunity for their views to be heard, (2) collectively working together in the design process, (3) having their apprehension about mHealth reduced, and (4) an opportunity to increase their knowledge of how they could manage their health through mHealth. This feedback informed us about how we approached each design session and how we engaged the participants. In addition, the specific findings for each design session (not reported in this methodology paper) informed the design of the app for both communities.

Reason 1: Opportunity for Their Views to Be Heard

Both African American and Hispanic participants said that having their *perspectives* heard was important. Hispanic participants reported the following:

> I like that you take our views and perspectives into account as elders and facilitate access to cell phone research.

> I appreciate very much that you are taking all of us into account.

Reason 2: Collectively Working Together in the Design Process

African American participants reported the following: "I agree with everyone but I think the gathering, us networking, being able to share our experiences, being able to talk about ourselves openly and not being judgmental about what somebody else is going through."

This quote also reflected another reason for participants' positive experiences, as it reflects their appreciation of working together in the design process. Participants felt valued and respected, resulting in comfortably sharing their honest opinions with one another and the research team about what they thought of the app. Another participant reported the following: "In regards to the app I think that it is actually a good tool that we are part of and that you guys are trying to put out there for people to have more knowledge and have more control of their health."

In addition, an African American participant inquired how the research team established a relationship with the community to conduct this research, and we explained how the community partnerships connected us to the participants. The participant responded by saying the following:

> I think that this is a good thing because we really don't have enough of that [research] and with so much going on...we need to do research...

Reason 3: Having Their Apprehension About mHealth Reduced

The third reason for the participants' positive experience with using the app was the reduced apprehension about mHealth. An African American participant reported the following:

> You guys explaining everything to me. My vision is bad and I suffer sometimes when I'm looking at things. But you guys made it easy for me by assisting me. I've kind of understood and I'm not lost. At first I was concerned because I thought, 'Oh gosh, I'm going to sit here and be lost. I'm not going to be able to see this...etc.' But you guys made sure that I'm comfortable, I'm not intimidated...

This particular participant reported apprehension while using mHealth technologies but wanted to be involved in the study to learn how to use the technology and overcome their fear. Their comment also provided insight into the app function that needed to be adjusted based on physiological abilities.

Reason 4: An Opportunity to Increase Their Knowledge of How They Could Manage Their Health Through mHealth

Finally, the other positive experience participants reported was an opportunity to increase their knowledge of how they could manage their health through mHealth. A Hispanic participant stated the following:

> I like what they (the research team) are doing (the session) at the University of Maryland for the Hispanic community. There are many times that they (Hispanic community) don't find or don't know that a stomach ache or something simple can become something chronic. I like it [the app] a lot.

African American participants reported the following:

> That's what I got out of it. The app enables you to take care of yourself.

Discussion

Principal Findings

Overview

Our study design aimed to create a positive app development experience for a small group of English-speaking African American and Spanish-speaking Hispanic adults and generate rich data to inform an app development project. The mHealth literature reports the importance of community participation and user-centered design, and participants' responses to the research methods reported in this paper confirm these strategies. However, this study went further than others in applying health literacy principles at every step of the mHealth design process—from recruitment of participants to selection of app content, feature design, and the report-back process. Our study provides 4 key lessons and recommendations in mHealth Design for racial and ethnic groups with health disparities [37,38].

Lesson 1: Community Partnerships Are Key in Engaging Racial and Ethnic Groups With a Disproportionate Burden of Health Disparities in mHealth App Development Research

The research team in collaboration with the community partner organizations was able to successfully recruit and retain the necessary number of participants over a 6-month design session series. We tapped into the *chain of trust* that our community

partners had with the intended app users. The research team remained connected with the community partner organizations to discuss strategies to engage Hispanics and African Americans in the research process and app design. For example, when the research team and community partners were initially designing recruitment materials (ie, fliers and recruitment screening tools), both community partners stated that one standard flier for both groups would not be effective. On the basis of their experience with the local community members, the African American flier required a message stating how their community would benefit from the technology if they participated. The community partner stated that African Americans are constantly bombarded with negative statistics and information about their community, and they want to hear information framed as gains rather than losses (eg, what we will gain if we participate). The Hispanic community partner advised us to frame their recruitment message as both the gains and losses of healthier lifestyle adoption (eg, our community can gain new information and will lose out if we do not participate). Similar input informed design session moderator guides and session materials. Discussions with community partners also revealed similarities in how African American and Hispanic participants would prefer to engage in design sessions as it relates to the type of materials used, topics discussed, and technology preferences. The constant feedback and support from the community partners helped create an engaging design session environment that produced the positive and transparent participant experiences reported. We were able to apply cultural tailoring not only to the app but also in the development of the design sessions. Routine interaction and feedback with the community partners assisted us in navigating and avoiding potential pitfalls that might have occurred had we not established the collaboration.

Lesson 2: Application of CBPR Principles Continues to Yield Promising Results When Engaging Racial and Ethnic Groups With a Disproportionate Burden of Health Disparities in mHealth Research

Owing to the equitable and colearning environment that CBPR brings to the research environment, people are more likely to see value in participating in the research process because they see how their input is valued while also gaining additional information and resources. Several participants stated they appreciated that they had the opportunity to share their input about a product intended for them. A large body of literature demonstrates the benefits of applying some or all of the CBPR principles when engaging community members in research [39-41]. CBPR is also being applied specifically in mHealth app development and encouraged by other mHealth and public health researchers and developers [6,14,42,43].

Lesson 3: Interactive Design Sessions Allow Individuals to Uncover Their Needs and Opportunities for the mHealth Tool Being Developed

Several of the design session participants reported that participating in the sessions increased their awareness of health issues and the need for an mHealth information-seeking app. When presented with the prototype app for review, several reported not knowing that this information was or could be available to them and also stated how helpful it would be for themselves and others they know. Adult learning theory posits that adults will invest in learning when they perceive a strong *need to know*, and an mHealth information-seeking app can be the prompt. The team's design approach provides a tangible method that allows participants to uncover their needs and opportunities for the mHealth tool. It allows participants to manipulate something and discover something new in the process.

Lesson 4: Sustained Design Sessions Using Multiple Approaches Can Provide an In-depth Understanding in mHealth Preferences and Needs in Appearance, Function, and Content

Participants had the opportunity to provide their views about health and its relationship to information-seeking through various methods. These types of approaches aid developers and help them avoid unnecessary and potentially biased errors in the development process [6]. The use of design sessions that built on each other (eg, collaging, card sorting, user–app interaction, and cultural appropriateness strategies) allowed the research team and participants to learn about each other and develop a deeper understanding of what motivates and maintains engagement in mHealth apps among health disparity populations.

Strengths and Limitations

Two of our study's strengths focus on health literacy issues for smartphone app design and language access for people who prefer health information in languages other than English. Excluding higher education and information-seeking participants extended recruitment because many people who expressed interest did not meet these 2 criteria. However, we felt it was important to work with participants with limited health literacy and design an app for their needs that would likely work well for others with higher health literacy [28]. Working with English- and Spanish-speaking groups in parallel allowed us to see cultural and language similarities and differences in how groups might vary in app use, although we did not set the goal of conducting an explicit comparative study.

The extended engagement over 4 sessions with the same group of African American and Hispanic adults is also a strength of our study. We were able to use multiple methods to collect participant insights on different app design issues, and our participants informed our decisions at different development stages and experienced app development along with the research team. Furthermore, our app developers attended many design sessions, and they could visualize and hear participants in their own words, which kept them grounded in our participants' lived experiences.

Having participants participate in real-time app development also had its limitations. They could not experience the app in its fully functional form as we were learning and prototyping based on their input. The research team continued to iterate the app for several months after the design sessions concluded. One key feature of the app, a personalization algorithm, was added during the final development phase. We described the algorithm and personalization of the participants, but they could not try it in real time.

Although our design groups had a typical number of participants (5 to 6) for these types of user-centered design studies, a limitation is the small number of participants, as they cannot represent the needs, experiences, and perspectives of all African American and Hispanic smartphone users. However, the multiple design sessions with the same participants performing concrete tasks allowed them to provide detailed information not available through other methods. As other researchers note, user-centered methods have high information yields and rich data [37].

Conclusions

Our study contributes to the small and growing literature on the involvement of marginalized groups in mHealth design and evaluation. Although health literacy and language access issues are cited as barriers to some groups' engagement with mHealth, our project shows how careful attention to these issues can be incorporated into standard user-centered methods and CBPR principles. Participants' comments about how much they appreciated the sessions and the chance to engage with mHealth tools on their own terms validates our approach.

To reduce cultural bias errors, sustain engagement, and provide culturally relevant mHealth information apps to African American and Hispanic adults who continue to be affected disproportionately by preventable chronic conditions, developers should consider a multifaceted participatory research process that includes user-centered design and health literacy approaches. Because of social factors that increase their vulnerability to chronic diseases, it is imperative that these communities have access to digital tools that truly address their health information needs. Although health information–seeking apps are not a common or popular type of app, they have significant potential to serve as a tool that can support individuals' health care management. The comments from our participants indicate that these communities would greatly benefit from an mHealth information-seeking tool that is personalized to their health information needs. Future developers should consider more integrative app development approaches to ensure that the apps on the market contribute to eliminating health disparities and achieving health equity. It is the responsibility of those who are developing mHealth apps to ensure that studies are inclusive of the communities they intend to serve.

Abstract

Background: The prolonged COVID-19 pandemic has affected mental health among workers. Psychoeducational intervention via a website could be effective for primary prevention of mental illness among workers in the current COVID-19 pandemic.

Objective: The aim of this randomized controlled trial is to examine the effect of a newly developed online psychoeducational website named Imacoco Care on reducing psychological distress and fear about COVID-19 infection among workers.

Methods: Participants in the study were recruited from registered members of a web survey company in Japan. Participants who fulfilled the eligibility criteria were randomly allocated to the intervention or control group. Participants in the intervention group were invited to access the Imacoco Care program within a month after the baseline survey. The Kessler Psychological Distress Scale (K6) and the Fear of COVID-19 Scale (FCV-19S) scores were obtained at baseline and at 1- and 3-month follow-ups.

Results: A total of 1200 workers were randomly allocated to the intervention and control groups (n=600 [50%] per group). The Imacoco Care intervention group showed a significant favorable effect on K6 scores (P=.03) with a small effect size (ES; Cohen d=–0.14) and an adverse effect on FCV-19S scores (P=.01) with a small ES (Cohen d=0.16) at 3-month follow-up. In the per protocol analysis (including only participants who had read the Imacoco Care content at least 1 time), the Imacoco Care intervention group also showed a significant favorable effect on reducing K6 scores (P=.03), while an adverse effect on FCV-19S scores was not significant (P=.06) in the intervention group at 3-month follow-up.

Conclusions: A web-based psychoeducation approach may be effective for improving psychological distress among workers; however, it may be important not only to distribute information but also to encourage active engagement with the content of the program to prevent adverse effects of psychoeducational intervention.

Introduction

Background

The prolonged COVID-19 pandemic has affected the mental health not only of essential health care workers [1-5] but also of other workers (ie, non-health-care) [6,7]. Previous studies have reported a high prevalence of depression (34.6%), anxiety (42.3%), and psychological distress (65.1%) among workers [6,7], as well as a decline in the health-related quality of life [8] during the COVID-19 pandemic. Providing effective primary prevention stress management interventions is essential for protecting and promoting the mental health of workers during the prolonged COVID-19 pandemic [9].

Psychoeducational intervention is 1 of the effective treatments for primary prevention of mental health problems in the working population. A recent systematic review aiming to identify and summarize interventions for dealing with mental health issues of health care workers during infectious disease outbreaks, including COVID-19, reported that emotional and psychological intervention, including psychoeducation, is an important approach [10], especially since the 2000s, online-delivered psychoeducational interventions have received much attention. A recent meta-analysis reported that online psychological and psychoeducational interventions, which are mainly based on the principle of cognitive behavioral therapy (CBT), have a significant small effect (pooled standardized mean difference [SMD] –0.26) on reducing depressive symptoms in nondepressed and varied populations, with a moderate quality of evidence [11]. One of the effective online formats for delivering psychoeducational information is a website. Some previous studies before the COVID-19 pandemic have reported that psychoeducation websites significantly improved depressive symptoms among community residents with elevated depressive symptoms [12] and workers who visited a mental health specialist in the past month at baseline [13]. Psychoeducational intervention via a website could also be effective for primary prevention among workers in the current COVID-19 pandemic.

Although online/website-based psychoeducational intervention may be promising for improving the mental health of workers in the COVID-19 pandemic, only a few randomized controlled trials (RCTs) have been conducted during the COVID-19 pandemic. Regarding studies targeting community residents, 2 RCTs applying CBT-based intervention among people with elevated mental symptoms showed favorable effects on mental health outcomes [14,15], while another RCT applying low-intensity online mindfulness-based intervention in the general population could not find a significant effect on any outcomes [16]. In the working population, only 1 study focusing on health care workers who had provided direct face-to-face health care to patients with a diagnosis of infection with COVID-19 was conducted during the COVID-19 pandemic [17]. This RCT reported that a self-guided CBT and mindfulness-based mobile health intervention (the PsyCovidApp) significantly improved overall mental symptoms (total score of depression, anxiety, and stress) among health care workers who used psychotropic medications (SMD –0.29) or received psychotherapy (SMD –0.25) at baseline, while there was no significant intervention effect among the whole sample [17]. Developing an effective online psychoeducational intervention and examining its effect on promoting mental health are needed for workers during the COVID-19 pandemic. Although demonstrating the efficacy of such a cost-effective psychoeducation website would be beneficial, there is no other RCT aiming to examine the effect of a psychoeducational website on improving mental health problems in the working population in the current COVID-19 pandemic. Therefore, a further RCT is needed to examine the effect of psychoeducational intervention in a sample of workers.

Objective

The aims of this study were to examine the effect of a newly developed self-guided, low-intensity, and easy-to-disseminate psychoeducational website named Imacoco Care on improving mental health (ie, reducing psychological distress and fear about COVID-19 infection) among workers, using an RCT design.

The hypotheses in this study were as follows: (1) Imacoco Care would reduce psychological distress as the primary outcome among workers, and (2) Imacoco Care would reduce fear about COVID-19 as the secondary outcome among workers.

Methods

Trial Design

This study was an RCT. The allocation ratio of the intervention group to the control group was 1:1. The study protocol was registered at the University Hospital Medical Information Network Clinical Trials Registry (UMIN000042556). This paper was reported according to the Consolidated Standards of Reporting Trials (CONSORT) guidelines [18,19].

Ethical Considerations

The Research Ethics Review Board of the Graduate School of Medicine and Faculty of Medicine, University of Tokyo, approved the study procedures (number 3083-6).

Participants

Participants in this study were recruited from registered members of a web survey company in Japan (Rakuten Insight, Inc [20]). Over 2 million members are registered in this company. Of those, 10,000 adult workers who were potentially eligible for the study were randomly selected. These candidates received a URL of a webpage that included detailed information about the study. The aims and procedures of the study were fully explained on the webpage. Participants were asked to click the Agree button to show their consent to participate in the study; then they proceeded to the baseline questionnaire page. Written consent was not required by the National Ethical Guidelines for Epidemiologic Research, Japan; the Research

Ethics Review Board of the Graduate School of Medicine and Faculty of Medicine, University of Tokyo, approved this procedure for obtaining participants' consent.

Eligibility Criteria of This Study

The inclusion criteria of this study were (1) adults (over 20 years old) and (2) full-time employees. The exclusion criteria were (1) having 15 sick leave days or more during the past 3 months, (2) having consultations with mental health professionals during the past month, and (3) having participated in this intervention program in the past.

Intervention Program: Imacoco Care

Imacoco Care is a newly developed self-guided psychoeducation website-based program for providing information about coping with stress or problems under the conditions of the COVID-19 pandemic [21]. Imacoco Care provides information for managing stress and maintaining mental health among people staying at home under the state of emergency. The content is mainly composed of text, illustrations, video, and audio narration. There are about 30 pages in total, with around 1000 Japanese characters (500 words in English) per page. All content is explained in plain language, easy to understand for most workers, and does not presume prior knowledge of stress management.

Imacoco Care provides information about evidence-based psychological interventions for psychological distress (see Table 1), and the website can be accessed anywhere the internet is available. All of the Imacoco Care content was developed by the authors. Recent studies focusing on mental health among workers in the COVID-19 pandemic have reported that psychological/physical interventions, such as mindfulness, CBT-based psychoeducation, and physical activity, could improve mental health problems during the COVID-19 pandemic [14,22,23]. Details of the content included on the Imacoco Care website are listed in Table 1.

Table 1. Overview of the content of the Imacoco Care website.

Modules	Content
Mindfulness	This module provides information about the benefits of mindfulness and how to engage in it with easy-to-understand audio and video.
Behavioral activation (BA)	This module introduces how to relate behaviors/actions to feelings, how to maintain mental energy, and how to perform activities that lead to good feelings.
Physical activity	This module provides knowledge and tips for leading an active life while people are asked to stay at home, being properly aware of the spread of the new coronavirus.
Sleep education	This module provides information about how to regulate the sleep rhythm without using medication.
Tips for working from home	This module provides tips to make telecommuting (working from home) a little more comfortable.
Coping with the stress about COVID-19	This module provides stress management tips that can be practiced in daily life.

Mindfulness

An operational definition of mindfulness is "the awareness that emerges through paying attention on purpose, in the present moment, and nonjudgmentally to the unfolding of experience moment by moment" [24]. A previous meta-analysis reported that mindfulness meditation programs yielded moderate evidence of improved anxiety (effect size [ES]=0.38 at 8 weeks and 0.22 at 3-6 months) and depression (ES=0.30 at 8 weeks and 0.23 at 3-6 months) [25]. Imacoco Care provides information about the benefits of mindfulness and how to engage in it in the following lessons, with easy-to-understand audio and video: (1) For When You Feel Uncomfortable—an Introduction to Mindfulness; (2) The Body Relates to Our Feelings—Using mindfulness to Pay Attention to the Sensations of the Body; (3) Mindfulness by Narrating Like a Live Broadcast; (4) Mindful Eating; and (5) Self-Compassion Exercises to Calm Painful Feelings [26].

Behavioral Activation

Behavioral activation (BA), one of the most readily applied techniques in CBT, is a process to increase pleasurable and rewarding activities using behavioral strategies, such as activity scheduling [27]. A previous meta-analysis showed that CBT including BA could significantly reduce the risk of the onset of major depression (incidence rate ratio=0.62) [28]. Imacoco Care introduces how to relate behaviors/actions to feelings, how to maintain mental energy, and which activities lead to good feelings in the following lessons: (1) Tips for Keeping Your Mind Energized During Difficult Daily Life, (2) The Relationship Between What You Do or Don't Do and Your Feelings, (3) Reflecting on Your Life Patterns, (4) Think of a "Safe Activity" That Doesn't Fit Into the "Three Cs" (Crowded Places, Close Contact, Confined and Enclosed Spaces), (5) Let's Make Your Action Plan!, and (6) Reflections: Tips for Acting to Keep Energy in Your Life.

Physical Activity

Physical activity is defined as any bodily movement produced by skeletal muscles that requires energy expenditure, which encompasses moderate-vigorous exercise and lower-intensity walking [29]. A previous meta-analysis showed that physical activity reduced depression by a medium effect (SMD –0.50) and anxiety by a small effect (SMD –0.38) [30]. Doing physical activity is also recommended during the COVID-19 outbreak [31]. Imacoco Care provides knowledge and tips for leading an active life while people are asked to stay at home and being properly aware of the spread of the new coronavirus, in the following lessons: (1) Physical Activity for Mental Health—Introduction; 2) Let's Find a Physical Activity That Suits You—for Beginners; and (3) Let's Find a Physical Activity That Suits You—for Advanced Learners.

Sleep Education

Some studies have shown that sleep problems or insomnia were detected in around 35% of participants (ie, community residents or health care workers) during the COVID-19 pandemic [32,33]. CBT for insomnia (CBT-I) is one of the effective treatments for improving sleep problems, and it is recommended as the first-choice treatment for insomnia in the COVID-19 outbreak [34]. Imacoco Care provides information about how to regulate the sleep rhythm without using medication in the following lessons: (1) Psychological Advice for Those Whose Sleep Cycle Has Become Worse and (2) Life Tips to Try When You Can't Sleep.

Tips for Working From Home

Previous literature reviews have reported that the effects of working at home are inconsistent and might depend on various factors, such as demands of the home environment, the level of organizational support, and social connections external to work, among others [35]. This module provides some tips to make telecommuting (working from home) a little more comfortable, such as ergonomic tips when teleworking, keeping the time of the lunch break, getting fresh air, stretching and exercising, and keys for effective communication [36,37].

Coping With the Stress About COVID-19

This module provides stress management tips that can be practiced in daily life, including (1) prioritize personal hygiene (preventive measures), (2) stay connected with others, (3) keep a healthy lifestyle, (4) use psychological coping strategies (eg, mindfulness), (5) limit media consumption, and (6) prevent stigma and discrimination [36,38].

Intervention Group

Immediately after the baseline survey, participants in the intervention group were invited to access Imacoco Care and requested to view Imacoco Care within 1 month after the baseline survey. During this period, the participants received a reminder email twice (1 week after the baseline survey and 1 week before the 1-month follow-up survey).

Control Group

Participants in the control group were only asked to complete the baseline and follow-up surveys. They were not invited to the Imacoco Care website, but they were not restricted from accessing any other information or service as treatment as usual (TAU).

Outcome Measures

All outcomes were measured using a web-based self-report questionnaire at baseline, 1-month follow-up, and 3-month follow-up.

Primary Outcomes

Psychological Distress

The Kessler Psychological Distress Scale (K6) consists of 6 items assessing the frequency with which participants experience symptoms of psychological distress during the past 30 days [39,40]. The response options range from 0 (none of the time) to 4 (all the time). The internal reliability and validity found in previous studies are acceptable [39].

Fear of COVID-19 Infection

The Fear of COVID-19 Scale (FCV-19S) consists of 7 items assessing the fear of COVID-19 [41,42]. The response options range from 1 (strongly disagree) to 5 (strongly agree), with total scores ranging from 7 to 35. The higher the score, the greater the fear of COVID-19. The internal reliability and validity found in previous studies are acceptable [43].

Process Evaluation

Implementation Aspects of the Intervention Program, the Number of Views, and Progress in Learning About Imacoco Care

The Implementation Outcome Scale for Digital Mental Health (iOSDMH) for users was used to assess the implementation aspects of Imacoco Care [44]. The iOSDMH for users consists of 19 items assessing acceptability (3 items), appropriateness (4 items), feasibility (6 items), satisfaction (1 item), and harm (5 items). The response options range from 1 (disagree) to 4 (agree). The number of views was evaluated by using 1 item: "How many times did you view Imacoco Care during the past month?" There were 4 response options (never, once, twice, and 3/4 times or more). This scale was originally developed and has not yet been validated. To assess progress in learning about each of the 6 modules of Imacoco Care, participants in the intervention group were also asked, "Have you read and tried each content of Imacoco Care?" There were 3 response options (have not read, only read, and read and tried). This scale was also originally developed and has not yet been validated. These questions were asked of only participants in the intervention group in the 1-month follow-up survey.

Contamination of Information

To evaluate the degree of contamination of information, the control group participants were asked the following question in 1- and 3-month follow-up surveys: "During the past, have you ever viewed a website named Imacoco Care?" There were 4 response options (none, once, twice, and 3/4 times or more). This scale was originally developed and has not yet been validated.

Demographic Characteristics

Demographic data, such as age, gender, marital status (never married, married, divorced, or bereaved), education (high school or lower, some college, university, graduate school or higher), occupational status (manager, professional, clerical, production, sales, others), working style (working from home only, both working from home and at the office, working at the office only), and chronic disease (yes/no) were collected in the baseline survey.

Sample Size Calculation

The required sample size was calculated for psychological distress assessed by K6. A previous meta-analysis of an unguided eHealth intervention on improving workers' mental health in the workplace yielded an ES of 0.22 [45]. To detect a small ES (ie, 0.2) or more at an α error rate of .05 and a β error

rate of .10, the estimated sample size was 527 participants in each group. The statistical power was calculated using the G*Power 3.1 program [46,47].

Randomization

Participants who fulfilled the eligibility criteria were randomly allocated to 1 of 2 arms (intervention or control group). Stratified permuted-block randomization was conducted. The block sizes of this study were fixed to 2. Participants were stratified into 2 strata according to the K6 score (<4 or ≥5) in the baseline survey [48]. A stratified permuted block random table was generated by an independent biostatistician. Enrollment was conducted by a clinical research coordinator, and assignment was conducted by an independent research assistant. The stratified permuted-block random table was password-protected and blinded to the researcher. Only the research assistant could access it during the work of random allocation.

Statistical Methods

For the main analysis, a mixed model for repeated measures (MMRM) analysis of variance model was conducted using a group (intervention and control) × time (baseline, 1-month follow-up, and 3-month follow-up) interaction as an indicator of the intervention effect. Missing values at follow-up surveys were imputed applying the maximum likelihood estimation using the mixed procedure. An intention-to-treat (ITT) principle was applied.

The ES was estimated in 2 ways. First, we estimated a regression coefficient for a group (intervention vs control group) × time (baseline and 2 follow-ups) interaction using the mixed procedure, which was converted to an ES by dividing by a pooled SD at baseline and at follow-ups. Second, we calculated the Cohen d values [49] among participants who completed surveys at baseline and at each follow-up. The level of statistical significance for all analyses in this study was set at .05 (two-tailed), and 95% CIs were calculated. All statistical analyses were conducted using SPSS Statistics V.26.0 (IBM Corp).

Per Protocol Analysis

For the per protocol analysis, the same MMRM analysis was conducted using only participants who had viewed the Imacoco Care website at least once in the intervention group and all participants in the control group.

Results

Participant Recruitment

The participant flowchart is shown in Figure 1. Recruitment and the baseline survey were conducted in December 2020. Follow-up surveys in both groups were conducted 1 month (January 2021) and 3 months (March 2021) after the baseline survey. Participants who had fulfilled the inclusion criteria (ie, aged over 20 years and full-time employed) were recruited from monitors of an internet survey company (N=9484). Of those, 1367 (14.41%) were excluded according to the exclusion criteria. Of the 8117 eligible participants, 1200 (14.75%) who completed the baseline survey were selected on a first-come-first-served basis. Participants were randomly allocated to an intervention or a control group, with 600 (50%) participants in each.

Figure 1. Participant flow.
Baseline Characteristics

Demographic characteristics are presented in Table 2. In the whole sample, most participants were male, were married, received university or higher education, and did not report having chronic diseases. Only less than 30% were using telecommuting. Between the 2 groups, demographic characteristics of participants were similar. About 192 (32%) participants in each group had psychological distress (ie, scored 5 or more on K6).

Table 2. Baseline characteristics of participants in the intervention and control groups.

Variables	Intervention (N=600)	Control (N=600)
Age (years), mean (SD)	46.4 (10.3)	46.7 (10.0)
Gender, n (%)		
Male	441 (73.5)	442 (73.7)

Both working from home and at the office	133 (22.2)	136 (22.7)
Working at the office only	440 (73.3)	436 (72.7)
Chronic disease, n (%)		
Yes	116 (19.3)	100 (16.7)
No	484 (80.7)	500 (83.3)
5 or more on K6 score	192 (32.0)	193 (32.2)

Effect of the Imacoco Care Program on Psychological Distress

The average K6 and FCV-19S scores in each survey are shown in Table 3. The K6 score increased at 1-month follow-up in both groups and decreased at 3-month follow-up only in the intervention group. The Imacoco Care intervention group showed a significant ES in reducing the K6 score at 3-month follow-up compared to the control group (Cohen d=–0.14, 95% CI –0.26 to –0.02). The FCV-19S score also increased at 1-month follow-up and decreased at 3-month follow-up in both groups. The Imacoco Care intervention group showed a significant adverse ES in increasing the FCV-19S score at 3-month follow-up compared to the control group (Cohen d=0.16, 95% CI 0.04-0.28).

Table 4 shows the estimated effects of the Imacoco Care intervention on K6 and FCV-19S scores on the basis of MMRM analyses. In ITT analyses, the Imacoco Care intervention showed a significant favorable effect on reducing the K6 score (P=.03) and an adverse effect on the FCV-19S score (P=.01) in the intervention group at 3-month follow-up. In the per protocol analyses, the Imacoco Care intervention also showed a significant favorable effect on reducing the K6 score (P=.03), while the adverse effect on the FCV-19S score was not significant (P=.06) in the intervention group at 3-month follow-up.

Table 3. Means (SDs) of outcome variables at baseline, 1-month follow-up, and 3-month follow-up in the intervention and control groups.

Outcome variables	Intervention		Control		ES[a]
	n (%)	Mean (SD)	n (%)	Mean (SD)	Cohen d (95% CI)
Psychological distress

[a]ITT: intention to treat.

[b]Participants who saw the Imacoco Care website at least 1 time in the intervention group (n=235 [39.2%]) were included.

[c]ES: effect size, calculated by dividing the estimated effect by a pooled SD at baseline and at follow-ups.

Process Evaluation

Among participants (n=545, 90.8%) in the intervention group at the 1-month follow-up, 52 (9.5%) viewed the Imacoco Care website 4 times or more, 96 (17.6%) viewed it 2 or 3 times, 87 (16.0%) viewed it once, and 310 (56.9%) never viewed the Imacoco Care website.

Among participants (n=235, 39.2%) who viewed the Imacoco Care website at least once, 13 (5.5%) read all the content, 82 (34.9%) read most of the content, 73 (31.1%) read some of the content, 66 (28.1%) read a little of the content, and 1 (0.4%) read little of the content. In addition, 174 (74.0%) read or tried mindfulness techniques, 159 (67.7%) read or tried BA, 170 (72.3%) read or tried physical activity, 195 (83.0%) read or tried sleep education, 121 (51.4%) read or tried the tips for working from home, and 165 (70.2%) read or tried techniques for coping with stress about COVID-19.

Regarding the result of implementation outcomes assessed by the iOSDMH, around 105-174 (44.7%-74.0%) of the 235

participants answered "agree" or "relatively agree" on each item of acceptability (n=105-158, 44.7%-67.2%), appropriateness (n=115-164, 48.9%-69.8%), and feasibility (n=135-174, 57.4%-74.0%). The highest proportions of positive responses in each of the 3 aspects were "Advantages outweigh the disadvantages for keeping my mental health" (n=158, 67.2%) in acceptability, "Appropriate (from your perspective, it is the right thing to do)" (n=164, 69.8%) in appropriateness, and "Lower physical effort" (n=174, 74.0%) in feasibility, respectively. Regarding overall satisfaction with Imacoco Care, 135 (57.4%) answered "agree" or "relatively agree." Regarding harms, around 47 (20%) or fewer participants answered "agree" or "relatively agree" on each item, except for "Time-consuming" (n=63, 26.8%). The details of the number of participants for each item are shown in Multimedia Appendix 1.

Regarding the contamination of information, 9 (1.5%) of 600 participants in the control group had viewed the Imacoco Care website at least once at 1-month follow-up and 17 (2.83%) had viewed the Imacoco Care website at 3-month follow-up.

Discussion

Principal Findings

This large-scale RCT showed that the newly developed psychoeducational website during the COVID-19 pandemic, named Imacoco Care, significantly improved psychological distress at 3-month follow-up among workers in Japan, with a small ES. In concordance with previous studies conducted before the COVID-19 pandemic, a web-based psychoeducation approach including information about evidence-based psychological interventions may be effective for improving psychological distress (ie, depressive and anxiety symptoms) among workers in the current COVID-19 pandemic. The Imacoco Care website may promote mental health among workers, which mainly consisted of male, married, university graduates without chronic disease or current mental health problems, during the COVID-19 pandemic.

Comparison With Prior Work

To our knowledge, this study is the first to examine whether a psychoeducational website can improve psychological distress symptoms among workers during the COVID-19 pandemic. A significant intervention effect of the Imacoco Care intervention was found on psychological distress at 3-month follow-up, while the ES was small (Cohen d=–0.16) compared to previous studies of participants with elevated psychological distress or worry about COVID-19 (around 0.7) [14,15]. One of the possible reasons for the small ES in this RCT may be the lower intensity of the intervention. A previous RCT provided 5 modules with a few tasks to practice. Participants were encouraged to report on their progress in digital worksheets in the online platform [14]. The other pilot RCT provided 7 selected modules out of 16 possible modules, with a therapist's (ie, clinical psychologist) support. Each participant had a therapist who provided online support and feedback on the work with the modules and exercises and motivated the participant to continue to work with the treatment [15]. The Imacoco Care program only provided information via the website, and participants received a reminder email only twice. This may have led to a small ES; nevertheless, the Imacoco Care program still has merit because of its greater accessibility and lower cost. The other possible reason may be the difference in the baseline characteristics of the participants. The study excluded workers with current mental health problems (ie, having 15 sick leave days or more during the past 3 months or consultations with mental health professionals during the past month). This may have led to an underestimation of the intervention effect (floor effect).

Regarding fear about COVID-19, Imacoco Care showed a significant adverse effect (Cohen d=0.16) at 3-month follow-up. This slight increase in the fear about COVID-19 may be due to increased awareness of stress caused by learning from the Imacoco Care program [13,50]. In contrast, the result from per protocol analysis that included only participants who had read the Imacoco Care website at least 1 time showed a nonsignificant adverse effect on the fear of COVID-19 at 3-month follow-up (Cohen d=0.15). An adverse effect on the fear about COVID-19 may have been more common among participants who never saw the Imacoco Care website during

the intervention period. Both distributing the information and encouraging people to access and read the content may be necessary to prevent adverse effects of psychoeducational intervention. Users should be informed about the possible adverse effects of seeing the Imacoco Care website in advance to decide whether to take the program, balancing merits and demerits.

Process evaluation of the Imacoco Care program showed that the proportion of those who viewed the Imacoco Care website at least once was 235 (39.2%) of 600 participants. Of those, only 95 (40.4%) read all or most of the content on the Imacoco Care website. The low rates of reading the content may weaken the intervention effect. Regarding the results from per protocol analyses, the Imacoco Care program showed a greater effect for psychological distress (Cohen d=–0.17) among workers who had viewed the Imacoco Care program at least once. Increasing readers may be effective in improving the effect of Imacoco Care. From the implementation aspects, Imacoco Care showed moderate rates (around 105-174 [44.7%-74.0%]) of acceptability, appropriateness, and feasibility among participants who viewed the Imacoco Care website at least once. The features of the Imacoco Care program (explaining evidence-based psychological intervention in an easy-to-understand way by using plain language, illustrations, video, and audio narration) may contribute to these implementation outcomes. Further study is needed to develop an implementation strategy for increasing adoption of the Imacoco Care program among workers and examine its effect on implementation outcomes.

Limitations

Several limitations of this study should be considered. First, all participants were recruited from registered members of a web survey company in Japan. Most of participants were male, married, and university graduates without chronic disease and psychological distress at the baseline survey. Therefore, generalization of the findings to the general working population may be limited. Second, website access logs by users were not collected. The actual proportion of access to each content area of Imacoco Care could not be analyzed. The effectiveness of each content area could not be examined, and the results from process evaluation may be biased. Third, all outcomes were measured by self-report, which may be affected by the perceptions of the participants or by situational factors at work. A further RCT and implementation study should be conducted to examine whether psychoeducational intervention via an online program is effective among workers with diverse characteristics, particularly in terms of education.

Conclusion

An RCT was used to evaluate a new website-based psychoeducational program, named Imacoco Care, which was developed to address mental health issues during the COVID-19 pandemic. Results showed significantly reduced psychological distress at 3-month follow-up among workers in Japan, with a small ES. Thus, a web-based psychoeducation approach may be an effective intervention for reducing psychological distress in the working population. To enhance outcomes from this type of intervention and reduce any adverse effects, it may be important to not only distribute information about the program

XSL•FO

RenderX

but also encourage workers to access and actively engage with   the content of the program.

Abstract

Background: Adolescents and young adults (AYA) in the United States, and in Washington, District of Columbia (DC), specifically, are disproportionately affected by HIV. Both the national Ending the HIV Epidemic initiative and DC-specific plans emphasize HIV testing, and innovative strategies to encourage testing among AYA are needed.

Objective: The purpose of this study is to identify sexual behaviors, HIV knowledge, HIV perceptions (eg, susceptibility and severity), and perceived barriers and facilitators to HIV testing among AYA at risk for HIV in DC.

Methods: This study was part of a larger study to determine the acceptability of using a life-and-dating simulation game to increase HIV testing among AYA. Focus groups and surveys stratified by self-reported sexual orientation were conducted among, and administered to, AYA aged 13-24 years in DC. HIV knowledge was explored during focus groups and measured using an adapted version of the Brief HIV Knowledge Questionnaire. Survey data were summarized using descriptive statistics and compared by self-reported sexual orientation. Transcripts were thematically analyzed.

Results: Of the 46 AYA who participated in the focus groups, 30 (65%) identified as heterosexual and 16 (35%) as lesbian, gay, bisexual, transgender, or queer. A higher proportion of lesbian, gay, bisexual, transgender, or queer AYA reported sexual activity (12/16, 75%, vs 18/30, 60%), condomless sex (11/12, 92%, vs 15/18, 83%), and HIV testing (13/16, 81%, vs 17/29, 58%) than heterosexual AYA. HIV prevention ("condoms" and "...PrEP") and transmission ("exchange of fluids") knowledge was high, and most (34/44, 77%) of the AYA perceived HIV testing as beneficial. However, the AYA also demonstrated some misinformation concerning HIV: an average of 67% (31/46; SD 0.474) of the participants believed that an HIV test could deliver accurate results 1 week after a potential exposure and an average of 72% (33/46; SD 0.455) believed that an HIV vaccine exists. The AYA also identified individual ("...people...are scared"), interpersonal ("it's an awkward conversation"), and structural ("...people don't...know where they can go") barriers to testing. Most of the AYA indicated that they were very likely to use the demonstrated game prototype to help with getting tested for HIV (median 3.0, IQR 2.0-3.0, using a scale ranging from 0 to 3, with 3 indicating high likelihood) and strongly agreed that the game was interesting (median 5.0, IQR 5.0-5.0), fun (median 5.0, IQR 4.0-5.0), and easy to learn (median 5.0, IQR 5.0-5.0, using a scale ranging from 1 to 5, with 5 indicating strong agreement).

Conclusions: These results suggest a need for multilevel HIV testing interventions and informed the development of a mobile health intervention aiming to increase HIV knowledge and risk perception among AYA, while reducing barriers to testing at the individual and structural levels, supporting efforts to end the domestic HIV epidemic.

Introduction

HIV Among Adolescents and Young Adults in the United States

Adolescents and young adults (AYA) aged 13-24 years are disproportionately affected by HIV in the United States. Among the estimated HIV transmissions in 2016, AYA had the highest transmission rate of all age groups [1]. In 2019, AYA accounted for 21% of the new HIV infections, and young men who have sex with men (YMSM) and transgender women who identified as Black or Latinx were severely affected [2]. Approximately 50% of the AYA living with HIV in the United States are unaware of their infection and are more likely to be unaware of their infection than any other age group [2,3]. Nevertheless, once AYA are diagnosed, they often reduce their sexual risk behaviors, which limits the risk of infecting others [4-6]. In addition, AYA who are diagnosed with HIV early in the course of their infection can access antiretroviral therapy to slow disease progression and reduce mortality [4].

HIV Among AYA in Washington, District of Columbia

Just as HIV infections and diagnoses in the United States are not evenly distributed across different ages, races and ethnicities, genders, and modes of transmission, they are more concentrated in certain geographic locations than in others. The southern United States, which includes Washington, District of Columbia (DC), accounted for 53% of the new diagnoses in 2019 despite being home to just 38% of the population [7]. In DC specifically—a metropolitan area that also includes parts of Maryland, Virginia, and West Virginia—AYA are disproportionately affected by HIV, with those aged 13-24 years accounting for 21% of the new diagnoses in 2019 [8]. Furthermore, Black AYA and YMSM in DC accounted for 75% and 60%, respectively, of the new HIV diagnoses among AYA in 2019 [9]. The recently launched *Ending the HIV Epidemic in the U.S.* (EHE) initiative aims to end the domestic HIV epidemic by 2030, and the first strategy includes ensuring that HIV testing is widely available to diagnose infections as early as possible [10]. DC is among several localities across the nation considered geographic HIV hotspots that will be the focus of initial EHE efforts [10]. The DC-specific plan to end the HIV epidemic also includes emphasis on HIV testing and timely diagnosis [11], and DC's Youth Sexual Health Plan [12] has the explicit goal of reducing the unintended consequences of condomless sex among AYA (eg, HIV infection) by increasing use of sexual and reproductive health services, including HIV testing.

Lack of HIV Testing Among AYA

Despite engaging in high-risk behaviors [13-19] and the existence of national guidelines that support routine HIV testing among persons aged 13-64 years [19,20], AYA do not regularly seek nor are they routinely offered testing for HIV. Barriers to HIV testing among AYA include privacy concerns, parental involvement, inconvenient clinic times, providers not assessing sexual behavior, cost, low access, and low health literacy [21-25]. Furthermore, AYA may have limited knowledge of HIV [26-29] and underestimate their risk for infection [21,25,30]. In DC, differences in perceived access to HIV education exist among AYA based on sexual orientation. According to the 2019 Youth Risk Behavior Survey (YRBS), heterosexual middle school students in DC were more likely to report either not being taught or not being sure that they were taught about HIV/AIDS in school than lesbian, gay, and bisexual middle school students [31]. YRBS data also suggest that high-risk behaviors among youth in DC differ based on sexual orientation. Among middle school and high school students who reported sexual activity on the 2019 YRBS, lesbian, gay, and bisexual students were more likely to report having condomless sex during their last sexual encounter than heterosexual students [31,32].

Potential of Mobile Health Interventions and Study Objectives

Innovative strategies to overcome these barriers and increase HIV testing among AYA include social media campaigns [33,34] and mobile health (mHealth) interventions [35,36], both of which have been endorsed by the Centers for Disease Control and Prevention (CDC) to reduce HIV risk and improve sexual health among adolescents [37]. New mHealth interventions for HIV treatment and prevention have been developed specifically for AYA in urban areas [35,36,38-42]. These interventions transcend traditional behavior modification approaches to HIV prevention and incorporate adolescent-friendly and -informed models that support the design and development of mHealth interventions. The purpose of this study is to identify sexual behaviors, HIV knowledge, HIV perceptions (eg, susceptibility and severity), and perceived barriers and facilitators to HIV testing among AYA at risk for HIV and to identify potential differences based on self-reported sexual orientation. The results from this study were used to inform the development of an mHealth intervention aiming to increase HIV testing among AYA living in DC.

Methods

Data Collection

The study was conducted as part of a larger study to determine the acceptability of using a life-and-dating simulation game to increase HIV testing among AYA; the methods have been described elsewhere [43]. The game will allow AYA to play characters that are similar to, or different from, their gender identity. The character can then spend their leisure time meeting new people and engaging in relationship scenarios—including implied sexual activity—tailored to both same-sex and opposite-sex couples. On the basis of in-game sexual activity, AYA will be shown their character's risk of acquiring HIV and be allowed to locate nearby AYA-friendly testing locations.

Guided by the Health Belief Model [44]—a widely used framework to explain and predict individual-level changes to health-related behavior [44] and to assess HIV testing uptake specifically [45-48]—we hypothesized that the game would increase perceived susceptibility to HIV infection, perceived severity of HIV infection, perceived benefits of HIV testing, motivation to test, and self-efficacy to test while decreasing perceived barriers to testing among the study participants (Figure 1).

Figure 1. Conceptual framework for assessing HIV testing uptake among adolescents and young adults. PrEP: pre-exposure prophylaxis; SES: socioeconomic status.
From February 2017 to December 2017, HIV-negative or status-unknown AYA aged 13-24 years who were living in the DC metro area were recruited from an adolescent health center during routine visits, 2 community-based organizations, and a youth advisory council [43]. Recruitment was primarily facilitated by CT, a female researcher. Of the 52 AYA approached for the study, 6 (12%) declined to participate; the reasons for refusal included lack of time to undergo the eligibility screening process or not being available on the date of the focus group. To assess the baseline perceptions of AYA regarding HIV susceptibility and severity as well as potential benefits of, and barriers to, testing, we conducted a series of focus group discussions that lasted 50-120 minutes and were held at the adolescent health center, a local community-based organization, and a DC government building where the youth advisory council met. Focus group discussions, stratified by sexual orientation, were facilitated by ADC (a female researcher) using a semistructured focus group guide and covered the following topics: HIV knowledge, perceptions and personal experiences regarding HIV testing, and perceived barriers and facilitators to HIV testing. The focus group guide can be found in Multimedia Appendix 1.

Next, DG (a male researcher) demonstrated the game to participants and asked questions related to game acceptability. The game showed two dating scenarios: one at a house party and one at a skateboard park. DG controlled a character that had the freedom to go wherever they wanted in the 3D environment and talk to other AYA in the game by selecting from a menu of dialogue options. These conversations, combined with the player's actions, resulted in the player's character becoming friends, rivals, or dating partners with the people they met. Participants played the game as a group by voting on the actions and dialogue options the player character should choose in navigating dating scenarios. When the player managed to negotiate sex with another character in the game, the participants chose the kinds of sex acts the characters would engage in and whether a condom would be used. The sex acts were not depicted graphically but rather implied by fireworks, and the screen abruptly transitioned to a depiction of the risk of the sex acts chosen based on the CDC Risk Estimator Tool. The player then had the option of seeing a map of nearby HIV testing providers, with the ability to select low-cost and free options. Participants could replay the game, trying other options and seeing other outcomes.

Focus groups continued until data saturation—the point at which new data repeat data already collected [49]—was met, which occurred after 7 focus groups. Before the start of each focus group, participants completed a survey that collected information on their sociodemographic characteristics, HIV knowledge and HIV testing patterns, sexual behaviors and perceptions regarding susceptibility to HIV, self-efficacy to get tested for HIV, and barriers and benefits to HIV testing. As in the case of other research assessing HIV knowledge using a limited number of questions [50,51], HIV knowledge in this study was measured using an adapted version of the Brief HIV Knowledge Questionnaire that included 11 of the 18 questions [52]. After the game demonstration, the AYA completed a brief survey to assess game acceptability. All AYA participants were remunerated with gift cards and transportation vouchers for their participation in each focus group.

Data Analysis

All focus groups were audio recorded and professionally transcribed, and transcripts were imported into NVivo 11 (QSR

International) for data analysis. Initial codes were deductively derived: BW created a codebook containing a priori codes based on the topics included in the semistructured focus group guide, and 2 coders (BW and THH) conducted independent thematic coding to link the common themes and ideas discussed among study participants in each respective focus group [53]. Next, the coders reconvened to reach intercoder agreement through reconciliation of discrepant coding. Specific themes across focus group data were developed based on patterns of shared or similar meaning identified through codes ascribed to each respondent's feedback. Finally, final codes across focus groups and coders were compared to generate overall themes that supported the purpose of the study. In addition to focus groups, data collected from surveys were summarized using descriptive statistics in SAS 9.3 (SAS Institute Inc) by BW. Survey responses related to demographics, sexual behavior, and risk perception were stratified by self-reported sexual orientation; frequencies and percentages were used to describe categorical variables, whereas mean and range or mean and SD were used to describe continuous variables. To describe acceptability of the game prototype, survey responses were stratified by self-reported sexual orientation and median values were reported for each survey item.

Ethics Approval

Study materials were reviewed and approved by the George Washington University Institutional Review Board (IRB) (number 051602) and the Children's National Hospital IRB.

Results

AYA Demographics, Sexual Risk Behaviors, and Perceptions

Of the 46 AYA who participated in the focus groups, 30 (65%) identified as heterosexual and 16 (35%) identified as lesbian, gay, bisexual, transgender, or queer (LGBTQ; Table 1). The mean age of participants was 17.6 (SD 2.110; range 13-24) years, 85% (39/46) were Black, and 63% (29/46) were female. Most of the participants lived in DC (44/46, 96%), and 67% (30/45) had not yet graduated from high school. Higher proportions of the LGBTQ participants reported engaging in sexual activity (12/16, 75%, vs 18/30, 60%), having a history of condomless sex (11/12, 92% vs 15/18, 83%), and previous testing for HIV (13/16, 81%, vs 17/29, 59%). Most (41/44, 93%) of the participants perceived HIV infection to be severe or very severe (Table 1).

Regarding their perceived risk of acquiring HIV, on a scale of 0%-100%, the reported likelihood of HIV infection among heterosexual AYA (mean 13%, SD 28%) was similar to that of LGBTQ AYA (mean 14%, SD 27%). Most (34/44, 77%) of the participants perceived HIV testing to be beneficial or very beneficial (Table 1). Furthermore, most of the participants perceived finding a testing location (38/46, 83%), paying for testing (23/45, 51%), and disclosing their sexual orientation during testing (27/45, 60%) to be easy or very easy.

Table 1. Demographics, HIV testing, and risk behaviors of adolescents and young adults and their peers (N=46).

Demographics and sexual behaviors	Heterosexual (n=30)[a]	LGBTQ[b] (n=16)[a]	Total (N=46)[a]

HIV Knowledge and Perceptions

Qualitatively, both heterosexual and LGBTQ AYA expressed an advanced understanding of HIV and of the differences between HIV and AIDS (Table 2). An LGBTQ participant explained that HIV "...attacks your immune system" and a heterosexual participant explained that AIDS "...is like the worst...it's like after your T-cells gets to a certain amount then you have AIDS." Both groups of AYA similarly expressed an advanced understanding of HIV prevention strategies and modes of transmission. A heterosexual participant stated of HIV prevention "if you're going to have sex...know your partner...know their status," and an LGBTQ participant stated that HIV could be transmitted through "exchange of fluids." However, both groups also stated myths and misunderstandings about HIV prevention and transmission. Regarding HIV, an LGBTQ participant asked, "...can you get it from urine?" and a heterosexual participant asked, "Is there some kind of vaccine you can take?" In addition, regardless of sexual orientation, both groups held both negative and positive perceptions about HIV. A heterosexual participant shared, "It takes away your sexual life...," whereas an LGBTQ participant felt "you still have a second chance to live...So, if you're still alive I think that you should...say 'I'm still here, I'm still sexy.'" On the basis of the adapted Brief HIV Knowledge Questionnaire, there were only two items for which the average number of participants responding correctly was <50%: an average of 33% (SD 0.474) of the participants knew that HIV infection could not be determined by taking an HIV test 1 week after a potential exposure and an average of 28% (SD 0.455) knew that a vaccine for HIV does not exist (Table 3).

Table 2. Summary of focus group themes related to HIV knowledge.

Themes and subthemes	Representative quotes
HIV knowledge	
General	• "HIV is like you can get treatment, if you get AIDS you could die." [Heterosexual participant]
	• "AIDS is like the worst...it's like after your T-cells gets to a certain amount then you have AIDS." [Heterosexual participant]
	• "...it tears you up, like your immune system and all of that, like it chews you up on the inside." [LGBTQ[a] participant]
Prevention	• "Don't be silly, wrap your willy." [Heterosexual participant]
	• "It's called PrEP[b]." [Heterosexual participant]
	• "Condoms." [LGBTQ participant]
	• "I say don't get drunk and don't get high." [LGBTQ participant]
	• "And you can do PrEP. I think there's this new thing out called PrEP you take it every day I think, it's like a medicine that helps you, yeah." [LGBTQ participant]
Transmission	• "I'm pretty sure it's transmitted sexually, like sexual intercourse." [Heterosexual participant]
	• "Or like sharing needles." [Heterosexual participant]
	• "You can get it from...shooting up [with] dirty needles, getting tattoos with dirty needles...And then you can get it from blood...You can get it from having a lot of unprotected sex...Oh yeah and you can get it from your parents." [LGBTQ participant]
Myths and misunderstandings	• "Mosquitoes, right?" [Heterosexual participant]
	• "AIDS is when you already have an STD[c], and you know next you get infected with HIV like it acts together." [LGBTQ participant]
Perceptions regarding HIV: severity	• "But it's not really a death sentence...some people assume that it's like that. Like when you first hear you have cancer it's like 'oh my gosh I've got cancer I'm about to be dead.' Like people think that it's terminal but it's not like that." [Heterosexual participant]
	• "Okay, so...it's not like a death sentence. People can live with it. But...it's kind of like you feel like your life is ruined afterwards you know you're socially shunned so to speak...You feel like no one's there for you when you really need them..." [LGBTQ participant]

[a]LGBTQ: lesbian, gay, bisexual, transgender, or queer.

[b]PrEP: pre-exposure prophylaxis.

[c]STD: sexually transmitted disease.

Table 3. Individual item means and SDs for the adapted Brief HIV Knowledge Questionnaire among adolescents and young adults.

	Values, mean[a] (SD)
There is a female condom that can help decrease a woman's chance of getting HIV (T[b])	80 (0.401)
People who have been infected with HIV quickly show serious signs of being infected (F[c])	76 (0.431)
Having sex with more than one partner can increase a person's chance of being infected with HIV (T)	69 (0.465)
A person can get HIV from oral sex (T)	63 (0.488)
A person can get HIV by sharing a glass of water with someone who has HIV (F)	61 (0.493)
A person can get HIV by sitting in a hot tub or a swimming pool with a person who has HIV (F)	61 (0.493)
Using Vaseline or baby oil with condoms lowers the chance of getting HIV (F)	61 (0.493)
All pregnant women infected with HIV will have babies born with AIDS (F)	61 (0.493)
Coughing and sneezing DO NOT spread HIV (T)	58 (0.497)
Taking a test for HIV one week after having sex will tell a person if she or he has HIV (F)	33 (0.474)
There is a vaccine that can stop people from getting HIV (F)	28 (0.455)
Average total correct score (of 11 items)	6.52 (2.681)

[a]Mean indicates the average percentage of participants who answered the question correctly.

[b]T: true.

[c]F: false.

Barriers and Facilitators to HIV Testing

During the focus group discussions, the heterosexual and LGBTQ participants described their perceptions of the benefits of HIV testing, prior experiences with HIV testing using various testing modalities, and their perceived barriers and facilitators to HIV testing (Table 4). Regarding HIV testing, a heterosexual participant felt that it should be done even if you are not sexually active: "...I still would say it's best that you do it just so you...get into the habit of getting tested." An LGBTQ participant thought that HIV testing should be offered on college campuses because of the risky behaviors of students: "...'cause I know...campuses...are very risky." When describing their personal experiences with HIV testing, a heterosexual participant explained not knowing that they needed to explicitly opt out: "...I didn't know they tested me. And so, when they took my blood to find out if I had something else...they was like 'everything's negative...HIV negative.'" An LGBTQ participant shared being surprised by the different options for HIV testing: "The first time I did mine it was interesting 'cause I thought you had to get the needle...I got the swab and was kinda surprised."

Regarding perceived barriers to HIV testing, at the individual level, the participants identified fear and a sense of invincibility among AYA. An LGBTQ participant explained: "...with us being so young we believe that we have a whole life ahead of us...some people wouldn't want to get tested because...they want to ignore it." At the interpersonal level, a heterosexual participant cited the lack of parental support as a potential barrier to testing: "...because my mom would be like 'what are you doing that would warrant you to go get tested?'...And so, it's an awkward conversation." At the structural level, an LGBTQ participant explained that if AYA "...don't even know where they can go," they might not get tested for HIV. Regarding perceived facilitators to HIV testing, the participants identified factors at the individual and structural levels. An LGBTQ participant felt that, on an individual level, AYA should be intrinsically motivated to get tested: "It shouldn't have to be a material motive...you should be willing to just go and get tested without something in it for you." On a structural level, a heterosexual participant thought that if commercials and advertisements "...showed where the free clinics are it would help," whereas another LGBTQ participant posited that HIV testing efforts should try "...to appeal to...people using social media...like...Facebook, Twitter, Instagram, and Snapchat...So, like you can definitely submit those sponsored ads to say you know 'hey get tested.'"

Table 4. Summary of focus group themes related to perceived barriers and facilitators to HIV testing.

Themes	Representative quotes
Perceived benefits	• "It allows you to tell if your partner who you're doing things with you can tell them 'Oh, I have HIV' or 'I have this and that' and you can be more conscious about what you're doing." [Heterosexual participant] • "If you get tested right away you won't be able to spread it to other people who are unaware that we had it." [Heterosexual participant] • "...I just prefer like if we talking then I prefer us to go together. Just so it would be like I know what you got, you know what I got and it's no secrets in between." [LGBTQ[a] participant] • "...when I do have sex I think, well I know for sure that I'm always going to get tested because I really don't want no HIV or AIDS." [LGBTQ participant]
Personal experiences	• "They came to us and took me into a private room, and they pricked my finger...And while the resolution was happening, she talked to me about what would happen and everything if it was positive or negative." [Heterosexual participant] • "The first time it was scary because you know it's your first time engaging in sexual intercourse, so you really don't know even though I maintained enough knowledge about it. I still was nervous." [LGBTQ participant]
Perceived barriers to testing	• "A lot of people they just are scared like what if they do have HIV, they probably would rather not know..." [Heterosexual participant] • "There are some places I believe that will charge you. That would make people stay away from it." [Heterosexual participant] • "I don't think there [are] enough commercials and billboards and stuff like that...I always hear about it either from [organization X] or the doctors, the hospital but there's not enough promoting of getting tested." [LGBTQ participant]
Perceived facilitators to testing	• "It's good to have it more accessible like that it shouldn't matter where. Just giving more options." [Heterosexual participant]

[a]LGBTQ: lesbian, gay, bisexual, transgender, or queer.

Acceptability of Game Prototype

In addition to the engaging focus group discussions, brief surveys using Likert scales were used to evaluate acceptability of the game prototype among AYA (Table 5). On a scale of 1 to 5, with 5 indicating strong agreement, most of the participants agreed that the game was interesting (median 5.0, IQR 5.0-5.0), fun (median 5.0, IQR 4.0-5.0), and easy to learn (median 5.0, IQR 5.0-5.0). Most of the participants also liked the game environment (median 5.0, IQR 4.0-5.0), the game interface (median 5.0, IQR 5.0-5.0), the interactions with other characters in the game (median 5.0, IQR 4.0-5.0), the idea of playing games about behaviors that may be associated with HIV infection (median 5.0, IQR 5.0-5.0), and the idea of playing games about different dating scenarios (median 5.0, IQR 5.0-5.0). Participants also agreed that they would share the game with friends to help them get tested for HIV (median 5.0, IQR 4.0-5.0).

Using a separate Likert scale with a range of 0 to 3, with 3 indicating high likelihood, participants reported that they would play the game if it were available to them (median 3.0, IQR 2.0-3.0), they would use this game to help with getting tested for HIV (median 3.0, IQR 2.0-3.0), they would be more likely to get tested for HIV if the game determined their character to be at risk for HIV infection (median 3.0, SD 2.0-3.0), and they would be more likely to get tested if the game connected them with an actual person who could help (median 3.0, IQR 2.0-3.0).

Table 5. Acceptability of game prototype stratified by sexual orientation (N=46).

Item	Heterosexual (n=30), median (IQR)	LGBTQ[a] (n=16), median (IQR)	Total (N=46), median (IQR)
The game playing was very interesting[b]	5.0 (5.0-5.0)	5.0 (5.0-5.0)	5.0 (5.0-5.0)
The game playing was fun[b]	5.0 (5.0-5.0)	5.0 (4.0-5.0)	5.0 (4.0-5.0)
It was easy to learn how to play the game[b]	5.0 (5.0-5.0)	5.0 (5.0-5.0)	5.0 (5.0-5.0)
I liked the art and animation[b]	5.0 (4.0-5.0)	5.0 (4.0-5.0)	5.0 (4.0-5.0)
I liked the game environment[b]	5.0 (4.0-5.0)	4.0 (4.0-5.0)	5.0 (4.0-5.0)
I liked the game interface[b]	5.0 (5.0-5.0)	5.0 (4.0-5.0)	5.0 (5.0-5.0)
I like the interactions with other characters in the game[b]	5.0 (4.0-5.0)	5.0 (4.0-5.0)	5.0 (4.0-5.0)
I like the idea of playing games about behaviors that may be associated with HIV infection[b]	5.0 (5.0-5.0)	5.0 (5.0-5.0)	5.0 (5.0-5.0)
I like the idea of playing games where my character can meet people and make friends[b]	5.0 (5.0-5.0)	5.0 (5.0-5.0)	5.0 (5.0-5.0)
I like the idea of playing games about different dating scenarios[b]	5.0 (5.0-5.0)	5.0 (5.0-5.0)	5.0 (5.0-5.0)
I would share the game with friends or people I know to help them get tested for HIV[b]	5.0 (4.0-5.0)	5.0 (4.0-5.0)	5.0 (4.0-5.0)
I would play these games if I had access to them[c]	3.0 (2.0-3.0)	3.0 (3.0-3.0)	3.0 (2.0-3.0)
I would recommend the games to a friend[c]	3.0 (2.0-3.0)	3.0 (2.0-3.0)	3.0 (2.0-3.0)
I would be interested in playing these games in multiplayer mode with my friends[c]	3.0 (2.0-3.0)	3.0 (2.5-3.0)	3.0 (2.0-3.0)
I would use this game to help with getting tested for HIV[c]	2.0 (2.0-3.0)	3.0 (2.0-3.0)	3.0 (2.0-3.0)
I would be more likely to get tested for HIV if the game determined my character to be at risk for HIV infection[c]	3.0 (2.0-3.0)	3.0 (3.0-3.0)	3.0 (2.0-3.0)
I would be more likely to get tested if the game connected me with an actual person who could help me get tested[c]	3.0 (1.0-3.0)	3.0 (2.0-3.0)	3.0 (2.0-3.0)

[a]LGBTQ: lesbian, gay, bisexual, transgender, or queer.

[b]Responses provided on a scale of 1 to 5: strongly agree (5), somewhat agree (4), neither agree nor disagree (3), disagree (2), strongly disagree (1).

[c]Responses provided on a scale of 0 to 3: very likely (3), somewhat likely (2), not at all likely (1), don't know (0).

Discussion

Principal Findings

The key findings of this study conducted among AYA in DC include a high level of engagement in sexual behaviors that increase the risk of HIV acquisition, a high level of HIV knowledge, and the identification of perceived barriers and facilitators to HIV testing at multiple levels. The findings from the study informed the development of an intervention to increase HIV testing among AYA. As in other studies, AYA in our study engaged in behaviors that might put them at risk for HIV, such as sexual activity and condomless sex [16,17,54,55], with a higher proportion of LGBTQ AYA engaging in these behaviors than heterosexual AYA [3,56]. However, the proportion of AYA in our study having ever been tested for HIV was much higher than that reported in other studies (67% vs 22%-34% in other studies) [14,16,17,54]. This may be the result of DC-wide efforts to increase HIV testing and education among AYA to curb new infections [11,57]. Furthermore, a higher proportion of LGBTQ AYA in our study had been tested for HIV than heterosexual AYA, consistent with other research [55,58].

Compared with AYA in other studies [27-29], the AYA in our study displayed relatively high HIV knowledge, and there were no differences in knowledge between LGBTQ and heterosexual AYA. Again, this may be the result of jurisdiction-wide efforts to increase HIV education among AYA. However, the participants expressed some persistent misconceptions around modes of transmission, the existence of a vaccine, and the appropriate window period for testing after a potential exposure, implying a need for continued education of AYA. The participants also perceived barriers to testing at the individual, interpersonal, and structural level, suggesting a need for

multilevel interventions. Get Connected, one such intervention, is a web-based intervention that aims to reduce individual and structural barriers to HIV and sexually transmitted infection testing and pre-exposure prophylaxis access among YMSM in Philadelphia, Atlanta, and Houston by tailoring content based on individual sociodemographic characteristics, testing history, and sexual behavior and only referring participants to culturally competent, high-quality testing and pre-exposure prophylaxis sites [35].

Limitations

Our study includes several limitations that warrant discussion. First, our study used convenience sampling by recruiting from specific organizations. Thus, our findings may not be generalizable to AYA who do not routinely seek medical care, do not frequent the participating community-based organizations, and are not part of the youth advisory council. The study included a small number of focus group participants, although this is common in qualitative research. Furthermore, most of the participants identified as Black or African American. Although the racial distribution of the study could have been broader to increase the generalizability of the findings, the racial distribution of our study population reflects the high burden of, and risk for, infection among Black AYA in the United States and in DC specifically. Similarly, the generalizability of the study's findings to AYA of other sexual orientations may be limited because most of the AYA in our study identified as heterosexual.

Implications for Research

Achieving the first strategy of the EHE initiative will depend in part on maximizing the perceived benefits of, and minimizing the perceived barriers to, HIV testing among key populations, including AYA. Toward that goal, this study provides useful information because we were able to determine the behaviors potentially placing AYA at risk for HIV, measure baseline HIV knowledge, assess perceived barriers and facilitators to HIV testing, and assess acceptability of the game prototype. These data informed the development of an mHealth intervention, a life-and-dating simulation game, tailored for, and guided by, AYA in an urban area that aims to increase the perceived susceptibility to, and knowledge of, HIV infection of AYA; increase the perceived benefits of HIV testing, motivation to test, and self-efficacy to test; and decrease the perceived barriers to testing among AYA. These aims will be achieved by displaying the consequences of unsafe sexual behavior in real time using the CDC Risk Estimator Tool while also providing a zip code testing locator and empowering messaging around testing to further facilitate access to convenient testing sites [43]. The efficacy of this intervention will be tested in a randomized controlled trial, and the results will, we hope, reduce barriers to HIV testing faced by AYA and further reduce new infections among this key population.

Conflicts of Interest

DG, a principal investigator on the grant, has a stake in Media Rez consistent with the policy on small business innovation research.

Abstract

Background: AIDS, caused by HIV, is a leading cause of mortality in Africa. HIV/AIDS is among the greatest public health challenges confronting health authorities, with South Africa having the greatest prevalence of the disease in the world. There is little research into how Africans meet their health information needs on HIV/AIDS online, and this research gap impacts programming and educational responses to the HIV/AIDS pandemic.

Objective: This paper reports on how, in general, interest in the search terms "HIV" and "AIDS" mirrors the increase in people living with HIV and the decline in AIDS cases in South Africa.

Methods: Data on search trends for HIV and AIDS for South Africa were found using the search terms "HIV" and "AIDS" (categories: health, web search) on Google Trends. This was compared with data on estimated adults and children living with HIV, and AIDS-related deaths in South Africa, from the Joint United Nations Programme on HIV/AIDS, and also with search interest in the topics "HIV" and "AIDS" on Wikipedia Afrikaans, the most developed local language Wikipedia service in South Africa. Nonparametric statistical tests were conducted to support the trends and associations identified in the data.

Results: Google Trends shows a statistically significant decline ($P<.001$) in search interest for AIDS relative to HIV in South Africa. This trend mirrors progress on the ground in South Africa and is significantly associated ($P<.001$) with a decline in AIDS-related deaths and people living longer with HIV. This trend was also replicated on Wikipedia Afrikaans, where there was a greater interest in HIV than AIDS.

Conclusions: This statistically significant ($P<.001$) association between interest in the search terms "HIV" and "AIDS" in South Africa (2004-2019) and the number of people living with HIV and AIDS in the country (2004-2019) might be an indicator that multilateral efforts at combating HIV/AIDS—particularly through awareness raising and behavioral interventions in South Africa—are bearing fruit, and this is not only evident on the ground, but is also reflected in the online information seeking on the HIV/AIDS pandemic. We acknowledge the limitation that in studying the association between Google search interests on HIV/AIDS and cases/deaths, causal relationships should not be drawn due to the limitations of the data.

Introduction

A major obstacle to combating the impacts of disease in developing countries is the paucity of high-quality health data, including data regarding people's health information needs [1]. If they do not understand people's everyday concerns, health organizations and policy makers are less able to effectively target education and programming efforts for all genders and age groups [1]. People's information needs and their everyday concerns are often expressed via search engine queries as millions go online to meet their health information needs.

HIV/AIDS remains a major global public health concern, despite concerted efforts aimed at combating the disease. There are an estimated 37.9 (32.7-44.0) million people worldwide living with HIV, the virus that causes AIDS [2]. Sub-Saharan Africa has the greatest burden of HIV/AIDS, with South Africa bearing the greatest burden of the disease in the world. An estimated 7.7 million people were living with HIV and AIDS in South Africa in 2018, with an adult prevalence rate of 20.4% [2]. In 2018, approximately 71,000 South Africans died of AIDS-related causes.

Considerable progress has been made in the fight against HIV/AIDS globally. Globally, an estimated 37.9 (32.7-44.0) million people were living with HIV in 2018 [2], an increase from previous years (eg, 35.3 million in 2012), as more people receive life-saving antiretroviral therapy. At the same time, the number of AIDS-related deaths is also declining, with 770,000 deaths in 2018 [2], down from 1.6 (1.4-1.9) million deaths in 2012 and 2.3 (2.1-2.6) million in 2005 [3]. Gains have also been made toward many of the 2020 Sustainable Development Goals targets and elimination commitments, although significant challenges remain [4]. This is within the context of high-risk behavior among people living with HIV in low- and middle-income countries [5] and insufficient human resources in HIV care in low- and middle-income countries [6].

A key component of the fight against HIV/AIDS has been behavioral interventions [3]. A global meta-analysis of studies determined that behavioral interventions reduce sexual risk behavior and reduce sexually transmitted infections and HIV [3]. Behavioral interventions typically involve harmonizing messages and the dissemination of information about HIV transmission and various prevention approaches using television, radio, outdoor advertising, and information and communications technology. The outcome of all these behavioral interventions is that in sub-Saharan Africa, the percentage of young people (15-24 years) demonstrating a comprehensive and accurate understanding of HIV has generally increased over the years. For example, this understanding rose by 5 percentage points for men and by 3 for women from 2002 to 2011, although knowledge levels remain low (36% for young men and 28% for young women) [3].

In South Africa, there have been a number of nationwide communication campaigns related to raising awareness of HIV and AIDS. Soul City and MTV Shuga are two examples of such multimedia campaigns that promote good sexual health and well-being and have effective outcomes [7]. Research into the impact of the Soul City and other communication campaigns found that they had a positive effect on the sexual behavior of adults that had been exposed to the campaign message, for instance by bringing about positive changes in condom use and HIV testing [8].

The combined effects of these awareness campaigns have been an increase in knowledge and understanding of HIV/AIDS. One likely outcome of an increase in awareness of HIV/AIDS in South Africa is that a percentage of the population will turn to the internet via search engines for information on HIV/AIDS. Internet penetration in South Africa is 56% (32.9 million) [9].

An increasing number of people are using the internet to support their health care needs [10,11] and search engines such as Google, Yahoo! and Bing are often their first port of call. One of the early studies on search engine use found that 1 in every 28 (3.5%) pages viewed on the web is a search results page, making the use of a search engine the second most popular internet task next to email [12]. Another early study found that there are over 6.75 million health-related internet searches carried out every day worldwide, representing approximately 5% of all internet searches [13]. Search engine use is the most common approach to online information seeking [14], and a study by the Pew Research Center found that half of all internet users now use search engines on a typical day [15]. It has also been estimated that about 1 billion Google searches daily are health-related, which is about 7% of all daily searches [16].

This paper examines trends in online search on HIV and AIDS on Google, which is the dominant search engine worldwide [17] and is the top search engine in most countries with a few exceptions, such as Russia (Yandex) and China (Baidu). In South Africa, Google is also the dominant search engine [17]. Google search data have been used for understanding health information needs, health surveillance, and health forecasting [10,18-23]. Although the use of Google search engine data for health and development in general has been criticized [24,25] in recent years due to an unbalanced and opaque approach that did not satisfy scientific transparency, in recent years, organizations such as the World Bank [26,27] and several government departments around the world have begun revisiting the behavioral big data methods of search engine data in aid of international development. Drawing on feedback from the scientific community on the best practices of big data research [24,25,28,29], particularly paying attention to integrating both big data and "small data" (eg, survey data and other traditional data collection mechanisms) to create more complete and accurate data sets, they have made significant advances in this field. This paper advances the hypothesis that the online search behavior of people looking for health information can be used to understand their health information needs, and also for health surveillance and monitoring [10,18-23].

Methods

The methods employed in this study were derived from the considerable literature regarding using search data to understand the health information needs of the public and for health surveillance [10,18-23]. The first step involved search term selection. The search terms chosen as proxies to gauge public interest in HIV and AIDS in South Africa were "HIV" and

"AIDS." These were the only search terms selected given the specificity of the topics concerned. Data [30] on online searches for the terms "HIV" and "AIDS" were thus obtained on Google Trends (categories: health, web search) to visualize how searches were conducted on both search terms. The data were obtained for the years 2004-2019. Some of the most important search queries (top and rising) searched for by South Africans on "HIV" and "AIDS" were downloaded from the Google Trends data set [30] and recorded. Data on regional interest in both search terms for South Africa were downloaded. In addition, the top and rising search queries related to "HIV" and "AIDS" were also accessed via Google Trends.

The nonparametric Mann-Kendall test [31] was conducted to evaluate the significance of trends. The Mann-Kendall test accounts for the autocorrelation of time series (for the alternative hypothesis of monotonic trends) by the design of its test statistic on the time series increments. The Mann-Kendall test was adapted based on the log ratio of search volumes between search terms to evaluate their associations (between "HIV" and "AIDS") and to investigate the search trend of the term "AIDS" with adjustment (log ratio between "flu" and "AIDS").

Nonparametric Mann-Kendall tests were conducted to indicate the significant decline in AIDS-related deaths in South Africa and the increasing trend for the number of estimated adults and children living with HIV. Permutation test based on nonparametric Spearman rho [32] was conducted to verify the association between Google search interest for the term "AIDS" and AIDS-related deaths in Africa. Due to the difference in time frequency, monthly Google search data for the term "AIDS" were aggregated through moving average to estimate yearly search interest. All statistical analysis was conducted with R (version 4.1.2; R Foundation for Statistical Computing); Mann-Kendall tests were done using the *trend* package and the Spearman test was performed using the *stats* package.

Pageviews for the topics "HIV" and "AIDS" from 2015-2020 in Wikipedia Afrikaans, the most developed indigenous language Wikipedia service in South Africa, were obtained from Wikipedia [33]. The year with the earliest data on HIV and AIDS on Wikipedia Afrikaans is 2015.

Review studies on the use of search engine data to understand public interests and trends have noted the "traps in big data" [24,25,28,29], emphasizing that data sources such as search engines are best used to supplement traditional data sources like surveys and that, in general, confidence in such data is strengthened when their findings can be replicated using other data sources and platforms. Thus, this paper also obtained and plotted data [34] on the estimated number of adults and children living with HIV, as well as AIDS-related deaths in South Africa, from the United Nations Joint Programme on HIV/AIDS for the years 2004-2019.

Results

Search term trends for "HIV" and "AIDS" from 2004-2019 in South Africa showed a decline in "AIDS" searches relative to "HIV" ($P<.001$; Figure 1). This observed online behavior mirrors progress on the ground for both HIV and AIDS ($P<.001$, association between "AIDS" searches and deaths), as there was a decrease in AIDS-related deaths ($P<.001$) and an increase in the number of people living with HIV ($P<.001$) in the country from 2004-2019 (Figure 2).

Some of the most important search queries (top and rising) searched for by South Africans on "HIV" and "AIDS" can be seen in Multimedia Appendix 1 and Multimedia Appendix 2, respectively. A complete visualization of the search data, regional interest in South Africa for the search terms "HIV" and "AIDS," and rising and top search queries on "HIV" and "AIDS" can be accessed via Google Trends [30].

Similarly, on Wikipedia Afrikaans, for the years 2015-2020, there was greater interest in "HIV" than "AIDS" (Multimedia Appendix 3).

Figure 1. Search interest in the search terms "HIV" and "AIDS" (category: health, web search) in South Africa, 2004-2019 (accessed December 24, 2020).

Figure 2. UNAIDS data on estimated adults and children living with HIV and AIDS-related deaths in South Africa [34]. UNAIDS: Joint United Nations Programme on HIV/AIDS.
Discussion

Principal Findings

This paper shows a statistically significant decline ($P<.001$) in search interest on Google for AIDS relative to HIV in South Africa. This trend mirrors progress on the ground in South Africa and is significantly associated ($P<.001$) with a decline in AIDS-related deaths and people living longer with HIV. This trend was also replicated on Wikipedia Afrikaans, where there was a greater interest in HIV than AIDS. The data on the search terms "HIV" and "AIDS" in South Africa (2004-2019) reveal a decrease in interest over time in AIDS-related search queries relative to HIV-related search queries. This mirrors progress on the ground in South Africa, where AIDS-related deaths have reduced over the years (2004-2019) and people are living longer with HIV due to life-changing medications. Similarly, behavioral

interventions through messages delivered through media sources in South Africa, including the internet, have increased the number of people with an accurate understanding of the differences between HIV and AIDS [3]. In response to these behavioral interventions, a proportion of the populations in these countries will use the internet via search engines to seek information on HIV and AIDS. From the earliest data available on Wikipedia Afrikaans (2015-2020), there has been a greater interest in HIV than AIDS in South Africa.

Comparison to Prior Work

This work contributes to the growing literature on infodemiology, which seeks to employ search engine data in the service of health information seeking, forecasting, and surveillance [35]. Previous research has covered a wide variety of infectious diseases such as influenza [36], dengue [37],

norovirus [38], COVID-19 [39], and sexually transmitted infections [40], as well as other topics like cancer [22,23], dementia [18], and mental health [20]. Among the limited literature exploring HIV/AIDS with internet search data, the methodology is often restricted to qualitative [41] or parametric methodology [42], with limited research on Africa. Our work contributes to the limited literature (eg, [1,43]) on HIV/AIDS in the African context. Moreover, the nonparametric methodology we adopted requires minimal assumptions about the data and its distribution, and is thus robust and adaptive. Our work contributes to the niche of infodemiological study on HIV/AIDS in Africa and South Africa in particular while possessing the potential to extend to other countries/regions or geographical resolutions.

Further Directions

An important follow-up to this study might be to understand how South Africans search for health information on other diseases and topics of public interest on search engines. In addition, motivated by our findings in this work, we may further investigate and develop a statistically principled and coherent framework to use Google search data for forecasting HIV/AIDS trends. In the meantime, a quantitative (survey) and qualitative (interviews) study of how South Africans access HIV/AIDS information online is planned, to provide insights for the research question by using traditional research methods. This study aims to provide data across South African provinces, disaggregated by age and gender. Additionally, broadening the scope of future studies could be achieved by studying other search engines, social media, and knowledge repositories, as research shows that, for example, Wikipedia is a good reflection of medical interests of the lay population [44], search engine queries are a good way of estimating outbreaks [45], and social media platforms are an important source of medical information today [46].

Limitations

This paper reports on how, in general, interest in the search terms "HIV" and "AIDS" mirrors the increase in people living with HIV and the decline in AIDS cases in South Africa. Here, we report some limitations of the study.

First, there is an acknowledgement that the population of health information seekers on HIV/AIDS online may be quite different from the offline population. For instance, not everyone searching for information on HIV/AIDS may be connected online or use search engines, and the number of people connected to the internet changed over the years of the study (2004-2019). Hence, this paper is not an exact mapping of the online behavior of all the people searching for HIV/AIDS information in South Africa. This limitation is common in research using online big data methods such as search engine data, where the nature of the specific platform from which the data were obtained shapes the results obtained [25]. To mitigate this, a follow-up quantitative

and qualitative study of the HIV/AIDS health information seeking behavior of South Africans using Google is planned. This would provide data through traditional (non–big data) research methods, following best practices from digital big data research, where the best results are often obtained when traditional data collection methods like surveys are combined with big data methods to inform research inquiry [25].

Second, we also acknowledge that the observed trends in the Google search data could be explained by the general decrease in people's interest in such diseases and public health matters. To adjust for this, we used the search term "flu" as a control and the declining trend of the search term "AIDS" remained significant after adjustment ($P<.001$). In addition, this paper acknowledges the effects of media coverage on interest in specific terms, which is not accounted for in this paper.

Third, this paper focuses only on studying the association between the Google search interest in HIV/AIDS and cases/deaths. We acknowledge that causal relationships should not be drawn due to the limitations of the data. In addition, we acknowledge that although we used the Google Trends category "health, web search" to refine the search results for "AIDS," the returned results may contain other meanings or associations of the word "AIDS," as seen in some entries in Multimedia Appendix 2.

Conclusions

A major obstacle to combating the impacts of disease in developing countries is the paucity of high-quality health data, particularly for understanding people's health information needs [1]. People's information needs and their everyday concerns are often expressed via search engine queries as millions go online to meet their health information needs. This paper shows a statistically significant decline ($P<.001$) in search interest on Google for AIDS relative to HIV in South Africa. This trend mirrors progress on the ground in South Africa and is significantly associated ($P<.001$) with a decline in AIDS-related deaths and people living longer with HIV. This trend was also replicated on Wikipedia Afrikaans, where there was a greater interest in HIV than AIDS.

In developing country contexts where high-quality data on the health information needs of people is often lacking, understanding the population's use of search engines to meet health information needs can provide useful data. Investigating people's use of search engines to meet information needs can also reveal if education and programming efforts have been effective. Consequently, a natural progression of this study might be a quantitative and qualitative study of the use of search engines and other online information sources to meet HIV- and AIDS-related health information needs in South Africa, which might mitigate platform-specific limitations of findings as outlined in the Limitations section.

Abstract

Background: Management of patients with multiple chronic diseases is a growing public health challenge, especially in rural sectors where access to physicians may be limited. Connected medical devices monitoring vital signs, associated with eHealth program and structured telephone support, may improve complex patient management through early detection of disease complications, positive impact on patients' health, and health resources consumption optimization.

Objective: The aim of this study was to evaluate the technical performance and user experience of the NOMHAD eHealth system in patients with multimorbidity.

Methods: This was a pilot, single-arm, interventional study. Patients with multimorbidity with any combination of chronic heart failure (CHF), chronic obstructive pulmonary disease, and diabetes were followed for 80-100 days using the NOMHAD eHealth system. This system used connected devices telemonitoring symptoms and vital signs (eg, body weight, oxygen saturation, pulse rate, blood pressure, and blood glucose), associated with structured telecoaching and educational support by call center nurses. An overall risk indicator (ORI) was automatically computed after each data teletransmission. The ORI was color coded; green indicated no action required; yellow, orange, and red (low to high priority, respectively) generated telenotifications and indicated to the nurses the need for a telecoaching action. Each ORI was calculated by combining 7 clinical stability system indicators based on symptom questionnaires and vital signs. Technical accuracy of the system was assessed by comparing system-generated ORIs with ORIs recalculated from raw data. Ease of use, usefulness, satisfaction, and acceptability of the system were assessed through patient adherence to self-assessments, and through self-administered questionnaires to patients, call center nurses, and physicians.

Results: A total of 23 patients were enrolled in this study and participated between April 2016 and March 2017 at 5 study centers in France. All patients were successfully equipped and evaluable for analysis. Mean age was 68.5 (SD 10.4) years and most patients were men (n=20). The most common multimorbidity was CHF + diabetes (n=15), followed by patients with all 3 diseases (n=5). Mean effective follow-up was 78.7 (SD 24.2) days. The system generated 6263 ORIs, as several ORIs could be generated on a single day for any patient. Overall system sensitivity was 99.2% (95% CI 98.9-99.4) and overall specificity was 91.3% (95% CI 87.7-94.1). Most patients (20/23, 87%) were satisfied with the system and agreed that it helped them to better understand and manage their diseases, and 19/23 (83%) valued the nurse regular contacts. Nurses and physicians were generally satisfied with the system and considered it useful. All users indicated they would agree to long-term use of the system.

Conclusions: This study provides evidence that the NOMHAD eHealth system is accurate, acceptable, informative, and feasible for patients with multimorbidity, supporting further investigation of its clinical benefits.

Introduction

Background

The management of patients with chronic diseases is a major public health challenge that continues to grow as the numbers of these patients continue to increase [1]. In developed countries, advances in medical care and consequently longer life expectancies have contributed to a steady rise in the numbers of patients with chronic diseases such as chronic heart failure (CHF), chronic obstructive pulmonary disease (COPD), and diabetes, all of which are among the leading causes of death [2]. These patients now account for a major share of many national health care budgets. In France, it was estimated that approximately 80% of the national health care budget in 2012 was dedicated to care for patients with chronic illnesses [3].

Medical deserts due to uneven geographic distribution of health care practitioners are a reality for many patients in France. Despite a steady increase in the number of physicians, many will retire in the next few years, which will further decrease health care availability in some territories. This trend is exacerbated by a large disparity across France in the numbers of physicians available per person, which is highest near Paris [4].

Faced with the rising prevalence and burden of chronic illnesses, health care systems have recognized that traditional reactive medical care involving repeated hospitalizations for disease complications is unsustainable [5,6]. Thus, alternative remote methods of managing patients with chronic diseases are needed to promote and stabilize patient health at home, while minimizing the risk of hospitalization and the burden on health care resources. Chronic disease telemanagement programs aim to foster continuity between hospital and home care, prevent disease worsening and the onset of complications, prevent or reduce hospitalizations, ensure appropriate and timely treatment when needed, educate patients to empower disease self-management, and optimize physician involvement. The ultimate goal for patients is to live safely at home while continuing to receive optimal care.

French national recommendations have called for the development of such telemedicine interventions in patients with CHF, COPD, and diabetes—the 3 chronic diseases that impose the highest burdens on the health care system. The sudden episodes of deterioration that characterize these diseases, such as cardiac decompensations in CHF, acute exacerbations in COPD, and major hypoglycemic events in diabetes, require hospitalization and very often a second hospitalization soon after discharge. Some of these hospitalizations and

rehospitalizations may be partially preventable if symptom worsening is detected and managed early [7,8].

Home telemonitoring programs are among the solutions currently investigated for remote disease management. The intent is to provide high-quality health care to patients while they live at home. In patients with CHF, remote telemonitoring programs have been shown to reduce mortality [9-13], hospitalizations [9,10,12-14], emergency care unit visits [9], and health care costs [9]. In a review of transitional care interventions, programs that included home visits and multidisciplinary interventions reduced mortality and all-cause readmissions, but telemonitoring had no beneficial effect [15]. In patients with COPD, the benefits of telemonitoring programs versus usual care have been less clear. In the recent COPD Patient Management European Trial (COMET) that investigated a COPD disease management intervention that included remote telemonitoring in patients with severe COPD, acute care hospitalization days and mortality were significantly lower in the disease management group [16]. Other analyses have found inconsistent impact of telemonitoring on hospitalizations [17-19] and quality of life [17-20], a trend toward reduced costs [20,21], improved physical activity but no effect on physical capacity or dyspnea [22], and no effect on length of hospital stay or mortality [19]. Most reviewers concluded that despite some encouraging results, additional evidence from larger, high-quality studies is needed before definitive conclusions and recommendations can be made on the benefits of telemonitoring programs for patients with COPD [12,19,20,22,23]. For patients with diabetes, clinical trials and systematic reviews have consistently demonstrated that telemonitoring programs are feasible and can sustain improved glycemic control over time versus usual care [24-26]. Evidence for other benefits, such as reduced BMI [24], reduced use of health care resources and costs [26,27], and lower mortality and cognitive decline in older patients, has been modest or inconsistent [27].

Some of the difficulty in interpreting the results of the many studies investigating the benefits of telemonitoring programs in patients with chronic diseases stems from the heterogeneity in the programs and in the patient populations studied. Most telehealth programs have focused on a single chronic disease, but the reality is that many patients with chronic diseases have more than 1 disease [28-30]. The overall prevalence of such multimorbidity was 23% among all patients in a national health care database in Scotland [28], whereas the prevalence of multimorbidity is much higher (>60%) in the growing European population of patients over the age of 65, who tend to accumulate chronic conditions as they age [28,30]. Multimorbidity is well described in patients with CHF, COPD,

XSL•FO

RenderX

or diabetes. In another study conducted in Scotland, 42% of patients with CHF also had diabetes and 26% also had COPD [27]. Similarly, 39% of patients with COPD had CHF and 22% had diabetes, and 45% of patients with diabetes had CHF and 15% had COPD [27]. Thus, telehealth and telemonitoring programs designed for use in patients with a single chronic disease may be limited in their capacity to provide benefits to patients with multiple chronic conditions or comorbidities.

The NOMHAD eHealth System: Overview

The NOMHAD eHealth system, consisting of a web interface for physicians and nurses (NOMHAD Chronic) and an app for patients (NOMHAD Mobile), is derived from a Spanish system and is specifically designed to handle patients with multiple chronic diseases [31]. This system aims to provide telemonitoring by means of detecting health status deterioration based on connected devices and telecoaching based on educational support by dedicated call center nurses.

Study Objectives

In this exploratory study, the technical performance of the NOMHAD eHealth system was evaluated in patients with multimorbidity with any combination of CHF, COPD, and diabetes. The ease of use, usefulness, satisfaction, and acceptability of the system were also investigated from the perspectives of the patients, call center nurses, and physicians.

Methods

Study Design and Objectives

This was a pilot, multicenter, nonrandomized, single-arm, open-label, uncontrolled interventional study to evaluate the performance of the NOMHAD eHealth system of telemonitoring, telenotification, and telecoaching (Agence Nationale de Sécurité du Médicament et des Produits de Santé [ANSM] registration number [ID-RCB]: 2015-A01106-43). The system was evaluated over 3 months of follow-up in a single group of approximately 30 ambulatory patients with multimorbidity.

The primary objective of the study was to evaluate the technical performance of the NOMHAD eHealth system in this population. This objective was to be achieved by comparing patient overall risk indicators (ORIs) generated by the system

with those recalculated on the basis of raw data teletransmitted to the software platform. Secondary objectives were to evaluate the impressions and perspectives of NOMHAD eHealth system users (patients, study physicians, and nurses) using different self-questionnaires about overall ease of use, usefulness, satisfaction, and acceptability. Feasibility of the intervention, technological performance of the system, clinical events, adverse events (AEs), and adverse device events were also assessed.

Ethics Approval

The study protocol (2015-A01106-43) and subsequent amendments were approved by a local independent ethics committee (Comité de Protection des Personnes Lyon Sud-Est IV) and the French Medicine Agency (ANSM). The study was conducted in compliance with Good Clinical Practice guidelines, the Declaration of Helsinki, the EU Council Directive 93/42/EEC regarding Medical Devices, and International Standard ISO 14155. Study protocol, benefits, and risks were explained to participating patients, who were required to provide written informed consent.

Study Participants

Patients were recruited and enrolled at 5 study centers in France (Rhône-Alpes region). Adults over the age of 18 years with at least two chronic diseases among CHF, COPD, and diabetes and with at least one hospitalization for acute decompensation of CHF or exacerbation of COPD during the year prior to inclusion were eligible to participate in the study. Patients were also required to speak and understand French and have a landline phone. To be enrolled, patients had to meet the French Health Authorities (Haute Autorité de Santé) diagnosis criteria [32], briefly summarized in Table 1. No biological or clinical examinations were required at study entry, but the results of the most recent examinations performed per routine practice were to be reported. Patients were excluded if they were pregnant or breastfeeding, were institutionalized, had a life expectancy of less than 3 months, had received within the past 6 months or were receiving chemotherapy or radiotherapy for cancer, required dialysis for chronic renal insufficiency, had a condition likely to interfere with study procedures, were not covered by the French National Health System, or had participated within the past 30 days or were participating in another interventional trial.

Table 1. Main diagnosis criteria[a] for enrollment of patients with chronic obstructive pulmonary disease, diabetes, or chronic heart failure.

Disease	Criteria
Chronic obstructive pulmonary disease	Clinical signs AND exposure to a known risk factor AND forced expiratory volume in 1 second/forced vital capacity ratio <70% after bronchodilator
Diabetes	Blood sugar >1.26 g/L (7.0 mmol/L) after 8-hour fasting (assessed twice) OR diabetes symptoms with blood sugar >2 g/L (11.1 mmol/L) OR blood sugar >2 g/L, 2 hours after a 75-g oral glucose challenge
Chronic heart failure	Clinical symptoms or signs AND objective evidence of structural or functional cardiac abnormality at rest. Systolic heart failure OR heart failure with preserved ejection fraction

[a]Criteria from the French National Health Authorities (Haute Autorité de Santé [32]).

NOMHAD eHealth System

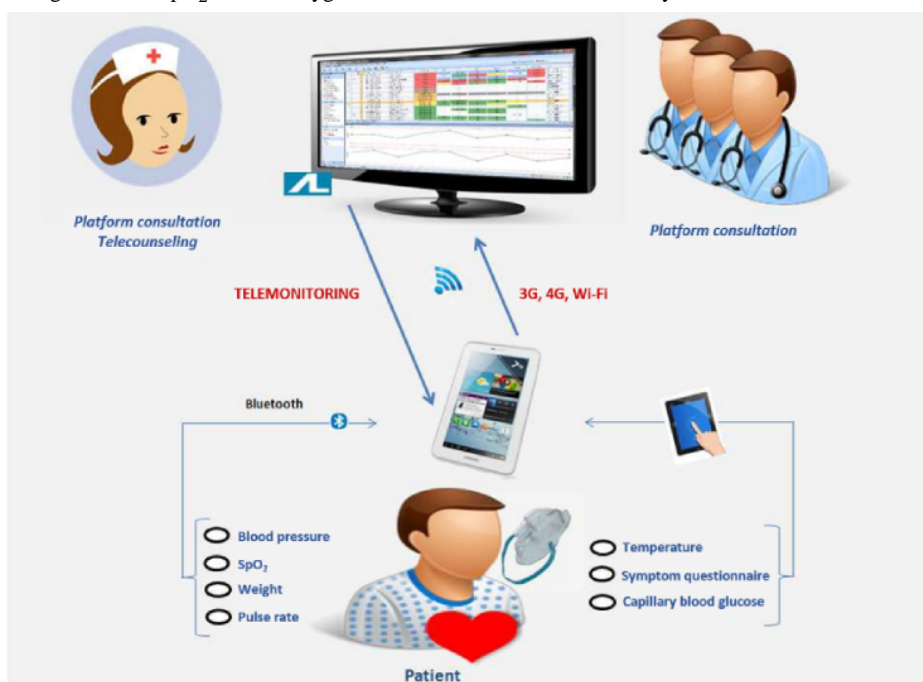
The NOMHAD eHealth system employs the NOMHAD Chronic software platform (version 1.6.4; Connected Health Services)

and the remote NOMHAD Mobile app (version 1.2.1) installed on an interactive tablet (Figure 1). Through NOMHAD Mobile, patients self-measure their vital signs through connected devices

XSL·FO
RenderX

(or manually), provide additional health status–related information by answering questionnaires, and transmit the information to the central database.

The NOMHAD Chronic software platform consists of a web interface for physicians to define personalized patient care plans and browse patient data, and a call center station web interface for nurses (skilled home health care provider nurses working at the VitalAire France nurse call center) to browse patient data, prioritize nurse activities, and report telecoaching actions.

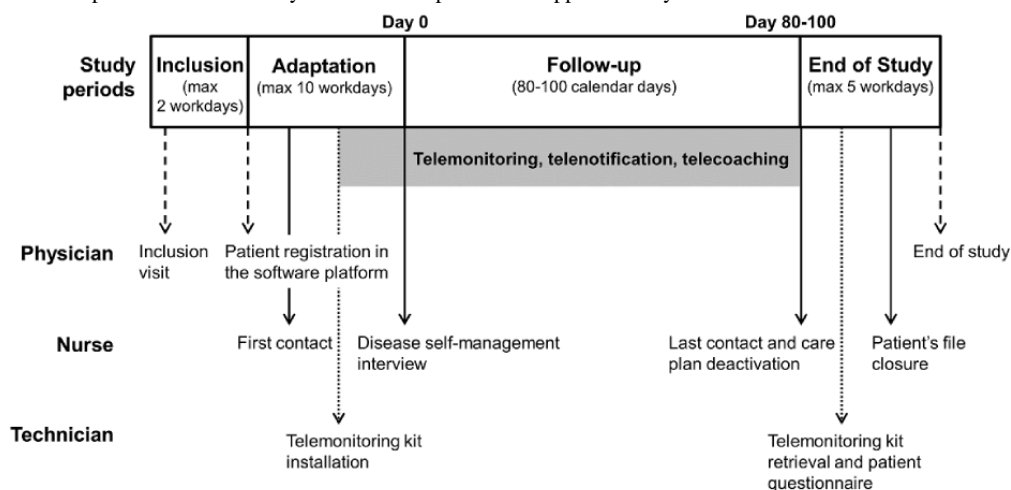
Figure 1. Overview of the NOMHAD eHealth system. The NOMHAD eHealth system consists of the NOMHAD Chronic software platform and the remote NOMHAD Mobile app installed on an interactive tablet, which is used by the patient to enter vital sign data, either manually or through connected devices, and answer questionnaires. These data are transferred to the NOMHAD Chronic software platform using available 3G, 4G, or Wi-Fi connections. The NOMHAD eHealth system is a global system including health care technicians, call center nurses, study physicians, and referring physicians. 3G: third generation; 4G: fourth generation; SpO$_2$: arterial oxygen saturation; Wi-Fi: wireless fidelity.


NOMHAD Chronic monitors up to 7 clinical stability systems indicators that inform about chronic disease/health status parameters according to patient medical conditions and individual-specific thresholds: hemodynamic stability, respiratory stability, pain/sleep quality, diet/diuresis, tissue integrity, cognitive system/mood, and medication.

The software platform incorporates an algorithm that calculates the ORI to guide the nurse in prioritizing telecoaching actions. ORIs are color coded, enabling immediate identification of the patients to be contacted and their level of priority. A green ORI indicates that no action is required, whereas yellow (low priority), orange (medium priority), and red (high priority) ORIs generate telenotifications and indicate to the call center nurse the need for a telecoaching action, from simple reinforcement, repeating measurements and adapting the care plan, to advising the patient to call an emergency medical service. The ORI is calculated by combining the 7 clinical stability system indicators, which are themselves calculated by combining the results of symptom questionnaires and vital signs. An individual ORI is calculated by the algorithm every time a new value of any monitored parameter is transmitted by the patient. Therefore, several ORIs and corresponding telenotifications may be generated on a single day for a given patient.

Patient Interventions

Patients participated in the study over a period of approximately 3 months (Figure 2). Inclusion was followed by an adaptation period during which the telemonitoring kit was installed by a home health care provider technician and first used autonomously by the patients in their home. The follow-up period began with a phone interview with the nurse to evaluate the patient's self-management skills specific for their chronic diseases, establish objectives for improvement, and collect patient lifestyle data. During the follow-up period, patients performed regular self-assessments of their health status according to their chronic diseases. Patients used the tablet to enter their answers to health questionnaires and the devices connected to the tablet to measure vital signs (eg, blood pressure, pulse rate, arterial oxygen saturation, daily blood glucose, body weight depending on their medical condition, and personalized care plan) and transmit them to the NOMHAD Chronic system. The standard patient care plan (consisting of self-measurements twice a week and questionnaires once a week in stable state) could be personalized according to patient needs, the system notifications generated, and study physician assessment.

Figure 2. Study flow for the patient. The total study duration for a patient was approximately 15 weeks.


Patients were contacted by a nurse at regular intervals (at least every 15 days for the first 2 months) and when the system generated a telenotification. Patients could also contact a nurse whenever necessary during regular business hours via a toll-free phone number, for instance, to report a hospitalization. Through the NOMHAD Mobile app, patients could consult disease self-management support modules installed on their tablet and could voluntarily participate with other study patients in online video classroom sessions conducted by the nurses. The objective of these sessions was to provide patients with supplementary information about their chronic diseases and their management while taking advantage of group dynamics. The telemonitoring program could be suspended temporarily by a call center nurse for patient's personal reasons or during a hospitalization.

Nurses from the call center were trained to provide support by phone to patients with chronic diseases and were connected to the NOMHAD Chronic system to manage telenotifications (according to their priority level) during regular working hours. They performed standardized telecoaching actions, such as advising patients to seek physician consultation or emergency care, according to the type and severity of the telenotifications.

Physicians could access patient data at any time; were prompted to log-on to the system during patient consultations; and could modify patient medical data, medications, procedures, system threshold values for health status parameters, and recorded any AE. After a follow-up period of 80-100 days, the care plan was deactivated, equipment was retrieved, and study physicians completed the electronic case report form.

Outcomes and Evaluation Methods

For the primary performance criterion, the sensitivity and specificity of the ORIs generated during the follow-up period were assessed by comparing the ORIs generated by the NOMHAD system using a specific algorithm (ORI_{NOMHAD}) with those expected when recalculated from the raw data teletransmitted to the software platform (ORI_{EXP}) based on its algorithm specifications. Each combination of ORIs (ORI_{NOMHAD} vs ORI_{EXP}) obtained was categorized as follows: if the ORI_{NOMHAD} and ORI_{EXP} were both green, the scoring was considered "correctly not telenotified" (ie, true negative [TN]);

if the ORI_{NOMHAD} and ORI_{EXP} colors were the same for yellow, orange, or red, the scoring was considered "correctly telenotified" (ie, true positive [TP]); if the ORI_{NOMHAD} priority color was lower than the ORI_{EXP} color, the scoring was considered "incorrectly identified as lower priority" (ie, false negative [FN]); and if the ORI_{NOMHAD} priority color was higher than the ORI_{EXP} color, the scoring was considered "incorrectly identified as higher priority" (ie, false positive [FP]). Secondary performance criteria were the numbers and frequencies of telenotifications and the sensitivity (defined as $TP/[TP + FN] \times 100$) and specificity (defined as $TN/[TN + FP] \times 100$) of the clinical stability system indicators. The overall sensitivity and specificity were calculated from all ORI recordings.

At the end of the study, patients, nurses, and physicians completed user-specific self-questionnaires to assess their perspectives on the ease of use, usefulness, and satisfaction of the system. These self-questionnaires were developed by the sponsor specifically for the study. System acceptability was assessed from the actual duration of follow-up and the duration of effective follow-up (after deduction of the temporary suspensions periods). System feasibility was assessed from the numbers of patients refusing or discontinuing the program for any nonmedical reasons. Safety was evaluated from device deficiencies and AEs starting during the study follow-up period.

Sample Size Estimation

An appropriate sample size could not be calculated because no assumptions could be made prior to the start of the trial regarding the primary technical performance criterion in patients with multimorbidity. It was estimated that approximately 30 evaluable patients would be sufficient to establish preliminary descriptive conclusions for the primary criterion.

Statistical Methods

Statistical analyses were performed using SAS software, version 9.2 (SAS Institute). Summary statistics for continuous variables were number of observations, mean, SD, median, first and third quartiles (Q1 and Q3), minimum and maximum values, and the number of missing information. Summary statistics for dichotomous or categorical variables were the number and percentage of each of the scores or categories with 95% CIs

calculated using the exact binomial distribution for percentages, where applicable. The agreement between all pairs of ORIs generated by the software platform and by those recalculated on the basis of the raw data teletransmitted (each time the algorithm was run by the software platform) was evaluated with SAS by calculating the weighted Fleiss–Cohen κ coefficient for all pairs of ORI scores and by testing the null hypothesis that this coefficient was equal to 0 (ie, no agreement apart from pure chance agreement existed between both scorings). Results are presented for all patients who were enrolled in the study.

Amendments to the Study Protocol

After the study began, the study protocol was amended to stop recruitment before the planned number of enrolled patients was reached. This was done because the recruitment period had already been extended and it revealed that investigators had reached their maximal recruitment potential based on the study inclusion criteria.

Results

Study Patients

A total of 23 patients were enrolled in the study and participated between April 2016 and March 2017 at 5 study centers. Three patients did not complete the study: 1 withdrew consent, 1 moved into a care facility that precluded study procedures, and 1 requested to discontinue telemonitoring. Thus, 20 patients completed study over a mean duration of 99.7 (SD 18.9) days. There were 18 patients with at least one minor protocol deviation, most were for missing data (n=15) or time window deviations (n=8). No major protocol deviations (defined as those affecting the minimal 2-month required self-recordings) occurred, except the 7-day follow-up of the patient who withdrew consent.

The mean age of the patients in the study was 68.5 (SD 10.4) years and most patients (20/23, 87%) were men (Table 2). The mean BMI was 33.9 (SD 7.2) kg/m^2 with a range of 24.5-54.6 kg/m^2. Most patients did not live alone, had a caregiver, and declared having an occupational activity outside the home and regular physical activity.

Table 2. Patient demographics, lifestyle, therapy, and vital signs at study entry.

Characteristic	All patients (N=23)
Sex, male, n (%)	20 (87)
Age (years), mean (SD)	68.5 (10.4)
BMI (kg/m^2), mean (SD)	33.9 (7.2)
Never or former smoker, n (%)	21 (95)[a]
Living alone[b], n (%)	8 (35)

The most frequent multimorbidity was CHF + diabetes (n=15; Table 3). Five patients had all 3 diseases (CHF + diabetes + COPD). The severity of CHF was most frequently reported as New York Heart Association class II (11/19, 58%) or III (7/19, 37%), and patients with CHF (n=21) had a mean left ventricular ejection fraction of 44.5% (SD 13.5%). Patients with COPD (n=6) had a mean forced expiratory volume in 1 second of 55.0% (SD 16.9%) predicted (n=6). Patients with diabetes had

mainly type 2 diabetes (n=19), with a mean last measured glycosylated hemoglobin (HbA_{1c}) of 7.7% (SD 1.6%) (n=18). Micro- and macro-angiopathic complications were reported in 11 and 4 patients, respectively. Overall, patients had a mean of 6.5 (SD 2.9) concomitant diseases that were recorded by their study physician at inclusion in addition to their targeted chronic diseases.

Table 3. Patient multimorbidity.

Multimorbidity profile of study patients	All patients (N=23)
Patient's main chronic disease profile, n (%)	
CHF[a] + COPD[b]	2 (9)
CHF + diabetes	15 (65)
COPD + diabetes	1 (4)
CHF + COPD + diabetes	5 (22)

System Performance

For all patients, the NOMHAD eHealth system generated a total of 6263 ORIs that could be recalculated from the raw data teletransmitted during the 3-month follow-up period. Among these ORIs, 294 (4.69%) were green, 4480 (71.53%) were yellow, 1441 (23.01%) were orange, and 48 (0.77%) were red. ORI proportions by color were similar for each chronic disease individually.

For all patients, there was good agreement between the telenotifications generated by the NOMHAD eHealth system and those recalculated from the raw data. In the primary analysis, overall sensitivity was 99.2% (95% CI 98.9-99.4) and overall specificity was 91.3% (95% CI 87.7-94.1). Sensitivity and specificity results were similar for each chronic disease individually. Agreement evaluation of all ORI pairings yielded a weighted Fleiss–Cohen κ coefficient of 0.975 (95% CI 0.969-0.981; $P<.001$), indicating good agreement between all pairs that was not due to pure chance. Kappa coefficients for each chronic disease individually were similarly high (≥0.975).

System Effectiveness

During the 3-month follow-up period, all patients generated at least one telenotification and triggered, therefore, nurse telecoaching actions. The highest proportions of telenotifications were yellow and orange (ie, low and moderate priority, respectively). All 23 patients generated at least one yellow

ORI-low priority telenotification (with a mean of 190 per patient over the 3-month period), 17 patients generated at least one orange ORI-moderate priority telenotification (with a mean of 83 per patient), and 7 patients generated at least one red ORI-high priority telenotification (with a mean of 6 per patient).

The management of the telenotifications resulted in a median of 21 nurse contacts per patient (Q1-Q3, 6-49). The call duration lasted 11-20 minutes at least once for most patients (22/23, 96%). The mean time interval between a telenotification during business hours and registration of telecoaching action was 68.3 (SD 63.6) minutes.

Physicians did not change the predefined parameters or thresholds. On average, physicians connected 3 times per patient for approximately 30 minutes in total, during the 3-month follow-up.

End User Perspectives

Patients

Most (21/23) patients felt that health care technicians spent sufficient time installing the study devices and training them to use the eHealth system. Most patients were satisfied with the coaching they received from the nurses.

Eighteen patients agreed or strongly agreed that the information contained in the app was useful in helping them better understand their illnesses and 14 patients agreed or strongly agreed that it helped them better manage their symptoms. Patient

contact with the call center nurses was considered helpful, as 16 patients agreed or strongly agreed that it helped them become more independent in managing their illnesses, and 17 patients agreed or strongly agreed that they received effective advice when needed. Sixteen patients participated in at least one online video classroom session. However, only 7 patients agreed or strongly agreed that the conferences helped them to better cope with their illnesses through sharing their experience with other patients.

Overall, 20 patients agreed or strongly agreed that they were generally satisfied with the eHealth system, 10 patients agreed or strongly agreed that it improved their relationship with their study physician, and 15 patients agreed or strongly agreed that they would be prepared to use it long term.

Nurses

Nurses (n=3) strongly agreed that their involvement in the study helped them to communicate more effectively with patients and agreed that it helped patients to better understand how to manage their diseases with self-measurement and self-management tools. All nurses strongly agreed that they would be prepared to use the system long term. Overall, they ranked the remote vital signs measurements and the planned regular phone calls with the patients to be the best components.

Study Physicians

Study physicians (n=5) agreed that the software platform was somewhat or fairly intuitive and user-friendly, and 4 agreed that its content met their expectations. One of them modified the standard monitoring patient care plan of 1 or more patients and felt this was a medically relevant action and easy to perform.

Three physicians agreed that the telemonitoring and telecoaching interventions by the nurses resulted in physicians seeing only those patients with a genuine need, whereas all agreed that the frequency of notifications and patient consultations was sufficient.

Three physicians agreed or strongly agreed that the information available on the software platform enabled them to better understand their patients' disorders and to better manage their patients. Four of the physicians agreed or strongly agreed that they could better anticipate complications affecting patients with multiple morbidities and that their patients were better equipped with self-measurement and self-management tools. Four agreed or strongly agreed that it improved their relationship with their patients and 4 were fairly or very prepared to use the system long term. The study physicians ranked the vital signs, the availability of the telemonitoring platform, and the telecoaching actions among the more preferred components.

System Acceptability, Feasibility, and Technical Performance

Acceptability, as assessed by the extent to which planned events were completed, was generally high (Table 4). An average of 87.3% (SD 34.6) of the total planned regular phone contacts every 2 weeks were performed by the patients. Acceptability was lower for the online video classroom sessions. Out of a total of 8 different contents, patients actively participated in an average of 4.7 (SD 5.8) sessions. Patients consulted the chronic disease self-management support modules available on their tablet an average of 11.2 (SD 15.2) times during the 3-month follow-up and spent an average total time of approximately 16 hours on these consultations (median 5 hours).

Table 4. Acceptability of the nomhad eHealth system by the patients.

Variable	All patients (n=23)
Follow-up	
Duration of follow-up period (days), mean (SD)	85.8 (19.0)
Duration of effective follow-up period (days), mean (SD)	78.7 (24.2)
Duration of system temporary suspension (days), mean (SD)	7.2 (14.4)
Ratio of duration of effective follow-up to duration of follow-up period (%), mean (SD)	90.1 (18.2)
Planned regular phone contacts with the call center nurse	
Number of actual planned phone contacts, mean (SD)	3.5 (1.4)
Number of planned phone contacts scheduled, mean (SD)	3.7 (0.8)
Ratio of actual to planned number of phone contacts (%), mean (SD)	87.3 (34.6)
Online video classroom sessions	
Number of attended sessions (any type), mean (SD)	4.7 (5.8)
Total duration of actual participation (minutes), mean (SD)	136.3 (206.7)
Ratio of duration of actual participation to overall session duration (%), mean (SD)	60.5 (39.6)
Information modules	
Number of consultations, mean (SD)	11.2 (15.2)
Total duration of consultations (minutes), median (Q1-Q3)	310.4 (3-1561)

The program also appeared to be feasible. No eligible patients refused to participate in the study. One patient withdrew consent after 1 week of follow-up but no patients discontinued prematurely due to lack of connection or inability to use the

XSL•FO
RenderX

study equipment. Eight patients (35%) required at least one maintenance visit and 6 patients (26%) needed at least one device replacement or had technical issues with the study equipment. Data transmission failures were mostly due to connection issues related to the mountainous study area, and represented an average of 3.4% (SD 5.9%) of the total number of data transmissions per patient.

Safety Evaluations

Nine patients (39%) experienced a total of 16 AEs during their follow-up period. None of these AEs were considered to be related to the study medical device or procedures and no study discontinuation resulted from any AE. Seven patients (30%) experienced a total of nine serious AEs (Table 5), all of which were related to unscheduled hospitalizations. All these serious AEs were considered by the investigators to be related to the chronic diseases under investigation or to other diseases. The most frequent serious AEs were cardiac failures (3/23, 13%).

Table 5. Serious adverse events occurring during study follow-up.

Sex/age	Chronic diseases	Serious adverse event (MedDRA-preferred term)[a]	Time from inclusion to onset (days)	Duration (days)	Severity	Time since last ORI[b] (days)	Last color of ORI[c,d]	Last color of SSI[e,f]

[a]Serious adverse events were coded using the MedDRA dictionary version 19.1.

[b]ORI: overall risk indicator.

[c]Last color of ORI is a weighted combination of the SSI status with specific calculation rules in case of missing data, depending on the time interval since their last available transmission.

[d]Green ORI, no action required; yellow ORI, low-priority action; orange ORI, medium-priority action; and red ORI, high-priority action.

[e]SSI: stability system indicator.

[f]Green SSIs indicate stability, whereas blue, yellow, orange, and red SSIs indicate decreasing stability, from slightly to markedly unstable. Blue SSI triggers increased frequency of data measurements.

[g]CHF: chronic heart failure.

[h]SSIH: hemodynamic stability system indicator.

[i]SSIR: respiratory stability system indicator.

[j]SSIP: pain/sleep quality stability system indicator.

[k]SSID: diet/diuresis stability system indicator.

[l]SSIT: tissue integrity stability system indicator.

[m]SSIM: medication stability system indicator.

[n]Patient was in the NOMHAD suspension period at his own request.

[o]Not available.

[p]Patient was in the NOMHAD suspension period due to programmed hospital admission.

Discussion

Principal Findings

This exploratory study demonstrated that the NOMHAD eHealth system was accurate in generating ORIs that reflect health status changes in patients with multimorbidity. The ORIs generated by the system agreed well with the ORIs that were expected when they were recalculated using the raw data teletransmitted. Sensitivity and specificity were both high for the ORIs and for the individual clinical stability system indicators. These results indicate that the system provided an efficient and accurate means of transmitting health status data and that the ORIs generated by the algorithm accurately reflected the health stability of the patients.

All study patients generated telenotifications, most of which were of low or moderate priority. Less than one-third of the patients required a high-priority telecoaching action. However, because ORIs were systematically recalculated every time new data were teletransmitted, a high number of ORIs (N=6263) were generated. This total was almost 3 times higher than what was anticipated for 23 patients over the study duration (100 days), assuming 1 telenotification per patient per day (~2300 ORIs). This disparity reflected the conservative nature in which the telenotifications were programmed to assure the safety of these patients with multimorbidity, which was a main priority during this study. In addition, each time a patient variable was out of the expected normal range, the self-measurement had to be repeated. Another reason for the high number is that some patients became high consumers of the system and performed their own repeated measurements every day. This could also explain why 71.53% (4480/6263) of the ORIs were of low (yellow) priority. A high number of ORIs were generated, leading to a substantial nurse workload, as a median of 21 outgoing telenotification management–related contacts were made to each patient over the 3-month follow-up. In managing the telenotifications, the call center nurses were able to effectively filter those requiring high-priority telecoaching actions. It is anticipated that future technical developments will reduce the number of low-priority ORIs.

The study showed that the NOMHAD eHealth system was generally well accepted by patients, nurses, and physicians, all of whom indicated high levels of satisfaction with most aspects of the program and a willingness to use the system long term. Responses to the self-questionnaires indicated that the system achieved a key aim of telehealth programs: to better manage and coordinate timely care for patients with multiple chronic diseases. Importantly, most users felt that it helped patients to better manage their diseases and symptoms and better understand their illnesses. Nurses felt that it helped them to communicate with patients more effectively, whereas most physicians felt that it helped them to better manage their patients. Most of the physicians also felt that the patients seen in consultation were only those who truly needed physician intervention. For patients, regular contact with the call center nurses was considered an important aspect of the program, and many of them considered this as the best part. Chronic diseases often limit social contact, especially for patients who live alone. It appears that contact with the nurses provided a key social interaction for many patients.

Patient satisfaction and participation were lower for the online video classroom sessions. Not all of the 8 different 40-minute sessions were relevant for every patient and attendance was relatively low. In addition, the mountainous terrain of the study setting caused some technical and connectivity issues, which affected the transmission quality of the videoconferences and may have frustrated some patients. By contrast, patients consulted the disease self-management support modules provided on their tablet approximately 11 times, indicating that they were interested in learning about their chronic diseases. These support modules were likely considered more convenient because patients could consult these at any time, unlike the online video classroom sessions, which were scheduled weekly at fixed times.

A recent study also investigated the views and experiences of patients and health care personnel using a telehealth and online self-management program for patients with multiple chronic diseases (diabetes, cardiovascular disease, and hypertension) in the Renewing Health Project [33]. Although there were differences between the 2 programs, both focused on patient-reported health status variables and on improving self-management skills. An important finding was that the expectations of patients, who expected feedback and support, differed from those of the health care staff, who expected the program to make patients more independent and able to perform self-management tasks without staff support. By contrast, the regular every 2-week patient–nurse contact, which provided consistent feedback and support, was a key aspect of the NOMHAD program and highly regarded by the patients. Together, these findings suggest that telehealth programs should provide a means of maintaining a level of personal contact that preserves patient engagement. Insufficient contact may result in patients feeling isolated or abandoned.

XSL•FO

RenderX

Strengths

This study has several strengths. Whereas most previous telehealth programs have focused on a single disease, the NOMHAD eHealth system was designed for patients with multiple chronic diseases. With multimorbidity on the rise, the study patients likely represent a more realistic "real-world" situation than those studied in many other telehealth programs. In addition, patients were living in a rural mountainous area, whereas the call center nurses were nearly 750 km away and the physicians were in private practice or a hospital nearby. Despite some connectivity issues, which are to be expected in such settings, this study demonstrated the system's feasibility in remote conditions where many patients may face medical isolation. The telenotification accuracy of the system was verified, both for overall assessments of health status and for the individual clinical stability systems indicators. In addition, the NOMHAD eHealth system collects a comprehensive array of patient data that include subjective assessments of well-being, as well as objective self-measurements of patient health variables.

Limitations

Regarding limitations, the self-questionnaires were created specifically for this study and were not independently validated. Besides, very few nurses and physicians participated in the study. Therefore, the questionnaire results for these health care providers must be viewed with caution. Although the feasibility results were positive, the follow-up period was relatively short for a program designed to be used long term. These results need to be confirmed in a longer study. Other minor problems were that the standard glycemia thresholds were too narrow, which resulted in irrelevant notifications, and that the blood pressure cuffs were too small for some patients with obesity.

The NOMHAD eHealth system was derived from earlier Spanish versions of the NOMHAD Chronic software platform (version 1.5.2) and the NOMHAD Mobile app (version 1.2.0). The Spanish version was used in a 3-arm randomized clinical trial comparing a structured telephone intervention, with and without the NOMHAD eHealth system, with usual care in 472 elderly patients with multimorbidity [31]. In Spain, the telemonitoring was performed by a hospital nurse team, whereas in this study in France, it was based on call center nurses. After a 12-month follow-up, the main outcome of health-related quality of life was significantly higher with the telehealth intervention than with usual care ($P<.001$). No differences in mortality or health care utilization were found. Nevertheless, this earlier study also demonstrated that the NOMHAD eHealth system was feasible for long-term use [31].

The medical relevance of the medium- to high-priority telenotifications (orange and red ORIs) also needs to be evaluated because of the significant workload they generated for nurses. As the aim of the study was to support high-risk patients, those included in this study were highly comorbid, with a mean of 6.5 concomitant diseases, and had severe targeted diseases, documented by a low left ventricular ejection fraction, a low forced expiratory volume in 1 second, and high proportions of insulin-dependent patients or those requiring home oxygen or ventilator support. Moreover, 7 patients underwent an unscheduled acute hospital admission during their 3-month follow-up. This preliminary study was not designed to assess medical relevance of the generated ORIs or clinical benefits, which would require a much larger and longer randomized controlled trial. However, several recent studies of similar telehealth and telemonitoring programs in patients with multimorbidity have reported positive results, suggesting that such programs can reduce disease exacerbations and health care costs [34,35]. A program for patients with chronic conditions in Australia found that, compared with the previous year, the telemonitoring program reduced medical expenses by 46.3%, pharmaceutical expenses by 25.5%, unscheduled hospital admissions by 53.2%, hospital length of stay by 67.9%, and mortality by over 40% [34]. In Spain, the ValCrònic program for patients with multiple chronic conditions found significant reductions in body weight; significantly smaller proportions of patients with high systolic or diastolic blood pressure, or elevated glycosylated hemoglobin concentrations in patients with diabetes; and significant reductions in emergency service use and hospitalizations [35].

Conclusions

In conclusion, this study met its principal objectives by providing evidence that the NOMHAD eHealth system is accurate, useful, acceptable, informative, and feasible to implement and use. These favorable outcomes depended on the commitment and coordination of all users and study staff, all of which were facilitated by the system network. Although the NOMHAD eHealth system is based on efficient teletransmission of electronic data and accurate algorithmic evaluation, the system also facilitates human interaction on a regular basis, which appeared to be one of its most important features. The system was also considered useful to support disease education and promote patient awareness toward a better understanding of health data. This study confirms that the system is feasible for larger, longer studies to investigate its impacts on clinical variables, patient-reported outcomes, and medical resources used. However, in their comprehensive meta-review, Elbert et al [36] concluded that, given the consistent effectivity of telehealth for most patients, greater attention should be given to intervention evaluation rather than to obtaining additional evidence for their efficacy.

Abstract

Background: Early diagnosis of cognitive disorders is becoming increasingly important. Limited resources for specialist assessment and an increasing demographical challenge warrants the need for efficient methods of evaluation. In response, CoGNIT, a tablet app for automatic, standardized, and efficient assessment of cognitive function, was developed. Included tests span the cognitive domains regarded as important for assessment in a general memory clinic (memory, language, psychomotor speed, executive function, attention, visuospatial ability, manual dexterity, and symptoms of depression).

Objective: The aim of this study was to assess the feasibility of automatic cognitive testing with CoGNIT in older patients with symptoms of mild cognitive impairment (MCI).

Methods: Patients older than 55 years with symptoms of MCI (n=36) were recruited at the research clinic at the Blekinge Institute of Technology (BTH), Karlskrona, Sweden. A research nurse administered the Mini-Mental State Exam (MMSE) and the CoGNIT app on a tablet computer. Technical and testing issues were documented.

Results: The test battery was completed by all 36 patients. One test, the four-finger–tapping test, was performed incorrectly by 42% of the patients. Issues regarding clarity of instructions were found in 2 tests (block design test and the one finger-tapping test). Minor software bugs were identified.

Conclusions: The overall feasibility of automatic cognitive testing with the CoGNIT app in patients with symptoms of MCI was good. The study highlighted tests that did not function optimally. The four-finger–tapping test will be discarded, and minor improvements to the software will be added before further studies and deployment in the clinic.

(JMIR Form Res 2022;6(3):e23589)   doi:10.2196/23589

KEYWORDS

internet; cognitive testing; software; testing; impairment; cognition; feasibility; diagnosis; app; assessment; cognitive impairment

Introduction

The global burden of dementia is estimated to increase from 43-47 million in 2016 to over 100 million patients by 2050 [1]. Early diagnosis of cognitive diseases is of increasing importance to assure optimal and early care, prognostics, and treatment. This is highlighted by the development of criteria for mild cognitive impairment (MCI), in which diagnostic criteria exist today for predementia stages of Alzheimer disease, dementia in Parkinson disease, and vascular cognitive impairment. Early detection might be even more important in the future when more potent treatments might exist that are likely to be more effective at an early stage of disease.

In the latest revision of the American Academy of Neurology practice guidelines for MCI (September 2019), yearly cognitive screening in healthy adults above 65 years old is encouraged [2]. Longitudinal assessments of patients with MCI are even more important, as approximately 50% might have a cognitive disease with progressive cognitive decline, and many patients revert to normal cognitive functioning [3,4]. This predicts an increasing demand for cognitive testing. Commonly used screening instruments such as the Mini-Mental State Exam

XSL•FO
RenderX

(MMSE) are rapid but crude, and measurement error is larger than the typical yearly decline in Alzheimer disease [5,6]. Also, the utility for differential diagnostics is limited. Neuropsychological assessment with sensitive measures of several cognitive domains may aid diagnostics when basal investigation including screening instruments are inconclusive.

Today, less than one-third of patients in Sweden referred from primary to specialist care centers undergo a neuropsychological investigation. Given the demographical challenge, this portion is likely to decrease further. In response, CoGNIT, a computerized neuropsychological test battery, was developed, initially for assessing hydrocephalus patients. Tests are automatically delivered and scored on a tablet computer, assuring portability, standardization, and efficiency. Made for repeated assessments, included tests are chosen to be able to capture performance on a spectrum, rather than dichotomous variables, thus being able to pick up nuances in cognitive change. The test battery includes tests to cover several cognitive domains (memory, visuospatial function, attention, psychomotor speed, executive function, and manual dexterity). A summary score is calculated for all tests, making it possible to track changes in specific domains as well as global functioning over time.

A previous version of CoGNIT that ran on a touch-screen computer has been validated, norms and reliability data have been collected, and the test has been used in clinical practice in the management of hydrocephalus patients for over 5 years [7,8]. A novel version of CoGNIT running on a tablet has been expanded with tests of language, visuospatial ability, and upper extremity motor speed, to cover the cognitive domains of a typical evaluation in a memory clinic. The intended use cases are (1) as part of the investigation at a memory clinic for early detection of cognitive impairment; (2) in differential diagnostics, since diseases have different patterns of cognitive impairment; and (3) in follow-up testing after initiation of treatment (eg, acetylcholinesterase inhibitor) to assess the treatment effect.

The aim of this study was to assess the feasibility of automatic testing with CoGNIT in older persons with MCI. Data will be used to adapt the software for better performance before collecting normative data in a healthy population.

Methods

Ethical Approval

Ethical approval for this study was granted by the regional ethical review board in Lund, Sweden (dnr 2016/470).

Recruitment

Patients with symptoms of MCI were recruited from the ongoing SMART4MD project at the research clinic at the Blekinge Institute of Technology (BTH), Karlskrona, Sweden [9]. This project evaluates a digital platform that supports patients with reminders, information, and memory support in everyday life. Patients in this project have several visits to the research clinic during their follow-up and were recruited for cognitive testing with CoGNIT during their second visit. The examiner (a research nurse) explained the experiment and collected signed consent from each subject. Patients were included in February 2020 and March 2020. Inclusion criteria were (data collected at first visit) MMSE of 20 to 28 points; subjective memory problems for >6 months; older than 55 years; participants in charge over their own medication; and no specific conditions reducing their ability to use an app, such as visual, hearing, or motor impairments.

Exclusion criteria were a terminal illness with less than 3 years of expected survival, Geriatric Depression Scale (GDS) score above 11, or cognitive impairment due to a known condition such as abuse or psychiatric illness.

Procedures

The MMSE was administered to participants by the research nurse (the examiner). In direct succession, the CoGNIT computerized neuropsychological test battery was administered. While testing, the examiner was sitting by, answering questions, and taking notes regarding technical or testing issues. Patients were also asked to answer the TechPH questionnaire, a short instrument assessing older people's attitude towards technology [10].

CoGNIT Test Battery

Test Presentation and Instructions

Tests were presented on a 10.5" tablet computer (Samsung Galaxy Tab S6, 6 GB RAM, 128 GB internal storage; Samsung Electronics, South Korea) running the Android 11.0 operating system. The tablet was connected via Wi-Fi to the internet. CoGNIT was accessed on the Chrome web browser via an online server. Results from testing were stored in a database on the server for access via a web interface. Test instructions are presented with animations and sounds via a speaker. A trial round with automatic feedback precedes all tests. Two tests require verbal input from the patient that is recorded by the tablet microphone (10-word list test and category fluency test). These tests are manually corrected by the examiner after the testing session (simple procedure by "checking boxes" in the software). All other tests are automatically scored by the software. When scoring is completed, a pdf test report is automatically produced. Included tests are described in the following sections.

Memory

In the 10-word list test, 10 nouns are consecutively presented via text and sound. The patient is asked to say the remembered words aloud after presentation. The test is repeated for 3 trials. The sound is recorded for later manual scoring of the test. After approximately 15 minutes and 2 intervening distractor tasks, a free recall test is performed, without prior presentation of the words. In direct succession, a recognition test is performed. The patient is asked to press yes/no buttons indicating if the word was included in the learning test. A total of 20 words is presented: 10 correct and 10 distractor words.

Executive Function and Psychomotor Speed

The Stroop test consists of 2 parts, the Stroop congruent test and Stroop incongruent test. In the Stroop congruent test, the patient is asked to press 1 of 2 colored buttons on the screen indicated by text. In the Stroop incongruent test, the text is colored, and the patient is asked to press the button indicated

by the color of the text and not what is written. Each trial includes 50 color-words. Response time and errors are collected.

Similarly, the Trail Making Test also includes 2 tests. In Trail Making Test A, the numbers 1 to 25 are presented on the screen, and the patient is asked to press each number in numerical order. In Trail Making Test B, both numbers (1-13) and letters (A-L) are presented on the screen. The patient is asked to press letters and number in order by alternating between successive numbers and letters of the alphabet (ie, 1-A-2-B-3-C...). Time to completion and errors are collected.

Attention

In the 2-choice reaction test, the patient is asked to press 1 of 2 buttons indicated by an arrow. The arrow appears after a random interval of 5 seconds to 15 seconds. Reaction time is measured for 20 trials.

Language

In the category fluency test, the patient is asked to say aloud as many words from a category (eg, animals) as possible for 1 minute. Sound is recorded and corrected by the examiner after all tests are completed.

Motor Speed

In the four-finger–tapping test, the patient is required to tap on a small keyboard with the digits 2 through 5. The correct order of taps is (digits) 2-3-4-5-4-3-2-3... The number of correct taps over 5 trials is scored. In the one-finger–tapping test, the patient taps 1 finger repeatedly between 2 circles on the screen. The number of taps during a 10-second period is recorded for 3 trials for both the left and right hands.

Visuospatial Ability

The block design test, a figure composed of 4 colored blocks is presented on the screen. The patient is asked to rearrange blocks presented on the top of the screen to match the pattern. Time to completion is scored for 3 different patterns.

Depression

Symptoms of depression were screened using the GDS, in which 15 questions are presented on the screen and the patient is required to answer by pressing buttons marked yes or no.

Statistical Analysis

The completion rate without testing issues in patients was previously estimated at 80% in hydrocephalus patients. With a sample size of 36, an 80% issue-free completion rate can be estimated with a 95% CI of +/-13%, which was regarded as sufficient. This also assured for detecting issues for improvement. Influences on test completion by age and score on the TechPH and MMSE scales were assessed with Mann-Whitney U tests. Influence by gender and education was assessed with chi-squared tests. Significance level was set at $P<.05$. All statistics were analyzed in SPSS (Version 25; IBM Corp, Armonk, NY).

Results

Sample Characteristics

Of 42 patients, 36 (86%) agreed to participate; 4 patients declined participation due to a lack of interest or time, and 2 patients declined because of medical reasons (hemiparesis and severe visual impairment). Demographics for the study population are presented in Table 1. The age was rather high (mean 75.6 years). There was a slight overrepresentation of men (22/36, 61%).

Table 1. Demographic data for the study population.

Characteristics	Results
Age, (years), mean (SD)	75.6 (5.0)
Sex, n (%)	
Male	22 (61)
Female	14 (39)
Education, n (%)	
Low	9 (25)
Medium	14 (39)
High	13 (36)
MMSE[a] (points), mean (SD)	28.2 (2.1)
TechPH[b] (points), mean (SD)	3.0 (0.8)

[a]MMSE: Mini-Mental State Exam.

[b]TechPH: novel scale assessing older people's attitude towards technology. The score range is 1-5. Higher scores indicate higher level of technophilia.

Testing Issues

Testing issues are summarized in Table 2. Excluding failure due to technical or physical issues impairing the ability to complete a test, failure to complete a test due to

misunderstanding of instructions was observed for 11 patients (10 four-finger–tapping test, 2 one-finger–tapping, and 1 block design test). Age, gender, education level, MMSE, and TechPH scores were not associated with failure. The patient in the cohort

with the lowest MMSE (21 points) misunderstood instructions in both the four- and one-finger–tapping tests.

Table 2. Testing issues identified by the examiner.

Test	Issue
Four-finger tapping	Of the 36 patients, 15 (42%) did not perform the test as intended because of physical difficulties (rheumatoid arthritis, fractures, or arthrosis) or misunderstanding of instructions; 3 patients did not comprehend how to use the keypad and instead tried to perform the test on the screen of the tablet.
Stroop test	A yellow button was perceived as light green by 2 patients.
Block design test	One patient did not understand when the test started.
Geriatric Depression Scale	Two patients gave a wrong answer to 1 question. Once answered it was not possible to correct.
One-finger tapping	One patient performed all tests with the left hand. One patient needed extra instructions from the examiner regarding that the buttons were supposed to be tapped and not to drag the finger between buttons.

Technical Issues

We observed 2 technical issues. In 3 test sessions of the 10-word list test, 1 instruction was repeated several times. For 1 testing session, 2 pdf reports were created.

Discussion

Principal Findings

We developed CoGNIT, a tablet app for assessing cognitive function in several cognitive domains in an automatic, standardized, and efficient manner. A previous version was developed for assessment of hydrocephalus patients, which has now been redesigned for tablet computers and expanded with new tests for more general assessments, aimed at aiding diagnostics and tracking of cognitive function in patients at memory clinics. This study aimed to assess the feasibility of testing patients with symptoms of MCI.

Overall, the feasibility for testing with patients with symptoms of MCI was good, although some issues were identified. Software bugs were identified that are straightforward to correct. Some tests did not perform optimally. On a group level, there was no indication that this was due to a lower level of a technophilia personality trait or cognitive ability as measured by the TechPH and MMSE scales. However, cognitive ability might interfere with testing in the lower range of the MMSE, as the patient with the lowest MMSE in the cohort failed to complete 2 of the included tests due to miscomprehension of instructions.

Most notably, 42% of the patients did not perform the four-finger–tapping test as intended, both due to physical limitations (eg, rheumatoid arthritis) and difficulty understanding instructions. Though a measure of manual dexterity, scores from this test correlate with tests of executive function [11]. Tests of executive function have a component of "getting it," and this test might just be too cognitively demanding for the MCI population. Also, introducing a second means of input from the attached keyboard might be confusing. The test was originally included in the CoGNIT battery because of evidence for assessing patients with hydrocephalus [12]. A more prevalent

disease in memory clinics is any of the parkinsonian syndromes, where the one-finger–tapping test has evidence [3,13]. After evaluation, the four-finger–tapping test was discarded in favor of this test in further deployment of CoGNIT.

Other testing issues are more straightforward to improve. The block design and the one-finger–tapping tests will be improved with updated instructions for the tests. In the Stroop test, a simple color adjustment will be done to improve discrimination between yellow and green. In the GDS, a button to access the previous question will be added.

Limitations

Though inclusion criteria at the first visit included an MMSE score in the range of 20 to 28, many patients scored higher at the second visit, when the CoGNIT was administered. There was a skewed distribution, with many patients scoring in the higher range. The feasibility for testing with more cognitively impaired patients is thus less tested. However, sensitive neuropsychological testing is needed less in the cognitive range where screening instruments show marked impairment.

Comparison With Prior Work

There are several computerized test batteries for neuropsychological testing of older adults [14]. Most batteries are administered by a trained testing technician who explains instructions for each test. This hampers standardization and scalability. A major criticism of computerized tests has been a lack of reports of reliability, normative data, validity, and, finally, poorly designed computer-person interfaces. All these issues were addressed when designing CoGNIT. Also, testing free recall memory is, to our knowledge, unique to CoGNIT. Free recall is the most sensitive test for disorders of episodic memory. We believe this will give CoGNIT an edge in early detection of cognitive disorders.

Conclusions

The feasibility for automatic neuropsychological testing with the CoGNIT app on a tablet device in patients with symptoms of MCI was good. After minor modifications, the app is ready for further studies. The next step is collecting normative data from a healthy population.

Abstract

Background: Anxiety and depression are among the most commonly prevalent mental health disorders worldwide. Chatbot apps can play an important role in relieving anxiety and depression. Users' reviews of chatbot apps are considered an important source of data for exploring users' opinions and satisfaction.

Objective: This study aims to explore users' opinions, satisfaction, and attitudes toward anxiety and depression chatbot apps by conducting a thematic analysis of users' reviews of 11 anxiety and depression chatbot apps collected from the Google Play Store and Apple App Store. In addition, we propose a workflow to provide a methodological approach for future analysis of app review comments.

Methods: We analyzed 205,581 user review comments from chatbots designed for users with anxiety and depression symptoms. Using scraper tools and Google Play Scraper and App Store Scraper Python libraries, we extracted the text and metadata. The reviews were divided into positive and negative meta-themes based on users' rating per review. We analyzed the reviews using word frequencies of bigrams and words in pairs. A topic modeling technique, latent Dirichlet allocation, was applied to identify topics in the reviews and analyzed to detect themes and subthemes.

Results: Thematic analysis was conducted on 5 topics for each sentimental set. Reviews were categorized as positive or negative. For positive reviews, the main themes were confidence and affirmation building, adequate analysis, and consultation, caring as a friend, and ease of use. For negative reviews, the results revealed the following themes: usability issues, update issues, privacy, and noncreative conversations.

Conclusions: Using a machine learning approach, we were able to analyze ≥200,000 comments and categorize them into themes, allowing us to observe users' expectations effectively despite some negative factors. A methodological workflow is provided for the future analysis of review comments.

Introduction

Background

Mental health disorders can have a real impact on society, with ≥264 million people affected by depression alone, and anxiety accounts for an alarming 3.76% of the population globally [1]; depression is also a leading cause of disability [2]. When it comes to the working population, anxiety and depression are among the most commonly prevalent mental disorders worldwide, which can lead to high rates of sick leave and low job performance [3]. Smartphone-based chatbot apps with self-care interventions can provide cost-effective solutions compared with hospital-based therapeutic interventions. They can also increase the capacity of such care using assessment and mood tracking or by providing human-like conversation in times of loneliness. A chatbot is an artificial intelligence (AI) software that simulates conversations or chatting with users in natural language through messaging apps, webpages, and mobile apps or on the phone [3]. In a recent review, titled *A Review of Mobile Chatbot Apps for Anxiety and Depression and their self-care features*, published in Computer Methods and Programs in Biomedicine Update, we searched the Apple App Store and Google Play Store following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) protocol guidelines and identified 11 chatbot apps related to anxiety and depression, which were assessed for quality and characteristics [3]. Using known quality measures for mobile apps, such as authority, complementarity, confidentiality, validity, technological features, general information, usability, and intervention approaches, we found that available anxiety- and depression-related chatbot apps were highly rated and had high rates of user satisfaction [3]. The 11 apps included Ada, your health companion; Dr Sila, your smart health assistant; InnerHour Self-Care Therapy, anxiety and depression; MindDoc, depression and anxiety; Mindspa: Self Help 4UR Mental Wellbeing & Wellness; Pocketcoach, anxiety helper; Replika, My AI Friend; Serenity: Guided Mental Health; Woebot, your self-care expert in cognitive behavioral therapy and mindfulness; Wysa, stress, sleep, and mindfulness therapy chatbot; and Youper, anxiety and depression. These 11 apps targeted anxiety and depression disorders, and all contained chatbots. They were all of high quality and popularity and met the mHONCode principles [3]. The apps were built with various self-care interventions and other types of interventions, such as cognitive behavioral therapy and mindfulness. We found that anxiety and depression chatbot apps have the potential to improve the capacity of mental health self-care and provide low-cost support to professionals [3]. As a follow on from our initial study, we wanted to conduct in-depth analysis using a thematic review by extracting publicly available review comments and ratings from the Apple App Store and Google Play Store. By doing so, we gain better insight into the user satisfaction of these 11 apps. We considered this part 2 of our initial study, where we further explored users' opinions, satisfaction, and attitudes about anxiety and depression chatbot apps. Several studies have examined users' opinions and satisfaction with mental health apps but very few have analyzed app reviews in detail. For instance, a scoping review explored users' perceptions and opinions about

mental health chatbots, as reported by 37 previous studies using cross-sectional survey methods [4]. However, the scoping review, as well as the included 37 studies, did not analyze the qualitative reviews of the actual users of the apps, who downloaded and used the apps and then gave their feedback in app stores such as the Apple App Store and Google Play Store [4]. Web-based reviews reflect a user's perspective on a service or product. We consider these topics as dimensions along which different users evaluate the chatbots. Therefore, this study aims to explore users' opinions, satisfaction, and attitudes about anxiety and depression chatbot apps by conducting a thematic analysis of users' reviews of 11 anxiety and depression chatbot apps using topic modeling techniques. In addition, we propose a workflow to provide a methodological approach for future analysis of app review comments. Topic modeling is an unsupervised and automated machine learning (ML) technique that identifies abstract topics found in a body of documents using probabilistic models. They are frequently used as tools for text mining to find semantic structures in a text. For example, a text regarding certain topics will have specific words that appear more frequently than others. Such techniques are useful for classifying documents, organizing large chunks of texts, retrieving information from unstructured data, and selecting features. They are also more accurate and efficient than traditional data mapping approaches [5]. This review followed the thematic analysis approach, including data cleaning processes, clustering of reviews by one group of coauthors into positive or negative groups, validation of the accuracy of the clustering by a second group of coauthors, and finally analyzing the main topics extracted from each cluster and categorizing them into themes and subthemes. Investigating web-based reviews on apps designed for mental health conditions, such as depression and anxiety, is essential to understand users' preferences, feedback, and suggestions. This can add valuable insights into both clinical apps' development field and research in this rapidly evolving domain in relation to this specific clinical area.

Related Work

Previous studies of a similar nature have focused on various smartphone apps, and most of them successfully analyzed users' feedback and reviews. However, many studies failed to report their used methodologies in sufficient detail so that other research works could use such proposed approaches and build on what has been developed. A study in 2014 evaluated 229 medicine reminder apps, but their thematic analysis was limited to 1012 user reviews [5]. A study in 2017 analyzed users' emotions for ≥7 million reviews from the Apple App Store using a self-developed scraper tool. Such data scraping tools extract and import data from webpages and to spreadsheets to transform such data into human-readable output. They used a third-party sentiment extraction tool to extract meanings and impressions from short sentiment sets that include user views or opinions [6]. A recent study analyzed 63,398 reviews of e-commerce apps [7]. They conducted a thematic analysis and compared the performance of ML algorithms and Linguistic Inquiry and Word Count (LIWC). ML is an approach to data analysis in which the building of analytical models is automated. It is considered a part of AI, as it is based on the idea that systems can learn

from data, identify data patterns, and make decisions with minor human interventions [8]. Similarly, LIWC uses a predefined list of words in its dictionary to determine the positive and negative tones in English. The study reported a higher F1-score for the LIWC approach (86.7%), which statistically reflects a very high accuracy rate, based on the precision and recall of the test, where precision is known as the positive predictive value and recall is known as sensitivity in diagnostic binary classifications. A study in 2014 reported an average accuracy of 59% when using natural language processing (NLP) techniques to identify app features from reviews, followed by extracting user sentiments about these features and eventually used topic modeling techniques to group fine-grained features into more meaningful high-level features [9]. We found that various studies have developed tools to automate the analysis of reviews. One of them, a tool named Mining and Analyzing Reviews by Keywords, is a semiautomated tool to support the analysis of app reviews [10]. A study in 2018 was conducted as part of a 2-part study evaluating user experience through a thematic analysis of publicly available user reviews of cognitive behavioral therapy apps for depression [11]. They extracted 2904 reviews from 24 apps and manually assessed the reviews according to their sentiment (positive, negative, or neutral). Several studies [12] have used tools to allow thematic analysis, such as NVivo (QSR International), a qualitative analysis tool

[13]. The latter study [14] used a third-party tool to extract reviews and NLP for preprocessing the data and developed several ML classifiers to predict the polarity (positive or negative) of reviews. They trained the classifiers for prediction and then used NVivo to conduct thematic analysis. We reviewed existing studies and found no clear consistent approach to conduct a similar analysis. Therefore, based on existing literature, we propose our own workflow, which includes an ML technique to automatically analyze text data (topic modeling), and aim to also provide a methodological approach for future analysis of review comments.

Methods

Overview

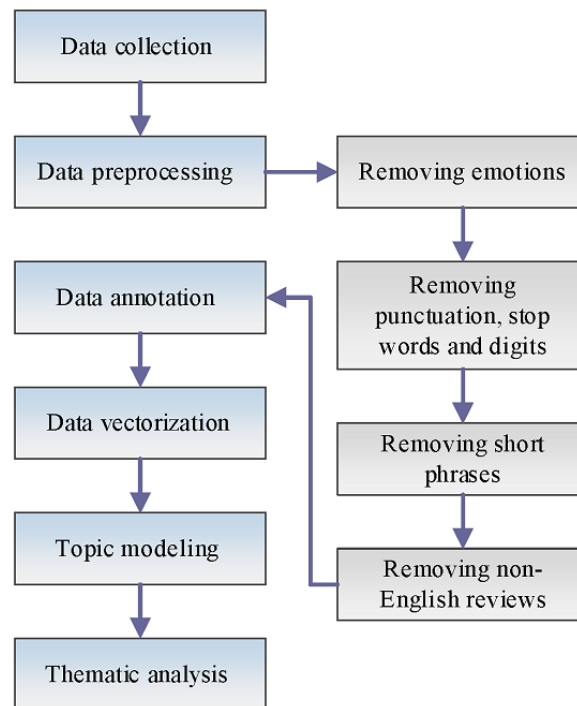
We aimed to identify how 11 depression and anxiety chatbots were scrutinized by users, as shown in Table 1.

Using the Apple App Store and Google Play Store, we extracted 205,581 reviews and classified them under positive and negative headings and used the following workflow. There were six steps, as illustrated in Figure 1: data collection, data preprocessing, data annotation, data vectorization, topic modeling, and thematic analysis. Further details regarding these steps are presented in the following subsections.

Table 1. Apps, supported platforms, and total reviews.

App name	Platform	Reviews (N=205,581), n (%)
Ada: your health companion	Android	60,441 (29.4)
Dr Sila: your smart health assistant	Android and iOS	2 (<0.01)
InnerHour Self-Care Therapy: anxiety and depression	Android and iOS	1975 (0.96)
MindDoc: depression and anxiety	Android and iOS	8010 (3.9)
Mindspa: Self Help 4UR Mental Wellbeing & Wellness	Android and iOS	43 (0.02)
Pocketcoach: anxiety helper	Android and iOS	83 (0.04)
Replika: My AI Friend	Android and iOS	102,534 (49.88)
Serenity: Guided Mental Health	Android and iOS	3328 (1.62)
Woebot: your self-care expert in CBT[a] and mindfulness	Android and iOS	4316 (2.1)
Wysa: stress, sleep, and mindfulness therapy chatbot	Android and iOS	24,349 (11.84)
Youper: anxiety and depression	iOS	500 (0.24)

[a]CBT: cognitive behavioral therapy.

Figure 1. Workflow to prepare reviews for thematic analysis.


Data Collection

We used 11 apps from our previous study, *A Review of Mobile Chatbot Apps for Anxiety and Depression and their self-care features*, published in Computer Methods and Programs in Biomedicine Update [3]. In this previous study, a search was performed in the Apple App Store and Google Play Store following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) protocol to identify existing chatbot apps for anxiety and depression. The eligibility of the studies was assessed by two researchers (AA and SA), based on 5 predefined eligibility criteria. Eligibility criteria outlined that the app should be related to either anxiety or depression or both, the apps should contain a chatbot feature as opposed to human interaction as the main chatting agent, the apps should be free of cost at the point of download, the apps that have ratings above 4 stars as a sign of user satisfaction only should be included, and only apps that had a total number of ≥5 raters were included [3]. Metadata of the included chatbots and their characteristics were extracted from their description and after installation by two reviewers (AA and SA). We extracted 205,581 user reviews from the 11 apps identified in our previous study using a scraper tool that we built using the Google Play Scraper and Apple App Store Scraper Python libraries. All Google Play Store reviews for the 11 apps were extracted, whereas for the Apple App Store, it only allowed a maximum of 500 reviews per app to be extracted because of privacy policies. Table 1 outlines the selected apps and the total number of consumer reviews extracted from each app.

Data Preprocessing

Web-based reviews can contain many irrelevant comments, such as those that do not describe the apps or mention their advantages and disadvantages. Therefore, preprocessing the reviews using NLP techniques was needed in the following stages:

1. Normalizing the data, converting the text of all reviews to lowercase.
2. Removing emoticons, symbols and pictographs, and transport and map symbols from the reviews.
3. Removing punctuation marks and digits from the reviews using the natural language toolkit Python library.
4. Removing short phrases (eg, "Good," "Nice," "very Helpful," or "really impressive app"). As we are identifying the key themes or features or issues pointed out by reviewers, short phrases provide no additional value to our thematic analysis.
5. Removing non-English reviews (eg, German and Dutch as app secondary languages).

Data Annotation

A star rating score on a scale of 1 to 5 was assigned by app users within each user review, which was part of our extracted data. One star represents *very dissatisfied* and 5 stars represents *very satisfied*. The reviews were divided into 2 sets by annotating them as either positive or negative sentiment polarity based on the rating given to each review. We adopted this approach from previous studies that categorized the data in a similar manner [15]. Table 2 outlines the criteria adopted for mapping sentiment polarities to user ratings.

Neutral feedback was considered not positive and was included in the negative sentiment polarity. We further validated our technique for accuracy by randomly selecting 50 positive and negative reviews, 2 reviewers manually validated the results, and our results showed 100% accuracy for annotation on the 50 respective sentiment reviews.

Table 2. Criteria for user rating to polarity mapping.

User ratings	Rating description	Sentiment polarity
1	Very dissatisfied	Negative
2	Dissatisfied	Negative
3	Neutral	Negative
4	Satisfied	Positive
5	Very satisfied	Positive

Data Vectorization

For the model to handle the data, it must be represented in numerical form. One of the most popular ways to achieve this is the word's Term Frequency–Inverse Document Frequency score [16] or their frequency counts (bag-of-words [BOW] approach). We opted for the BOW approach [17] representation to vectorize the terms by identifying the unique terms in our corpus and used the *CounterVectorizer* function from *Sklearn's* feature extraction module in Python. This function converts a collection of text to a matrix of word counts, allowing us to extract bigrams and use a count vectorizer, which is a known technique for retrieving the relevant counts of each bigram.

Topic Modeling

Topic modeling is based on unsupervised and automated ML techniques that discover abstract topics in the body of text using probabilistic models. These techniques are frequently used as text mining tools to identify semantic structures and conduct thematic analyses [18]. It is considered superior to other manual thematic analysis techniques, traditional statistical models, or standard text mining techniques. Manual thematic analysis techniques [14] applied with software tools such as NVivo use themes or topics that are manually predefined by the reviewer, and the corresponding reviews are further mapped, which can be challenging when the amount of data is large. Traditional statistical techniques are used for clustering data, primarily K-means clustering, which is a method that partitions data observations into data clusters based on the nearest mean. This method works on numeric data as opposed to text data. Standard text mining techniques use keyword information representation and count-based mining of these keywords instead of analyzing the use of these keywords and their contexts. Topic modeling has an advantage over the aforementioned techniques in that it performs clustering on the textual data provided inside of the data in depth. Furthermore, it is useful for identifying the key issues and topics discussed in large corpora. Topic modeling algorithms use latent Dirichlet allocation (LDA), which determines a word's meaning based on its co-occurrence with other words. In this study, we used a bigram LDA model for topic modeling. LDA is a Bayesian inference method that estimates the most likely topics given for the observed corpus.

We used the LDA model and analyzed the bigram range of the corpus of reviews in each set.

Furthermore, we divided our data set of reviews into 2 sets of positive and negative reviews and performed topic modeling on each set separately to identify the main themes within our data set. We worked with 5 topics from each set of sentimental data, selected through consensus after deeming the results of 3 topics as inappropriate.

Thematic Analysis

Thematic analysis was conducted on the 5 topics of each sentimental set. Through these 5 topics of negative and positive sets, we were able to identify the factors that contribute to the effectiveness of anxiety and depression chatbots both negatively and positively. We identified the topic names and analyzed them thoroughly to identify the themes encapsulated within each theme.

Ethics Approval

No ethics approval needed, as we used publicly available data.

Results

Data Collection, Preprocessing, Annotation, and Vectorization

We analyzed 205,581 comments extracted from 11 anxiety and depression chatbots identified in our previously published study on both the Apple App Store and Google Play Store [3]. The steps of review selection and inclusion are shown in Figure 2. Of the 205,581 reviews, 1093 (0.53%) reviews were removed, containing only emoticons (smiley face, sad face, heart shape, etc). From the remaining 204,488 reviews containing only text, a further 1360 (0.67%) non-English reviews were excluded. Furthermore, 32.48% (66,423/204,488) reviews with simple praises were removed, as they did not contribute anything meaningful to our analysis, leaving a remainder of 136,705 reviews.

The 136,705 reviews were divided into two meta-themes: positive and negative, as presented in Table 3.

Multimedia Appendix 1 shows the complete app-by-app breakdown of the preprocessing and meta-theme division.

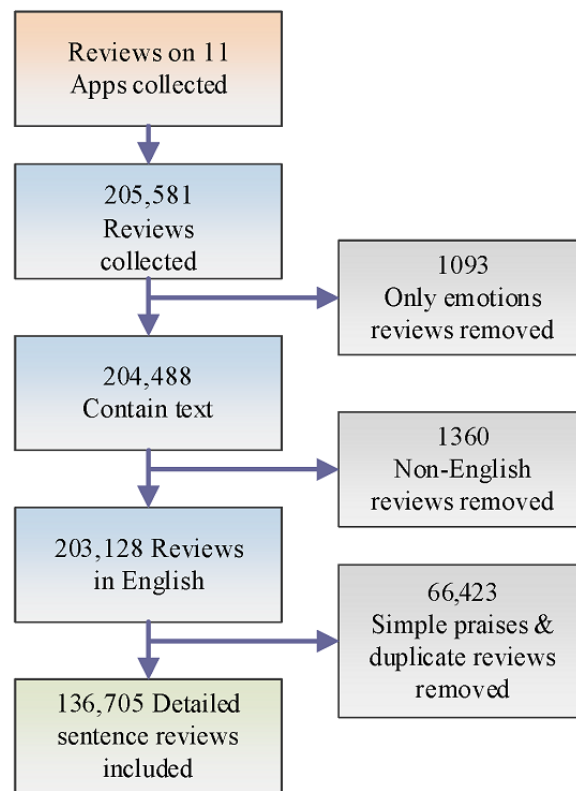
Figure 2. Steps for the selection and inclusion of reviews.


Table 3. Sentiment polarity with corresponding reviews.

Sentiment polarity	Number of reviews
Positive	124,458
Negative	12,247

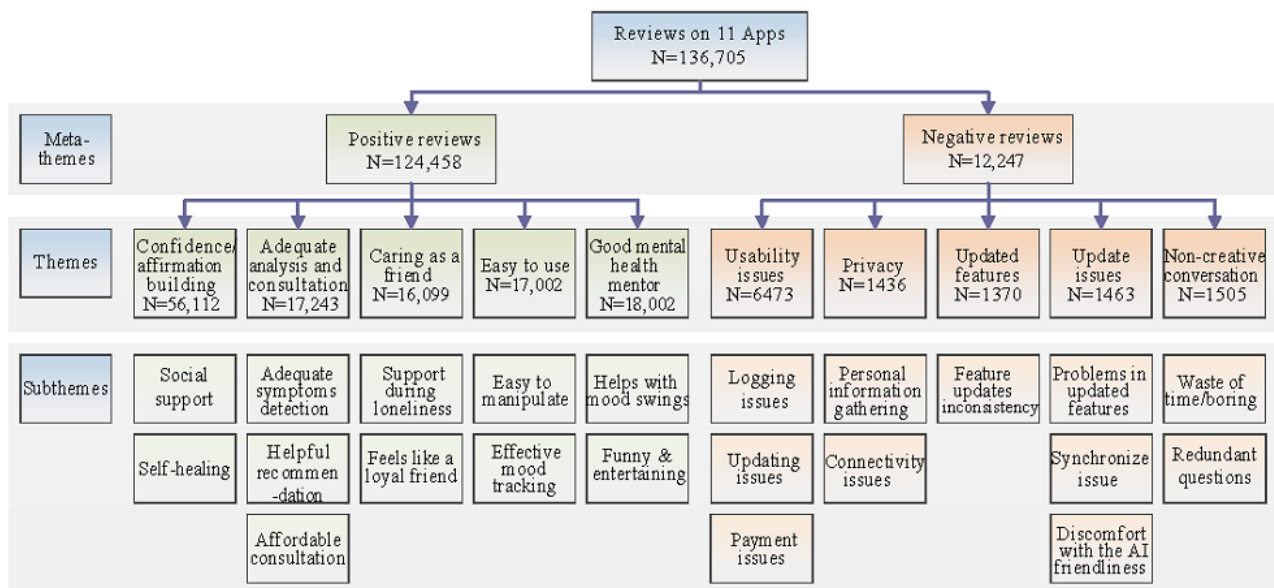
Topic Modeling and Thematic Analysis

Topic Extraction Model for Positive and Negative Reviews

Having preprocessed (cleaned) the data, we divided it into two meta-themes (positive and negative). Topic modeling was performed on each set of reviews separately, as per previous studies, as it is said to be a fast approach for identifying themes in large corpora [19]. We identified 5 topics from the positive and negative reviews, forming 5 topics in each set. Multimedia Appendix 2 presents the most common words used in each set of topics. The relative composition in the corpus with respect to each topic was calculated using LDA by computing the appearance of each topic occurring with respect to the underlining review. Thus, each review obtained the appearance frequencies corresponding to each topic, and the highest value indicated the review mapping into that respective topic. Each topic was assigned a name, and the respective subthemes were identified by analyzing the number of reviews in each respective topic. Multimedia Appendix 3 depicts the respective topics in each set of reviews.

Categorizing Themes

All subthemes identified in each topic were classified under one specific larger theme. Although the topics addressed different issues, identifying the main themes allowed them to be grouped together under the same category and further analyzed. More than 90% of the reviews were classified as positive, and <10% were classified as negative. Figure 3 shows the themes and subthemes from both positive and negative perspectives. Figure 3 shows the meta-theme categories for positive and negative reviews, along with each theme-encapsulated subtheme. For positive reviews, the main themes were "confidence and affirmation building," "adequate analysis and consultation," "caring as a friend," and "easy to use." For negative reviews, the main themes were "usability issues," "update issues," "privacy," and "noncreative conversation."

Figure 3. Meta-themes, themes, and subthemes for positive and negative reviews.


Positive Reviews

The following section highlights the positive experiences people reported while using the 11 anxiety and depression chatbots. A sample of positive reviews is included in Multimedia Appendix 4 and classified into 4 themes.

Theme 1: Confidence and Affirmation Building

The first theme, confidence and affirmation building, consists of three subthemes: (1) social support, (2) self-healing, and (3) help with mood swings, as illustrated in Figure 1. Social support was a major concern for users, the chatbot provides comfort by appreciating even the smallest of users' achievements and providing encouragement, allowing users to believe in themselves and overcoming social anxieties. The second subtheme shows the ability of the chatbot to provide users with tools to overcome self-control issues, allowing users to provide their own solution and raising self-esteem and will power, as well as allowing them to feel comfortable in their own body. The third subtheme states that chatbots allow the control and tracking of mood swings for better treatment.

Theme 2: Adequate Analysis and Consultation

The second theme consists of three subthemes: (1) adequate symptom detection, (2) helpful recommendations, and (3) affordable consultation. Adequate symptom detection was considered an important aspect for chatbot users selected in this review. The chatbots can relate to users' symptoms and provide empathy. The following subtheme is *helpful recommendation* in which chatbots support recommendations that are synchronized with the user's counselor or health care professional. Affordable consultation is the third subtheme in which users highlight that they appreciate the effectiveness of the chatbot with the bonus of using a consultation app with minimal to no cost.

Theme 3: Caring as a Friend

The third theme is composed of three subthemes: (1) support during loneliness, (2) feeling like a loyal friend, and (3)

entertaining talks. The first subtheme involves chatbots becoming the user's go-to person during times of loneliness. The second subtheme is identified as *feeling like a loyal friend* because users indicated that having someone to talk to is not always the only solution; trusting that person as a friend is also important. Users felt that chatbots could provide this, as reflected in their comments. The third subtheme highlights that engaging in conversations containing humor provides a boost to users' mood and is entertaining. Slang language and memes are also enjoyed by users. The chatbots had the intelligence to understand the mood of a person and to boost their mood accordingly.

Theme 4: Easy to Use

The last theme in the positive reviews includes two subthemes: (1) easy to manipulate and (2) effective mood tracking. The first subtheme is easy to manipulate. By manipulation, we refer to how conversations with chatbots occur in an easy manner in which the questions are easy to be followed and understood. In addition, chatbots are easy to use and require minimal assistance. The anxiety and depression chatbots were easy to navigate, which the users appreciated. The second subtheme is effective mood tracking, in which the chatbot assigns tasks to individuals that are easily achievable with good results.

Negative Reviews

The following section describes users' concerns regarding the negative experiences encountered while using chatbots. A sample of negative reviews is included in Multimedia Appendix 4 and classified into 4 themes.

Theme 1: Usability Issues

This theme outlines various usability issues that are encountered while accessing the different functionality of the chatbots. Subthemes identifying these issues are (1) logging issues, (2) payment issues, and (3) connectivity issues. Nonresponsive interfaces or lack of guidance to navigate with regard to signing is one of the major issues encountered. The second subtheme highlights the issue regarding payments; although most apps

were free, people did not take well to in-app purchases in some cases, and these were reflected in some comments. The last subtheme signifies the connectivity glitches experienced by many while using the apps. Although the apps connected well via the internet, some server accessibility issues were observed, which left a negative taste for users.

Theme 2: Update Issues

The second theme, updating the apps, consists of two subthemes: (1) problems in updated features and (2) synchronization issues. The updates caused people to drop out of the apps by interrupting their ongoing processes or tasks. Changes in features or added costs to previously free features post updates were not welcomed by many users. The second subtheme states a lack of synchronization between different app versions. The version updates made simple tasks more difficult in newer versions or were sometimes removed completely without considering current users.

Theme 3: Privacy

The third theme, privacy, consists of two subthemes: (1) personal information gathering and (2) discomfort with AI friendliness. The first subtheme talks about users' dislike when many personal questions are asked. The second subtheme reflects the reviews emphasizing the discomfort they experience while talking to the chatbots; users expressed that some dialog used by the chatbots was inappropriate, as indicated in sample reviews, making users feel they are under surveillance or being interrogated, and some highlighting how the AI bot becomes too friendly.

Theme 4: Noncreative Conversation

The first theme, confidence and affirmation building, consists of two subthemes: (1) waste of time or boring and (2) redundancy of questions. The first subtheme was developed as users continuously emphasized that the chatbot is wasting their time and it is becoming boring. Short-term memory of the chatbot and not building upon previous conversations was also highlighted, along with chats turning out to be monotonous as the questions were repeated with no new engaging questions asked. The second subtheme is the redundancy of questions, in which users emphasize that the questions are repetitive questions daily, and some sentence structure change is required.

Discussion

Principal Findings

Chatbots are promising tools for those who have anxiety and depression, providing confidence and support via user-friendly tools. Users enjoy engaging and creative content while remaining conscious of security issues. Through thematic analysis, 4 positive and 4 negative themes and relevant 12 subthemes in each group were identified in the users' reviews of 11 depression and anxiety chatbot apps. Positive reviews highlighted the features that users enjoyed most using chatbots. Users identified several areas in which we clustered into two major parts: positive and negative reviews. Our methodological approach identified thematic content by categorizing a large corpus of reviews into 5 clusters based on each sentimental division set. Important inferences can be deduced from the

empirical findings, and most of the reviews were positive, indicating that the majority of users found anxiety and depression chatbots effective and fit for purpose. Negative experiences are also encountered while using these chatbots.

In Figure 3, our findings revealed that the majority of the 11 anxiety and depression chatbots worked well in this regard, boosting a user's social support, self-healing, and dealing with mood swings. The first theme is confidence and affirmation building, which is a key aspect that allows a person to maintain their well-being, especially when it comes to mental health. Affirmation generally works as a tool for mindset shifting and achieving goals through social support [20]. Finally, as chatbots help patients with mood swings, it is important to highlight that mood variability is a major trait in those affected by anxiety and depression [16]. The second theme in positive reviews was adequate analysis and consultation. Most health apps that are currently available lack clinically validated evidence of their efficacy [21]. Our findings revealed that most of these anxiety and depression chatbots played their part in the best possible way by providing symptom detection and helpful recommendations with the best affordable consultation one can expect with freely available apps.

This is aligned with the findings of a previous study [22], which highlighted the issue of waiting times and the affordability of psychotherapy. Chatbots can provide access to affordable care before waiting for approval to meet a clinician [23]. The third theme is *caring as a friend*, and the evidence behind it is that feelings of loneliness are a major factor in mental health issues [21]. Loneliness and social isolation are tantamount to feeling unsafe and are classified as social threats accompanied by feelings of hostility, low self-esteem, anxiety, stress, and pessimism [24]. This issue has been exacerbated during the COVID-19 pandemic, resulting in a large number of mental health issues [25]. Many of the review comments reveal how users benefited from chatbots during dark times, especially during the current pandemic.

Issues of accessibility were highlighted when using apps. An app has to be *easy to use* [26] and must be a key design thought when developing mental health–related apps. Users are less accepting of complex scenarios and tasks, particularly when they are already affected. We observed that users regarded the chatbots as easily operable, and the tasks were quick and to the point.

The first observed theme among negative reviews was related to usability issues. Understanding user experience is essential for chatbot design to overcome usability issues that could be achieved by applying usability testing metrics such as the system usability scale and user experience questionnaire scales to measure and evaluate user experience and satisfaction [27].

From the perspective of usability, effectiveness, efficiency, and satisfaction [28] are key considerations when achieving a specific task or goal. We found that users disliked issues related to logging or startups. The last 2 subthemes in this section are related to payment and connectivity issues, the cost of apps, and problems with connectivity, which are powerful platforms that do not rely on costly servers [29]. The second theme in the negative reviews highlighted problems related to new updates

in the app that caused the chatbot to lose its essence or meaning, as some users did not like the inconsistency in updates. Although updates are welcomed, users become frustrated whenever an update of previously running features is blocked or they are asked to pay for them.

Privacy is the third theme in negative reviews, which is a key issue that users face with chatbots [30]. The subthemes are divided into personal information gathering–related issues and observations with users who do not feel comfortable with the overfriendliness of the AI robotic chatbot. Users become wary of what and with whom they share personal conversations, and many ethical and legal (data protection) questions remain unanswered [31]. In addition, in our subtheme, discomfort with AI friendliness was in line with the findings of previous studies [32], showing that users linked the technical systems with human-like attributes, which makes users feel uncomfortable about content sharing and possible data sharing and general mistrust toward the app. The last theme in the negative reviews is noncreative conversation. Unsurprisingly, unintelligent conversations proved a big dislike to users. The creativity of the chatbot is questioned when a chatbot is repetitive, asking similar questions throughout the day, and users lose interest. Questions also arise about the susceptibility of users to receive therapeutic advice from chatbots, whose algorithms may be harmful to users [31]. The frequency of themes, shown in Multimedia Appendix 3 and Figure 3, should help app developers understand the main advantages that users highlight in their reviews and the main challenges they faced. Consequently, developers should work to fix the weaknesses of their apps and invest more in areas that users consider important to manage their medical conditions. Eventually, this should improve the public adoption of apps designed for mental health conditions such as anxiety and depression.

Strengths and Limitations

This study has several strengths and limitations regarding the review analysis of anxiety and depression chatbots. The study enabled us to explore such a large review corpus in a short span, which was otherwise not possible. To the best of our knowledge, no such thematic analysis is available using an ML approach. This approach provides a high-level view of all the possible themes that the topics encapsulate. However, this study was analyzed on English reviews only. In addition, the Apple App Store privacy policy did not allow researchers to exceed 500 review extractions per app; thus, the findings may be restricted in view of Apple users of the app. Moreover, reviews that sometimes included emojis or emoticons only were excluded from this thematic analysis. The study method approach of combining neutral and negative into one category could be seen as a limitation, although this methodology has been reported in previous studies. Finally, our findings are limited to 11 chatbots related to anxiety and depression, and we emphasize that the generalizability and applicability of our results may not be

applicable to other chatbots in the market outside of mental health.

Practical and Research Implications

Practical Implications

This review serves most researchers, clinical app developers, and professionals interested in developing chatbots related to mental health and well-being. We identify a gap in research as researchers highlight issues related to clinical psychotherapy approaches and neglect the psychosocial aspect of using mental health apps. We highlight factors related to the social, technical, and understanding of user experiences and opinions. On the basis of positive and negative reviews, users were put off by issues related to privacy, repetitiveness of conversation by the chatbot, connectivity issues, and poor usability. Among the positive themes, we found that ease of use, providing support, good human conversation, and providing feelings of mood uplifting were perceived as indicators of desired attributes. With the involvement of health care providers and policy makers, future development needs to seriously consider our findings when developing such chatbots by chatbot app developers and researchers.

Research Implications

Analysis of user reviews has been explored previously, and although powerful techniques exist, we found that clear guidance was lacking when we looked at previous studies on how to implement such techniques for large amounts of review data. In this study, we documented our approach and invited other researchers to test and validate our proposed method and to check its feasibility in analyzing users' reviews of other apps. In addition, future developers of mental health–related chatbots can use our findings to build chatbots with more positive opinions and higher rates of satisfaction.

Conclusions

Through thematic analysis of users' reviews, this study explored opinions, satisfaction, and attitudes regarding 11 anxiety and depression chatbot apps. Our proposed workflow provides a methodological approach for the future analysis of app review comments. We used an ML-based technique known as topic modeling to cluster reviews to obtain insight into textual data, as opposed to traditional data-mapped approaches that determine themes. Users tend to dislike technical and privacy issues. Users expect engaging and creative conversations through more appealing user interfaces. Moreover, users of chatbots designed for anxiety and depression feel supported and confident as they use apps that are easy to manipulate, affordable, and free of cost. Consequently, users do not prefer chatbots with less creative content and conversations and those that are overly friendly and invade their privacy. These themes allowed us to observe users' expectations effectively, despite some negative factors. Future researchers can work toward better generalizing topics by closely refining reviews into specific issues or features.

Abstract

Background: Interest in developing machine learning models that use electronic health record data to predict patients' risk of suicidal behavior has recently proliferated. However, whether and how such models might be implemented and useful in clinical practice remain unknown. To ultimately make automated suicide risk–prediction models useful in practice, and thus better prevent patient suicides, it is critical to partner with key stakeholders, including the frontline providers who will be using such tools, at each stage of the implementation process.

Objective: The aim of this focus group study is to inform ongoing and future efforts to deploy suicide risk–prediction models in clinical practice. The specific goals are to better understand hospital providers' current practices for assessing and managing suicide risk; determine providers' perspectives on using automated suicide risk–prediction models in practice; and identify barriers, facilitators, recommendations, and factors to consider.

Methods: We conducted 10 two-hour focus groups with a total of 40 providers from psychiatry, internal medicine and primary care, emergency medicine, and obstetrics and gynecology departments within an urban academic medical center. Audio recordings of open-ended group discussions were transcribed and coded for relevant and recurrent themes by 2 independent study staff members. All coded text was reviewed and discrepancies were resolved in consensus meetings with doctoral-level staff.

Results: Although most providers reported using standardized suicide risk assessment tools in their clinical practices, existing tools were commonly described as unhelpful and providers indicated dissatisfaction with current suicide risk assessment methods. Overall, providers' general attitudes toward the practical use of automated suicide risk–prediction models and corresponding clinical decision support tools were positive. Providers were especially interested in the potential to identify high-risk patients who might be missed by traditional screening methods. Some expressed skepticism about the potential usefulness of these models in routine care; specific barriers included concerns about liability, alert fatigue, and increased demand on the health care system. Key facilitators included presenting specific patient-level features contributing to risk scores, emphasizing changes in risk over time, and developing systematic clinical workflows and provider training. Participants also recommended considering risk-prediction windows, timing of alerts, who will have access to model predictions, and variability across treatment settings.

Conclusions: Providers were dissatisfied with current suicide risk assessment methods and were open to the use of a machine learning–based risk-prediction system to inform clinical decision-making. They also raised multiple concerns about potential

XSL·FO

RenderX

barriers to the usefulness of this approach and suggested several possible facilitators. Future efforts in this area will benefit from incorporating systematic qualitative feedback from providers, patients, administrators, and payers on the use of these new approaches in routine care, especially given the complex, sensitive, and unfortunately still stigmatized nature of suicide risk.

Introduction

Background

It is estimated that approximately 800,000 people die by suicide each year worldwide, representing approximately 1 suicide every 40 seconds [1]. In the United States, suicide is the 10th leading cause of death [2]. More than 48,000 Americans die by suicide each year, which works out to approximately 129 suicide deaths every day [2]. Encouragingly, from 2018 to 2019, the US suicide rate declined (by 2.1%) for the first time after 13 years of consecutive increases [2]. However, most states did not experience significant decreases, and whether this downward trend will continue remains to be determined [3]. To achieve the ambitious goal of reducing the suicide rate by 20% before by 2025 in the United States [4], it is critical to prioritize the large-scale implementation of existing evidence-based suicide prevention strategies, as well as the development of new approaches.

The health care system is a key setting in which to target suicide risk detection and prevention efforts. Estimates show that upwards of 75% of people who die by suicide pass through the health care system within the year (and up to 50% within the month) before their death [5]. Visits in medical specialty and primary care settings, followed by the emergency department (ED), are the most common leading up to death by suicide; notably, most of these visits do not include a documented mental health diagnosis [6]. In part owing to these findings, increased national efforts have been made to implement standardized self-reported or clinician-rated tools to assess suicidal thoughts and behaviors [7] as well as psychiatric disorders commonly associated with suicide [8]. Indeed, leading national organizations now recommend such validated screening tools for suicide risk as best practice across treatment settings [9].

Although screening questionnaires represent a key component in health care–based suicide prevention, they are not without limitations. For one, such assessments rely on patients to honestly and accurately report on their experiences and symptoms. The myriad barriers to disclosing suicidal thoughts (eg, concerns about involuntary hospitalization or other unwanted consequences and stigma) [10], as well as biases associated with retrospective recall [11], are well established. Indeed, prior studies have shown that up to three-quarters of patients who go on to die by suicide deny any suicidal thoughts in their most recent health care encounter [12]. Second, suicidal thoughts can fluctuate rapidly over short periods [13], posing the possibility that patients may not be experiencing suicidal thoughts at the time of assessment but experience an escalation in suicidal thinking soon after [10]. Third, even brief screening measures take time for patients to complete and providers to

administer and review, which may result in suboptimal completion rates and data quality [14], especially in fast-paced treatment settings. Finally, widely used screening measures have evidenced less than ideal diagnostic accuracy for predicting future suicidal behavior, with some research suggesting that even *high-risk* classifications on traditional suicide risk scales are not sufficiently accurate for clinical use [15,16]. It is recommended that validated tools be used in conjunction with clinical judgment to determine suicide risk; however, clinicians are generally quite poor at predicting who will make a suicide attempt [17]. Clearly, there is room for novel approaches to identify patients at risk for suicide in health care settings—not necessarily to replace but rather to complement traditional methods [18].

The development of automated machine learning–based models that use electronic health record (EHR) data (eg, demographic and health information) to predict patients' risk of suicidal behavior in the future is one such promising approach that has received increasing attention in the literature [19] and media [20]. There are many potential advantages of machine learning models for suicide risk prediction. For example, because such models leverage vast amounts of routinely collected clinical data, they should require little additional provider or patient burden at the point of care and do not rely exclusively on patients to accurately report on their suicidal thoughts. This also makes EHR-based models potentially useful for population-wide suicide risk screening of patients in the health care system, rather than responding only to those individuals who actively self-report suicidal thoughts or whose clinicians who identify suicide risk. Multiple research teams, including ours [21,22], have published results from studies that build and evaluate such suicide risk–prediction models. Overall, findings from this body of work are promising, with algorithms generally demonstrating high levels of accuracy (eg, classification accuracy up to 94% at Mass General Brigham, with similar model performance across 4 other large health care systems) [21,22]. Perhaps most promising is the potential to pair such scalable, low-cost models with evidence-based interventions; for example, patients stratified at the higher end of a suicide risk distribution might be prioritized for more costly and targeted clinical evaluation and monitoring and possibly receive a suicide-focused intervention [23,24]. Along these lines, recent work shows that existing suicide risk–prediction models have sufficient accuracy to be cost-effective if implemented and paired with various evidence-based interventions [25].

Despite the promise of statistical suicide risk–prediction models when used to inform clinical decision-making, with few exceptions [26-28], these efforts have yet to be widely deployed or evaluated in clinical practice. There are many complex

practical and ethical questions about how such models—and corresponding clinical decision support (CDS) tools [29] that alert providers with statistical information about patients' suicide risk and offer decision support contingent on their risk (and potentially other patient factors) at the point of care—would fare in *real-world* clinical settings that currently remain unanswered. For example, when and how frequently would suicide risk–prediction models be updated and providers notified? Would the additional workload associated with responding to automated suicide risk alerts be manageable for providers [27]? Would some machine learning (sometimes referred to as *black box*) models be interpretable or actionable [30]? Questions related to the clinical implementation of such tools also impact the patients whose data are being used to generate predictions—for example, regarding data privacy and communication model results—as well as the health care systems more broadly in which such approaches are used. A key concern, for instance, is that using automated models to identify at-risk patients who are not currently identified via clinical assessments would add more burden to health care systems with already limited resources.

Thus, before widespread clinical deployment, it is critical to partner with stakeholders (eg, frontline clinicians, patients, administrators, and payers) who can help guide such efforts. Recent work in this area has involved collecting self-report survey data from mental health professionals [30] and patients [31] on clinical and operational issues pertaining to automated suicide risk models. A recent study used self-report surveys (n=35) and interviews (n=12) to collect qualitative data from Veterans Affairs (VA) clinicians involved in the recently implemented VA program that uses predictive analytics to identify and provide outreach to veterans at high risk for suicide [32]. However, we are not aware of any published or systematic qualitative research in the form of focus groups or interviews with key stakeholders regarding the clinical implementation of suicide risk–prediction models in non-VA health care settings. Now considered essential to real-world implementation efforts, qualitative methods have the potential to both rigorously and efficiently answer key questions related to both *whether* and *how* [33] we should proceed with implementing new and automated approaches to suicide risk prediction in clinical care.

Objectives

The aim of this study is to solicit perspectives on the deployment of suicide risk–prediction models in clinical care via focus groups with providers from various departments at a large (>1000 beds, >1.5 million outpatient visits/year) urban hospital. We conducted this study to guide the ongoing development and, ultimately, clinical implementation of a CDS system that provides statistical information from suicide risk–prediction models and corresponding decision-making support to providers at the point of care. Our specific goals are to (1) better understand providers' current practices for suicide risk assessment and intervention in routine care; (2) determine providers' perspectives on the use of machine learning models and corresponding CDS tools for identifying and managing suicide risk, including barriers and facilitators; and (3) identify key factors and recommendations to consider in the development of such a CDS system.

Methods

Participants

Focus group participants were providers at the Massachusetts General Hospital (MGH) in Boston. Participants were selected via convenience sampling. The senior author (JWS) contacted leadership (eg, chiefs and clinical or training directors) of 4 MGH departments (psychiatry, internal medicine and primary care, emergency medicine, and obstetrics and gynecology) to provide a brief overview of the study and request that they identify providers in their respective departments who might be interested in participating. Leadership from these departments then either circulated (via email or face-to-face communication) the opportunity to individual providers or sent the study team names and contact information of prospective participants, whom the study team then contacted directly. The study team additionally extended several direct invitations to specific individuals within psychiatry and emergency medicine with known interest in suicide prevention or expertise in treating suicidal patients. Of the 60 total providers whom the study team contacted, 56 (93%) agreed to participate (via *implied consent* because a waiver of documentation of informed consent was obtained); of these 56 who agreed, 71% (40/56) ultimately attended a 2-hour focus group. A total of 3 focus groups comprised only primary care providers, whereas the other 7 groups included either psychiatry providers alone or psychiatry, emergency, and obstetrics and gynecology providers. Participants were paid US $250 per hour for the focus groups.

Ethics Approval

All procedures were approved under MGH Institutional Review Board 2019P001774.

Procedure

Overview

New participants were recruited until no new relevant knowledge was being obtained from the discussions (ie, data saturation achieved) for a total of 10 two-hour focus groups. All 10 groups were conducted from January through March 2020. A total of 7 groups were conducted in person (before the COVID-19 pandemic) and 3 via videoconference (during the COVID-19 pandemic; late March 2020).

Baseline Questionnaire

Upon arrival, participants were asked to complete a self-report questionnaire in REDCap (Research Electronic Data Capture) [34], a secure, web-based, electronic data capture tool. This questionnaire consisted of 30 items spanning four categories: demographic characteristics, clinical experience, EHR use (eg, number of automated EHR alerts per week), and current suicide risk assessment practices.

Focus Group Discussion

Each focus group ran for 2 hours and was led by 2 to 3 doctoral-level facilitators (KHB, KLZ, and RGF). The study coordinator (EMM) also was present for 8 of the 10 groups, and for 2 groups, 1 or 2 members of the senior author's (JWS) team observed the discussion. All focus group components after the

baseline questionnaire were audio recorded. After the baseline questionnaire, a facilitator met 1:1 with each participant for approximately 10 minutes to review their typical workflow in the EHR, with the goal of gathering information to inform the potential incorporation of a CDS system for identifying and managing suicide risk into workflows.

Next, the majority (approximately 1 hour) of each focus group was spent in an open-ended discussion assessing providers' current suicide risk assessment and intervention practices and perspectives and attitudes toward incorporating machine learning models for suicide risk prediction (and corresponding CDS tools) in clinical practice, as well as key barriers and facilitators. For this and all group discussions, facilitators used an interview guide (Multimedia Appendix 1) that was developed and refined over several months by the study team and underwent pilot testing in an initial *mock* focus group with volunteers (ie, colleagues not directly involved with the research) identified by the study team.

Finally, to elicit more specific recommendations about a potential CDS system for identifying and responding to suicide risk, providers were asked to give feedback on an initial prototype of a CDS tool that communicates statistical information (from a machine learning model using routinely collected EHR data [21,22]) about patients' suicide risk at the point of care (see the screenshot in Figure 1). Built as a webpage, the prototype consisted of a dashboard displaying demographic characteristics of a mock patient and the patient's automated *suicide risk score* (from the EHR-based model) as well as their *top risk factors* (ie, strongest predictors in the model) and absolute and relative risks of suicide attempt in the next 90 days, with links embedded to additional resources (eg, clinical suicide risk assessments). This initial prototype did not include clinical recommendations tailored to the suicide risk score. Participants were given 5 minutes to navigate the prototype on their own, after which the interview guide was used to elicit feedback in a brief (approximately 15-minute) group discussion.

Qualitative Data Analysis

Codebook Development

Audio recordings of the group discussions were first transcribed by an external service (TranscribeMe). Then, 3 doctoral-level team members (KHB, KLZ, and RGF) independently reviewed and annotated 2 randomly selected transcripts (for a total of 6 of the 10 transcripts) to inductively derive major and recurrent

themes related to key guiding interview questions (Multimedia Appendix 1). Themes were then organized into an initial draft of a codebook, and a comprehensive training manual with coding guidelines was provided to study the staff responsible for coding. Five team members (KHB, RGF, EMM, HL, and DK) then each used the draft codebook to practice coding another transcript using NVivo (version 12) [35] with the goal of identifying new codes to add or irrelevant or redundant codes to delete.

The results of this practice coding and potential new or redundant codes were reviewed, as well as coding issues troubleshooted, in a series of team meetings. Whereas some codes were removed, others were merged or renamed for clarity. The codebook was then finalized to contain 140 unique themes (each with example quotes), organized into the following eight subcategories: (1) current suicide risk assessment practices, (2) current suicide risk intervention practices, (3) attitudes about current assessment and interventions, (4) general reactions and attitudes toward using machine learning models for suicide risk prediction in clinical practice, (5) factors to consider when developing or implementing such models and corresponding CDS tools for suicide risk, (6) barriers and concerns to using such systems, (7) recommendations about system content or format, and (8) recommendations about placement of systems within the EHR.

Coding Process

Each of the 10 transcripts was then independently reviewed and coded by 2 of the 3 study coders (EMM, HL, and DK) in NVivo. All coded text was reviewed, and discrepancies were resolved in consensus meetings among the 3 coders and at least one doctoral-level team member who facilitated the focus groups. To account for the fact that some participants were more talkative than others and repeated the same theme across multiple distinct consecutive statements, the same theme was only coded once when the same speaker made the same point multiple times within a 2-minute time span. The final coded versions of each transcript, with consensus achieved on all discrepancies, were used to generate the findings (ie, recurrent, frequently coded individual themes or clusters of individual themes) presented in the *Results* section.

Results

Sample Characteristics and Questionnaire Data

The mean age of the participants was 43.1 (SD 12.1; median 40.0) years. Of the 40 participants, 15 (38%) were aged between 25 and 34 years, 7 (18%) between 35 and 44 years, 9 (23%) between 45 and 54 years, 7 (18%) between 55 and 64 years, and 2 (5.0%) between 65 and 74 years. The majority were women (27/40, 68%), with 33% (13/40) identifying as men. Participants were predominantly White (35/40, 88%), followed by Asian (2/40, 5%); of the 40 participants, 1 (3%) was Black or African American, 1 (3%) identified as belonging to >1 race, 1 (3%) preferred not to answer, and 1 (3%) was Hispanic or Latino. Of the 40 providers, 24 (60%) were from psychiatry, 10 (25%) were from internal medicine and primary care, 5 (13%) were from emergency medicine, and 1 (3%) was from obstetrics and gynecology. In addition, of the 40 participants, 28 (70%) were physicians, 10 (25%) were psychologists, 1 (3%) was a social worker, and 1 (3%) was a nurse practitioner. Less than one-third (11/40, 28%) identified as residents or trainees. Providers reported an average of 15.1 (SD 10.9) years of experience treating patients (median 10.5 years); 44% (17/39) of participants reported between 0 and 9.9 years treating patients, 15% (6/39) between 10 and 19.9 years, 26% (10/39) between 20 and 29.9 years, and 15% (6/39) reported ≥30 years. All physicians and psychologists reported working in outpatient settings and 63% (25/40) also in inpatient, emergency, or urgent care settings. All internal medicine and primary care physicians (PCPs) reported working in outpatient settings and just less than one-third (12/40, 30%) also in inpatient or urgent care settings. More than half (22/40, 55%) of the participants reported spending ≥33 hours per week on direct patient care.

More than two-fifths (17/40, 43%) of the participants reported using an EHR for ≥10 years. Just more than one-third (14/40, 35%) of the participants received >20 automated alerts each week, and more than half (21/40, 53%) of the participants reported receiving *too many* automated EHR alerts. It was most common for providers to report feeling *somewhat* burned out (17/40, 43%) by their clinical work, and 30% (12/40) felt *a little bit* burned out. Similarly, providers were most likely to report feeling *somewhat* (21/40, 53%) or *a little bit* (7/40, 18%) burned out by their use of the EHR. Just more than half (21/40, 53%) of the participants reported documenting a patient's risk for suicide at every visit, followed by 38% (15/40) at less than half of patient visits. The majority (27/40, 68%) of the participants reported commonly using at least one structured or semistructured tool to assess suicide risk: most often, the Patient Health Questionnaire-9 [8] or the structured suicide risk assessment tool embedded in the EHR (both endorsed by 22/40, 55% of participants), followed by the Columbia-Suicide Severity Rating Scale [7] (12/40, 30% of participants).

Themes From Group Discussion

Both the count of coded themes (across the 10 focus groups) and proportion of groups in which themes were coded are provided in Table 1. The top 5 coded themes in each category are displayed in Figure S1 (Multimedia Appendix 2). Example quotes are presented in Table S1 in Multimedia Appendix 3.

Table 1. Counts and percentages of frequently coded themes.

Theme	Times theme was coded	Groups with coded theme, n (%)
Current suicide risk assessment and intervention practices		
Other risk assessment practices (eg, review EHR[a] and obtain collateral)	56	10 (100)
Use unstructured clinical interviewing	42	10 (100)
Use structured or semistructured tools	41	9 (90)
Consult with colleague, supervisor, or external service	26	9 (90)
Refer for emergency evaluation or inpatient hospitalization	22	9 (90)
Assessing or predicting suicide risk is challenging or frustrating	17	7 (70)
Do not use structured or semistructured tools	17	7 (70)
Structured or semistructured tools are unhelpful, or clinical interviewing best	13	8 (80)
Access problem in mental health treatment	13	7 (70)
Time constraints (associated with thorough suicide risk assessment)	13	6 (60)
Risk and liability concerns for providers treating suicidal patients	12	6 (60)
Refer to on-site mental health support	12	4 (40)
Connect with patient's current psychiatry provider	11	6 (60)
Low threshold for consulting psychiatry (includes sending to ED[b] for evaluation)	10	5 (50)
Behavioral health team not accessible for consults or supports	9	3 (30)
Lack of comfort with suicide risk assessment or current practices	8	4 (40)
Value of on-site (or consulting) behavioral health presence	8	2 (20)
Structured or semistructured (or mandated) tools are helpful	5	4 (40)
Develop safety plan or other brief suicide-focused intervention	2	2 (20)
General attitudes about automated suicide risk–prediction models		
General interest or promise, or would trust once implemented	47	9 (90)
Interest in using tool at point of care or as a BPA[c]	38	10 (100)
General skepticism, sounds anxiety-provoking, or would not trust	33	9 (90)
Must outperform clinical judgment or show accuracy before clinical use	33	8 (80)
Promise in primary care	24	8 (80)
Promise for identifying high-risk patients who might otherwise be missed	15	7 (70)
Promise for population-level risk stratification (and resource allocation)	12	7 (70)
Promise in ED (or psychiatric ED)	9	7 (70)
Promise for new evaluations and certain types of patients	9	6 (60)
Little or no promise in ED (or psychiatric ED)	5	4 (40)
Barriers and concerns		
Liability	39	10 (100)
Low data quality in EHR	19	6 (60)
Alert fatigue or desensitization to suicide risk alerts	18	7 (70)
Increase in rates of patients needing emergency evaluations or inpatient beds	18	6 (60)
Increase access problem in psychiatry or contribute to overall system burden	16	5 (50)
Other harmful effects for patients (eg, stigma and provider-patient alliance)	15	8 (80)
Utility depends on interventions that would be triggered	14	5 (50)
Potential for alert to come during a visit unrelated to mental health	14	5 (50)
Time constraints (associated with using additional CDS[d] tool)	10	5 (50)

Theme	Times theme was coded	Groups with coded theme, n (%)
How to respond to risk communicated by tool outside of face-to-face visits	9	4 (40)
Facilitators and specific recommendations		
Interest in viewing patients' predictors or features contributing to risk score	49	10 (100)
Must have good user interface and user experience	37	9 (90)
Want to see changes in risk scores over time	34	9 (90)
Need for standardized workflows for responding and documentation	29	8 (80)
Information should be available to all patients' providers	18	7 (70)
Importance of provider training (including instruction if tool is mandatory)	17	6 (60)
Should be pushed to, not pulled by, provider	14	7 (70)
Want more information on how algorithm works or test characteristics	12	8 (80)
Prompt further assessment with structured or semistructured tools or specific questions	11	5 (50)
Use tool in combination with clinical judgment	11	5 (50)
Should distinguish between chronic and time-varying predictors or features	10	6 (60)
Do not recommend interventions for specific risk scores or features	9	3 (30)
Information in tool should not be available to others with EHR access	7	4 (40)
Give recommendations of interventions for specific risk scores or features	7	4 (40)
Should be pulled by, not pushed to, provider	3	2 (20)
Other factors to consider		
Patients should be able to see information in the tool	21	6 (60)
Timing of when information is given to provider	20	7 (70)
Importance of considering whether patients will see this information	18	7 (70)
Risk-prediction window	16	7 (70)
Patients should not have access to the information in the tool	14	6 (60)
Variability in interventions, thresholds, resources, or EHR use across settings	10	5 (50)

Current Suicide Risk Assessment and Interventions

All types of providers most often described using unstructured clinical interviewing (not necessarily in isolation from other assessment methods) to determine suicide risk. Although it was also very common for providers to report using structured or semistructured tools, there were also providers in most groups who stated that they do not use structured or semistructured risk assessment tools. Other common risk assessment practices included reviewing the EHR for relevant historical information, considering known suicide risk factors, obtaining information from collaterals, assessing access to lethal means, and using clinical observation (eg, mental status examination).

Regarding current interventions, providers most commonly described consulting with a colleague or supervisor. It was also common for providers to indicate referring high-risk patients for emergency evaluation or inpatient hospitalization, with a subset having a low threshold for doing so. Providers often acknowledged the access problem in mental health treatment.

For PCPs, referring patients to an on-site mental health professional for evaluation or support was often reported, as well as connecting with a patient's current mental health provider (if they have one). Notably, developing a safety plan or other brief, suicide-focused interventions with empirical support [24] was only mentioned in 20% (2/10) of the groups.

Providers expressed a variety of attitudes about their current practices for assessing and treating suicide risk. Predominantly, participants referred to assessing suicide risk or predicting whether a patient will make a suicide attempt as challenging or frustrating; notably, this was more common among providers in psychiatry and emergency medicine than in primary care. Despite how often structured or semistructured tools are used, it was more common for providers to describe these tools as unhelpful than helpful. Expressing concerns about the risk and liability associated with managing patients at risk for suicide was also fairly common. Some providers also noted the time constraints during visits that can make thoroughly assessing suicide risk difficult, and others expressed an overall lack of

comfort with suicide risk assessment and intervention practices. PCPs emphasized both the value of on-site mental health professionals for consultations or support *and* that they are not as available or accessible as would be ideal.

General Attitudes About Automated Suicide Risk–Prediction Models

The predominant attitude toward the use of automated suicide risk–prediction models in clinical practice was positive, with providers generally highlighting their overall interest in this approach and potential to trust model predictions once implemented in routine clinical care. However, many also emphasized the importance of demonstrating that such a tool outperforms or supplements clinical judgment and is accurate before clinical use. It was less common, but still mentioned in nearly all of the focus groups, for providers to also express varying degrees of skepticism, such as that they would either distrust such a tool or find it anxiety-provoking.

Regarding specific potential use cases, providers (especially PCPs) noted the potential promise to inform clinical decision-making and treatment planning at the point of care (eg, as a best practice advisory) and, to a lesser extent, for purposes of population-level risk stratification and resource allocation. The latter was indicated more often by providers in psychiatry and emergency medicine. Providers were especially interested in the potential for the tool to identify high-risk patients who could be missed via traditional assessments. Providers often noted that the value of suicide risk–prediction models would vary by treatment setting, with primary care as the most optimal, followed by the ED. Less commonly, others explicitly emphasized that such a tool would not be useful in the ED. It was also noted in a few groups that such a tool may have more value during new evaluations than during follow-up visits and with certain types of patients.

Barriers and Concerns

The single most common barrier to the potential use of automated suicide risk–prediction models in routine care was the implication for liability. For example, many were concerned about being held legally responsible if they decided not to hospitalize a patient who was categorized as high risk and then went on to attempt or die by suicide. It was also fairly common to express concerns about low data quality in the EHR affecting the quality of model output (ie, *garbage in, garbage out*). Another frequent concern was the potential for alerts generated by automated suicide risk–prediction models to increase alert fatigue and, specific to this application, that providers may become desensitized to suicide risk alerts over time.

Providers were also concerned about the potential for such a tool to lead to increased rates of hospitalizing patients in health care systems already facing ED overcrowding and shortages of inpatient beds. The possibility for such a tool to further increase the (currently unmet) demand for outpatient mental health services was often raised, and participants noted that the system must offer additional resources if this tool were implemented. Indeed, some providers emphasized that the usefulness of the tool would depend on what *next steps* (eg, interventions or referrals) are available. Whether there might be other associated

harmful effects for patients (eg, stigma) was a concern frequently voiced by psychiatry and ED providers. It was especially common for PCPs (less so other providers) to question the benefits (and actionability) of learning that a patient is at high risk for suicide during an encounter unrelated to mental health (eg, ED visit for a medical reason). Other less frequently noted barriers included time constraints and issues associated with responding to suicide risk alerts if received outside of visits.

Facilitators and Specific Recommendations

Providers strongly believed that such a tool must have a good user interface and user experience to be helpful. Providers also overwhelmingly described an interest in being able to view the specific predictors (eg, diagnoses, demographic characteristics, and treatment attendance) that contribute to an individual patient being identified as high risk for suicide via the model, with some who encouraged distinguishing between chronic and time-varying predictors (or *risk factors*) within the tool. Providers were also extremely interested in being able to view *changes* in patients' suicide risk scores over time. The need to establish clear, standardized workflows for both responding to suicide risk predictions generated by the tool and documenting interactions with the tool was also a common theme. Similarly, providers emphasized the importance of receiving systematic training on how to use the tool before it is rolled out clinically, including instruction on whether or not its use is mandatory.

It was more common for providers to state that information about suicide risk generated by the tool should be available to all treaters (across disciplines and departments) for a given patient and less common to indicate that model predictions should not be viewed by certain types of providers (eg, physical therapists and cardiologists) and other medical or administrative staff (eg, medical assistants and receptionists). It was generally preferred that suicide risk scores (or alerts) be *pushed to*, rather than *pulled by*, the provider. Some requested having information available within the tool on how the algorithm works and key test characteristics (eg, sensitivity and specificity). It was fairly common for providers to suggest that the tool offer specific follow-up questions to ask, or standardized scales to use, for additional (clinical) suicide risk assessment. However, it was slightly more common to express the view that the tool should not recommend specific interventions based on risk score or primary predictors as opposed to the view that the tool *should* recommend specific interventions. Non-PCPs (eg, psychiatry or ED) often emphasized that the tool be used in combination with (not as a substitute for) clinical judgment.

Other Factors to Consider

Other factors that participants recommended be considered included the timing of when statistical information about suicide risk is delivered or made available to providers (eg, before, at the start of, or during visits, particularly given the possibility of no-shows) as well as the temporal window used for model predictions (eg, risk over the next week, month, or year). Providers generally believed it would be vital to decide early on whether patients will have access to their suicide risk scores, as this could have implications for what information is included in the tool and wording of the text. It was more common for providers to express the view that patients should (vs should

not) have access to model predictions. Providers also noted that there is wide variability across treatment settings in interventions available, conventions of EHR use, and relevant risk thresholds (eg, to warrant categorizing a patient as *high risk* for suicide) and that taking this into account would be important to consider when developing a tool intended for use across the health care system.

Discussion

Principal Findings

Interest in machine learning models for suicide risk prediction has proliferated in recent years. The potential to use such models and corresponding CDS systems in routine care is compelling; however, before incorporation into practice, it is critical to partner with key stakeholders who can offer the perspectives and feedback necessary for successful clinical implementation. This focus group study with hospital-based providers revealed several key areas of findings that have direct implications for ongoing and future development and deployment efforts.

First, providers were not satisfied with currently available suicide risk assessment methods. For example, despite the fact that most providers endorsed using structured or semistructured measures of suicide risk, existing tools were more often described as not particularly helpful rather than helpful. However, it is important to consider that this finding in the context of providers also tended to report feeling burned out by their clinical work, posing the possibility that negative attitudes toward current assessments are driven in part by burnout about their job in general (rather than only a specific dislike for current tools). Although unstructured clinical interviewing was generally viewed as the best available method for determining suicide risk, recent research suggests that providers tend to be quite poor at predicting the risk of suicidal behavior [17]. Indeed, many providers referred to how challenging and frustrating it can be to determine a patient's risk for suicide. Taken together, these findings underscore the clear opportunity to improve upon existing, traditional methods of suicide risk assessment.

Encouragingly, reactions to incorporating machine learning models for suicide risk prediction in clinical practice were positive overall. These approaches appeared especially promising to providers if used to identify and notify providers about patients at the high end of the suicide risk distribution either at the point of care (eg, to inform clinical decision-making) or for purposes of population-level resource allocation, meaning that those identified as higher-risk would be prioritized to receive suicide-specific interventions or more costly or difficult-to-access treatment and follow-up. Our recent work suggests that suicide risk–prediction models may have especially good accuracy when identifying patients at both the very high *and* very low ends of the risk distribution [36]. Given this, it may be worthwhile to frame and leverage these models such that they are also clinically useful for providers seeing patients who are very *unlikely* to go on to make a suicide attempt (and thus may not require further intervention).

Some providers also expressed skepticism, a lack of trust, or anxiety about the potential use of automated suicide risk

assessment models in clinical practice, with liability as the single most discussed concern about using these methods in practice. These findings suggest the importance of partnering with individuals and organizations who specialize in medical risk management, as well as with other relevant legal and payer stakeholders, as these tools are brought closer to clinical use. Overarching concerns about liability may be somewhat mitigated by emphasizing both the importance of using model predictions in conjunction with clinical judgment and that high-risk scores should be interpreted in the context of all other available information to make treatment or discharge decisions. Broadly, developing standards of care accompanied by systematic psychoeducation, training, and protocols to accompany such CDS tools for the providers who will ultimately use them may be critical to address concerns about liability and foster buy-in and promote confidence in their use.

Another concern was that alerts from such a CDS tool that incorporates suicide risk–prediction models would be disruptive to providers' workflows and result in alert fatigue. To maximize the clinical utility and cost-effectiveness of machine learning–based suicide risk models, empirically derived risk thresholds that balance the relative value of avoiding false-negative and false-positive errors [25,27] must be established. Indeed, recent work in the Kaiser Permanente health care system suggests that the degree to which suicide risk models add to clinical workloads depends heavily on the risk threshold selected, along with the approach for responding to these alerts [27]. Such thresholds may also vary by setting; for example, in psychiatry, a higher threshold may be preferred to reduce the number of false positives.

An overarching concern was that EHR-based suicide risk models and corresponding CDS tools would result in an increased burden on already overburdened health care systems. This could happen via either increased rates of sending patients to the ED for further evaluation or inpatient hospitalizations (possibly in part driven by provider anxiety and liability concerns) or more demand for outpatient specialty services. This is consistent with the fact that providers noted already having a low threshold to section patients and problems accessing mental health treatment. Moreover, as some providers stated that the tool's usefulness would depend on what interventions are available to them, health systems may benefit from determining the approximate number of *newly identified* (via the model) patients who will require interventions or referrals (eg, through simulation studies) and whether current resources can handle potential increases in demand. Developing new resources (eg, urgent care clinics and suicide-focused treatment options) or partnering with organizations outside the hospital system (eg, crisis services and referral programs) may be needed before clinical implementation.

In addition to practical concerns, providers also overwhelmingly voiced interest in viewing the individual predictors or risk factors that contribute to a patient's elevated risk score. Providers suggested that this information may also guide next steps for intervention. This suggestion is in line with recent research [30] showing that providers may be less likely to use the information from suicide risk–prediction models if the relevant clinical features are hidden *or* they do not view the

provided features as intuitively connected to suicide risk. Thus, there appear to be both pros and cons for sharing information on the specific features in these models. Displaying these features could also lead to misinterpretations about causality (eg, the assumption that if a provider targets a certain feature, suicide risk will decrease), which would not accurately reflect the complex, interactive nature of features in machine learning models.

Providers also raised various complicated yet important-to-consider issues such as the timing of when risk alerts would be delivered to providers (and corresponding concerns about, eg, receiving a *high-risk alert* outside of a visit or when a patient does not attend a scheduled appointment) and risk-prediction windows. Although there is great interest in improving short-term suicide risk prediction (eg, over hours, days, or weeks) [37], the degree to which EHR-based models accurately predict short-term risk and are sensitive to change may be limited. In the future, in addition to the clinical questionnaire data that some models incorporate [38], combining EHR-based data with fine-grained *real-time* data (eg, from smartphones or wearable devices [39]) that may capture more acute increases in risk may help meet this need. In the meantime, balancing clinical utility with the accuracy of different risk-prediction windows is critical.

Providers had mixed views on who should have access to the results from automated suicide risk–prediction models. Some felt it was important for all treaters of a given patient to access these results, whereas others thought there may be certain providers for whom such information would be irrelevant or unnecessary and who, for example, may lack training and experience with approaching the issue of suicide sensitively. Providers were also mixed as to whether patients should be able to receive this information. Given the increasing momentum of the OpenNotes movement [40], including within the mental health domain [41], it seems likely that over the long term, we can expect more EHR information to be available to service users. Thus, partnering with patient stakeholders [31] to develop protocols for transparent, sensitive communications about suicide risk, including key contextual information (eg, how to interpret being in a *high-risk* category) and language, may also be strategic.

Limitations

There are several notable limitations of this study. First, our findings reflect only the views of providers from a single academic medical center in the Northeastern United States and may not generalize outside of this clinical context. Second, the vast majority of participants were White, and thus, the findings of this study may not generalize to providers who identify as minorities. Third, convenience sampling was used for recruitment, which may also limit generalizability; for instance,

it is possible that participants were more enthusiastic about suicide risk–prediction models because some were selected for their known interest or expertise in suicide prevention. Fourth, we did not systematically assess providers' prior experience with suicide risk–prediction models, which may influence attitudes toward these tools. We were also unable to systematically disaggregate theme frequency by provider type or clinical setting, which may obscure important differences in perspectives on using suicide risk–prediction models in practice.

Future Directions

There are a few key priorities for future investigation. First, as the development of CDS tools for suicide risk prediction is ongoing, qualitative data must be collected both on more fully developed prototypes and during or after initial clinical implementation of such tools. Our emphasis in this study's series of focus groups was on general attitudes and perspectives toward such approaches, whereas future work will focus on tool development, refinement, and implementation. Second, given the potential scalability of suicide risk–prediction models, future work must include the full range of providers working in a broader range of urban and more rural hospitals nationwide, as well as community health centers and other nontraditional health care settings (both psychiatric and other medical settings, particularly given the enthusiasm from providers here about potential use in primary care). Relatedly, as noted earlier, patient stakeholders must be included in the process of developing and implementing these new tools. More work is also needed to determine how health care systems and individual providers may best leverage and combine information from machine learning models and traditional clinical assessments [18,36]. Finally, given recent work suggesting the potential for suicide risk–prediction models to exacerbate existing racial or ethnic disparities [42], upcoming work should explicitly probe providers' (and other stakeholders') perspectives on how to address this critical issue before clinical implementation.

Conclusions

Deploying virtually any new tool in practice has challenges, but given the complex, sensitive, and unfortunately still stigmatized nature of suicide, it is especially vital that researchers working in this area involve the full range of stakeholders in each stage of the implementation process. Overall, providers in the current qualitative study were dissatisfied with current suicide risk assessment methods and were open to the use of a machine learning–based suicide risk identification and management system to inform their clinical decision-making. This work highlights several key potential barriers and facilitators to be addressed in ongoing and future efforts to develop and implement such models and corresponding CDS tools in routine care and thus potentially better prevent patient suicides within health care systems.

Abstract

Background: A healthy diet throughout the life course improves health and reduces the risk of disease. There is a need for new knowledge of the relation between diet and health, but existing methods to collect information on food and nutrient intake have their limitations. Evaluations of new tools to assess dietary intake are needed, especially in old people, where the introduction of new technology might impose challenges.

Objective: We aimed to examine the usability of a new web-based dietary assessment tool in older adult women and men.

Methods: A total of 60 women and men (participation 83%, 57% women) aged 60-74 years recruited by convenience and snowball sampling completed a 24-hour web-based dietary recall using the newly developed Norwegian version of Measure Your Food On One Day (myfood24). Total energy and nutrient intakes were calculated in myfood24, primarily on the basis of the Norwegian Food Composition Table. No guidance or support was provided to complete the recall. Usability was assessed using the system usability scale (SUS), where an SUS score of ≥68 was considered satisfactory. We examined the responses to single SUS items and the mean (SD) SUS score in groups stratified by sex, age, educational level, and device used to complete the recall (smartphone, tablet device, or computer).

Results: The mean total energy intake was 5815 (SD 3093) kJ. A total of 14% of participants had an energy intake of <2100 kJ (ie, 500 kilocalories) and none had an intake of >16,800 kJ (ie, 4000 kilocalories). Mean energy proportions from carbohydrates, fat, protein, alcohol, and fiber was within the national recommendations. The mean SUS score was 55.5 (SD 18.6), and 27% of participants had SUS scores above the satisfactory product cut-off. Higher SUS scores were associated with younger age and lower education, but not with the type of device used.

Conclusions: We found the overall usability of a new web-based dietary assessment tool to be less than satisfactory in accordance with standard usability criteria in a sample of 60-74–year-old Norwegians. The observed total energy intakes suggest that several of the participants underreported their intake during the completion of the dietary recall. Implementing web-based dietary assessment tools in older adults is feasible, but guidance and support might be needed to ensure valid completion.

Introduction

A healthy diet throughout the life course improves health and reduces the risk of disease [1]. The World Health Organization's Thirteenth General Programme of Work (GPW13) [2] emphasizes the encouragement of healthier life choices and behaviors including improvements in diet. The Norwegian National Action Plan for a Healthier Diet involves multiple objectives [3] in line with the United Nations (UN) Decade of Action on Nutrition 2016-2025 [4]. A key point is the need for research to enhance knowledge of the relation between diet and health [3].

Life expectancy is increasing, and the world's population is ageing [5]. Therefore, middle-aged and older adults are important target groups for monitoring food and nutrient intake as well as for dietary interventions to ensure healthy ageing. Information on food and nutrient intake can be collected from a variety of sources, including objective methods such as direct observation or analysis of biomarkers, and self-report methods, such as food frequency questionnaires (FFQs), 24-hour recalls, or food records. All methods have methodological limitations [6-8], including high costs and participant burden, and none are essentially optimal to accurately capture all elements of diet. Objective measurements, such as biomarkers, are not influenced by the participant's personal beliefs or perceptions. However, biomarkers do not cover all components of the diet and are affected by absorption and metabolism; hence, they are not always suitable or feasible and are dependent on the study context [7]. Self-report tools, such as FFQs assessing habitual intake, food records, or dietary recalls are noninvasive and usually feasible to use in a variety of research settings. However, self-reported measures are prone to large measurement errors occurring from the knowledge and beliefs of the study participants and rely on long- or short-term memory [7]. The 24-hour dietary recall is considered one of the most accurate self-report tools, as it collects information about diet within a short recent period; however, repeated measurements are required to capture the usual diet. New technology provides increased convenience for using the 24-hour dietary recall [6] and improves their usage in large-scale studies.

Measure Your Food On One Day (myfood24) is a self-administered web-based dietary data collection tool and analysis software developed [9] and validated [10] at the University of Leeds, the United Kingdom. The tool can be set up as a 24-hour dietary record or recall, for one or multiple days of prospective or retrospective recording. The myfood24 software can be used not only as a research instrument but also for teaching or clinical use. Region-adapted versions of myfood24 already exist for use in Australia, the Caribbean, Denmark, France, Germany, the Middle East, and Peru. The use of the same tool enables between-country comparisons. A Norwegian version of myfood24 [11] was developed and finalized in 2020 with further updates in 2021. The adaption from the original UK version consisted mainly of adapting the food database and images in the data bank to the Norwegian food cuisine, and the portion size images used in the Norwegian version has shown favorable properties in young adults [11].

The UK version of myfood24 has demonstrated reasonable response proportions for repeated 24-hour dietary recalls in 60-85–year-old individuals in the United Kingdom [12], and the German version has shown satisfactory usability in adults aged ≥65 years who were provided instructions and assistance during a study visit [13]. The usability of the Norwegian version has yet to be examined. There is an overall need for studies on the usability of web-based dietary data collection tools in the older adult population, as such data are scarce. It is of particular interest to examine the properties of the newly developed Norwegian version of myfood24, as this has not been examined before. Therefore, we aimed to examine the usability of a web-based 24-hour dietary recall tool, the Norwegian version of myfood24, in a sample of Norwegian older adult women and men who have been provided no prior tutoring or instructions.

Methods

Study Design and Participant Recruitment

We recruited participants by combining targeted convenience and snowball sampling to ensure an even distribution of sex, age (between 60-74 years), and educational level (elementary school, high school, or other, or higher or university education). Only individuals with an email address and access to a smartphone, tablet device, or computer were invited. We approached individuals accessible to the researchers through their personal networks (convenience sampling), and further invited individuals approached by already recruited individuals (snowball sampling). A total of 72 (convenience sample size) women and men aged 60-74 years (58% women) were invited to complete a single dietary recall. Invitations were sent in 3 rounds between May 12 and June 8, 2021, of which the first 2 groups received 1 reminder after 2 weeks (reminders were sent to all, as participation was anonymous).

Instruments

myfood24 24-Hour Dietary Recall

myfood24 [9,10] dietary recall can be completed on the internet using a smartphone, tablet device, or computer. The participants were asked to report the intake of food during the previous day (24 hours), a so-called 24-hour dietary recall. The myfood24 is partially based on a multiple pass method, including an optional first quick list, a foods search in addition to prompts both for forgotten foods (for commonly forgotten foods and those often combined with other foods) and a final review before submission of the recall [9]. Participants can search for and add food items from a detailed list of foods primarily based on the Norwegian Food Composition Table 2019 [14] and chose portion sizes from pictures, natural measures (eg, number of potatoes), or household measures (eg, number of spoons of sugar added), as well as in an open-text response option. The portion sizes are a combination of pictures from the original UK version and the newly developed Norwegian version [11]. Based on the reported food intake, the total energy, macronutrient, micronutrient, and food intake were calculated in myfood24 (except for information from the open-text response).

System Usability Scale

The System Usability Scale (SUS) is a postsession questionnaire [15] and one of the most commonly used usability scales to evaluate a variety of products and services including hardware, software, mobile devices, and websites. The user (study participant in this case) is asked to evaluate the system (myfood24 in this case) after a user test (completing the myfood24 web-based dietary recall in this case). The SUS has 10 items answered with a 5-point Likert scale from "Strongly disagree" to "Strongly agree," with alteration between positive and negative items to prevent response biases [16]. The 10 SUS items were as follows: (1) "I would like to use myfood24 again," (2) "I found myfood24 was unnecessarily complicated," (3) "I thought myfood24 was easy to use," (4) "I needed the support of a technical person to use myfood24," (5) "I found the various functions in myfood24 were well integrated," (6) "I thought there was too much inconsistency in myfood24," (7) "I imagine most people would be able to use myfood24 very quickly," (8) "I found myfood24 very cumbersome (awkward) to use," (9) "I felt very confident using myfood24," and (10) "I needed to learn a lot of things before I could get going with myfood24."

Data Collection

The invitees were sent an email with a weblink to myfood24 and an SMS text message to their mobile phone with information that the email had been sent. The email included a brief description of the aim of the study (ie, to study the usability of a web-based dietary data collection tool) and a common (ie, not individual) weblink to complete the 24-hour dietary recall and a questionnaire about usability and demographics. No detailed guidance about how to complete the myfood24 was provided; that is, no preparation or tutoring.

By clicking the weblink in the email, the participant was directed to myfood24 and asked to report all food and drink intake from the previous day. After completion of the 24-hour dietary recall (ie, by clicking "submit" in myfood24), the participant was automatically redirected to a separate external web-based questionnaire created using Nettskjema [17], a web-based questionnaire tool resource developed by the University of Oslo, Norway. The Nettskjema questionnaire included the 10 SUS items, 3 related to demographic characteristics—sex, age group (60-64, 65-69, or 70-74 years), and education level ("What is your highest level of education?" with response alternatives of "elementary school/high school/other" or "higher education/university")—along with 1 question about the device used to complete myfood24 ("smart phone," "iPad/tablet," or "PC/computer/Mac") and an open-ended question ("Do you have other comments?") where the participant could add supplemental information (as free text). Demographic data from Nettskjema could not be linked to the information about dietary intake from myfood24.

Ethics Approval and Consent to Participate

According to the Norwegian Health Research Act [18], analysis of anonymous data does not require ethical approval; therefore, this study is not evaluated by the Regional Committees for Medical and Health Research. In this study, true anonymity was ascertained through the following procedures: (1) the weblink

to the questionnaires (sent to the participants' personal emails) was a nonpersonal URL (ie, all participants received the same weblink with no possibility to identify individuals), (2) the demographic data collected were aggregated (ie, group-level data for age and education), and (3) demographic variables from Nettskjema could not be linked to the information about dietary intake from myfood24. The email to all participants included information about the study. Completion of the questionnaire was regarded as consent.

Data Analysis

The SUS score was calculated in accordance with Sauro 2011 [16]. The scoring is 0-4 for each item, where for odd items (positive) 1 is subtracted from the user response, and for even-numbered items (negative) 5 is subtracted from the user response, added up and multiplied by 2.5 (to convert the score to 0-100), with a score of 68 points or higher considered a "satisfactory product" [16]. We examined the mean (SD) SUS score and median (IQR) values as means as well as proportions within the satisfactory product cut-off limit in groups stratified by sex, age (60-69 and 70-74 years), and education. We used Stata (StataCorp LLC) to calculate study sample characteristics, including energy intakes, as well as total energy intake in kJ, including proportions with energy intakes outside standard cut-offs of <2100, >16,800 [19], and >8000 kJ (ie, 500, 4000, and 1900 kilocalories, respectively), mean and energy percentages (E%) for macronutrients, and mean SUS scores with 2-sample t test for differences between age groups (normal distribution observed with histograms). We used Excel (2016; Microsoft Corp) to present the response to each usability item as frequencies. Participants' free-text comments were grouped into themes.

Results

A total of 60 women and men participated (participation 83%, 57% women). Study sample characteristics and energy intakes are shown in Table 1. Half of the participants were in the oldest age group. Two-thirds reported having higher education, equally distributed by age. To complete myfood24, 41% (n=24) used a smartphone, 18% (n=11) used a tablet device, and 41% (n=24) used a computer. Two participants had not recorded any foods or beverages in myfood24. When excluding these, the mean and median total energy intake calculated from myfood24 were 5815 (SD 3093) kJ and 5896 (IQR 3815-7089) kJ, respectively, for the overall study sample. In total, 14% (n=8) had an energy intake of <2100 kJ, 17% (n=10) had an energy intake of >8000 kJ, and none had an energy intake of >16,800 kJ. The E% for all macronutrients were within the range of the national recommendations. In total, 10 participants recorded food items in the open-text option (eg, "home-made bun with spread for lunch" and "cloudberries with cream for dessert").

The response to each SUS item is presented in Figure 1, where the positive items (the 5 odd-numbered questions) and the negative items (the 5 even-numbered questions) have been grouped to enhance readability. The positive items were highly correlated, with responses 25%-28% above the middle category (agree or strongly agree), except for the item "I felt very confident using myfood24," where 40% (n=24) responded above

the middle category (agree or strongly agree). Two negative statements that stood out were "I needed support of a technical person to use myfood24®" where 72% (n=43) responded with "strongly disagree" and in total 85% (n=51) responded below the middle response category (disagree or strongly disagree), and "I needed to learn a lot of things before I could get going with myfood24®" where 68% (n=41) responded below the middle category (disagree or strongly disagree).

A total of 16 participants (27%) had SUS scores of ≥68 (ie, within the satisfactory product cut-off). Table 2 presents mean

SUS scores in women and men, low and high educational groups, and smartphone, tablet device, and computer users by age group. The mean and median overall SUS scores were 55.5 (SD 18.6) and 55.0 (IQR 41.3-70.0), respectively, with higher scores in the younger age group (*P*=.02). For each group stratified by sex, education, and device used, there was a tendency toward higher SUS scores in the younger compared to the older age group, but only significantly different among those with higher education.

Table 1. Participant characteristics and energy intakes for the overall sample (N=60) and by age group.

Characteristics	Total	Age group 60-69 years (n=30)	Age group 70-74 years (n=30)
Women, n (%)	34 (56.7)	19 (63.3)	15 (50.0)
Higher education, n (%)	44 (73.3)	21 (70.0)	23 (76.7)
Device, n (%)			
Smartphone	24 (40.7)	13 (43.3)	11 (37.9)
Tablet device	11 (18.6)	4 (13.3)	7 (24.1)
Computer	24 (40.7)	13 (43.3)	11 (37.9)
Total energy intake[a] (kJ), mean (SD)	5815 (3093)	—[b]	—
Carbohydrates (energy percentage), mean (SD)	41.7 (11.1)	—	—
Protein (energy percentage), mean (SD)	19.9 (6.0)	—	—
Fat (energy percentage), mean (SD)	32.9 (11.6)	—	—
Alcohol (energy percentage), mean (SD)	2.7 (5.9)	—	—
Fiber (energy percentage), mean (SD)	2.7 (1.3)	—	—

[a]Energy and nutrient intakes were only calculated for participants with a total energy intake of >0 kJ (n=58). One participant did not report the device used.

[b]—: not available.

Figure 1. Distribution (frequency) of the response to each System Usability Scale item after completion of myfood24.
Table 2. Mean usability score[a] for the overall sample (N=60) and by age group.

Categories	Total, mean (SD)	Age group 60-69 years (n=30), mean (SD)	Age group 70-74 years (n=30), mean (SD)	P value[b]
Total	55.5 (18.6)	61.3 (17.6)	49.8 (18.0)	.02
Women	56.3 (20.5)	61.6 (18.4)	49.5 (21.7)	.09
Men	54.5 (16.0)	60.7 (17.0)	50.0 (14.1)	.09
Lower education	62.0 (14.4)	65.6 (15.0)	57.5 (13.2)	.28
Higher education	53.1 (19.5)	59.4 (18.6)	47.4 (18.9)	.04
Smartphone	52.5 (20.1)	61.9 (14.8)	55.5 (10.8)	.24
Tablet	55.9 (25.1)	68.1 (28.1)	48.9 (22.3)	.24
Computer	59.0 (13.3)	58.5 (17.6)	45.5 (21.5)	.12

[a]A System Usability Scale score of ≥68 indicates that the usability criteria were satisfied.

[b]A 2-sample *t* test was performed to assess differences between age groups.

In total, 18 participants had left comments in the free-text option. These comments (examples in parentheses) could thematically be grouped to (1) lack of categories of meals or foods ("Found nowhere to register supper"), (2) complexity ("Unnecessary complex at the same time as not nuanced enough to catch important differences between foods"), (3) wording ("Why is the word 'generic' used?"), or (4) technical problems ("Two times nearly finished, got kicked out").

Discussion

Principal Findings

In this study of the usability of a new web-based dietary assessment tool among older adult Norwegian women and men who were provided no guidance or support, we found the overall usability to be less than satisfactory and the overall total energy intake to imply error (underreporting) in completion of the dietary recall. In total, 17% of participants had energy intakes above 8000 kJ, and 27% had usability scores within the range indicating a satisfactory product.

The E% for all macronutrients were within the recommendations from the Norwegian Health Directorate [20], but in the total sample, the calculated mean total energy intake was only 60% of the daily total energy intake of an average inactive adult. This could imply that, for most participants, a variety of foods were recorded, but some foods (or meals) were probably omitted from the recording, or the amounts reported were incorrect. A traditional 4-meal Norwegian diet consists of breakfast (typically bread with spread or cereal with milk or yogurt), lunch (typically sandwiches), dinner (typically a dish with vegetables and meat or fish), and a light supper (typically similar foods as in breakfast or lunch), while myfood24 is based on 3 main meals, and other meals are classified as snacks. Based on the qualitative feedback provided in the open-text fields, some of the participants seem to struggle with this difference. Further, a total of 16% recorded food in the open-text response (instead of finding an alternative in the foods list), and these foods were omitted from the calculation of energy intake. Including these items in the calculations would have increased the mean energy intake. Misreporting is, however, common in all self-administered tools for all age groups, and for dietary assessment tools most often in the direction of underreporting, leading to incorrectly low estimates of total energy intakes.

Our results deviate considerably from the findings from a usability study of the German version of myfood24 [13], who found a median SUS score above the good product cut-off (median 74, IQR 70-83) among older adults aged ≥65 years, as well as total energy intake within the normal range, implying that the study participants completed myfood24 correctly. A potential explanation for this difference could be that the data collection in the German study was performed during a study center visit, where the participants received instructions on how to complete myfood24 as well as on-site assistance [13]. Further, the participants completed 3-4 consecutive recalls (ie, probably resulting in the participant being acquainted with the tool), 11% had previous experience in completing 24-hour dietary recalls, and 21% had a nutritional or food science background [13], of which both are expected to increase the perception of usability. Furthermore, the German version of myfood24 contains a higher number of foods than the Norwegian version, including a large number of branded foods. This can make it easier to determine the exact food consumed, thus increasing usability. However, there is a need for balance in the number of foods listed. If the list of foods is regarded as too extensive by the user, this can decrease usability.

During the development of the original UK version of myfood24, a small sample of adults aged above 65 years was included to report expectations from myfood24 [10]. The sample's median SUS score was poor (29, IQR 63); however, this sample consisted of only 4 participants [9]. Thus, the findings could have resulted from chance events. A review of another web-based 24-hour recall tool, the Automated Self-Administered 24-hour (ASA24) Dietary Assessment Tool used in Canadian populations found that older adults encountered technical challenges and emphasized the need for tailored support [21]. However, the need for technical assistance was not limited to older adults, and although older adults had a lower technical troubleshooting capacity, they simultaneously were willing to spend more time troubleshooting than younger adults [21]. There is strong reason to believe that with increasing ownership of smartphones and tablets as well as preference to

use digital technologies in everyday life, the feasibility of using web-based dietary assessment tools will also increase in the older adult population [6].

Nonetheless, digital illiteracy is a concern for self-administered web-based assessment tools, particularly among older adults. In a feasibility study of myfood24 among 60-85–year-old individuals in the United Kingdom [12], those completing multiple recalls reported higher self-confidence with technology and had a higher technology readiness score than those who did not complete any recalls. Notably, the participants in the UK study were recruited from an ongoing cohort study of cognitively healthy older adults [12], which could introduce a risk of selection bias.

Even though the overall SUS score in our study was lower than that considered satisfactory, we do believe that myfood24 is a useful tool to measure dietary intake. The participants in our study were solely provided information about the aim of the study, with no guidance or support in completing the recall. We believe that additional tailored instruction on how to complete the recall could have improved the overall perception of usability considerably and led to less underreporting. Moreover, usability questions highlighting the need for technical support or training revealed that technical challenges did not constitute a major barrier. Thus, we believe that technical difficulty was not the main contributor to the observed SUS score. In telephone surveys by Statistics Norway, 70% of 75-79–year-old individuals reported daily use of the internet in 2021 compared to 40% in 2015 [22], implying that digital illiteracy is decreasing in Norwegian older adults. Therefore, we believe that the feasibility of using web-based assessment tools in older adults will increase substantially over the next few years. More work is needed in adapting the Norwegian version of myfood24 to older adults, such as explaining how to record supper. Based on the qualitative feedback from comments provided by the participants in this study, we also believe that adding more foods and more synonyms to the foods list would improve the user experience. Previous usability studies of self-administered

dietary assessment apps among older adults, include apps with voice-added reporting [23] or apps where health personnel can complete the reporting on behalf of the respondent [24]. For older adults with impairments, such modifications are helpful. Other apps are developed for clinical use by health personnel only. In addition to being a self-administrative tool for research or teaching purposes, myfood24 provides a separate health care solution for health personnel to set patients' personalized nutrient targets and track their progress. Thus, modification to fit the context and the need of the individual is possible when using myfood24.

Strengths and Limitations

The study was set up to be anonymous to protect participant privacy; therefore, the participants received unidentifiable weblinks. Thus, a major study limitation is that we could not link SUS scores and dietary intakes on an individual level, to examine the correlation between intake and SUS scores. Further, we collected no information regarding whether the participants were comfortable with using technology. We invited only women and men with an email address and access to a device to complete the recall, and we did not examine reasons for nonparticipation. People without email addresses or those who did not participate could be less digitally literate. Thus, lower SUS scores could be anticipated among nonparticipants. A strength of the study is testing of the tool in a mixed group of older adults (ie, both sexes, different ages, and educational levels).

Conclusions

In this population of older adult Norwegian women and men, the overall usability score for a web-based 24-hour dietary recall assessment tool, myfood24, was lower than what is considered satisfactory according to standard usability criteria. Implementing myfood24 in older adults is feasible, but additional guidance and support might be needed to ensure valid completion, and more work is needed for adapting myfood24 for use among older adult Norwegians.

Conflicts of Interest

The authors declare that they have no competing interests. ACM was the principal investigator in developing the Norwegian version of myfood24. She holds an unpaid advisory position in Dietary Assessment Ltd and receives no personal financial benefits from others using the tool.

Abstract

Background: The BETACONNECT autoinjector and myBETAapp app were designed to support patients with multiple sclerosis receiving interferon β-1b and are an ideal platform for digital observational studies. A recent pilot study in Germany demonstrated the feasibility of using the app to recruit patients, obtain informed consent, and evaluate medication-taking behavior over 6 months.

Objective: This study aims to describe medication-taking behavior for 1 year in patients with multiple sclerosis receiving interferon β-1b based on data collected from the app and to provide information on patient-reported outcomes (PROs). The optional use of the cognitive training tool PEAK (Peak, formerly Brainbow Ltd) is included to test the feasibility of gamification in this setting.

Methods: A prospective and retrospective, exploratory, digital, observational cohort study was conducted among users of the app in Germany. Invitations to participate were sent to patients' apps between February and May 2019. Participants provided electronic informed consent. Injection-related data from consenting patients' devices were collected prospectively for 1 year following the consent date and retrospectively for ≤1 year from the first day of use (if historical data were available). Participants also completed three electronic PRO instruments every 3 months: the EuroQol 5-Dimension, 5-Level questionnaire (EQ-5D-5L); the Treatment Satisfaction Questionnaire for Medication (TSQM; version II); and a questionnaire on satisfaction with treatment support (on a server accessed via an emailed hyperlink). All patients were offered optional access to the professional version of PEAK.

Results: Of 1778 registered app accounts (May 2019), 79 patients (4.44%) provided informed consent; 62 (3.49%) were eligible for inclusion in the prospective analysis, of whom, 60 (97%) also had retrospective data. The mean age of the 62 participants was 43.2 (SD 11.5) years and 41 (66%) were women. Compliance over the 1-year prospective observational period (primary end point) was high (median 98.9%, IQR 94.3%-100%) and similar among men and women. Persistence and adherence (coprimary end points) decreased from 85% (53/62) and 74% (46/62), respectively, at 6 months to 76% (47/62) and 65% (40/62), respectively, at 12 months; both were higher in men than in women. A retrospective analysis showed similar patterns. The PRO questionnaires were answered by 79% (49/62) of the participants at baseline and 50% (31/62) of them at month 12. Women had more severe problems in some EQ-5D-5L dimensions (mobility, usual activities, and pain/discomfort) and lower median convenience scores on the TSQM (version II) than men. At month 12, 84% (26/31) of the patients were satisfied or very satisfied with the app. PEAK was used by 67% (14/21) of men and 49% (20/41) of women.

Conclusions: This study showed high compliance and decreasing persistence and adherence over 1 year and demonstrated the feasibility of including remotely completed electronic PRO instruments in digital observational studies.

Introduction

Background

Digital clinical studies use technology to support recruitment and retention, data collection, and analytics [1], giving them several important advantages over conventional clinical studies. For example, slow recruitment is a common problem in clinical studies [2]. Digital studies allow rapid recruitment of patients outside of routine clinic visits (eg, by directly approaching them via their smartphones), with a corresponding reduction in study duration. In conventional clinical trials, the number of enrolled patients and number of clinic visits have been identified as key drivers of cost [3]. The inconvenience of making additional clinic visits is also a barrier to participation in clinical trials [4]. Digital studies avoid the need for clinic visits and allow enrollment of large numbers of patients at little extra cost once the digital study platform has been established.

In Germany, many patients with multiple sclerosis (MS) treated with interferon β-1b use the BETACONNECT autoinjector, which automatically records injections. An app (myBETAapp) allows patients who are being treated with interferon β-1b to document injection data manually or by automatic transfer from the autoinjector. This system is designed to support patients with MS, and it provides an ideal platform for digital observational studies. A recent pilot study in Germany demonstrated the feasibility of performing an observational study with digital recruitment, consent, and data collection performed via the app [5]. The pilot study results supported the extension of the digital observational approach to more comprehensive studies investigating clinical and patient-reported outcomes (PROs) over longer periods [5,6].

Objectives

The aim of this digital observational study is to investigate medication-taking behavior in patients with MS receiving interferon β-1b for 1 year and to provide additional information on PROs. As cognitive impairment is common in MS [7], optional use of the cognitive training tool PEAK was included to test the feasibility of gamification in this setting and to incentivize patients to remain committed to the study.

Specifically, the primary objective is to describe medication-taking behavior prospectively for 1 year in patients with MS treated with interferon β-1b based on data collected from the app.

The secondary objectives are as follows: to investigate past medication-taking behavior (since first documentation in the app) before participation in the study; to evaluate health-related quality of life (HRQoL), treatment satisfaction, and satisfaction

with treatment support prospectively for 1 year; to investigate HRQoL, treatment satisfaction, and satisfaction with treatment support at baseline in patients who were adherent or nonadherent as well as those who were persistent or nonpersistent over 1 year; to assess the relationship of HRQoL, treatment satisfaction, and satisfaction with treatment support at baseline with medication-taking behavior at 6 months and 1 year; and to evaluate how frequently and for how long the smartphone-based cognitive training tool PEAK was used.

Methods

Study Design and Patients

This was a prospective and retrospective, noninterventional, observational cohort study with the structure of a registry (ClinicalTrials.gov NCT03808142). Adult patients with MS treated with interferon β-1b, in Germany, were eligible to participate in the study if they were new or existing users of the app and provided electronic informed consent.

Study Conduct and Ethics Approval

During a 3-month enrollment period (February 20, 2019, to May 19, 2019), all patients with an active account for the app were invited to participate in the study. After 2 months, invitations were sent to all new users of the app (patients who started using the app during the enrollment period). In both cases, the invitations consisted of push messages sent to the patients' apps. Patients who did not respond to the initial invitation were sent a reminder after 2 weeks.

Patients who expressed interest in the study (by pressing a button within the app) were presented with a detailed informed consent form. The form provided study information in a sequential manner (background, aim of study, study design and data use, data privacy including how to withdraw consent, and contact information for the database hosts in case of questions), and the patients were required to confirm after each sequence that they understood the information and wished to participate. The form also clarified that prospectively recorded data and, among existing users of the app, injection-related data recorded in the past would be analyzed. It also included text to advise patients to report any side effects or possible side effects to their physicians, nurses, or Bayer, and to report any technical product complaints to Bayer. Only patients who consented to all the steps were able to participate in the study.

The study protocol was approved by the ethics committee of the Nordrhein Medical Chamber (number 2018381). In this observational study, interferon β-1b was prescribed in routine clinical practice by the treating physician in accordance with the terms of the marketing authorization, and the patient was

offered support from the BETAPLUS Patient Support and Disease Management Program (PSDMP) as normal. The prescription of interferon β-1b and provision of the BETAPLUS PSDMP were clearly separated from the decision to include the patient in the study. No additional diagnostic or monitoring process was required for enrollment or during the study. Each patient could refuse to participate further or withdraw from the study at any time and without giving a reason. After withdrawal of the patient from the study, data from that patient were not used for further analyses. Each patient was assigned a unique central patient identification code, which was used only for study purposes.

Data Collection

Demographic data (age and gender) were recorded in the app as part of the registration process. Injection-related data (date and time of injection, injection speed, and injection depth) were automatically recorded in the BETACONNECT for each injection and could be transferred to the app if the patient wished to do so. Patients could also manually record the injection data in the app. Demographic and injection-related data in the app were automatically transferred to an external database (hosted by TWT Digital Health GmbH) whenever the mobile device was connected to the web.

In addition, the patients completed three PRO instruments every 3 months from the time of informed consent to the end of observation: the EuroQol 5-Dimension, 5-Level questionnaire (EQ-5D-5L); the Treatment Satisfaction Questionnaire for Medication (TSQM; version II) [8,9]; and a questionnaire on satisfaction with the BETAPLUS PSDMP, the BETACONNECT, and the app (service questionnaire; Multimedia Appendix 1). For this purpose, each patient was provided with an individual log-in hyperlink (newly created for each data capture time point) via email to enter an electronic data capture server hosted by the contract research organization, Institut Dr. Schauerte (IDS). Hence, the participants were able to complete the questionnaires remotely. After the end of the observation period, participants received vouchers for completing each questionnaire.

Each patient was followed up for 1 year after providing informed consent (prospective analysis). For patients who had already started using the app before providing informed consent, prospectively collected injection-related data (BETACONNECT or manual records) were also available from the past. Among those patients, medication-taking behavior was also analyzed from the time of the first documented injection to 1 year later or the date of consent, whichever was earlier (retrospective analysis; Figure 1).

Figure 1. Examples of retrospective and prospective analysis periods for patients with a first documented injection at different intervals before the date of consent.
All patients were initially offered access to the professional version of the mobile-based cognitive training tool PEAK, developed and hosted by Peak (formerly Brainbow Ltd); this offer was renewed with each request to complete the PRO questionnaires (quarterly emailing of log-in hyperlinks). The patients were able to choose from all available games within PEAK, covering 7 cognitive areas, for the duration of the study. The decision to use the training tool and game selection was

purely voluntary and was not linked to treatment, study participation, or completion of the PRO instruments. All data generated by the patients while using PEAK were stored in a database hosted by Peak. The patients received study-specific log-in data, which identified them as participants of the study in the database, without personal identification.

Log-in details for the questionnaires on the IDS electronic data capture server and for PEAK were allocated to participants by

TWT Digital Health GmbH. Hence, only TWT Digital Health GmbH had the key to match data from Peak, IDS, and their own database. Data sets coded by log-in identifiers were transferred from Peak and TWT Digital Health GmbH to IDS, who merged these into their own data set. No investigator was involved in the data collection process.

Before the analysis, redundancies in the injection data were automatically corrected as described previously [5].

Outcome Measures

The primary end point was prospectively assessed compliance (the percentage of expected doses actually injected), based on injections recorded in the TWT Digital Health GmbH database from the date of informed consent to the end of the observation period.

The coprimary end points were persistence (the number of patients still using interferon β-1b at the end of the observation period), missed injections (expressed as a proportion of expected injections), and adherence (the number of patients who were both persistent and ≥80% compliant; a threshold of 80% is commonly used in studies of adherence in MS [10]). Patients without injection recordings for >2 weeks were regarded as nonpersistent.

Compliance, persistence, missed injections, and adherence were also analyzed retrospectively (from the first injection recorded in the app until 1 year later or the date of informed consent, whichever was earlier) as secondary end points among participants who had registered and used the app before enrolling in this study.

Other secondary end points included HRQoL assessed using the EQ-5D-5L, treatment satisfaction assessed using the TSQM (version II) [8,9], satisfaction with treatment support assessed using the service questionnaire (Multimedia Appendix 1), and use of the PEAK cognitive training tool. Frequency (trainings/week) and duration (days) of PEAK use by study participants and cumulative time played per game (minutes) were analyzed. For the analysis of the frequency of PEAK use and cumulative time played per game, only the 10 most frequently used games were considered.

Statistical Analysis

Statistical analyses were exploratory and descriptive, using summary statistics for categorical and quantitative (continuous) data. Associations of persistence and adherence with baseline HRQoL, treatment satisfaction, and satisfaction with support were evaluated using univariate logistic regression analysis, with $P<.05$ considered significant. All statistical analyses were performed using the software package SAS 9.4 (SAS Institute Inc).

Assuming an estimated SD of 15 for the mean compliance (as observed in the pilot study [5]), a sample size of 100 would produce a 2-sided 95% CI with a half-width of 3.0.

Results

Participants

Of the 1778 registered accounts for the app (May 2019), 79 (4.44%) patients provided informed consent to participate in the study. Of the 79 patients, 10 (13%) patients withdrew their consent, 6 (8%) patients were excluded because they were enrolled after the end of the registration period, and 1 (1%) patient had no injection or questionnaire data. Thus, 78% (62/79) of patients had injection-related data and were valid for inclusion in the prospective analysis. Of the 62 patients, 2 (3%) had no retrospective injection data and were therefore excluded from the retrospective analysis.

The mean age of the 62 participants was 43.2 (SD 11.5) years; 41 (66%) were women, and 21 (34%) were men. The distribution of age groups in women and men is presented in Table 1.

Table 1. Study participants according to age group and gender.

Age group (years)	Participants, n (%)		
	Total (N=62)	Female (n=41)	Male (n=21)
<30	9 (15)	8 (20)	1 (5)
30 to <40	15 (24)	9 (22)	6 (29)
40 to <50	19 (31)	11 (27)	8 (38)
50 to <60	13 (21)	9 (22)	4 (19)
≥60	6 (10)	4 (10)	2 (10)

Data Collected

Of the 62 patients, 14 (23%) used the BETACONNECT autoinjector to administer and record injections throughout the prospective observation period. For 19% (12/62) of the patients, only manual records of injections were available. Alternating recording methods (autoinjector or manual) were documented in 56% (35/62) of the patients. Switching from one mode of injection to the other (autoinjector to manual or vice versa) was documented in 2% (1/62) of the patients.

Use of the BETACONNECT to record injections was more common among men (8/21, 38%) than among women (6/41, 15%), whereas only manual recording of injections was more common among women (10/41, 24%) than among men (2/21, 10%). The injection location data were recorded for all 62 patients.

For the prospective analysis (N=62), 7 (11%) patients had <6 months of injection data and 55 (89%) patients had ≥6 months of injection data, with 48 of the 55 patients (87%) having ≥12

months of injection data. For the retrospective analysis (n=60), 8 (13%), 52 (87%), and 44 (73%) patients had <6, ≥6, and ≥12 months of injection data, respectively.

Of the 62 patients, 53 (85%) answered at least one questionnaire, and 34 (55%) used PEAK at least once. The EQ-5D-5L, TSQM (version II), and service questionnaire were each answered by 49 (79%) of the 62 patients at baseline and by 36 (58%), 35 (56%), 32 (52%), and 31 (50%) patients at months 3, 6, 9, and 12, respectively.

Medication-Taking Behavior

In the prospective analysis, persistence was 85% (53/62) at 6 months and decreased to 76% (47/62) at 12 months after the date of informed consent (Table 2). Persistence was higher in men than in women at both 6 months (20/21, 95% vs 33/41,

80%) and 12 months (19/21, 90% vs 28/41, 68%; Table 2). Compliance (the primary end point, based on injection data up to 6 months and up to 12 months in patients with injection data available for those time periods) was high at 6 months (mean 93.6%, SD 13.8%; median 100%, IQR 95.6%-101.1%) and at 12 months (mean 92.6%, SD 14.1%; median 98.9%, IQR 94.3%-100%), and was similar in men and women at both time points (Table 2 and Figure 2Ai). Mean and median compliance were high in all age groups (Figure 2Ai). In total, 69% (43/62) and 56% (35/62) of the patients had missed only 0% to 5% of their expected injections at 6 and 12 months, respectively (Figure 2Bi). Adherence was markedly higher in men than in women (Table 2 and Figure 2Ci). At 6 months, adherence showed no clear difference across age groups, whereas at 12 months, it was lowest in the youngest age group (Figure 2Ci).

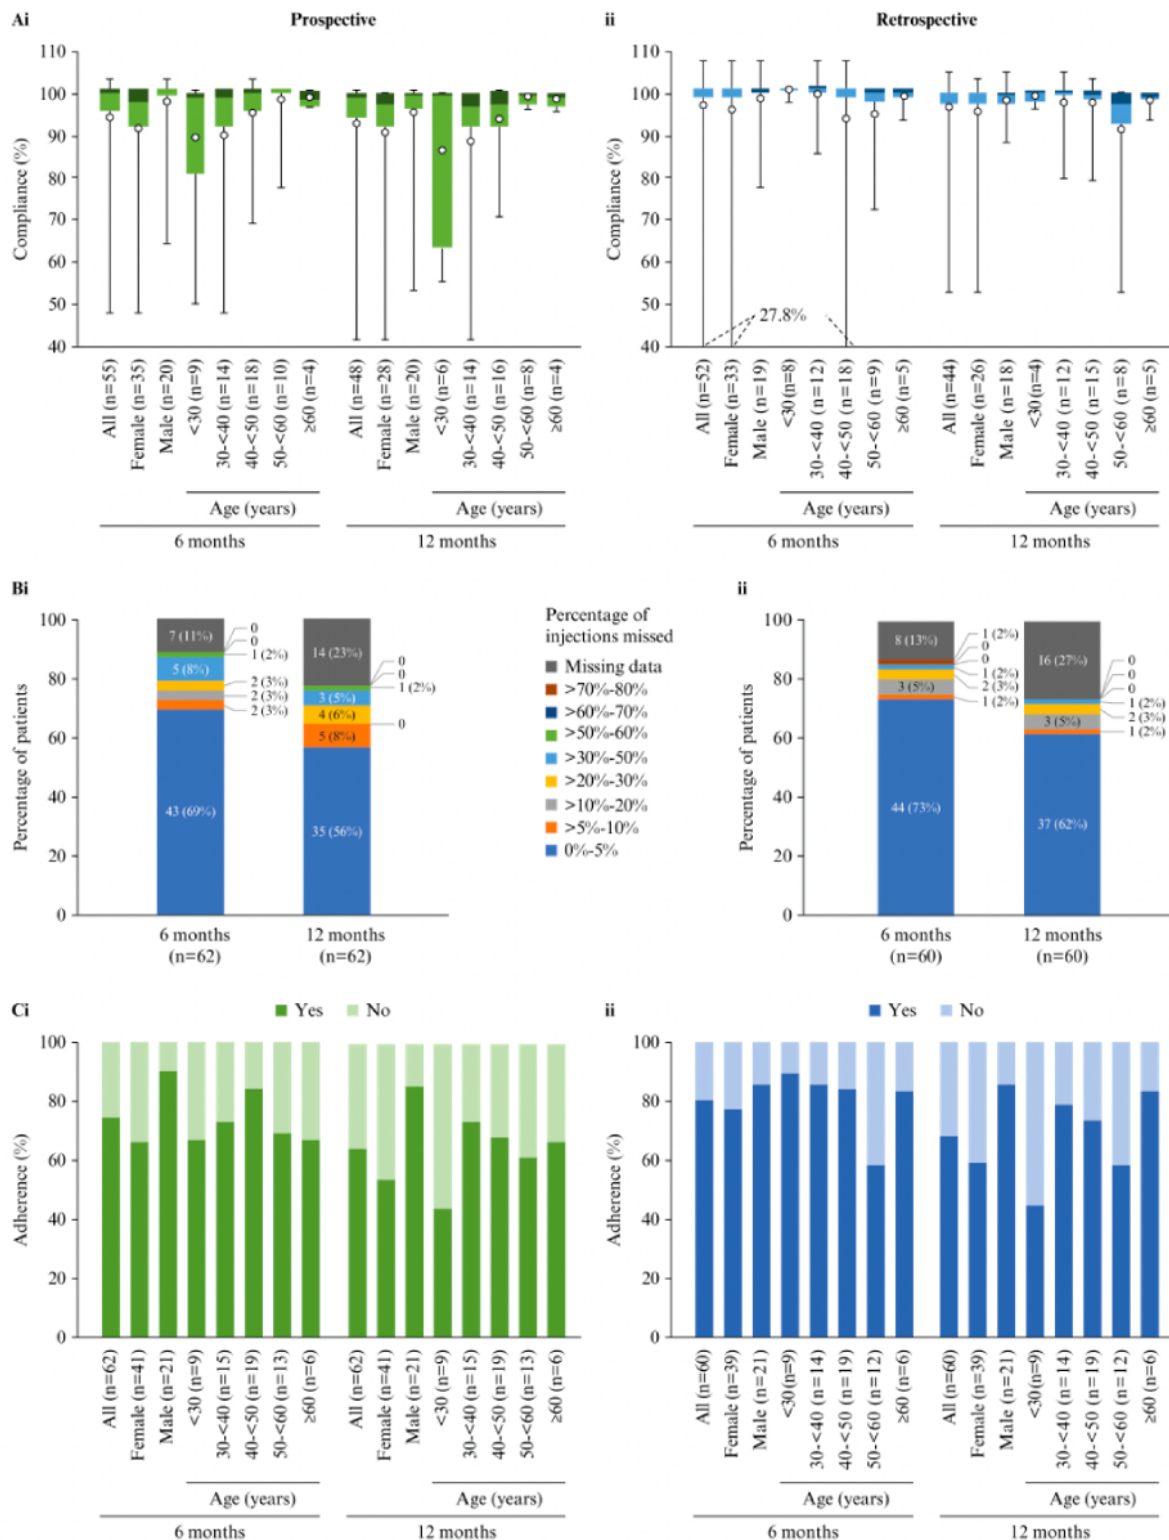
[a]On the basis of the injection data up to 6 months and up to 12 months in patients with injection data available for the periods (prospective analysis: n=55 at 6 months and n=48 at 12 months; retrospective analysis: n=52 at 6 months and n=44 at 12 months).

Figure 2. (A) Compliance overall and by gender and age group, (B) patients categorized by percentage of interferon β-1b injections missed (based on an expected frequency of 1 injection every other day), and (C) adherence overall and by gender and age group, analyzed (i) prospectively and (ii) retrospectively. Compliance at 6 and 12 months was assessed in patients with ≥6 and ≥12 months of injection-related data, respectively. In the box and whisker plots, the colored bars indicate median and IQR, the whiskers indicate minimum and maximum values, and the white circles indicate the mean.


In the retrospective analysis, persistence was 83% (50/60) at 6 months and markedly lower, 70% (42/60), at 12 months. It was higher in men than in women at 6 months (19/21, 90% vs 31/39, 79%) and 12 months (18/21, 86% vs 24/39, 62%) (Table 2). Mean and median compliance (based on injection data up to 6 months and up to 12 months in patients with injection data available for those time periods) were high in both men and women (Table 2 and Figure 2Aii) and in all age groups at both time points (Figure 2Aii). In total, 73% (44/60) and 62% (37/60) of the patients had missed only 0% to 5% of their expected injections at 6 and 12 months, respectively (Figure 2Bii). Adherence was higher in men than in women at both time points (Table 2 and Figure 2Cii). In the analysis by age group, those aged 50 to <60 years showed the lowest adherence at 6 months,

whereas those aged <30 years showed the lowest adherence at 12 months (Figure 2Cii).

HRQoL and Satisfaction With Treatment and Support

In the EQ-5D-5L analysis, women reported more severe problems with mobility, usual activities, and pain/discomfort than men (Figure 3). None of the dimensions showed a consistent difference across age groups. The median (IQR) EQ-5D-5L index was 0.9 (0.8-1.0) at baseline and 0.9 (0.9-1.0) at 6 and 12 months. The median (IQR) visual analogue scale (VAS) was 81.0 (65.0-90.0) at baseline, 82.0 (62.0-90.0) at 6 months, and 80.0 (66.0-88.0) at 12 months. The EQ-5D-5L index and VAS showed no consistent differences between men and women or across age groups.

Figure 3. Patient-reported assessment of (A) mobility, (B) self-care, (C) usual activities, (D) pain/discomfort, and (E) anxiety/depression at (i) baseline, (ii) 6 months, and (iii) 12 months in the EuroQol 5-Dimension, 5-Level questionnaire (EQ-5D-5L).
The median TSQM (version II) global satisfaction domain score remained stable during follow-up, showed no consistent difference between men and women, and was lowest in the youngest age group during follow-up (Table 3). Median domain scores for effectiveness and side effects showed no consistent differences between the age and gender subgroups. The median domain score for convenience was lower in women than in men and was lowest in the youngest age group (Table 3).

Most of the patients were satisfied or *neither satisfied nor dissatisfied* with the BETAPLUS PSDMP (Multimedia Appendix 2). Most patients were satisfied or *neither satisfied nor dissatisfied* with the BETACONNECT (Multimedia

Appendix 3) and satisfied or very satisfied with the app (Multimedia Appendix 4). In analyses stratified by gender and age groups, the sample sizes in the respective strata were very small and did not allow for any further reliable conclusions (Multimedia Appendices 2-4).

The baseline EuroQol VAS score was higher in persistent and adherent patients than in nonpersistent and nonadherent patients (Multimedia Appendix 5). Logistic regression showed a significant association of the baseline EuroQol VAS score with persistence and adherence at 12 months but not at 6 months (Multimedia Appendix 6).

[a]N/A: not applicable.

Baseline TSQM (version II) domain scores for effectiveness, side effects, convenience, and global satisfaction were higher in persistent and adherent patients than in nonpersistent and nonadherent patients (Multimedia Appendix 7). Logistic regression showed a significant association between the baseline side effects score and persistence at 12 months, between the baseline convenience score and adherence at 6 and 12 months, and between the baseline global satisfaction score and adherence at 6 and 12 months (Multimedia Appendix 6).

The proportion of patients who were satisfied or very satisfied with the PSDMP at baseline was higher in persistent patients than in nonpersistent patients, whereas it was similar in adherent and nonadherent patients (Multimedia Appendix 8). Regarding the BETACONNECT and the app, the proportion of patients who were satisfied or very satisfied at baseline was higher in persistent and adherent patients than in nonpersistent and nonadherent patients (Multimedia Appendix 8). Logistic regression analyses did not suggest significant associations of persistence and adherence with satisfaction with the PSDMP, BETACONNECT, or app (Multimedia Appendix 6).

PEAK Use

The proportion of patients using PEAK at least once was higher among men (14/21, 67%) than among women (20/41, 49%) and was lowest among those aged ≥60 years (1/6, 17% compared with 6/9, 67%; 9/15, 60%; 10/19, 53%; and 8/13, 62% among those aged <30; 30 to <40; 40 to <50; and 50 to <60 years, respectively).

In an analysis of PEAK use over 3-month intervals, the number of active days (days in which PEAK was used at least once) and the average number of games played per week varied widely between patients in each interval (Table 4).

The 10 most popular games included four games in the language category (Word Hunt, Babble Bots, Word Fresh, and Grow), two in the focus category (Must Sort and Objectifind), two in the problem-solving category (Pixel Logic and Low Pop), one in the memory category (Perilous Path), and one in the mental agility category (Turtle Traffic). Of the 10 most popular games, Pixel Logic was played for the longest cumulative time during each 3-month interval (median 37, IQR 3-107 minutes at months 1-3; median 6, IQR 0-99 minutes at months 4-6; median 11, IQR 0-55 minutes at months 7-9; and median 25, IQR 2-59 minutes at months 10-12).

Table 4. PEAK use over 3-month intervals.

Characteristics	Values (N=62)		
	n (%)	Median (IQR)	Range
Number of days active per patient[a]			
Data not assigned to any time interval	12 (19)	5 (2-37)	1-83
Months 1-3	32 (52)	23 (8-49)	1-91
Months 4-6	18 (29)	4 (1-68)	1-91
Months 7-9	14 (23)	14 (1-60)	1-81
Months 10-12	14 (23)	10 (2-27)	2-89
Number of games played per patient per week[b]			
Data not assigned to any time interval	12 (19)	0 (0-8)	0-33
Months 1-3	32 (52)	5 (1-12)	0-158
Months 4-6	18 (29)	0 (0-11)	0-218
Months 7-9	14 (23)	2 (0-10)	0-259
Months 10-12	14 (23)	4 (0-7)	0-116

[a]An active day was defined as a day on which PEAK was used at least once.

[b]Only the 10 most frequently played games (all PEAK users) were counted. A single game could be played multiple times per day.

Discussion

Principal Findings

This study builds on the results of a previous pilot study [5], performing follow-up for 1 year, and incorporating completion of PRO instruments.

The proportion of patients participating was 4.44% (79/1778) of registered accounts for the app. More than three-quarters (48/62, 77%) of the participants had ≥12 months of injection data for prospective analysis. Compliance over the 1-year prospective observational period was high (median 98.9%, IQR 94.3%-100%), with similar percentages among men and women. Persistence and adherence decreased from 85% (53/62) and 74% (46/62), respectively, at 6 months to 76% (47/62) and 65% (40/62), respectively, at 12 months, and were higher in men than in women in the prospective analysis.

The PRO questionnaires were answered by 79% (49/62) of the participants at baseline and 50% (31/62) of the participants at month 12. An immediate reward for participation rather than compensation at the end of the study may have increased the completion rate of the PRO questionnaires [11,12]. Women reported more severe problems than men in some EQ-5D-5L dimensions (mobility, usual activities, and pain/discomfort) and had lower median domain scores than men for convenience in the TSQM (version II). HRQoL showed no consistent changes across age groups. Convenience and global satisfaction (assessed using the TSQM [version II]) were lowest in the youngest age group. Persistence and adherence at 12 months were associated with baseline HRQoL (EuroQol VAS) and satisfaction with treatment (scores in specific domains of the TSQM [version II]) but not satisfaction with support.

PEAK was used at least once by 67% (14/21) of the male participants and by 49% (20/41) of the female participants. The frequency of PEAK use varied widely among patients.

Comparison With Previous Work

This study used the same digital approach as the previous pilot study [5] but recorded data over a longer period (1 year prospectively and ≤1 year retrospectively compared with 6 months in total in the pilot study) and allowed comparison of medication-taking behavior between retrospective and prospective study periods. In addition, this study recorded PROs and tested the acceptance of an optional cognitive training tool (ie, it involved active engagement by the participants), whereas the pilot study used only basic registration data and routinely recorded injection data.

The pattern of decreasing persistence and adherence with continuing high compliance over the 1-year follow-up period appeared in both the prospective and retrospective analyses. These findings confirm previous reports that an increasing number of patients stop their treatment over time [13-16], with substantial attrition occurring early in the treatment course, within 1 year [15,16]. In contrast, the high compliance at both 6 and 12 months suggests that patients remaining on treatment take their medication very reliably. The similarity in persistence, compliance, and adherence between the prospective and retrospective analyses argues against an observer effect prompting patients to act differently once they were aware that they were participating in a study (ie, after providing consent).

Persistence and adherence in the prospective observational period (53/62, 85% and 46/62, 74%, respectively, at 6 months) were lower than those reported in the pilot study (90/94, 96% and 84/94, 89%, respectively) [5]. This may be explained by patient motivation and stamina, which may be higher in a 6-month study than in a 1-year study.

Men appeared more persistent and more adherent than women in both prospective and retrospective analyses. We cannot say whether this is a valid finding or a result of confounding; for example, by men being more technophile than women. In this context, more women may have chosen to stop documenting injections in the app over time, which by definition would have resulted in their classification as nonpersistent and nonadherent thereafter.

Persistence and adherence showed little difference between men and women in the pilot study [5] and in an observational study of patients receiving interferon β-1b via the BETACONNECT autoinjector in Germany (the BETAPREDICT study) [13]. However, several large studies of patients with MS have shown greater adherence in men than in women [17-19], consistent with our current findings. A US-based administrative claims database study of 648 patients with MS showed that those who were adherent to disease-modifying therapy over a study period of ≥24 months were more likely to be men than in nonadherent patients (173/448, 38.6% vs 52/200, 26%; *P*=.002) [17]. Another US-based study used enrollment and claims data from an upper Midwest health plan between 2011 and 2013 and showed that female patients were 5.5% less likely to be adherent than male patients [18]. A third US-based claims database study of 8382 patients with MS followed for 12 months found that male patients had an increased likelihood of adherence to disease-modifying therapy (odds ratio 1.2, 95% CI 1.085-1.335; *P*<.001) [19].

We found the lowest rates of adherence and global treatment satisfaction in the youngest age group (<30 years) in the prospective analysis. In the pilot study, those aged 30 to 39 years had the lowest rate of adherence [5]. Although age thresholds vary across studies, these results are in general agreement with other studies reporting higher rates of adherence in older patients [17-19]. A US-based administrative claims database study showed that patients with MS who were adherent to disease-modifying therapy were on average older than those who were nonadherent (mean 43.5, SD 8.0 years vs mean 41.8, SD 8.1 years; *P*=.02) [17]. A US-based study using health plan data showed that patients aged >45 years were 13.7% to 18.6% more likely to be adherent than younger patients [18]. A third US-based claims database study found that age groups older than 18-34 years had an increased likelihood of adherence to disease-modifying therapy (odds ratios 1.220-1.331; *P*<.001 to *P*=.001) [19].

Women reported problems with mobility, usual activities, and pain/discomfort more frequently than men in our analysis. A previous study of 144 patients (99 women and 45 men) with MS in Germany also found that women reported problems with usual activities more frequently than men, although the

association was not significant in multivariate analysis [20]. In contrast, a large UK-based study of 4516 patients with MS (including 3198 women and 1301 men) showed that men reported problems with mobility, self-care, and usual activities more frequently than women [21]. The reasons for the inconsistency between studies are unclear but could include differences in study design and location.

There was a steep attrition of participants' use of the PEAK app after 3 months, as also seen for other apps [22]. Free access to the professional version of the brain training tool did not provide enough incentive for participants to continue using it over the entire study period. Hence, voluntary and free access to PEAK does not appear to be an effective approach to provide constant brain training over a longer period. Peer-to-peer interactions (eg, via social media challenges, multiplayer games, or guided training programs) may have a positive impact on long-term engagement with gamified apps [23-25].

Limitations

The generalizability of the results is limited by the small sample size and the possibility of selection bias. The number of patients was lower than in the pilot study [5], and it is possible that mainly technophile patients agreed to participate. We were unable to compare app users who participated in the study with those who did not, because demographic and clinical data from the latter group were not available.

Although we provided incentives (vouchers) for the completion of each questionnaire after the end of the observation period, the number of participants still decreased over the 1-year period. More immediate ways to incentivize patients directly after completing the questionnaires may be warranted to encourage continued active study participation.

Only patients using interferon β-1b were eligible to participate in this study. However, the aim of our study was to describe medication-taking behavior and collect PROs among patients treated with interferon β-1b and not to compare their behavior with that of other patient groups. In the future, open platforms that do not restrict participation to users of certain drugs will be more versatile in terms of patient pool, study design, and indication than drug-specific platforms. IDS and Bayer have codeveloped a data capture tool, the my ePRO app, which can be used for stand-alone studies or in association with randomized controlled trials and observational studies. The usability of the my ePRO app was assessed in the DePRO study [26]. The DePRO study showed that digitally authenticating eligible patients, with participants registering by scanning the 2D matrix code on the outer packaging of their prescribed medication (a standard feature of prescription medications in the European Union) is a feasible approach for a digital study (manuscript in preparation).

We were unable to perform source data verification or clarify incomplete data from individual patients because the analysis results were anonymized. We were also unable to assess whether offering access to PEAK had any influence on adherence or commitment to the study because of the lack of a control group. Other limitations are similar to those described for the pilot study [5], including the use of nonvalidated technology to obtain data on medication-taking behavior, missing data (which have not been replaced), and the inability to distinguish between patients discontinuing treatment and those simply ceasing to document their injections.

Conclusions

This study showed high compliance and decreasing persistence and adherence over 1 year and demonstrated the feasibility of including remotely completed electronic PRO instruments in digital observational studies. The feasibility and influence of gamification in this setting remain unclear.

Conflicts of Interest

VL has served as an adviser or speaker or received research grants from Antisense, Allergan, Bayer, Biogen, Genzyme, Novartis, Roche, and TEVA. CM and MS are full-time employees of Bayer Vital GmbH (Leverkusen, Germany). KB-G is an employee of the Institut Dr. Schauerte (Munich, Germany). Bayer selected the Institut Dr. Schauerte for the statistical analysis of the study.

Abstract

Background: Artificial intelligence and digital health care have substantially advanced to improve and enhance medical diagnosis and treatment during the prolonged period of the COVID-19 global pandemic. In this study, we discuss the development of prediction models for the self-diagnosis of polycystic ovary syndrome (PCOS) using machine learning techniques.

Objective: We aim to develop self-diagnostic prediction models for PCOS in potential patients and clinical providers. For potential patients, the prediction is based only on noninvasive measures such as anthropomorphic measures, symptoms, age, and other lifestyle factors so that the proposed prediction tool can be conveniently used without any laboratory or ultrasound test results. For clinical providers who can access patients' medical test results, prediction models using all predictor variables can be adopted to help health providers diagnose patients with PCOS. We compare both prediction models using various error metrics. We call the former model the patient model and the latter, the provider model throughout this paper.

Methods: In this retrospective study, a publicly available data set of 541 women's health information collected from 10 different hospitals in Kerala, India, including PCOS status, was acquired and used for analysis. We adopted the CatBoost method for classification, *K*-fold cross-validation for estimating the performance of models, and SHAP (Shapley Additive Explanations) values to explain the importance of each variable. In our subgroup study, we used *k*-means clustering and Principal Component Analysis to split the data set into 2 distinct BMI subgroups and compared the prediction results as well as the feature importance between the 2 subgroups.

Results: We achieved 81% to 82.5% prediction accuracy of PCOS status without any invasive measures in the patient models and achieved 87.5% to 90.1% prediction accuracy using both noninvasive and invasive predictor variables in the provider models. Among noninvasive measures, variables including acanthosis nigricans, acne, hirsutism, irregular menstrual cycle, length of menstrual cycle, weight gain, fast food consumption, and age were more important in the models. In medical test results, the numbers of follicles in the right and left ovaries and anti-Müllerian hormone were ranked highly in feature importance. We also reported more detailed results in a subgroup study.

Conclusions: The proposed prediction models are ultimately expected to serve as a convenient digital platform with which users can acquire pre- or self-diagnosis and counsel for the risk of PCOS, with or without obtaining medical test results. It will enable women to conveniently access the platform at home without delay before they seek further medical care. Clinical providers can also use the proposed prediction tool to help diagnose PCOS in women.

Introduction

Background

There has been substantial advancement in artificial intelligence and machine learning technologies in health care owing to the prolonged COVID-19 pandemic, resulting in improvements and enhancements in medical diagnosis and treatment that were previously impossible or unavailable [1]. Telehealth using remote technologies between medical providers and patients is another emerging trend during the pandemic, and many conditions are diagnosed and managed through telehealth, including polycystic ovary syndrome (PCOS) [2,3]. Diagnosis of PCOS with telehealth is based on a few symptoms such as irregular menstrual cycles, hirsutism, skin problems, and other symptoms caused by an imbalance of androgen hormones [3]. Through our proposed study, integrating the current trends addressed above, we provide a more systematic self-diagnostic tool that allows users to conveniently access and learn the predicted diagnosis result of PCOS without delay before they seek further medical care.

PCOS is the most common endocrine disorder among women of reproductive age, possibly causing infertility. The prevalence of PCOS ranges from 6% to 20%, depending on the population and the diagnostic criteria reported in previous studies [4-6]. Although the cause of this syndrome is not clearly known, there is increasing evidence that PCOS is a complex multigenic disorder with strong epigenetic and environmental influences [4]. According to the Centers for Disease Control and Prevention, overweight women with PCOS may develop serious health problems such as diabetes, gestational diabetes, heart disease, high blood pressure (BP), sleep apnea, and stroke. PCOS is also known to be linked to anxiety and depression [7]. It is important to note that not all women with PCOS experience the same combination or severity of symptoms, which makes early detection more challenging [8].

Although several criteria for PCOS diagnosis have been proposed, the Rotterdam criteria were accepted by the National Institutes of Health, and they have been most commonly adopted for the diagnosis of PCOS [9]. On the basis of the Rotterdam criteria, the diagnosis is made if at least two out of three of the following criteria are met: ovulatory dysfunction (oligo-ovulation or anovulation), higher levels of androgens in the blood, and polycystic ovaries appearing on ultrasound. However, the Rotterdam criteria have been controversial in many studies [9-11].

There are two types of PCOS: lean and obese, each with different biochemical, hormonal, and metabolic profiles [12]. Toosy et al [8] noted that a smaller proportion of women with lean PCOS had a normal or low BMI (≤ 25 kg/m^2) and may or may not have symptoms, which makes diagnosis more challenging. In other studies, it has been noted that PCOS is closely associated with obesity and is more prevalent among overweight or obese women than in the general population of women of reproductive age [13-15]. In our proposed study, we incorporate the ideas of lean and obese PCOS types in earlier studies and group the data set into 2 subgroups based on anthropomorphic measures.

Objectives

Machine learning and deep learning techniques have been widely used to analyze health data and improve diagnostic accuracy and precision, disease treatment, and prevention [16,17]. In particular, feature selection, clustering algorithms, and classification have often been adopted for subgroup studies [18,19]. The goal of this proposed study is to develop a machine-aided self-diagnostic tool that predicts the diagnosis of PCOS with and without any invasive measures, using Principal Component Analysis (PCA), *k*-means clustering algorithm, and CatBoost classifier. The CatBoost method is one of the newer gradient boosting decision tree models, and it was recently used in diabetes prediction in the study by Kumar et al [20]. Our development ultimately enables users, either potential patients or clinical providers, to conveniently access this pre- or self-diagnostic digital platform for PCOS from anywhere. This work is well aligned with emerging artificial intelligence and digital health care [21].

The remainder of this paper is organized as follows. In the *Methods* section, we discuss data preparation, provide an overview of statistical analysis, and explain each machine learning technique used in our analysis. In the *Results* section, we report our findings in a subgroup study and evaluate the performance of our proposed prediction models. In the *Discussion* section, the major results are highlighted, and we conclude this paper.

Methods

Subjects and Data Preparation

In this retrospective study, we obtained and analyzed a publicly available data set that was collected from 10 different hospitals across Kerala, India [22]. After data cleaning and removing 15 partly missing or high-leverage data points, the study cohort consisted of 526 women aged between 20 and 48 years, of which 170 (32.3%) were diagnosed with PCOS and 356 (67.7%) were not diagnosed with PCOS. The data set included other health information for each subject, such as anthropomorphic attributes, symptoms, laboratory and ultrasound test results, age, blood type, marital status, pregnancy, abortion history, fast food consumption, and exercise. For later use, we classified and named these variables as *anthropomorphic* variables, *symptom* variables, *test result* variables, and *given* variables in this paper.

The *anthropomorphic* variables include six variables: BMI, height, hip circumference, waist circumference, waist-to-hip ratio, and body weight. The *symptom* variables are self-observable variables. The seven symptom variables are acanthosis nigricans (skin darkening in body folds and creases), acne, hair loss, hirsutism, irregular menstrual cycle, length of menstrual cycle, and weight gain. The *test result* variables are based on blood work and ultrasound or any other medical examination, and they include anti-Müllerian hormone (AMH), the number of antral follicles in the left ovary, the number of antral follicles in the right ovary, average follicle size in the left ovary, average follicle size in the right ovary, diastolic BP, endometrium thickness, follicle-stimulating hormone, follicle-stimulating hormone to luteinizing hormone ratio, glycated hemoglobin levels, human chorionic gonadotropin I,

human chorionic gonadotropin II, luteinizing hormone, progesterone, prolactin, pulse rate, random glucose test, respiratory rate, systolic BP, thyrotropin, and vitamin D3. The remaining variables in the data set, other than the status of PCOS and the variables mentioned above, are defined as *given* variables which are age, blood type, years of marriage, abortion history, fast food consumption, pregnancy status, and regular exercise.

Overview of Statistical Analysis

We first examined the difference in attributes between the PCOS-positive group and the PCOS-negative group as a preliminary investigation. In our analysis, we provided two types of prediction models, with and without invasive health measures. In a model, we used only noninvasive variables, that is, anthropomorphic, symptom and given variables, and called this model the *patient* model. In the other model, we used all variables including noninvasive and invasive variables, and called this model the *provider* model. The purpose of proposing both prediction models was to accommodate various users who may or may not have had access to medical test results.

Another part of the statistical analysis was a subgroup study. There have been several subgroup studies of PCOS diagnosis based on different combinations of the 3 Rotterdam criteria [23,24]. Kar et al [24] characterized and classified phenotypes of PCOS in a large cohort of women into subgroups and compared the data of various metabolic complications of these phenotypes. In our subgroup study, we divided 526 women into 2 subgroups based on anthropomorphic attributes. The motivation for this idea originated from predicting lean PCOS and obese PCOS in a more detailed manner. In the remainder of this section, we explain each machine learning technique and the application of these techniques in our analysis.

PCA Method

The PCA is a dimension reduction method that is often used when there are highly correlated variables in the data set. It increases interpretability to a certain extent and minimizes data loss by combining correlated variables together to create a new set of uncorrelated yet more representative variables [25,26]. We use PCA to perform feature extraction, where several highly correlated anthropomorphic variables are linearly combined to create new axes, that is, the principal components. For example, body weight and BMI are highly correlated and are consequently highly related to the same principal component. The number of principal components for the analysis can be determined by examining the proportion of variance explained and the elbow rule.

K-Means Clustering

We adopted *k*-means clustering, which is an unsupervised machine learning algorithm that makes inferences using only input variables without referring to known outcomes. It is often used to understand the latent structure within a data set by aggregating data points based on certain similarities. We adopted the *k*-means clustering algorithm and chose the *k* value, the

number of clusters, based on the silhouette method and elbow rule [27]. The 2 subgroups were generated by applying the 2-means clustering algorithm based on the first five principal components, PC1, PC2, PC3, PC4, and PC5, which were created based on the anthropomorphic attributes. Therefore, the resulting 2 subgroups were very distinct anthropomorphically.

CatBoost Classification and Cross-Validation

We modeled our classifier using the CatBoost model, which is a gradient boosting decision tree-based classifier. The CatBoost model was introduced by Yandex in 2017 and is known to be more accurate for categorical variables than other well-known gradient boosting algorithms such as XGBoost (The XGBoost Contributors), LightGBM (Microsoft Corporation), and GBM (H2O) [28].

To prevent the classification model from overfitting or underfitting, we used stratified *K*-fold cross-validation to train and test the classification models and evaluate the model performance. We first randomly divided the sample into stratified *K*-folds where the folds were formed by preserving the percentage of PCOS-positive in the sample. We used 1-fold as a validation (hold out) set and the remaining (*K*-1) folds for model training.

In the patient model, we used only noninvasive variables (anthropomorphic, symptom, and given variables) for classification. This prediction tool can be used by potential patients or other users who do not have medical testing available. As we do not use the complete set of predictor variables in this patient model, lower accuracy is unavoidable. The provider model uses all predictor variables. This model is expected to aid clinical providers or other users who have access to the patients' medical test results for the prediagnosis or self-diagnosis of PCOS status with higher accuracy. A subgroup study was applied to both models, as summarized in Table 1. We used 5-fold cross-validation with 3 iterations for the entire data set analysis (with a sample size of 526) and 3-fold cross-validation with 5 iterations for the subgroup analysis (with the sample sizes of 287 for Subgroup 1 and 239 for Subgroup 2) to achieve a comparable number of subjects in each fold and averaged the errors over the total 15 folds in both analyses for comparison.

To evaluate the performance of the models, we used four error metrics: accuracy, sensitivity, precision, and F_1 score. Accuracy is the most intuitive and common performance measure, and it is the ratio of correctly predicted observations to the total observations. Sensitivity is the ratio of correctly predicted positive observations to all true positive observations in the class. Precision is the ratio of correctly predicted positive observations to the total number of predicted positive observations. Finally, the F_1 score is the weighted average of the sensitivity and precision. Therefore, it considers both false positives and false negatives. The F_1 score is more useful than the accuracy when there is an uneven class distribution.

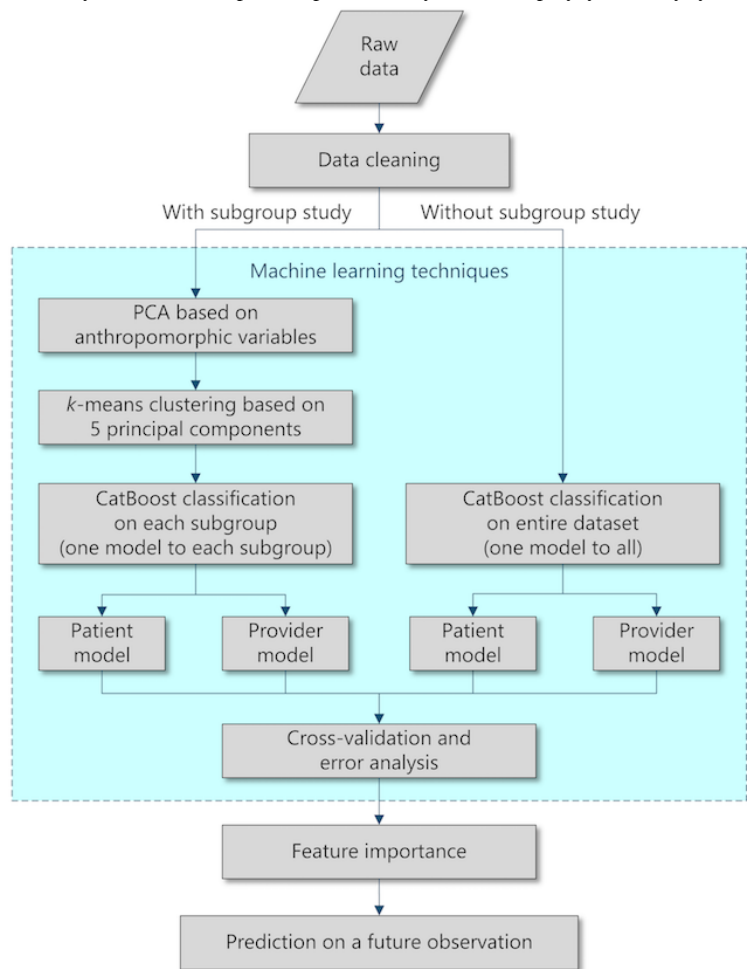
Table 1. Proposed models and the difference in method.

	Model description	Predictor variables
Patient model		
Subgroup model	Different model for each subgroup	Only noninvasive variables
One model to all	One model for the entire data set	Only noninvasive variables
Provider model		
Subgroup model	Different model for each subgroup	All variables
One model to all	One model for the entire data set	All variables

Shapley Additive Explanations Values and Feature Importance

The SHAP (Shapley Additive Explanations) values proposed by Lundberg and Lee [29] were used to examine how a single feature affects the output of the model by measuring the change in log odds. The SHAP values can be considered as credit values that are optimally allocated with local explanations using the classic Shapley values in game theory. The SHAP values were first calculated for each variable for each subject in the entire data set and averaged over the sample subjects. SHAP values farther away from 0 have a greater impact on the model output, either positively or negatively. The corresponding total variable importance was calculated by averaging the absolute SHAP values for the sample subjects. This variable importance depicts the magnitude of the total impact of each variable on the model output.

All statistical analyses were performed using R statistical software (version 4.0.3; R Foundation for Statistical Computing). Figure 1 illustrates the subgroup study and summarizes the statistical procedures in a flowchart.

Figure 1. Illustration of the subgroup study and the flowchart of data analysis. PCA: Principal Component Analysis; PCOS: polycystic ovary syndrome.


Results

Attributes

We first examined the differences between the PCOS-positive group and the PCOS-negative group to provide an overview of the data set. We used the Anderson-Darling test and found that none of the quantitative variables were normally distributed; therefore, we summarized those variables with median and IQR. For categorical variables, we used percentage. The Wilcoxon test was used to compare the medians for quantitative attributes, and the chi-square test was used to compare the proportions of qualitative attributes between the groups. The corresponding *P* values are presented in the last column of Table 2. Highly significant differences with *P*<.001 in variables were found in

BMI, hip circumference, waist circumference, and body weight among the anthropomorphic variables, all symptom variables, AMH, number of antral follicles in the left ovary and number of antral follicles in the right ovary among the test result variables, and age and fast food consumption among the given variables. These results are consistent with those of the previous studies. Anthropomorphic variables have often been linked to PCOS [30]. Symptoms and AMH have also been reported as important markers for the diagnosis of PCOS [31]. As the number of antral follicles in the left ovary and number of antral follicles in the right ovary are used in the diagnosis of PCOS, the significant differences in these variables between the 2 groups were significant. Finally, age and diet habits were found to be important factors for PCOS [32,33]. Figures 2-5 display the group comparison of these variables in detail.

Table 2. Anthropomorphic, symptom, test result, and given variables. Comparison between the PCOS[a]-positive group and the PCOS-negative group with *P* values (N=526).

	All women (N=526)	PCOS-positive size (n=170)	PCOS-negative size (n=356)	*P* value[b]
Anthropomorphic variables, median (IQR)				
BMI	24.27 (21.69 to 26.66)	25.1 (26.25 to 33)	23.61 (21.37 to 26.13)	<.001
Height (cm)	156 (152 to 160)	158 (152 to 161)	156 (152 to 160)	.12
Hip (inches)	38 (36 to 40)	39 (36 to 42)	38 (36 to 40)	<.001
Waist circumference (inches)	34 (52 to 65)	35 (32 to 37)	34 (31.75 to 35)	<.001
Waist-to-hip ratio	0.89 (0.88 to 0.93)	0.89 (0.86 to 0.93)	0.89 (0.86 to 0.93)	.91
Weight (kg)	59 (52 to 65)	62 (55 to 70)	58 (52 to 64)	<.001
Symptom variables				
Acanthosis nigricans (%)	158 (30)	105 (61.8)	53 (14.9)	<.001

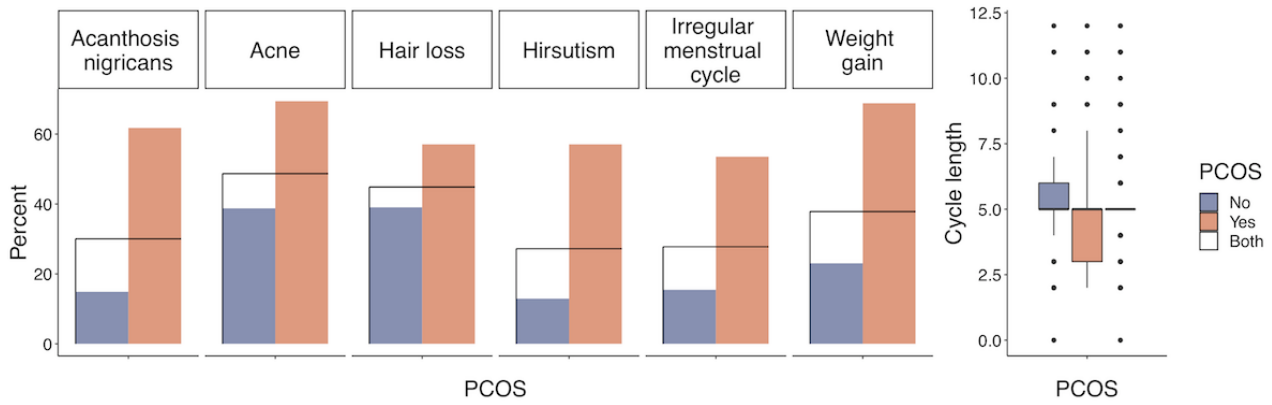

Figure 4. Test result variable comparison between the polycystic ovary syndrome (PCOS) positive group and the PCOS-negative group with $P<.001$. AMH: anti-Müllerian hormone.
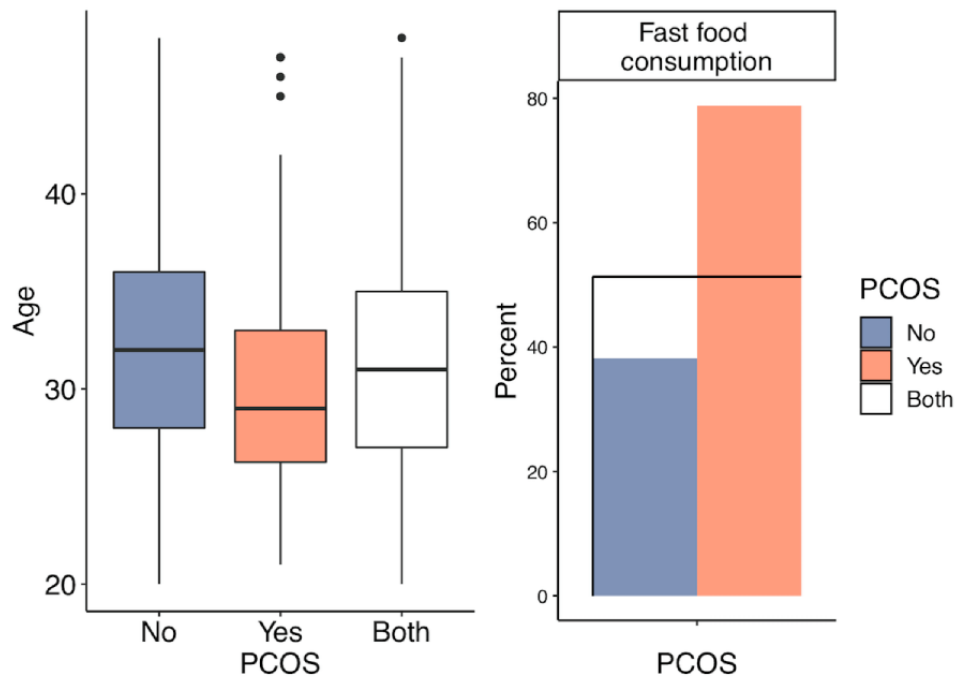
Figure 5. Given variable comparison between the polycystic ovary syndrome (PCOS) positive group and the PCOS-negative group with *P*<.001.


Feature Extraction and Clustering

For the subgroup study, we used the first 5 principal components constructed based on the anthropomorphic attributes and then applied *k*-means clustering using the 5 principal components to classify the 526 women into 2 subgroups. Figure 6 shows the correlation among the anthropomorphic variables. BMI, hip circumference, waist circumference, and body weight are highly and positively correlated, and height and waist-to-hip ratio are negatively correlated to the rest of variables. This can be also observed in PCA. The biplot in Figure 7 and Table 3 explain how each anthropomorphic variable contributes to the individual principal components. For example, as BMI, hip circumference, waist circumference, and body weight are closely correlated as depicted in Figure 6, these variables largely contribute to the first principal component (the horizontal axis, PC1) with high loadings in Figure 7 and Table 3. This newly constructed PC1 accounts for or *explains* 53.5% of the overall variability in Figure 7, and it is the first principal axis in the direction where the data points vary the most. The waist-to-hip ratio variable highly contributes to the second principal component (the vertical axis, PC2) with the second largest proportion (15.8%) of variance explained in Figure 7 and Table 3. The number of

principal components is chosen based on the amount of variance explained by using the principal components. In Figure 8, we observe that the proportion of variance explained drops at 5 principal components and we choose the first 5 principal components for clustering in the next step.

For *k*-means clustering, the optimal number *(k)* is determined based on the silhouette method and the elbow rule in Figure 9, which shows the average silhouette width versus the number of clusters. As indicated in Figure 9, we chose *k*=2, where the curve shows a sharp kink (the elbow rule). The motivation of the 2-subgroup study also originated from the idea of predicting lean PCOS and obese PCOS in a more detailed manner. In Figure 10, the 2 subgroups are shown in the PC1-PC2 plane. Subgroup 1 included 287 subjects with 76 PCOS-positive cases and subgroup 2 had 239 subjects with 94 PCOS-positive cases. The mean and SD of BMI for Subgroup 1 were 21.862 kg/m^2 and 2.921 kg/m^2, and those for Group 2 were 27.246 kg/m^2 and 3.183 kg/m^2, respectively. This clustering provides a similar yet more structured subgrouping to the lean and obese PCOS groups, where the lean PCOS group had a BMI <25 kg/m^2 and the obese PCOS group had a BMI of ≥25 kg/m^2 [34].

Figure 6. Correlation between the anthropomorphic variables.
Figure 7. Principal Component Analysis. Biplot of PC1 and PC2 based on the anthropomorphic attributes.
Table 3. Variable loadings[a] related to each principal component.

Anthropomorphic variable	Principal components				
	PC1	PC2	PC3	PC4	PC5
BMI	0.474	−0.060	0.322	−0.509	0.640
Height	0.194	0.145	−0.921	−0.040	0.302
Hip	0.486	0.241	0.119	0.500	0.010
Waist-to-hip ratio	0.013	−0.931	−0.146	0.028	0.003
Waist	0.490	−0.224	0.046	0.510	−0.010
Weight	0.511	0.010	−0.102	−0.477	−0.707

[a]Loading denotes the contribution of the variable to each principal component. Higher absolute value indicates more contribution to the corresponding principal component.

Figure 8. The optimal number of principal components to be used based on the proportion of variance explained.
Figure 9. Silhouette method to determine the optimal number of clusters.
Figure 10. Subgroups on the PC1-PC2 plane after applying *k*-means clustering using the first 5 principal components based on the anthropomorphic attributes.
In Table 4, these 2 subgroups are compared in great detail. The same statistical tests used in Table 2 were used for this comparison. These subgroups were generated by using the clustering algorithm based on the first 5 principal components of the anthropomorphic variables as discussed above. Consequently, there were significant differences in all anthropomorphic variables except waist-to-hip ratio. Otherwise, there were highly significant differences with *P*<.001 in hirsutism, irregular menstrual cycle, and weight gain among the symptom variables. We visually compare these variables in Figures 11 and 12.

Table 4. Characteristics of 2 subgroups classified by *k*-means clustering based on the 5 principal components of the anthropomorphic variables.

	Subgroup 1; n=287, PCOS[a]-positive, n=76	Subgroup 2; n=239, PCOS-positive, n=94	*P* value[b]
Anthropomorphic variables, median (IQR)

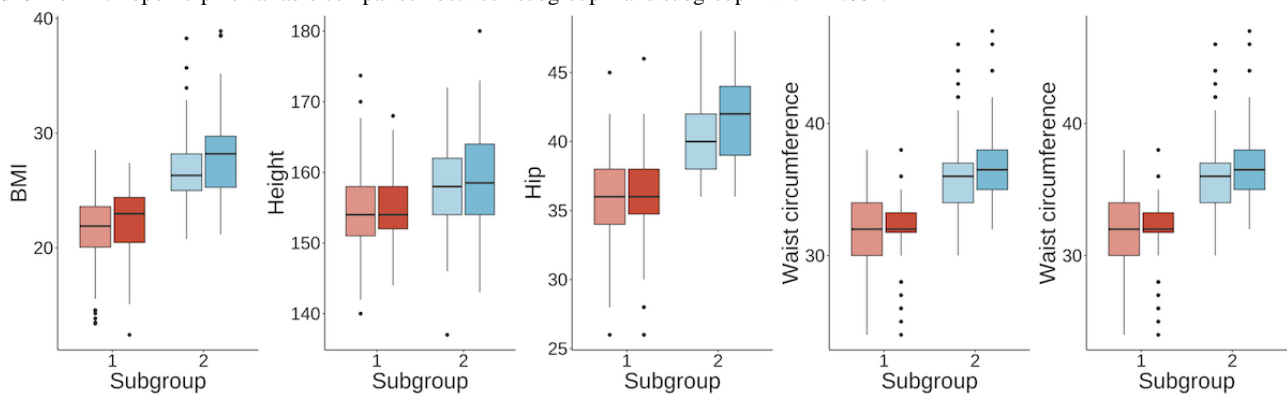

Figure 12. Symptom variable comparison between subgroup 1 and subgroup 2 with *P*<.001. PCOS: polycystic ovary syndrome.
Performance Evaluation

The prediction results from the 4 different models in Table 1 are compared in Tables 5 and 6. We used four different error metrics: accuracy, sensitivity, precision, and F_1 score. Table 5 shows the results of the patient models with and without using subgroups. As expected, the subgroup models had overall lower performance in predicting PCOS status. With subgroups, the prediction in the lower BMI group (subgroup 1) was slightly higher than that of the other subgroup. This might be because

women with higher BMI are more likely to have other complications [14,15], causing more difficulty in predicting the status of PCOS. In Table 6, we present a comparison of the error metrics for the provider models with and without subgroups. In the provider models, we predict the status of PCOS using the complete set of predictor variables, including the noninvasive variables as well as the test result variables. Therefore, the model prediction is overall better than the patient models, where we use only noninvasive predictors.

Table 5. Summary of averaged accuracy, sensitivity, precision, and F_1 score for one model to each subgroup (with subgroups) versus one model to all (without subgroups) in the patient model, using only noninvasive predictor variables in the models.

Metrics	Patient model with subgroup		Patient model without subgroup
	Subgroup 1	Subgroup 2	
Accuracy	0.815	0.810	0.825
Sensitivity	0.837	0.827	0.851
Precision	0.931	0.870	0.900
F_1 score	0.880	0.846	0.874

Table 6. Summary of averaged accuracy, sensitivity, precision, and F_1 score for one model to each subgroup (with subgroups) versus one model to all (without subgroups) in the provider model, using all predictor variables in the models.

Metrics	Provider model with subgroup		Provider model without subgroup
	Subgroup 1	Subgroup 2	
Accuracy	0.898	0.875	0.901
Sensitivity	0.907	0.862	0.909
Precision	0.960	0.945	0.950
F_1 score	0.932	0.901	0.928

Feature Analysis

The SHAP values and the corresponding feature importance are examined in this subsection. First, we present patient models based only on noninvasive predictor variables. Figures 13-15 show the total variable importance in the first column for all

noninvasive predictor variables, and the SHAP values for the 12 most important variables are graphed in the second column for the patient models. Figure 13 shows the result for subgroup 1 and Figure 14 shows the result for subgroup 2. In both subgroups, all symptom variables except hair loss and the two given variables, fast food consumption and age, are important

features. The major difference between the subgroups is that acanthosis nigricans (*Darkening* in the plot) is the most important feature in subgroup 1, and weight gain is the most important feature in subgroup 2. Another interesting finding is that exercise is more important in subgroup 1, and irregular menstrual cycle is more prominent in subgroup 2 than in the other subgroup. In Figure 15, the results from one model to all (without subgrouping) in the patient model are presented. All symptom variables except hair loss and the two given variables, fast food consumption and age, have high importance values as well.

Figure 13. Feature importance for all variables and SHAP (Shapley Additive Explanations) values for the 12 most important features of subgroup 1 in the patient subgroup model including only noninvasive predictor variables.
Figure 14. Feature importance for all variables and SHAP (Shapley Additive Explanations) values for the 12 most important features of subgroup 2 in the patient subgroup model including only noninvasive predictor variables.
Figure 15. Feature importance for all variables (with the middle importance variables omitted) and the SHAP (Shapley Additive Explanations) values for the 12 most important features of the one to all model (without subgroups) in the patient model.
The SHAP values provide detailed local behavior in terms of feature importance. Most binary variables have distinct positive and negative SHAP values. For example, the SHAP values for the darkening variable, top-ranked in subgroup 1 in Figure 13, are clustered on the negative side (yellow dots in the plot) and on the positive side (purple dots in the plot), and these 2 clusters are far away from zero. The yellow dots represent lower values in the darkening variable (Darkening=No) and these variable values negatively affect the model output, that is, negative change in log odds in the model output, whereas the purple dots show higher values in the darkening variable (Darkening=Yes), and these variable values positively affect the model output. However, the higher feature values (Darkening=Yes) in purple have a stronger impact on the model output than the lower feature values (Darkening=No) because the purple cluster is farther away from zero than the yellow cluster.

In Figures 16-18, we repeat the same process in the provider models. In all 3 figures, the number of antral follicles in the right ovary was most highly ranked in terms of feature importance. Otherwise, the number of antral follicles in the left ovary, all symptom attributes except hair loss, fast food consumption, and AMH are relatively more important than other variables, which are commonly observed in all 3 models. In comparison between subgroup 1 and subgroup 2, pulse rate and respiratory rate are more important features in subgroup 1 in Figure 16, and AMH is a more important feature (also note that the SHAP values of AMH are more spread out) in subgroup 2 than in the other subgroup, as shown in Figure 17. Regarding pulse rate and respiratory rate being important in subgroup 1, heart rate variability in normal weight women with PCOS has been subject to debate in the literature [35,36].

Figure 16. Feature importance for all variables (with the middle importance variables omitted) and SHAP (Shapley Additive Explanations) values for the 12 most important features of subgroup 1 in the provider subgroup model including all predictor variables. AMH: anti-Müllerian hormone; PRG: progrestrone; PRL: prolactin.
Figure 17. Feature importance for all variables (with the middle importance variables omitted) and SHAP (Shapley Additive Explanations) values for the 12 most important features of subgroup 2 in the provider subgroup model including all predictor variables. AMH: anti-Müllerian hormone; BP: blood pressure; FSH: follicle-stimulating hormone; LH: luteinizing hormone; PRL: prolactin.
Figure 18. Feature importance for all variables (with the middle importance variables omitted) and the SHAP (Shapley Additive Explanations) values for the 12 most important features of the one to all model (without subgroups) in the provider model. AMH: anti-Müllerian hormone; BP: blood pressure; FSH: follicle-stimulating hormone; LH: luteinizing hormone; PRL: prolactin.
Discussion

Principal Findings

PCOS is a common, chronic, yet underrecognized female hormone disorder. Owing to the complexity of the syndrome, identification and differential diagnosis remain challenging even with widely accepted criteria and tests. Another disparity comes from the gaps in early diagnosis, information, and accessible support that can help women to prevent or manage this life span syndrome more adequately.

The ultimate goal of this study was to develop a conveniently accessible digital platform for pre- or self-diagnosis of PCOS using machine learning techniques such as PCA, k-means clustering algorithm, and CatBoost classifier based on the health measures of 526 female subjects. PCA was adopted to extract features from highly correlated anthropomorphic variables. The 2-means clustering algorithm was used to classify the 526 women into 2 different subgroups based on the first 5 principal components, leading to 2 subgroups with distinct BMIs. The gradient boosting decision tree-based classifier, CatBoost model, was trained and tested, and the prediction (test) error rates were compared between models based on four different error metrics: accuracy, sensitivity, precision, and F_1 score.

We developed 2 types of prediction models targeting different groups of users. One model is for potential patients or other users who do not have medical test results available (the patient model) and the other is for clinical providers or other users who have access to the patients' medical records and test results (the provider model). In each model, we applied a subgroup study to obtain the detailed characteristics of the 2 subgroups in the analysis. For the patient models, the prediction accuracy ranged

from 81% to 81.5% with subgroups and 82.5% without subgroups. For the provider models, the prediction accuracy ranged from 87.5% to 89.8% with subgroups and 90.1% without subgroups.

Feature importance was performed in each model based on the SHAP values and the corresponding total feature importance. In the patient models, all symptom variables other than hair loss, that is, acanthosis nigricans, acne, hirsutism, irregular menstrual cycle, length of menstrual cycle, and weight gain, were important along with fast food consumption and age. For subgroup 1 (with lower BMI), acanthosis nigricans was the strongest marker in the prediction of PCOS status. Exercise was also an important factor in subgroup 1. For subgroup 2 (with higher BMI), weight gain was the top-ranked important marker and irregular menstrual cycle was also more prominent than subgroup 1. For the provider models, the number of antral follicles in the right ovary, the number of antral follicles in the left ovary, and AMH were important in all models in addition to the listed important variables in the patient models: acanthosis nigricans, acne, hirsutism, irregular menstrual cycle, length of menstrual cycle, weight gain, fast food consumption, and age. Another interesting finding was that the pulse rate and respiratory rates were also highly ranked in subgroup 1, which consisted of normal or underweight women with a mean weight of 52.353 kg and a mean BMI of 21.862 kg/m^2.

The proposed prediction models based on available health measures are expected to provide women with a simpler and quicker access to a pre- or self-diagnosis of PCOS and possibly provide the opportunity for users to be educated and informed effectively. Gibson-Helm et al [37,38] reported that many women experience a prolonged and frustrating diagnosis of PCOS because it requires multiple health care providers to

evaluate and diagnose PCOS, based on their study of a large community-based national sample. Our proposed work will resolve the concerns of delayed diagnosis and improve health care access for women.

Limitations and Future Works

The main limitation of this study is that the sample is from a very specific population in Kerala, India, which is a state along India's tropical Malabar coast. In previous studies, women experienced variations in PCOS symptoms depending on culture and ethnicity [38-40]. Another limitation is that the data set was collected from multiple hospitals where slightly different criteria might have been used to diagnose patients with PCOS, causing higher error rates in prediction. Our future work will include

collecting larger data sets from different cultures and ethnicities for comparison and improving our prediction models. This will enable us to provide more tailored prediction tools for users in different cultural and ethnic groups. In addition, there is abundant evidence that PCOS substantially contributes to women's anxiety disorders, depression, personality, and other psychological disorders [41,42]. A more in-depth study on the psychological effects of PCOS will be conducted in the future.

Conclusions

In summary, the proposed study offers great potential that our self-diagnostic prediction models for PCOS status can serve as a convenient and easy-to-use digital platform based on available health measures for both potential patients and clinical providers.

Abstract

Background: Similar to many low- and middle-income countries, Botswana has identified eHealth as a means of improving health care service provision and delivery. The National Malaria Programme (NMP) in Botswana has implemented the District Health Information System version 2 (DHIS2) to support timely malaria case reporting across its 27 health districts; however, the implementation of an eHealth system is never without challenges. Barriers to the implementation of eHealth innovations within health care settings may arise at the individual or organizational levels. As such, the evaluation of user perceptions of the technology is an important step that can inform its sustainable implementation. The DHIS2 was implemented without evaluating user perceptions beforehand; therefore, the Botswana Ministry of Health and Wellness was uncertain about the likelihood of acceptance and use of the platform.

Objective: We aimed to determine the acceptance of the DHIS2 platform by the NMP in Botswana to gauge whether adoption would be successful.

Methods: The study's design was informed by constructs of the technology acceptance model. A survey, with items assessed using a 7-point Likert scale, and focus group discussions were undertaken with DHIS2 core users from 27 health districts and NMP personnel at the Ministry of Health and Wellness. The web-based survey was administered from August 3, 2020 to September 30, 2020.

Results: Survey participants were core users (n=27). Focus group participants were NMP personnel (n=5). Overall, participants' survey responses (frequently occurring scores of 7) showed their confidence in the DHIS2 platform for case-based surveillance of malaria; however, participants also noted some organizational issues that could compromise user acceptance of the DHIS2 platform.

Conclusions: Participants' responses indicated their acceptance of the DHIS2 platform; however, the consideration of factors related to organizational readiness could further enhance successful acceptance, and consequently, successful adoption of the platform by the malaria program in Botswana.

Introduction

Botswana is among the countries that have made substantial progress, in the elimination continuum, in the fight against malaria. Between 2000 and 2015, the malaria incidence in Botswana fell dramatically, by 79%, from 0.136 in 2000 to 0.029 in 2015 [1]. Furthermore, mortality caused by malaria declined by 57%, from 1069 deaths in 2003 to 462 deaths in 2015 [2]. This reduction in malaria morbidity and mortality is mainly due to the government's implementation of malaria interventions [3,4] such as annual health care worker training on malaria case management to ensure accurate diagnosis and treatment of identified cases [5]. The transmission of malaria in Botswana is highly heterogeneous; transmission is mostly seasonal and unstable, occurring primarily between November and May during the rainy season [6] and primarily in the northern and eastern parts of the country [7]. However, malaria transmission in Botswana is very low compared to that in other sub-Saharan African countries [8]. Despite efforts toward malaria elimination, Botswana has not been successful in meeting its target of achieving zero indigenous cases [7]. Failure to meet the set target could be attributed to inadequate disease surveillance systems. This is because an adequate disease surveillance system will ensure that data collection, analysis, reporting, active case finding, and linkage to the response happens quickly to identify infections (symptomatic and asymptomatic), prevent ongoing transmission, and decrease the transmission efficiency of vectors. Similar to many low- and middle-income countries, Botswana has identified eHealth (ie, "the use of Information and Communications Technologies (ICT) for health" [9]) as a means of improving health care service provision and delivery, and other low- and middle-income countries have implemented eHealth systems for case-based surveillance of malaria [10,11]. Such trends continue to be spurred by the recent global awareness and application of eHealth technologies toward combating the current COVID-19 pandemic [12].

In Botswana, an eHealth system—the District Health Information System version 2 (DHIS2)—has been identified to improve malaria surveillance across the 27 health districts. The decision to consider DHIS2 was based on its documented benefits [13-15]. In spite of the availability of the DHIS2 platform for case-based surveillance of malaria, paper-based case notification forms continue to be utilized. Prior to the DHIS2, the National Malaria Programme (NMP) used a spreadsheet (Excel, version 2013; Microsoft Inc) for data capture, analysis, and reporting. At the district level, either monitoring and evaluation officers, a malaria focal person (the person who is responsible for management of the NMP in the district), or a community health nurse compiled information on malaria infections (patient name, age, date of diagnosis, physical address, the treatment offered, and method of detection) in the spreadsheet, based on presentations and diagnoses in the preceding week, which was then emailed to the NMP at the Ministry of Health and Wellness headquarters. In addition, a designated health care worker at each facility could complete a case notification paper form (in duplicate), which was sent to the district headquarters and to the NMP. The monitoring and evaluation officer compiled data from all 27 health districts in a spreadsheet arranged by year, month, district, and week.

Notwithstanding the potential benefits of the DHIS2 platform toward improving case-based surveillance of malaria in Botswana, the implementation of any eHealth system is never without challenges [16]. According to Ross et al [17], barriers to implementation of eHealth innovations within health care settings may arise at the individual, organization, or wider levels of the health care system. Acceptance by users (health care workers) has been documented as one of the key factors for successful implementation of an eHealth system [18]; therefore, evaluating user perceptions of the technology is an important step. The technology acceptance model features prominently among key theoretical approaches used to understand people's intentions to accept various forms of information technology [19,20]. Many studies [20-25] that focus on explaining end user acceptance and predicting successful adoption of eHealth systems by health care organizations use the technology acceptance model—that an individual's (1) acceptance of (intention to engage with) a technology depends on (2) perceived usefulness and (3) perceived ease of use [19-21]—as a basis. This model contends that a strong relationship exists between one's intention to use technology and their actual usage behavior [19,20], and perceived usefulness is characterized by an individual's belief that engaging a technology improves their job performance, while perceived ease of use refers to their belief that using technology requires minimal effort [19,20].

The DHIS2 platform for case-based surveillance of malaria in Botswana was implemented without evaluating user acceptance. Evaluation of user acceptance is necessary to inform sustainable implementation of technology. We aimed to evaluate user acceptance of the DHIS2 platform.

Methods

Study Design

Survey items and the focus group discussion guide were informed by constructs (acceptance of the technology, perceived usefulness, and perceived ease of use) of the technology acceptance model and were used to gain insights from users across the 27 health care districts in Botswana.

We developed a survey and focus group discussion guide, both in English. The drafts were first reviewed by a health care worker at the Ministry of Health and Wellness and by a medical librarian at the University of Botswana, after which, both tools were refined. The revised tools were then tested by 2 other

health care workers, whose input resulted in further enhancement of the tools through improved branching logic. The final survey was administered using REDCap (Vanderbilt University [23]) forms from August 3, 2020 to September 30, 2020. The final version of the focus group questions was utilized to guide focus group discussions.

For both the survey and focus group, we used purposive sampling. The DHIS2 was put into place across the 27 health districts in Botswana, with each district having at least one core user (a health care worker whose main role involves dedicated interaction with the DHIS2 platform for the NMP). The sample consisted 1 core user from each health districts and NMP personnel at the Ministry of Health and Wellness headquarters who were part of a unit dedicated to the use of DHIS2 platform for the NMP in Botswana (the NMP coordinator, a health informatics officer, a software developer, and 2 monitoring and evaluation officers).

Participants from the 27 health districts were recruited by the NMP coordinator, and those who consented were sent a link to complete the survey. Only one author was responsible for accessing and managing the web-based database through the use of username and password. The survey consisted of questions about the type of facility where the respondent was based and the name of the district and of statements that assessed users' acceptance of the DHIS2 platform, perceived usefulness, and perceived ease of use, using a 7-point Likert scale. There were 30 close-ended statements and 4 open-ended questions.

Focus group discussions, 1 session which lasted for 1 hour, involved the 5 NMP personnel based at the Ministry of Health and Wellness, who were invited by email and text messaging to a videoconference (Google Meet, Google LLC; which was chosen because it was the only platform to which all participants had access). The purpose of the focus group discussion was explained to participants, after which, they were asked to provide consent to participate in the study. The focus group discussion was recorded (with participant permission) and later transcribed verbatim.

Descriptive statistics (mean, standard deviation, median, and mode) were calculated (Excel, version 2013, Microsoft Inc) for quantitative data (close-ended statement ratings). Qualitative data (from open-ended questions and focus group discussion) were analyzed using thematic analysis (NVivo, version 11; QSR International). Thematic analysis of participants' responses was conducted to determine factors affecting the sustainable implementation of the DHIS2 platform for the case-based surveillance program. We used a deductive coding process [22]. A coding frame and a predefined list of descriptive codes were developed by 1 author and then discussed by all authors, which yielded 20 codes ("eHealth," "mHealth," "ICT," "user acceptance," "usefulness," "ease of use," "user interface," "capacity development," "internet connectivity," "mobile devices," "electronic medical record," "electronic health record," "security," "privacy," "confidentiality," "interoperability," "integration," "data management," "data analysis," and "data reporting"). Transcriptions of the discussions were systematically and iteratively searched (in 2 cycles) for elements relevant to the 20 codes. Participants' responses from focus group discussions, as well as open-ended responses from the survey, were matched to corresponding categories in the coding frame. This process was done iteratively to refine the alignment and identify high-level themes.

Ethics

The study was approved by the Office of Research and Development of the University of Botswana (UBR/RES/IRB/BIO/224) and the Ministry of Health and Wellness (HPDME: 13/18/1). Participants provided informed consent. During data collection, we presented and explained the consent form to seek permission from potential participants. The consent forms also clearly explained the purpose of the study and provided assurance that data would be kept safe and deidentified. Participants were informed of their right to refuse to participate or withdraw from the study at any time.

Results

The survey response rate was 89% (24/27). From a total of 27 DHIS2 core users (community health nurses: n=14; malaria focal person: n=9; health information and communication technology personnel: n=4), 24 responded (community health nurses n=13; malaria focal persons: n=7; health information and communication technology personnel: n=4). Of those who responded, 15 were from the district health management team, 3 were from public hospitals, and 6 were from public clinic facilities. Core users who did not respond were from public hospitals (n=2) and a public clinic (n=1). Participants most frequently responded that they agreed (4 items: mode 6) or strongly agreed (16 items: mode 7) with survey statements, which were aligned with technology acceptance model constructs (Table 1).

All 5 NMP personnel participated in the focus group and highlighted possible factors that could affect the sustainable implementation of the DHIS2 platform for case-based surveillance of malaria (Table 2). Ultimately, 5 themes were identified (governance, infrastructure, capacity building, data security, and usability).

Table 1. Acceptance of the District Health Information System version 2 based on the technology acceptance model.

Constructs[a]	Mean (SD)	Median	Mode
Perceived ease of use			
Overall, I am satisfied with how easy it is to use DHIS2[b]	5.2 (1.9)	6	7
It was simple to use DHIS2	5.4 (2.0)	6	7
It is easy to find the information I needed	5.2 (1.7)	5	7
It was easy to learn to use DHIS2	5.3 (2.2)	7	7
I feel comfortable using DHIS2	5.7 (2.1)	7	7
The information (such as online help, on-screen messages, and other documentation) provided with DHIS2 is clear	5.1 (1.7)	5	7
The interface of DHIS2 is pleasant	5.7 (1.5)	6	7
DHIS2 gives error messages that clearly tell me how to fix problems	3.8 (2.2)	3	3
Whenever I make a mistake using DHIS2, I recover easily and quickly	4.6 (1.9)	4	3
The organization of information on the system screens is clear	5.8 (1.3)	6	6
The information provided for the system is easy to understand	5.3 (1.9)	6	7
Perceived usefulness			
I am able to complete my work quickly using DHIS2	5.1 (2.2)	6	7
I can effectively complete my work using DHIS2	5.5 (1.9)	7	7
I believe I became productive quickly using DHIS2	5.4 (1.9)	6	7
The information is effective in helping me complete the tasks and scenarios	5.4 (1.8)	6	7
DHIS2 has all the functions and capabilities I expect it to have	5.4 (1.5)	6	6
Overall, DHIS2 improved data management activities for the malaria program	5.6 (2.1)	7	7
Overall, DHIS2 improved data analysis of malaria cases	5.6 (1.6)	6	7
DHIS2 contributed to timely decision-making processes	5.9 (1.6)	6	7
Overall, DHIS2 improved timely reporting of malaria cases	5.8 (1.8)	6	7
Acceptance of technology			
I like using the interface of DHIS2	5.1 (1.9)	6	6
Overall, I am satisfied with the DHIS2 system	5.1 (1.9)	6	6

[a]Responses were in the form of a Likert scale from 1 (strongly disagree) to 7 (strongly agree).

[b]DHIS2: District Health Information System version 2.

Table 2. Thematic presentation of factors affecting the sustainable implementation of the District Health Information System version 2 (DHIS2) platform for case-based surveillance of malaria.

Theme	Example quotes
Governance	"It adds on the already heavy workload, there should be people specific to do malaria data entry"
	"It brought about migration from manual system to electronic platform given that COVID-19 necessitates the use of technology."
	"Have government employees being part of the system programming and maintenance/being part of the project or have ownership to the system"
	"Majority of health care workers should be shown the importance of using the health systems"
	"Cascade mentoring of DHIS utilization in facilities as facility based training"
	"Every time an update is introduced on the paper data collection tools (guidelines), the same should also be updated on the DHI2 system to make sure that the paper forms and the system are in sync at all times".
Infrastructure	"Frequent network downtimes resulting in delays in reporting when the system is down"
	"It is not linked with other applications that the government has created to formulate reports and daily activities"
	"Data capture even when there is no connectivity and later sync when the internet connection is regained"
	"More gadgets should be availed for each facility and errors or SIM card malfunctions should be urgently addressed"
	"System linkage/interoperability with other existing systems"
	"Making sure internet is reliable at facilities"
Capacity building	"Requires more practice for better or improved competencies"
	"Capacity building to be strengthened for the local IT Officers"
	"Training should have frequent support visits"
	"Cascade mentorship programmes of DHIS utilization in facilities as facility-based training"
	"All health care workers should be trained and shown the importance of using the health information systems"
	"Topics covered to be taken step by step or explained in full with more practicals"
	"Training content coverage should be more than 80% practicals"
	"There should have been site visit immediately after training to assess situations on the ground"
Data security	"Use of authentication passwords and encryption algorithms for data security and privacy"
	"The link is not trustworthy"
Usability	"It picks everything you enter whether good or bad"
	"No free choice to select the period you want to view the data, all are fixed to daily, weekly, monthly, etc"
	"It's confusing sometimes as one can enter patients twice but not knowing"
	"Clients are attached to the diagnosing facility rather than the origin of infection"
	"If an error is made during entering of cases and you want to correct it, there isn't an option to edit especially on the date of diagnosis and notification"
	"Data management greatly improved for the intervention of positive malaria cases"
	"DHIS2 is easy to use as it simplifies data management and analysis"
	"It is pleasant, easier and quick to use, you can retrieve your information if you need to utilize it for something"
	"Timely data reporting"
	"Completeness of reports is achieved"
	"Easy analysis of data, using maps and graphs for visualisations"
	"Easy to formulate reports if used adequately and effectively"
	"It covered most aspects of malaria case-based surveillance"
	"DHIS2 has simplified malaria surveillance and indeed it is a very valuable tool"
	"Gives a good situational analysis of what is happening on the ground"
	"DHIS2 enables foursight mapping, by using the GPS coordinates to locate malaria case outbreaks or hotspots."
	"Everything is now at our fingertips, we have data in the form of tables, charts and reports generated from the dashboard than prior to the DHIS2 where we used to manually manage the data using excel charts."
	"We easily make decisions based on the data from the system"

Discussion

General

Overall, the study showed participants' satisfaction with the DHIS2 platform, with the majority of responses indicating agreement (20/22; 4 items: mode 6; 16 items: mode 7) with positive statements based on technology acceptance model constructs (Table 1). Key themes—*governance*, *infrastructure*, *capacity building*, *data security*, and *usability*—related to an

organization's role in influencing technology acceptance were identified (Table 2).

The technology acceptance model constructs of perceived ease of use and perceived usefulness have been previously documented as positive influences toward technology adoption [24]. Moreover, *perceived ease of use* has been defined as the extent to which a person believes that using a technology will be free of effort [24], and *perceived usefulness* is the belief that one's utilization of information technologies will enhance one's work performance [25]. For only 2 statements (addressing system usability) of the 22 survey items did the most common response by participants indicate that they somewhat disagreed (mode 3). Based on our findings, successful acceptance and adoption of the DHIS2 platform by the malaria program in Botswana could be assumed; however, NMP personnel highlighted some factors that could negatively influence acceptance of the DHIS2 for the malaria program. In an organization, factors that may affect sustainable implementation of the DHIS2 platform for case-based surveillance of malaria include the state of governance, the state of relevant infrastructure, the presence or absence of capacity building initiatives aimed at empowering potential users of the system, data security measures, and usability of the system (Table 2). As such, the application of project management practices by an implementing organization may be critical in ensuring sustainable implementation of the DHIS2 platform. Successful project management practices will ensure the fitness of a project for its political context (ie, in terms of organizational strategy, managership, and stakeholder management) [26]. Mlekus et al [27] highlighted that any organization planning for the successful acceptance and adoption of new technology should consider issues that fulfill user experience related to output quality, perspicuity, dependability, and novelty. Change management has been documented as one strategy that organizations could use to raise acceptance of new technology in a workplace and hence improve chances of successful adoption of the technology [28]. Change management is about supporting people through a process of change, and successful implementation of change is achieved when the systems, processes, tools, and technology of the change initiative are embedded in the new way in which health care providers do their work [29]. Ingebrigsten et al [30] identified 7 leadership behaviors that were associated with successful outcomes in Health Information Technology adoption: (1) communicating clearly about visions and goals, (2) providing support, (3) establishing a governance structure, (4) establishing training, (5) identifying and appointing champions, (6) addressing work process change, and (7) following up. Such leadership maybe necessary in addressing the issues highlighted in Table 2. Consequently, a lack of top management support and technology implementation strategy may play a negative role in influencing information and communication technology acceptance and adoption in any organization. Hu et al [31] noted that the ultimate success of an eHealth system in an adopting organization requires adequate attention to both technological and managerial issues. Therefore, for successful and sustainable implementation of an eHealth system, the health care organization should ensure availability of requisite resources

and processes. In fact, failures of eHealth system implementation have been associated with a lack of eHealth readiness [32,33].

The technology acceptance model is one of the most widely used theoretical frameworks for predicting individuals' likelihood to accept and adopt new technology [34]. The model is based on the assumption that when users perceive that a type of technology is useful and easy to use, they will be willing to use it [35]. However, some of our findings suggest the need for a model that considers the role of organizational readiness, the extent to which an institutional setting and culture support and promotes awareness, implementation, and use of eHealth [36], in influencing technology acceptance and hence the adoption of eHealth systems.

Guidance

In line with key study findings, the following acceptance-related issues and associated mitigation strategies are proffered: Perception of usability can influence acceptance of an eHealth system. As such, the usability of the current DHIS2 platform for case-based surveillance of malaria should be enhanced as it could deter users from interacting with the platform. One focus group participant reported usability concerns about the DHIS2,

> *It's confusing sometimes as one can enter patients twice but not knowing.*

Another participant reported that

> *If an error is made during entering of cases and you want to correct it, there isn't an option to edit especially on the date of diagnosis and notification.*

Previous studies [37-40] have suggested enhancing system usability with user-friendly interfaces, real-time feedback mechanisms, and decision-support capabilities. It is, therefore, important to involve all key stakeholders, from design to implementation, by using a user-centered design approach [41]. User-centered design is also considered to be an important contributor to system usefulness and usability [41]. This is of importance since user-centered design creates a sense of ownership among end users who participated in the design and development process, thereby increasing their acceptance of the system

Digital health literacy is also a factor in technology acceptance [42]. Study participants highlighted the need for frequent training on the DHIS2 platform, with one stating

> *Training should have frequent support visits*

while another suggested the DHIS2 platform

> *...requires more practice for better or improved competencies.*

This could be achieved through continuous health human resource capacity-building programs as technology and user needs to evolve.

A potential data security consideration, the

> *...use of authentication passwords and encryption algorithms for data security and privacy...*

was identified in this study, as well as, one security risk, that is,

The link is not trustworthy.

These issues require comprehensive well-documented regulatory approaches to facilitate protection of the highly sensitive clinical data. Given the limited documented data security and privacy best practices for open-source solutions, implementation of the DHIS2 platform in Botswana should be guided by and aligned to key national policy documents such as the Data Protection Act [43] or equivalent policy documents in other settings.

Focus group participants indicated that the DHIS2 could be enhanced by establishing

> *...system linkage/interoperability with other existing systems.*

This followed a previous finding [44] highlighting that the DHIS2 is not linked with other applications that the government has created to formulate reports and daily activities. Interoperability of eHealth systems in Botswana and similar low- and middle-income countries should be strengthened through increased adaptation of universally available software, services, and content, such as the DHIS2 platform, as these are already endorsed by the World Health Organization to be interoperable [9]. Furthermore, the DHIS2 supports a web application programming interface that allows for integration with other databases and supports the development of an "Integrated Information Portal [45]." Lastly, it is important to view interoperability of eHealth systems as an ongoing process that can be improved over time.

Conclusions

Health care environments in most low- and middle-income countries are generally data rich but information poor. In Botswana, the health care sector is compounded with vast amounts of clinical data which are seldom used for decision-making purposes. The DHIS2 is a platform that can improve data capture, analysis, and timely reporting, which will facilitate transitioning data to information. Evaluation of the DHIS2 platform for case-based surveillance of malaria by core users showed that it was accepted. There is, however, room to improve the usability of the current DHIS2 platform, through end user involvement and buy in, to ensure sustainable health human resource capacity building, to address security privacy and confidentiality issues, and to address interoperability, by considering guidance from the World Health Organization [9]. Our findings can be used to inform policy makers and health informatics leaders in Botswana and in similar low- and middle-income countries to successfully plan and implement effective eHealth platforms.

Abstract

Background: Chronic pain is a major health challenge to those affected. Blended care with psychomotor physiotherapy (PMP) combined with eHealth self-management might be beneficial.

Objective: This study aims to explore how patients with chronic pain experience the combination of PMP and the use of EPIO, an eHealth self-management intervention for chronic pain.

Methods: Individual semistructured interviews were conducted with 5 adult patients with chronic pain (ie, participants) who used EPIO in combination with PMP over a period of 10 to 15 weeks. Interviews explored participants' experiences using this treatment combination in relation to their pain and analyzed their experiences using systematic text condensation.

Results: Participants described having benefited from using EPIO in combination with PMP in terms of increased awareness of bodily signals and how pain was related to stress and activity. They also described changes in the relationship to themselves in terms of increased self-acceptance, self-assertion, and hope and their relationship to their pain in terms of seeing pain as less harmful and engaging in more active coping strategies.

Conclusions: Results indicate that a blended care approach combining eHealth self-management interventions such as EPIO with PMP may be of value to patients living with chronic pain.

Trial Registration: ClinicalTrials.gov NCT03705104; https://clinicaltrials.gov/ct2/show/NCT03705104

Introduction

Background

As much as 30% of the Norwegian population reports living with chronic pain [1-3], defined as pain lasting for more than 3 months [4]. Pain is one of the most common reasons for why people seek health care [5,6], sick leave, and disability pensions [7-10], and is also associated with increased mortality [11].

Chronic pain is complex, with physical, social, and psychological aspects interacting and impacting individual experience and often carrying major consequences for those

affected and their social network [1,12]. Commonly reported pain-related challenges include sleep disturbances [13,14], anxiety and depression [13,15,16], and impairments of daily activities [13,17] and quality of life [13,18,19].

In multidisciplinary chronic pain management, the focus is generally on maximizing function and quality of life and may include combinations of medication treatment, physical therapy, and additional self-management approaches such as working with one's own thoughts, perceptions, attitudes, emotions, and activities [20,21].

Self-management focuses on supporting people to actively manage their own health and live as well as possible with their chronic condition [22]. This includes problem solving relevant for dealing with the consequences of the chronic condition and making necessary changes in daily life to provide improved quality of life [22]. In recent years, active self-management has been increasingly considered an important factor for pain management. There is consistent evidence that the use of active pain self-management strategies, such as maintaining activities despite pain, causes less pain-related disability than those using more passive approaches, such as trusting others [23], and recent clinical guidelines also recommend including self-management interventions in chronic pain treatment [20].

Self-management for people living with chronic pain (ie, actively managing their own health) can be affected by biomedical factors (eg, bodily symptoms) and the psychosocial aspects of pain (eg, emotional distress, self-efficacy, motivation for change, acceptance, worst-case thinking, fear of pain, helplessness, and barriers to pain management) [24-26].

Many patients living with chronic pain are offered psychomotor physiotherapy (PMP) [27]. PMP focuses on changing and facilitating insight and awareness for the patient to recognize and understand the connections between their daily life and their physical condition [27]. On the basis of the notion that the body and psyche are deeply interconnected, PMP treatment aims to raise awareness and change the states of tension in the body, with the intention of increasing the patient's familiarity and contact with his or her own body.

Interventions with cognitive behavioral therapy (CBT) [28] and acceptance and commitment therapy (ACT) [29] may also support self-management of chronic pain. CBT centers around the impact and relationships among thoughts, feelings, and behaviors and involves techniques to challenge and change thoughts and behaviors [28]. CBT approaches to chronic pain management have been associated with improved self-management; reductions in pain, disability, and emotional distress [30,31]; and improvements in mood, coping, and social functioning [30]. ACT focuses more on acceptance of a situation or setting, commitment to change, and attention to helpful strategies, with the goal of increasing psychological flexibility (eg, ability to adapt to situations and demands) [29,32] and has been associated with improvements in pain acceptance or psychological flexibility, pain intensity, disability or physical functioning, depressive symptoms, and quality of life [33,34].

In recent years, there has been an increasing interest in, and development of, eHealth CBT- and ACT-based interventions

for pain management. The delivery of such interventions is not dependent on access to professionals with pain management competence, treatment waiting lists, or travel distances and may be less associated with stigma than more traditional forms of psychological treatment [13,35]. Although some eHealth interventions have been associated with decreased pain intensity and improved function and quality of life [35,36], the field of eHealth pain management is still at an early stage and most available eHealth programs so far lack a theoretical foundation and have not been subjected to research and rigorous efficacy testing [36,37].

Studies have shown that blended care (eg, combination of therapy via eHealth and in-person care) [38] can provide new treatment possibilities and make it easier for patients to follow up on their own treatment between consultations [39]. An advantage of such blended care is that the health care provider and patient may plan the course of treatment together and that the provider may guide the patient when needed. As such, blended care may offer treatment that can be effective and, at the same time, cost-effective in terms of fewer health care sessions and may lower dropouts because of the individualized follow-up, and the continued access to the eHealth intervention may potentially also help maintain achieved long-term changes [40].

Patients with chronic pain and those providing treatment and care services to these patients have displayed an interest in, and a positive attitude toward, using eHealth self-management interventions for chronic pain [41,42]. Still, blended care in terms of PMP combined with eHealth self-management interventions is yet to be implemented and studied in clinical practice in Norway.

Objectives

The aim of this study is to explore how patients with chronic pain experience the combination of PMP and the use of EPIO, an eHealth self-management intervention for chronic pain.

Methods

Study Design and Participants

This study is part of a larger project aiming to design, develop, pilot-test, and examine the effectiveness of EPIO, a digital self-management intervention for patients living with chronic pain in Norway. The design, development, and feasibility pilot-testing of EPIO have been published elsewhere [41-44], and a large-scale randomized controlled efficacy trial is currently ongoing.

This study adds to the larger project through reporting on qualitative findings from individual interviews conducted to explore patients' experiences using EPIO in combination with PMP. The study was conducted at a physiotherapy institute in Norway. Recruitment processes and study execution was conducted by the first author, who is a psychomotor physiotherapist. To our knowledge, a few, if any, studies have examined delivery of blended care within PMP (eg, digital self-management in combination with PMP), and conducting a small-scale study was, therefore, considered appropriate to test delivery forms and study procedures. With options for the

intervention to last up to 16 weeks (description of PMP and the EPIO intervention program is given later), good opportunities for in-depth descriptions from the participants regarding their experiences of using EPIO in combination with PMP were anticipated. Given the qualitative nature of the study, a predefined number of 6 participants representing patients living with chronic pain and receiving PMP was defined as acceptable (ie, minimum), as even a limited number of participants can allow for richness and depth in data related to participants' experiences (ie, provided data collection methods).

Even with a small number of participants, the study aims for purposively sampling [45] to ensure some variations in gender and pain-related diagnoses. Participants were recruited between May and August 2019 and had to be aged ≥18 years, be able to understand and speak Norwegian, and had to have access to a smartphone or tablet with web access. Exclusion criteria were self-reported untreated severe mental illness, migraine, or cancer-related pain. Potential participants, already enrolled in a PMP treatment program at the physiotherapy institute, were identified based on the inclusion or exclusion criteria and informed about the study by the first author. As the first author was also the psychomotor physiotherapist of the potential participants, recruitment processes were carefully reviewed and discussed by the research team before recruitment to ensure attention to ethical considerations.

The PMP Treatment Program

The PMP treatment program for people with chronic pain aims to facilitate change by raising insight into and awareness about the relationships between experiences and bodily pain [46]. Specifically, the psychomotor physiotherapist in this study worked to help facilitate changes related to bodily tensions, including aiming to strengthen coping mechanisms and reduce tension and pain in muscles, tendons, and joints. This was done by teaching specific movements and exercises and providing massages, all in parallel with seeking to increase patients' knowledge and understanding related to physical reactions and the expression of such.

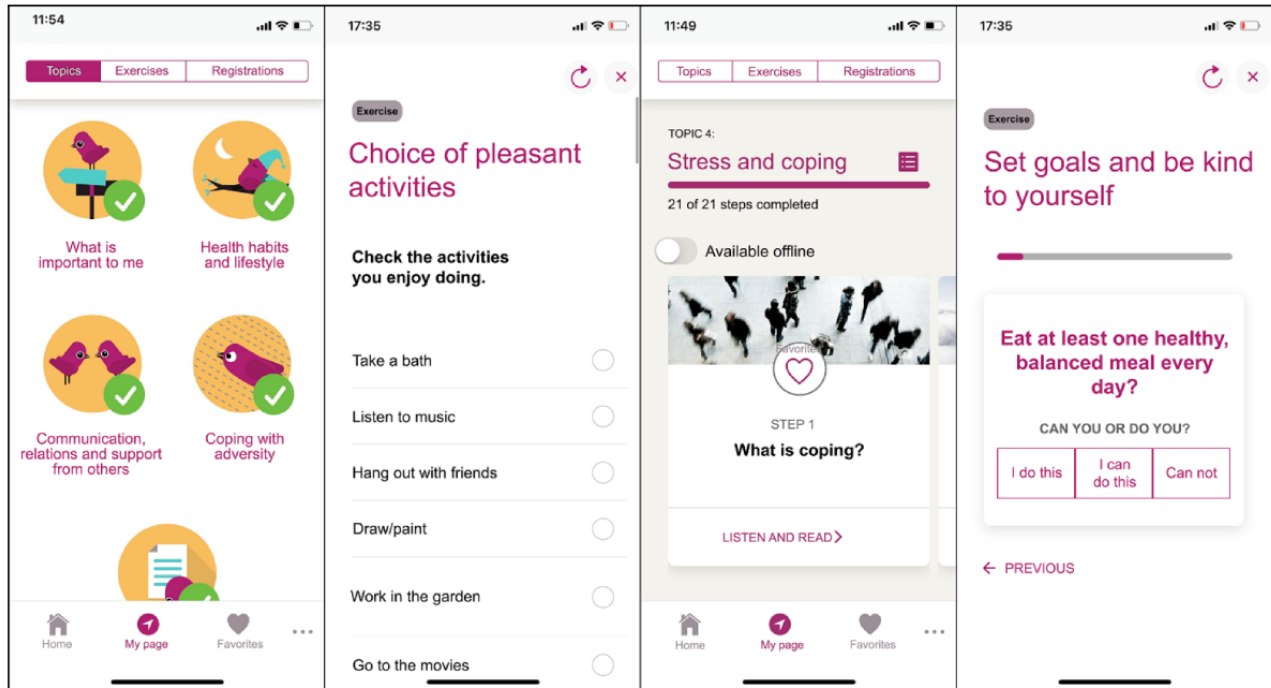
Part of the idea behind PMP is that people, often without real awareness of doing so, may use their posture, respiration, and muscles to *lock* feelings related to situations of conflict. By *pulling themselves together*, they may end up with tight muscles and subsequent related aches and pains [47]. In the PMP treatment program, the goal was to help raise insight into and awareness about these connections and reduce tension and facilitate change and ultimately to better understand potential *mind-body* connections so the patient could recognize their body as *one functional unit*.

The EPIO Intervention Program

EPIO (inspired by the Greek goddess for the soothing of pain, Epione) is an app-based intervention program designed and developed by a collaborative research team consisting of scientists, health care providers, eHealth experts, content and system developers, and end user representatives [44]. The content is based on well-known, evidence-based aspects from CBT and ACT [28,29] and input from patients, spouses [41], and health care providers [42]. The intention of the EPIO program is to support self-management and coping for patients living with chronic pain.

The EPIO program consists of 9 modules with informational and educational topics, including a variety of self-management–based coping techniques, such as breathing and relaxation exercises, cognitive restructuring exercises, and mindfulness-based information and training. The nine modules are (1) information about pain; (2) balance; (3) thoughts and feelings; (4) stress and coping; (5) what is important to me; (6) health behaviors and lifestyle; (7) communication, relation, and social support; (8) coping during difficult times; and (9) summary and the road ahead. Modules 1 to 5 must be opened in the presented order, whereas from 6 to 8, the user can choose what to open next. To encourage practice, each module must be completed and opened for 3 days before the next module can be opened. While working with the program, users can create their own favorite list by highlighting information and exercises they like, and they can also choose to receive reminders according to their own needs. Users can also choose between reading and listening to the program at any time. To ensure availability, the program can also be used in off-line mode. Screenshot examples from the EPIO intervention program are shown in Figure 1. The EPIO program has so far been tested in a feasibility pilot study with 50 participants, where the results showed EPIO to be perceived as useful and easy to use, with easily understandable content and excellent system usability [43].

When enrolled in the study, participants were introduced to the self-management program and received help downloading the EPIO app from App Store (Apple Inc) or Google Play Store, with instructions on how to get started. They were informed that they could use EPIO as much as they wanted in the study period of a maximum of 16 weeks. As such, they had access to a program containing some well-known but also many new exercises and aspects of information that they could use between PMP treatment sessions, potentially bringing new aspects into the treatment. When coming in for PMP treatment, the first part (ie, 5-10 minutes) of the face-to-face session with the psychomotor physiotherapist was spent talking about patients' experiences of using EPIO since the last PMP session. They were given the opportunity to ask questions or introduce topics they had been involved in through EPIO or tell if there was something special that occupied them, thereby delivering EPIO in a blended care type of model.

Figure 1. Example screenshots from the EPIO intervention program.


Data Collection Procedure

Information about age, diagnosis, and years of living with chronic pain was collected using a study-specific demographic form at study enrollment. Semistructured individual interviews were conducted following the completion of all modules in the EPIO program. A study-specific interview guide was developed based on literature examining and describing self-management of chronic pain, digital self-management interventions, and blended care health care delivery [4,24,27,30,35,36,39]. The interview guide contained questions about EPIO use and usefulness, pain impact, coping strategies, and potential experiences of change based on the use of EPIO (the interview guide is given in Multimedia Appendix 1). The questions were developed with the intention of allowing the participants to give a free description of their experiences. The interviews were conducted by the first author at her office from September to December 2019.

Each interview started with an open-ended question about the participant's experience with using EPIO. On the basis of the answers, either new topics were addressed for follow-up or the next topic from the interview guide was introduced. The interviewer did not follow a specific order for the topics to be addressed but rather focused on having a fruitful conversation where topics were introduced and they appeared to fit naturally into the conversation, focusing on topics and hints addressed by the participant to capture issues raised. Furthermore, the interviewer asked clarifying questions to ensure that the essence of what the respondents described was clearly understood. The interviews lasted between 35 and 65 minutes, depending on the richness of the conversation. The interviews were audio recorded and transcribed verbatim, resulting in a total of 60 densely written text pages for analysis.

Data Analysis

The transcripts were analyzed using systematic text condensation in 4 steps [48]. In step 1, the first author read through the transcripts several times while taking notes to get an overview of content and meaning. To strengthen the data analysis process, coauthors DN and CV also read through some of the transcripts to become familiarized with the material and prepare for further team analysis and discussions. In step 2, the first author identified meaningful entities (encoding) in collaboration with coauthors DN and CV and coded the identified material in the transcripts into 4 overarching themes using NVivo software (QSR International). In this process, the authors first identified preliminary themes, which were then discussed and negotiated into a final set of themes. In step 3, the 3 authors performing the analysis created subthemes and abstracted the content of the individual meaningful entities into each subtheme in the condensates. In step 4, the meaning of the condensates was summarized. The themes and subthemes were reviewed and rearranged into a final structure by AGE, DN, and CV. The authors met regularly throughout the analysis process, considering different ways of interpreting the results, and reached consensus through discussions.

Finally, the themes were approved before the authors selected representative quotes to support the analysis. The full transcripts were not translated from Norwegian to English. However, the third author (LSN), who is bilingual (ie, Norwegian or English), was well familiar with the transcripts and ensured that the translation of quotes and other aspects needed for interpretation preserved the original meaning of the transcripts and quotes.

Ethical Aspects

The study was planned and performed in compliance with the principles outlined in the Declaration of Helsinki [49]. The study was approved by the Regional Committee for Medical and Health Research Ethics (REK 2018/8911) and the Oslo

University Hospital Department for Data Protection and Information Security (ie, institutional review board equivalent; PVO 2017/6697). Written informed consent was obtained from all participants.

To ensure anonymity and privacy of the participants, personal data (eg, contact information and date of birth) and signed consent forms were stored on a secure server at Oslo University Hospital, separately from the collected data from the interviews. Each participant was assigned a study identity number, and the codebook connecting this identity number to the participant was stored separately on the secure server. During the audio-to-text transcription process, all names were removed, the data were deidentified, and the analysis was conducted using the deidentified transcribed text only.

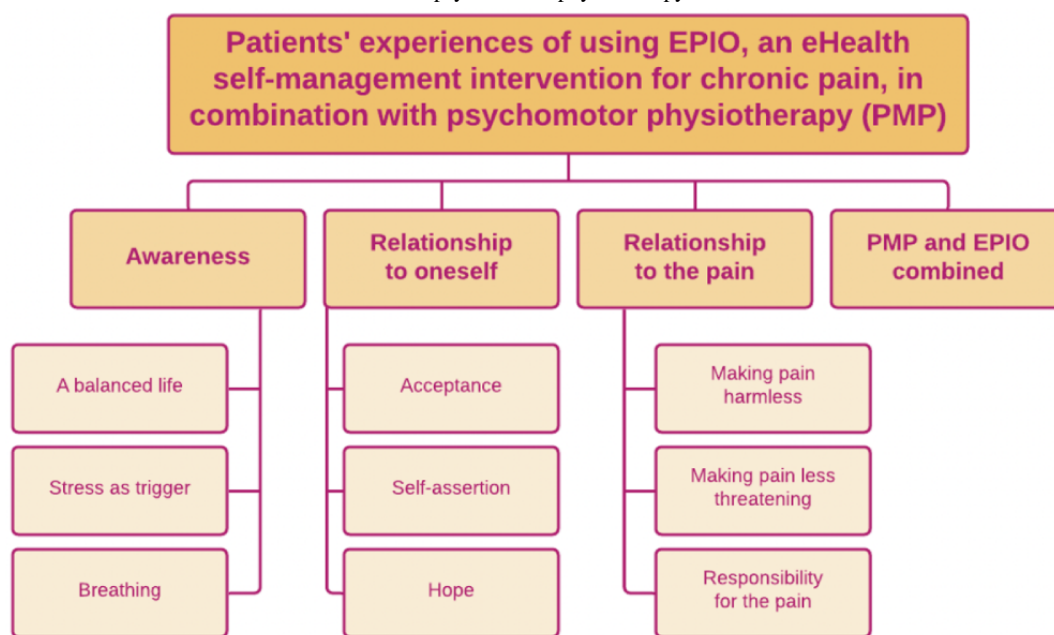
Results

Participant Information

A total of 6 patients were approached and agreed to participate in the study. Of the 6 participants, 1 (16.7%) did not complete the program because of personal life events and was therefore not interviewed after the intervention and 5 (83.3%; 4 women and 1 man) completed the program and participated in the interviews. These participants spent 10 to 15 weeks from the time they received access to the EPIO program until all the 9 modules were completed, and the interviews were conducted. During the same period, the participants had 7 to 13 PMP face-to-face sessions. The patients who completed the program were aged between 30 and 70 years, with an average age of 51 (median 52) years. All patients had lived with pain for more than 3 months, most of them for many years (ie, mean 12.4, range 2-40 years). Diagnoses included pain after trauma or postaccident traumas, neck pain, and diffuse pain in the musculoskeletal system. Other diagnoses included posttraumatic stress disorder, generalized anxiety disorder, and attention-deficit/hyperactivity disorder. All participants reported struggling with the impact of pain on various areas of their daily lives. The familiarity with the use of mobile apps varied from moderate to very experienced, with 4 of the patients completing the program reported having previously used other health-related mobile apps.

Overview

Transcripts from the interviews were classified into four main themes: (1) awareness, (2) relationship to oneself, (3) relationship to pain, and (4) PMP and EPIO combined. The main themes and subthemes are illustrated in Figure 2.

Figure 2. Overview of the main themes and subthemes. PMP: psychomotor physiotherapy.


Awareness

Overview

All participants reported increased awareness about how they lived their lives and how they have become more attentive toward their body after using EPIO combined with PMP. The changes described related to awareness were sorted into three subthemes: a balanced life, stress as a trigger, and breathing. The participants described changes in how they noticed and reacted to signals from their body and described new thoughts about balance in life as a key to being able to live better with pain. All participants also reported increased awareness of the causes of stress and ways to better handle stress.

A Balanced Life

All participants described how EPIO had helped them to consider their own balance of rest and activity, and most of them stated that they, because of EPIO, had become aware of how their activity level was often higher than what they had thought. Some of the participants described becoming aware of a gap between how they wanted, and tried, to live their lives and the extent to which they were actually able to live their lives this way. Explaining how EPIO had helped, one participant stated the following:

I have been 'on' for as long as it is possible to be "on". Until I'm exhausted, and then I am "off". So, to keep it more even during the days, it is easier to remind myself now that I have this more at the forefront of my mind. [Participant 5]

A number of the participants also stated that they had discovered how important it was to take short breaks and be conscious of their level of activity, rest, and sleep. Some reported feeling calmer after using EPIO, and some reported that they used EPIO as a reminder to take breaks and perform EPIO exercises throughout the day. A participant said this about how EPIO gave concrete suggestions to balance activity and rest:

But this was very specific, you know, can you do half the dishes and then rest? I never even thought of it that way. [Participant 4]

Stress as a Trigger

All participants stated that the use of EPIO had made the relationship between stress and pain clearer to them and that they realized they had to do something about the stress and the way they dealt with stress in their lives. A participant said the following:

It was quite early [after being introduced to EPIO], that I had to realize the importance of stress-reducing approaches. [Participant 3]

Participants did, however, present different stories about the causes and nature of their stress reactions. Some described stress at work or at home, whereas others described having been exposed to life trauma causing bodily and psychological stress. Several participants stated that EPIO helped them gain an increased awareness of the origin of their stress responses and had also provided tools for better self-management. A participant stated the following:

To realize that my breathing is connected to stress and traumas and improvement has been surprising. When I get flashbacks [...], this is what happens. My body goes into alert mode. [...] Sometimes it takes time to calm it down, sometimes it goes more quickly. But I HAVE a tool, to get my body out of alert mode. And it is the breathing techniques from the app. [Participant 4]

Participants also described often finding it challenging to make the changes needed to lower their stress levels, stating that taking frequent breaks and doing breathing exercises or actively using approach coping strategies can be easier said than done during demanding or stressful times. A number of them stated that it may take time and effort to start using such strategies frequently and that such suggested changes and approaches may sometimes seem impossible when an actual stressful situation occurs. However, all participants described the face-to-face contact with, and follow-up by, the psychomotor physiotherapist as an advantage when aiming to make the necessary changes. One participant reported realizing their home situation was their main source of stress, with years of *serving* other family members making the participant feel as if having almost *disappeared* as an individual. For the road ahead, the participant shared the following:

Having insight, or taking time for yourself, it's kind of...It hasn't really been there before, and it opens a few doors that can create a bit of a mess around you. Not just for yourself, but for the people around you too [...] Getting insight related to the fact that I do things for others all the time, for everyone else...It can make me irritated, and maybe a little bit angry [...] I haven't been angry for years. Maybe this is a good thing, there is after all a reason for all the tensions. [Participant 3]

The quote illustrates how challenging, and even stressful, it can be for a person to make the necessary suggested changes and how it can also impact people around them and their relationship with them.

Breathing

All participants described experiencing becoming more aware of, and attentive to, their bodies through the use of EPIO. The focus on breathing and diaphragmatic breathing techniques in EPIO was reported to be among the most important parts of the program, with the breathing focus reportedly bringing on reflections about, and experiences of, how deep breathing could help make the mind as well as the body more relaxed. Some of the participants had very specific experiences of how breathing could impact their pain, and one stated the following:

It was shocking to realize how breathing specifically helps with tolerating and coping with pain. I'm thinking, it hurts, I will try using the EPIO app now. Then I do one of the exercises, and I notice, it hurts to breathe, but I can see that...When I do that exercise, and manage to breathe properly, the pain eases...It eases and becomes more tolerable. [Participant 4]

Most participants described finding value in receiving information about the importance of deep breathing, stating that this created a new awareness about their own breathing and tension patterns. They also emphasized the importance of being guided through breathing and relaxation exercises by the EPIO voice, to feel the difference guidance could make, and the importance of being encouraged to repeat the exercises on their own over a period. With this new awareness related to the role of breathing, participants described the EPIO exercises as helpful in breaking old patterns. A participant stated the following:

My body can find relaxation without me forcing it to. I don't have to force my shoulders to relax in order to breathe. I can just think about it, and balance occurs. It has strengthened my belief, or convinced me, that things are connected. There is no doubt. Our mind controls a lot of what we do, whether we are aware of it or not. The fact that you can actually lead yourself out of what has just occurred - without even really being aware. [Participant 1]

Relationship to Oneself

The participants reported that EPIO had contributed to changes in how they related to themselves, with some of them even referring to EPIO as a program for self-management of life in general, sometimes even forgetting that the program was about pain and pain management. The changes described as

experienced by the participants were sorted into three subthemes: acceptance, self-assertion, and hope.

Acceptance

Some participants described that EPIO had helped them gain greater self-acceptance, stating that they now felt more confident, with a stronger belief in themselves, realizing that they were not *a bad person*, even if the pain kept them from doing and managing things the way they had previously been able to. A participant stated the following:

> *Some of the things I have learned using EPIO have made it easier for me to accept life the way it is. And to understand it, and not beat myself up about it.* [Participant 1]

In addition, some of the participants found it important to consider the qualities and skills they still had, what they wished for in life, and what they appreciated in the people they were close to. A participant said the following:

> *And, I think, it's not like I have to reinvent myself. [...] No, I AM there! [...] So the value, my personality, is not gone. The skills are there, but I cannot do as much as I did before.* [Participant 4]

Self-assertion

Several of the participants described feeling empowered by some of the content in the EPIO program, stating that EPIO encouraged them to assert themselves. Some of the participants described finding time to do what was important and right for themselves as challenging and unfamiliar, stating that prioritizing themselves and asking for help appeared unfamiliar and had not had precedence in their lives. A participant said the following:

> *I am the person helping others. No one thinks I should need help. So I really have myself to thank for that. People do not come and ask.* [Participant 5]

However, some of the participants described appreciating being reminded of the importance of taking time for themselves, prioritizing their own health, wishes, and needs. A participant even related his or her pain to the lack of prioritizing themselves and stated the following:

> *The pain in my muscles, it can of course come from the fact that I live to help others all the time, and forget to help myself in a way. And that's in this program. Help with self-management.* [Participant 3]

Hope

Some of the participants also reported having obtained new hope in life from the use of EPIO in combination with PMP. They described having gained hope of being able to manage life in a new and different way, including hope of being able to live a more balanced life, to know and actively use coping strategies in day-to-day life, and through that being able to live life, even with pain—in a more fulfilling and *normal* way. They described being able to have a tool such as EPIO, accessible anywhere and anytime, as providing them hope for better quality of life and a better future ahead. A participant described the link between EPIO and new hope this way:

> *This program has given me hope that I can continue to work on this. I will have a life with quality, I will have a life I can manage. I will live a life I don't have to be ashamed of. I will be a complete person, but I will do things a little differently, and at a different pace.* [Participant 4]

Relationship to the Pain

The participants described a number of ways that EPIO had contributed to changes in how they related to their pain. Descriptions of such changes related to experiences that EPIO had contributed to making the pain less threatening, encouraged and stimulated the participants to use distractions from the pain, and changed their view of their own responsibility in terms of managing the pain.

Making Pain Less Threatening

Most participants reported that they, after starting to use the EPIO program, had experienced less pain-related anxiety and described EPIO as helpful in making the pain seem less threatening in their day-to-day life. To some extent, it had been important to gain new insights into physiological explanations and pain coping techniques. They stated that the information and knowledge gained through EPIO made it easier to relate to potential causes of pain and understand the relationships between pain, thoughts, and feelings and that the information gained through EPIO made it easier to believe that the pain might not necessarily be dangerous. Learning new coping strategies also appeared to have contributed to making the pain seem less threatening, as expressed by a participant:

> *I can cope better with my pain if I know I have techniques I can use during the day to make it a little less tense and painful. Yes, the pain is still there, but...It does not get as much attention.* [Participant 2]

Distraction From the Pain

The EPIO program contains a number of coping strategies and exercises related to distraction from the pain, and all participants in the study described learning and using these techniques, aiming to distract and remove the focus from pain, as helpful. Some of the participants even explained that because of deliberately using these distraction techniques, they now had periods where the pain appeared to absorb less of their day-to-day attention. Others stated that the pain was still present but that it might be less dominating. One of the participants described the increased ability to distract themselves from the pain as follows:

> *Just to be able to move away from focusing on the pain. That things in my body are not as they should, to just focus on something else for a while. A break. [...] To just notice what happens around you. Not just inside you. Focus on that.* [Participant 2]

Responsibility for the Pain

After using EPIO, several participants stated that discovering strategies to influence and cope with their pain had made them realize that they have a greater responsibility of managing their own pain than what they had previously thought. They all stated

that they actively had to handle the pain and described how they could see more clearly how their pain related to the way they lived their lives, including impact on stress factors, relationships, breathing habits, and bodily tensions. However, most participants stated that making the necessary changes in life would be energy consuming and that establishing lasting changes would require motivation and energy. One participant described making significant changes as "impossible" because of the situation at home. Another participant described the significant work required to obtain the effect as follows:

> Pain is something I have to relate to in one way or another. How I think is very important, and I have to think that I can handle things in a different way. Quick fix, that is what you want [...] And this is the opposite, in a way. You have to really delve into it, absorb it, and let it have consequences for your body. [Participant 1]

However, the same participant added a contrary reflection, noting the possibility that EPIO could potentially produce guilt and feelings of resignation should the user do everything to integrate what they had learned while using the app, without experiencing improvements in pain levels:

> I have felt it myself and, well now I have felt better, and it may be because I have done all the right things. And if you're then suddenly in pain, then it may feel like it's your own fault. [Participant 1]

PMP and EPIO Combined

All participants in this study reported experiencing EPIO and PMP as complementary and stated that they found it easier to perform exercises and focus on pain management strategies while using EPIO in combination with PMP treatment. All participants described EPIO as a reinforcing tool for their pain self-management, bringing new aspects and themes to their PMP treatment, and reported finding it easier to work on their own, in between PMP treatment sessions, with EPIO at hand. They described EPIO as an enforcer, making it easier to integrate the necessary pain self-management into daily life. One of the participants said the following:

> I think this [EPIO] is a very useful tool to use in parallel [with PMP], and the patient can work in between. I think it could help many to integrate it into day-to-day life. [Participant 2]

Several participants also pointed to the combination of self-management through EPIO and face-to-face or physical touch provided by PMP as an important part of the process of raising mental and physical awareness. All participants described the massage techniques learned from PMP as having helped them become more aware of tension in their muscles, making it easier to achieve relaxation. One of the participants, having experienced significant traumas in life, also stated that the combination of PMP and EPIO helped involve the body as well as the mind in the process of treatment and healing.

During the interviews, participants frequently mentioned how making changes can be difficult and sometimes even frightening. As such, having a combination of in-person or EPIO treatment available was seen as a strength, enabling learning at the participants' own pace but with the safety of in-person discussions and guidance when needed. A participant stated the following:

> I think you need a combination. And some time. Because this is something you can choose not to do. With everything else going on in life. It's easier to just sit down and read the paper. And if you are in great pain, you don't have that much to go on. [Participant 5]

As EPIO was described as comprehensive, all participants stated that it was helpful to work together with the psychomotor physiotherapist to work through potential issues that occurred and sort out what was the most important aspect to focus on between each consultation. Several patients also stated that EPIO had started a process in which they had to actively keep working. They all said that they thought EPIO alone would have brought new experiences also without PMP but that the combination strengthened the impact.

Discussion

Principal Findings

This study explored patients' experiences of using the app-based intervention EPIO in combination with PMP for self-management of chronic pain. The study participants described experiencing EPIO as bringing well-known as well as new themes into the treatment and as supporting self-management between face-to-face sessions. Following the combined EPIO and PMP program, participants described increased awareness of a number of issues, including the importance of balancing rest and activity, the relationship between stress and pain, and the importance of being aware of signals from their bodies. They also reported that EPIO had contributed to changes in their relation to themselves, including increased self-acceptance and self-assertion, willingness to prioritize themselves, and increased hope for a better life. Participants' relationship with the pain itself was also reported to have changed when using EPIO in combination with PMP, including experiencing pain as less threatening, benefiting from the use of distractions, and taking more responsibility for self-management of the pain.

Comparison With Previous Work

Findings show that the participants experienced living and coping with pain as complex—involving challenges related to many aspects of life, including stress. Some researchers have suggested a link between stress and hypersensitivity to pain [50,51], and in accordance with existing research [52], participants in this study described how pain was triggered and reinforced by psychosocial stressors. The introduction of EPIO into PMP treatment led to positive changes in how the participants perceived their pain and approached their daily lives. In line with studies showing the interrelation between stress, pain, and coping [51,52], participants described becoming more aware of causes of stress in their daily lives, and how stress affected them and triggered their pain. Through the blended treatment of EPIO and PMP, most participants reported

having found new strategies to deal with life stress and better manage their pain.

The participants described psychosocial stressors related to social relationship challenges, feelings of guilt, difficulties meeting the many demands of daily life, and a general feeling of not being enough and constantly falling short of demands and expectations. Research has suggested that people living with chronic pain may benefit from treatment approaches aimed at reducing feelings of guilt, finding ways to cope with the many demands, and increasing levels of confidence [53]. Participants in this study reported becoming more self-accepting, assertive, and confident and feeling less shameful and vulnerable, which may therefore be of importance in this setting.

The interrelationship between fear, anxiety, and pain is commonly reported among patients with chronic pain, and scholars emphasize the importance of addressing these aspects in treatment [54,55]. In this study, participants reported having become less fearful and anxious about their pain following the blended EPIO and PMP treatment, attributing the changes to the general information about pain and tools for better coping provided by EPIO.

Following the blended EPIO and PMP treatment, participants in this study described having become more aware of breathing in general and the importance of deep breathing in particular. The importance of breathing is a core part of PMP treatment and had already been introduced to participants before the study. Still, some exercises in the EPIO program reportedly provided new experiences regarding the relationship between deep breathing and pain management, apparently raising new awareness of these relationships, and some of the participants reported experiencing reduced levels of stress and pain because of practicing breathing technique exercises. As deep, diaphragmatic breathing can impact breathing frequency (ie, slowing), these findings can also support the notion that associations exist between breathing frequency and pain [56].

Participants described a new awareness of the relationship between rest and activity. Some reported realizing that their activity level had reached beyond their capacity, and that this had been the case for quite some time. These participants described it as difficult to take breaks during the day and ask for assistance. Their observation of the importance of a better balance between rest and activity corresponds well with research reporting that imbalance can lead to reduced pain tolerance and decreased quality of life [57,58].

Self-management tools such as EPIO generally aim to help patients take an active role in managing their pain and day-to-day life. Self-efficacy is often seen as a determinant for keeping up efforts and not giving in when faced with obstructions [59], and findings from this study may indicate an increased sense of self-efficacy among participants posttreatment, in terms of a strengthened belief in being able to live a life less impacted by pain. A strengthened sense of self-efficacy may also have helped them make the necessary changes in life to achieve better coping.

Self-management can be demanding, entailing taking responsibility to *manage* one's own life, maintaining good

habits, and making changes when needed. To make the necessary changes requires energy and motivation, of which the patient may already be drained or depleted because of the many demands involved in living with chronic pain [1,12,60]. Although participants reported gaining new awareness and knowledge related to pain and self-management of pain from the EPIO program, they all underlined the demands and costs of being the agent of self-management and change in this way. EPIO was not considered *a quick fix* either, as the program requires users to be active and engaged throughout. Self-management programs such as EPIO may help users discover what they can or need to do to better live *with* pain. However, if unable to undertake the necessary steps toward better self-management, knowing that life could be better *if only* changes are made may possibly also produce feelings of guilt and shame, making life even worse. This implies responsibility and developers and/or providers of such self-management programs should be aware of the potential ethical implications of creating and recommending such independent self-management programs, regardless of potential benefits and intent. Participants in this study described appreciating the combination of EPIO and PMP in their treatment, and it could be that self-management programs such as EPIO could best be recommended in combination with existing care and in-person follow-up, as also supported by the participants in this study. However, several participants reported having gained increased awareness of their own responsibility for self-management in this study, which they were also willing to take. It is possible that, despite the demanding aspects of self-management, the CBT and ACT basis of EPIO may have helped the participants achieve a changed relation to their pain, pointing them toward a greater acceptance of living with pain and an enhanced knowledge of what could be done.

The use of blended care, here referred to as combining in-person and eHealth programs, may have a positive impact as patients may benefit from the best of 2 or more treatment approaches [38,39]. Having EPIO as a tool to work with between PMP sessions appeared to help the participants in this study, and this type of blended care may be suitable for stress- and pain-related self-management and coping, as indicated in this study.

With more than one treatment option available (eg, PMP and EPIO), patients can have the option to decide for themselves how to meet their treatment needs, for example, from their psychomotor physiotherapist or from a program such as EPIO or both. In line with previous research, the results from this study indicate that many prefer to go through the eHealth program at their chosen pace [61], without a health care provider or coach and guide trying to impact their progress. Furthermore, compared with in-person interventions, eHealth interventions can be experienced as a more neutral and nonjudgmental form of delivery, eliminating the fear of being judged or misunderstood by a provider [61]. This corresponds with participants' description of finding it easier to go through the contents of EPIO on their own, without necessarily discussing everything with the psychomotor physiotherapist. At the same time, some of the participants brought relevant topics from their EPIO use into psychomotor therapy; topics they may not have discovered had the information been less comprehensive.

Another important reason for combining EPIO and PMP is the notion that the patient–provider relationship can affect patient outcomes. A strong therapeutic alliance between the patient and health care provider can potentially predict positive treatment outcomes [62,63]. In addition, speaking to another person can be helpful. Simultaneously, if the therapeutic alliance is weak, the treatment process may become more difficult. In such cases, an option such as EPIO can be particularly useful. eHealth can likely not replace the relational processes involved in in-person treatment. However, eHealth interventions can offer support when in-person treatment is not available, and at the very least, eHealth can be offered as a supplement to in-person treatment and care, as in this study. Through EPIO, the participants in this study received a CBT and ACT approach beyond PMP regular competence, describing the information and content in EPIO as meaningful and complementary to PMP treatment.

Strengths and Limitations

This study has a number of limitations. First, the study was conducted at a single physiotherapy institute and included a limited number of participants. However, although the sample was small, the data material represented richness and depth about how the participants experienced using EPIO in combination with PMP, and statements from one participant could be as important as statements of most participants. Given the small predefined number of participants in the study, all participants were identified and selected by the psychomotor physiotherapist to ensure that the participants could use EPIO in the study period and be able to attend a postintervention interview. This could have introduced a selection bias and as such be considered a limitation, but it also ensured professional soundness (ie, able to attend the study). Although conducted with a limited number of participants, the interviews conducted in this study provided insight into a variety of patient experiences and allowed sufficient depth in the analyses, which can be considered a strength.

Second, 80% (4/5) women and 20% (1/5) men participated in this study. The results of the study might have been different if more men had participated. For example, men might bring different experiences of using EPIO in combination with PMP. However, the gender distribution in the study represents the general gender distribution among patients receiving PMP, and additional men were not available for inclusion at the time the study was conducted. This is also in line with the first author's experience from clinical practice, with approximately 1 man per 12 to 15 women enrolled to receive PMP. In addition, given the range related to age, years living with pain and other diagnoses, and most women living with chronic pain, the study can be considered representative of patients living with chronic pain. In addition, with the rich data material collected during and following study participation, even a small number of participants allows for in-depth insight related to participants' experiences using EPIO in combination with PMP.

As 80% (4/5) participants in the study had previously used health-related mobile apps, a certain bias related to previous eHealth experience could be present in the current findings. Such experiences could impact participants' opinions and views, and perceived benefits and findings might have looked different if the sample included a more balanced sample of experienced or inexperienced users. Experience in using digital tools could, however, impact findings positively (eg, have enjoyed using mobile apps) and negatively (eg, did not like using mobile apps), and the outcome of having a more balanced sample may therefore be challenging to predict.

Participants were also identified and selected by the first author and were already enrolled in the first author's PMP treatment program. This may have implied a selection bias but may also have ensured professional soundness (ie, patients who were able to complete the EPIO program). To ensure that patients did not feel coerced to participate in the study, they received oral and written information stating that study participation was voluntary; nonparticipation would have no consequences for their ongoing PMP treatment; and they, should they decide to participate, could withdraw from the study at any time without having to give a reason. Patients received information about the study in one PMP session and could then wait until a later time point (ie, time to reflect) to decide whether to participate and give their written consent. To limit the risk that participants provided more positive than negative feedback because of their relationship with the psychomotor physiotherapist, the participants were informed that study results would not affect the psychomotor physiotherapist, the ownership of EPIO was elsewhere, and the psychomotor physiotherapist did not receive any benefits or have any negative consequences, regardless of the study findings. Before the study interviews, participants were also informed that to truly evaluate the program, their honest feedback on EPIO, and about using EPIO in combination with PMP, was needed.

Throughout the study process, the authors adopted a reflexive approach to the dual role of the researcher or psychomotor physiotherapist. This was a point of discussion in all research meetings throughout the process and was also addressed by closely involving two of the coauthors in the data analysis process.

Third, the first author's professional background as a psychomotor physiotherapist could have influenced the process (ie, from interviews to manuscript write-up) through preconceptions drawing attention to certain aspects of information. The involvement of 2 coresearchers during analysis was, however, actively used to counter such threats to the trustworthiness of the findings [64].

Finally, the results showed that living with pain is overly complex, and a small qualitative study such as this cannot provide information about what contributed the most to participants' experienced benefits of using EPIO or the combination of EPIO and PMP. As such, factors unrelated to the EPIO tool may have contributed, including regular follow-up by a health care provider and the ability to talk about EPIO at every consultation. The close follow-up may also have contributed to the participants making a greater effort with EPIO than those who did not have the blended care type follow-up. The qualitative in-depth insight provided, even with a small sample, is a major strength of this study.

RenderX

Conclusions

This study offers insight into chronic pain patients' experiences with the use of EPIO, an app-based intervention for the self-management of chronic pain, in combination with PMP. Findings indicate that EPIO, used in this blended care context, was experienced as beneficial in raising awareness and finding a better balance between rest and activity; feeling more valuable as a person; and increasing self-acceptance, self-assertion, and hope and in relation to the participants' pain—seeing pain as less harmful and engaging in more active stress management and coping strategies. In conclusion, this study indicates that a blended care approach combining eHealth self-management interventions such as EPIO with PMP may be of value to patients living with chronic pain.

Abstract

Background: Latinx gay, bisexual, and other sexual minority men are disproportionately affected by HIV in the United States. As Latinx sexual minority men, particularly those who are foreign-born, experience inequitable access to health services, tailored strategies to engage them for HIV prevention are urgently needed.

Objective: Our study seeks to address the need for enhanced access to HIV prevention among Latinx immigrant sexual minority men. We developed and piloted a culturally sensitive technology-based campaign focused on HIV testing and pre-exposure prophylaxis (PrEP) uptake.

Methods: We used a two-phase approach to assess the feasibility of community-informed social media content in engaging Latinx immigrant sexual minority men for HIV testing and PrEP use. First, we conducted three iterative focus groups with 15 Latinx immigrant sexual minority men to refine the HIV prevention content to be piloted on social media platforms. The finalized content was placed on Instagram and Facebook for 9 days in July and September 2021 to individuals who were in Washington State. Individuals who clicked on the content were directed to a website with additional HIV prevention information. Second, we conducted online surveys (n=60) with website visitors that assessed sociodemographic characteristics, barriers to HIV prevention, and HIV-related transmission risk and prevention behaviors. We conducted descriptive analyses to examine the overall profile of survey respondents and determine the feasibility of culturally informed social media content in reaching Latinx immigrant sexual minority men.

Results: Overall, 739 unique users visited the website during the 9-day period when the social media content was posted on Instagram and Facebook. Our sample included 60 Latinx immigrant sexual minority men who completed the online survey. Participants' mean age was 30.8 years and more than half (n=34, 57%) completed the survey in Spanish. A quarter of participants indicated that they were unauthorized immigrants and 57% (n=34) reported not having medical insurance. Participants reported, on average, having 6 different sexual partners in the last 6 months. Nearly a third of respondents had not tested for HIV in the last 6 months. Only about half (n=32, 53%) of respondents had used PrEP in the last 12 months.

Conclusions: Community-driven social media and web-based strategies are feasible ways to engage Latinx immigrant sexual minority men who may traditionally lack access to HIV prevention information and services due to structural and social barriers. The results highlight that culturally relevant social media and web-based outreach strategies that are informed and developed by the community can reach Latinx immigrant sexual minority men for HIV prevention. Findings underscore the need to examine the effectiveness of social media content in promoting HIV testing and PrEP uptake in marginalized Latinx populations.

Introduction

Despite significant progress in reducing the number of new HIV infections, there were more than 36,000 new HIV diagnoses in the United States and dependent areas in 2019 [1]. The vast majority of these new diagnoses occurred in gay, bisexual, and other sexual minority men, with Latinx sexual minority men accounting for nearly a quarter of all new HIV infections [1]. Latinx sexual minority men encounter significant social and structural challenges to seeking and receiving appropriate HIV prevention services [2,3]. Specifically, factors such as language barriers, immigration status, education level, and discrimination may be linked to lower uptake of HIV prevention strategies such as HIV testing and pre-exposure prophylaxis (PrEP) use in Latinx immigrant sexual minority men [2,3]. Further, with the unprecedented disruptions related to the COVID-19 pandemic, Latinx immigrant sexual minority men may be less likely to seek in-person care and information for nonurgent conditions, potentially delaying HIV testing and PrEP use. Hence, while effective strategies for HIV prevention and treatment are available, increased efforts to enhance their access and use among Latinx immigrant sexual minority men are urgently needed.

The use of eHealth and related technology has the potential to improve the reach and implementation of HIV prevention strategies for marginalized populations such as Latinx immigrant sexual minority men [4,5]. HIV prevention information delivered via online and social media platforms may offer greater privacy and confidentiality, which may increase the acceptability of accessing HIV prevention resources [5]. eHealth tools have also served as a useful mechanism to deliver information and health services when in-person activities are limited or unavailable due to public health concerns such as COVID-19 [6]. Further, the wide use and availability of the internet and social media applications have made eHealth HIV prevention approaches increasingly accessible for hard-to-reach populations [7,8]. For Latinx immigrant sexual minority men who may be reluctant about seeking health services due to stigma or fear, eHealth may address barriers and support engagement with HIV prevention resources. Yet, despite the growing number of eHealth HIV prevention interventions, there has been limited attention to the acceptability of using eHealth strategies with Latinx immigrant sexual minority men [9,10].

To address the need to tailor HIV prevention programs for specific groups, we sought to enhance understanding of the specific preferences and acceptability of using eHealth strategies for HIV prevention among Latinx immigrant sexual minority men. We conducted an initial qualitative study to examine how to appropriately use social media platforms to recruit and engage Latinx immigrant sexual minority men for HIV testing and PrEP uptake [11]. We also assessed how specific content delivered on social media platforms can address barriers to HIV testing and PrEP in this population. The findings of this study indicated that Latinx immigrant sexual minority men were enthusiastic about receiving HIV prevention information via social media platforms. Participants offered specific suggestions and preferences regarding how social media content should be developed and emphasized that messaging be inclusive, motivational, and positive [11].

Based on the results of this initial study, which are published elsewhere [11], we developed content to be piloted on social media platforms to engage Latinx immigrant sexual minority men for HIV testing and PrEP uptake. This study examines the feasibility of using the culturally tailored content on social media platforms to reach Latinx immigrant sexual minority men for HIV prevention.

Methods

Overview

This feasibility study used a community-based participatory approach and was conducted in Seattle, Washington in partnership with a local community-based organization that serves the lesbian, gay, bisexual, transgender, and queer (LGBTQ+) Latinx community. The first phase of the study involved three focus groups that were developed to finalize the social media content for the study. During the study's second phase, the finalized content was piloted on social media platforms, and a web-based survey was conducted to assess whether the social media content was successful in reaching Latinx immigrant sexual minority men for HIV testing and PrEP uptake.

Focus Groups

We developed five initial designs of the culturally tailored HIV prevention content to be piloted on social media platforms based on the preferences identified from Latinx immigrant sexual minority men. We conducted three iterative focus groups with 15 Latinx immigrant sexual minority men to further revise the initial designs according to participants' preferences. During each focus group, participants offered suggestions to edit the content and ensure the cultural sensitivity of the designs. Participants also discussed the rationale behind their suggested changes. We finalized the designs to be piloted on social media platforms after the third and final focus group.

Pilot Testing of the Social Media Content for Latinx Immigrant Sexual Minority Men

The social media content was piloted on social media sites in July 2021. Specifically, the content was placed on Facebook and Instagram over a 9-day period. The content was available to individuals who were on Instagram or Facebook in Washington State. Individuals who clicked on the content were directed to a website that offered additional information on HIV testing and PrEP. Specifically, the website was developed with support from the study's community partner and offered

localized and culturally relevant HIV prevention information in Spanish. Information about how and why to get tested for HIV and use PrEP were included. Additionally, contact information to make an appointment to test for HIV or learn more about PrEP were also available on the website. We conducted an online survey with 60 website visitors to assess whether the social media content was a feasible strategy for reaching Latinx immigrant sexual minority men for HIV prevention. To be eligible to complete the survey, individuals had to meet the following inclusion criteria: be 18 years or older, identify as Hispanic or Latino/a/x, male sex at birth, born outside of the continental United States, and report sex with men. All individuals consented to participate prior to completing the survey. Surveys were completed in Spanish or English based on the participant's preference.

Measures

Surveys were available in Spanish or English and assessed sociodemographic characteristics, barriers to HIV prevention, and HIV risk and prevention behaviors. Barriers to HIV prevention included not having health insurance and sexual orientation disclosure (whether or not individuals disclosed their sexual orientation to friends who are heterosexual, family members, employers or teachers, and health care providers). We also assessed participants' perceptions of their community's tolerance toward individuals who identify as LGBTQ+ (1 strongly disagree, 2 disagree, 3 neither agree nor disagree, 4 agree, 5 strongly agree). Surveys also measured the extent to which participants experienced distress related to COVID-19 (1 no distress, 10 extreme distress). HIV transmission risk behaviors were assessed by the number of sexual partners in the last 6 months, drug or alcohol use before last sex, and condomless anal sex at last sex. HIV prevention behaviors included ever testing for HIV, testing for HIV in the last 6 months, PrEP awareness, and PrEP use in the last 12 months. Descriptive analyses were used to examine the overall profile of website visitors and to determine the feasibility of using community-informed social media content to reach Latinx immigrant sexual minority men in need of HIV testing and PrEP who encounter barriers to HIV prevention.

Ethics Consideration

The authors obtained informed consent from all study participants prior to their participation in the focus groups or web-based surveys. All study procedures were reviewed by the University of Washington Human Subjects Division and qualified for exempt status from federal human subjects regulations.

Results

Focus Groups

The focus groups provided feedback on the language, imagery, and overall designs of the community-informed social media content. The initial versions of the content were revised in the following ways based on focus group feedback: photographs were changed to depict more realistic images of Latinx sexual minority men, additional colors and illustrations were integrated to highlight the empowering aspects of HIV prevention, and designs that were text-focused were included to provide more discreet ways to engage with the content. The finalized content is presented in Figures 1-5.

Figure 1. Culturally tailored social media content for HIV prevention in Latinx immigrant sexual minority men: Be your hero.

Figure 2. Culturally tailored social media content for HIV prevention in Latinx immigrant sexual minority men: Illustrated men. PrEP: pre-exposure prophylaxis.

Figure 3. Culturally tailored social media content for HIV prevention in Latinx immigrant sexual minority men: Favorite sexual position. PrEP: pre-exposure prophylaxis.
Figure 4. Culturally tailored social media content for HIV prevention in Latinx immigrant sexual minority men: For love. PrEP: pre-exposure prophylaxis.

Figure 5. Culturally tailored social media content for HIV prevention in Latinx immigrant sexual minority men: Emojis. PrEP: pre-exposure prophylaxis.

Figure 1 states "Take charge of your life with PrEP" and "Be your hero" in Spanish, and presents a multimedia image of a man in the sky. Figure 2 presents an illustrated image of two men and a symbol of PrEP. Figure 3 is text-focused and states, "My favorite sexual position is the one that's safest" in Spanish with the hashtag "#PrEPWorks." Figure 4 includes an image of two men with the words "For love," "For me," "For him," in Spanish and "PrEP pill." Figure 5 states, "It's okay to play with your food" in Spanish and uses emojis and illustrations to demonstrate that sex with condoms and with PrEP is the "safest sex." These five designs reflect community priorities, preferences, and needs to receiving information and services related to HIV prevention. For example, the use of "Spanglish" or both English and Spanish in the designs was encouraged as it highlights that many Latinx immigrant sexual minority men speak both Spanish and English. Additionally, participants noted that the use of humor and cheeky language and imagery were an important way to catch their attention. Overall, the content relays the positive and motivational messages sought by focus group participants.

Characteristics of Feasibility Study Survey Respondents

There were 739 unique users who visited the website after clicking the pilot social media content on Facebook or Instagram over the 9-day period. Among the 60 Latinx immigrant sexual minority men who completed the online survey, slightly more than half (n=34, 57%) completed the survey in Spanish. Respondents' sociodemographic characteristics are presented in Table 1.

The mean age was 31 years, and the average length of time residing in the United States was 14 years. About half of the respondents (n=32, 53%) were born in Mexico and 20% (n=12) reported having less than a high school level education. More than half of the participants (n=35, 58%) reported their religion as Catholic or Christian. A quarter of participants were unauthorized immigrants, while 17% (n=10) were legal permanent residents (Table 1).

Table 1. Characteristics of 60 Latinx immigrant sexual minority men who were reached by the culturally informed pilot social media content.

	Participants, n (%)
Age (years), mean (SD)	30.8 (8.2)
Country of origin, n (%)	
Mexico	32 (53)
El Salvador	6 (10)
Honduras	4 (7)
Cuba	4 (7)
Puerto Rico	4 (7)
Other[a]	10 (17)
Length of time in United States (years), mean (SD)	13.9 (8.5)
Education, n (%)	
Less than high school	12 (20)
High school or GED[b]	14 (23)
Some college	13 (22)
Bachelor's degree or higher	21 (35)
Employment status, n (%)

Immigration status, n (%)	
Legal permanent resident	10 (17)
Naturalized citizen	8 (13)
Unauthorized immigrant	15 (25)
Eligible immigrant	24 (40)
Temporary resident or other	3 (5)

[a]Other included Argentina, Brazil, Panama, Guatemala, Colombia, Ecuador, and Peru.

[b]GED: General Educational Development.

[c]Other included: Nondenominational or independent, spiritual but not religious, and other.

Barriers to HIV Prevention

Select barriers to HIV prevention are presented in Table 2.

Approximately 42% (n=25) of respondents indicated that they did not have health insurance. While the majority (n=53, 88%) of participants reported disclosing their sexual orientation to their health care providers, less than three-fourths had disclosed their sexual orientation to friends who are heterosexual or to family members. About half (n=31, 52%) of respondents had disclosed their sexual orientation to employers or teachers. Participants reported an average rating of 3.5 (range 1-5) in community tolerance toward LGBTQ+ individuals. On a scale of 1 to 10 with "1" being no distress and "10" being extreme distress, respondents reported experiencing an average level of 5.0 in COVID-19–related distress.

[b]Data presented indicates respondents who disclosed.

[c]Data presented indicates respondents who reported "Yes" to the question.

[d]PrEP: pre-exposure prophylaxis.

HIV Transmission Risk and Prevention Behaviors

Table 2 also presents respondents' HIV transmission risk and prevention behaviors. Respondents reported an average of 6.2 sexual partners in the last 6 months and 30% (n=18) indicated using alcohol or drugs during last sex. While the majority (n=48, 80%) of participants had ever tested for HIV, 70% (n=42) had tested for HIV in the last 6 months. Less than half (n=28, 47%) of all respondents were currently using PrEP (Table 2).

Discussion

Primary Findings

Our results demonstrate that the pilot social media content reached a diverse sample of Latinx immigrant sexual minority men. Specifically, we engaged Latinx immigrant sexual minority men who were undocumented, had low levels of education, and were unemployed. While these factors often present challenges to accessing HIV prevention services [3,12,13], culturally tailored social media outreach strategies may provide unique opportunities to obtain HIV prevention information and resources that are traditionally out of reach for these communities. Further, more than half of respondents identified as Catholic or Protestant/Christian, which suggests that our social media content was a feasible approach to engaging Latinx sexual minority men who are members of religious organizations. Prior research has documented that Latinx sexual minority men who are religiously affiliated may experience greater internalized homophobia, which can have detrimental effects on HIV prevention and overall health [14]. While additional studies are needed to better understand the role of religion on HIV prevention in Latinx sexual minority men [15], culturally tailored HIV prevention content delivered via social media applications may provide a potential way to engage religious Latinx communities who may be deterred to access such information due to perceptions of internalized or societal stigma.

Our pilot content was also successful in reaching Latinx immigrant sexual minority men who reported several barriers to HIV prevention, including being uninsured. Not having health insurance can lead to missed opportunities for HIV testing and limit access to preventive health services [16]. As Latinxs have the highest uninsured rate of any racial or ethnic group in the United States [17], eHealth may be a valuable tool for reaching individuals who experience systemic health inequities. eHealth may also be a feasible HIV prevention strategy among Latinx immigrant sexual minority men in diverse contexts. Despite overwhelming challenges due to the COVID-19 pandemic, Latinx immigrant sexual minority men who reported experiencing distress related to COVID-19 engaged with the tailored HIV prevention social media content. Additionally, many respondents reported feeling that their communities were somewhat intolerant of individuals who identify as LGBTQ+.

As sexual minority men who face intolerance and discrimination may be less likely to use HIV prevention services, prevention services and information available through social media platforms may facilitate use among Latinx immigrant sexual minority men by creating a more acceptable environment in which to engage.

Further, a sizeable percent of respondents noted that they had not disclosed their sexual orientation to others, suggesting that many Latinx immigrant sexual minority men who were reached by the social media content may have concerns about prejudice and discrimination in their various social networks. Social media platforms and other eHealth tools can offer methods that may be more acceptable for individuals who seek to conceal their sexual orientation from specific groups and desire a discreet way to obtain HIV prevention services. Taken together, the tailored social media content was a feasible way to reach Latinx immigrant sexual minority men for HIV prevention given that its format and delivery method may overcome prior barriers to using services.

Notably, a considerable percentage of the Latinx immigrant sexual minority men reported engaging in sexual risk behaviors, including having multiple sexual partners, having condomless anal sex, and using drugs or alcohol before sex. Our results also demonstrated gaps in HIV prevention with nearly a third of respondents not having tested for HIV in the last 6 months and more than half not currently using PrEP. Hence, culturally tailored social media content is a feasible way to reach Latinx immigrant sexual minority men who not only experience barriers to HIV prevention but who also exhibit behaviors that may place them at elevated risk for HIV transmission.

Limitations

There are several limitations to this study. First, given that this study was designed to pilot the culturally informed content on Instagram and Facebook, a comparison to Latinx immigrant sexual minority men who did not engage with the social media content was not possible. Despite not having a comparison group, the authors believe that the characteristics of survey respondents highlight the opportunity that eHealth presents for reaching Latinx immigrant sexual minority men in need of HIV prevention services. Second, while the social media content was delivered virtually, the platforms focused on reaching individuals in Washington State and its Latinx population. Therefore, the social media content may not be appropriate or feasible for reaching all Latinx immigrant sexual minority men in the United States, including other locales with different compositions of Latinx immigrant populations. Further, our survey did not capture all individuals who engaged with or were impacted by the social media content. Hence, individuals who did not complete the survey may vary from those reported in this study.

Conclusions

Our culturally relevant social media and web-based outreach strategies that were informed and developed by the community are a feasible way to reach Latinx immigrant sexual minority men for HIV prevention. Community-driven social media and web-based content present opportunities for engaging individuals who may traditionally lack access to HIV prevention information and services. Future research may examine the effectiveness of culturally informed social media content in increasing HIV testing and PrEP use among Latinx immigrant sexual minority men.

Abstract

Background: Ongoing rumors and fake news regarding food fraud, adulteration, and contamination are highly visible. Health risk information circulating through media and interpersonal communication channels has made *health crisis* an important research agenda.

Objective: This study explored the issue of food fraud and the effect of misinformation. Further, it assessed whether and how these issues have provided evidence-based interventions for food handlers and regulators to mitigate fraud misinformation.

Methods: The Health Information National Trends Survey (HINTS) was adopted for a collaborative study in China, after which a cross-sectional survey with door-to-door interviews was performed. Participants from Beijing and Hefei were selected using multistage sampling of adults in May 2017. Based on 4 government surveillance reports on food rumors and safety incidents, a descriptive analysis, correlation analysis, and analysis of variance were performed on the data.

Results: A total of 3090 results were gathered and analyzed. Among the respondents, 83.6% (2584/3090) heard at least one food rumor. Learning about food fraud was correlated with interpersonal connections (eg, doctors or health specialists) for accessing food health information. Overall, Chinese citizens with a higher level of interpersonal connection were more likely to be concerned about food incidents with a statistical difference (*P*<.001). Interpersonal connection was the most frequent communication source (698/1253, 55.7%), followed by traditional media (325/1253, 25.9%) and internet portals (144/1253, 11.5%). There was a significant relationship between media use and media category in Beijing (*P*<.001) and Hefei (*P*<.001). Overall, responses to food fraud and incident risks were lower in Beijing than in Hefei (*P*=.006). The respondents in Beijing were confronted more frequently by food rumors (range 346-1253) than those in Hefei (range 155-946). The urban dwellers in Beijing and their rural counterparts in Hefei also differed in terms of perceiving different levels of food risks from different media sources. The food rumor narratives that examined the conspiracy belief showed that social media played more important roles in influencing attitudes against misinformation for users in Hefei than in Beijing.

Conclusions: This study shows that consumers have to be on guard against not only fake food, but also spreading fake information and rumors, as well as conspiracy beliefs involving fake food. This study focused on characterizing media sources, types of food fraud misinformation, and risk perceptions of food safety, which mix urgency and suspicion, and attempted to provide evidence-based interventions for risk management guidance, with the hypothesis of significant correlations between media types and sources, and consumer exposure and perception levels of food rumors and risks.

Introduction

Background

Food fraud has been practiced since ancient times but has become more sophisticated in recent years. The recent food supply chains have become complicated and accelerated in local markets. Government authorities may be able to trace some imported contaminated food items; however, they are smuggled from one country to another with switched packaging and altered production dates. Thus, the risk of food fraud has broadened to include the global population [1]. Food fraud that involves items, such as infant milk formula, olive oil, and Scotch whisky, has been examined for perception and attitude learning among consumers in first- and second-tier cities in China [2], and the conclusion indicated that food fraud represents a food hazard and poses a threat to the authenticity, quality, and reliability of food.

Investigating food fraud is an emerging research idea and is a newly defined area of food protection [1,3,4]. Food fraud is an intentional act for economic gain, whereas a food safety incident may be an unintentional act with unintentional harm [5]. Thus, studying food fraud and adulterants mainly focuses on food safety (eg, pesticide residue) and food defense with malicious intent to harm (eg, terrorism attack). Food fraud and adulteration are principally motivated by economic drive; however, food fraud–related public health risks are often riskier than traditional food safety threats [1,6]. This is because food contaminants are complicated risks, which may involve chemical, microbial, physical, and allergenic contaminants with food fraud conditions. This also explains why food handlers have a responsibility to ensure that the food they prepare is free from these contaminants and safe for the consumer [7].

In recent decades, health information has been particularly exposed to rumors, incidents, and fake news [6,8,9]. Until the recent 10 years, little was known about the access, sources, and trust levels of food fraud and related information, or factors that facilitate or hinder communication on a population-wide basis [10-12]. In order to help fill this gap, researchers have tried to employ conspiracy beliefs to explain health-related matters. Conspiracy beliefs adjoined to health information are reportedly on the rise and are beginning to receive significant attention (eg, water fluoridation, vaccines, cell phones, unhealthy diets, and alternative medicine) [9,13-15].

More recently, the outbreak of food incidents and rumors has provided evidence of how the spread of conspiracy thinking has reached beyond the narrow confines of individual or group believers [16-18]. A conspiracy belief works through emotional appeals and implausibility, which can be used as a rhetorical device to appeal to the emotions of a significant number of the public [19,20]. The conspiracy belief is significantly associated with health worries while considering variables such as demographics, ideology, and health perceptions [8,21]. However, it remains unclear whether the objective information of conspiracy beliefs matters.

China's food safety rumors and concerns involve fraud, implicated foods, adulterants, contaminants, and abnormal conditions, as well as concerned food sources [4]. For many in China, the term genetically modified foods (GMFs) evokes negative reactions as it is usually connected with food safety concerns such as poisoned seeds or contaminated fields [22]. Vast food fraud and related studies have focused on GMFs for supposed damage [23-26].

While academia researchers, government regulators, and industry practitioners alike struggle with this evolving issue [4,27], the terms and definitions of food fraud should include deliberate substitution, dilution, counterfeiting, or misrepresentation of food, ingredients, or packaging, as well as false or misleading statements made about a food product. All these examples of food fraud can have a negative impact on the quality and safety aspects of food, some of which have resulted in serious illnesses and even fatalities, damaging trust in domestically produced and imported food.

Media Exposure of Food Health Risk

Little is known about the sources and trust of food fraud information hindering communication on a population-wide basis. The Health Information National Trends Survey (HINTS) was developed to help fill this gap [28,29]. The HINTS reported that around 50% of American respondents preferred to go to their physicians for specific health information [30]; however, when asked where they actually went, up to 48.6% of respondents reported going online first.

People's perceptions of health risks are initially determined by the scope and width of coverage from the media for the most part [8]. With the growing influence of social media in the public sphere, the communication of alternative health discourse often circulates in opposition to the mainstream or government-owned media [31-33]. Consequentially, the narratives supporting alternative health discourses have increasingly become the growing consensus for laymen rather than health professionals or policymakers [24,34,35].

In order to determine the extent of health conspiracism in public, social media might play an increasingly important role in active information-seeking behavior [15,36]. Although previous studies provide important insights for understanding active seeking behavior, they neglect the incidental seeking behavior of health information.

The steady growth of food safety rumors and incidents would increase citizens' concerns, but media themselves inform, circulate, and even amplify the food safety risk perceived. In fact, tensions arise between medical science protecting the collective well-being and the emotive amplification of groups concerned with individual health. Such exchanges have developed in food health and safety discourses, with online forums working as echo chambers [37].

Goal of This Study

The narratives of scandals and rumors might correlate with media sources and impact actual health information seeking behaviors. Thus, this study focused on characterizing media sources, the types of food fraud misinformation, and the risk perception of food safety, which mixes urgency and suspicion.

The information regarding food risks and safety is becoming more relevant [7]. If information is viewed in a more comprehensive and complex way, the resulting importance of the topic would encourage clarification of the types of food fraud and consequentially which conspiracy beliefs are salient and whether the public has prescribed to these beliefs.

Research Questions

The abovementioned conspiracy beliefs are associated with the behavior of seeking information that impacts food fraud. Thus, the risk perceptions of food could be different for passive information seeking behavior. Concomitantly, demographic variables are significantly related to the concerns of food fraud and adulteration type [7,38]. Thus, the following 5 research questions were raised: (1) What types of food fraud–related incidents and rumors are spreading fear in China, regarding food safety concerns? (2) Are the conspiracy beliefs associated with demographic variables, such as income, age, gender, and education? (3) Is learning about food fraud correlated with media type and source? (4) Are citizens with more social media exposure more likely to be concerned about food rumors and scandals? (5) Is there any difference in the perception level of food risk between urban dwellers and their rural counterparts?

Methods

Data Collection

The Health Information National Trends Survey in China (HINTS-China) project extends the established HINTS from the United States [11,39-41]. The questionnaire was built upon the research framework of the HINTS by using identical core questions, as well as adding unique food fraud health misinformation and concerns, and communication characteristics for the Chinese public. It is a cooperative project supported by Beijing Normal University, George Mason University, the National Cancer Institute in the United States, the Chinese Food and Drug Administration, and the Chinese Health Media Group. The HINTS-China was approved by the institutional review board of the School of Journalism and Communication, Beijing Normal University in 2017.

Data were collected in 2017 from Beijing, the capital city of the People's Republic of China, and Hefei, a second-tier and capital city in Anhui Province. Considering the different developments in political and economic applications, this study compared the commonalities and differences of the 2 locations to learn the impacts of food rumors and incidents on consumers [11,39,42,43]. With respect to urban and rural respondents, it aimed to provide a picture of the information communication strategy and risk assessment.

A multistage stratified sampling method was employed, and the procedure included training interviewers for door-to-door interviews between March to May in 2017. The interviews took place from May 9 to 24, 2017. One member aged 18 years or above from each household was requested to take part. Respondents who took part in the survey gave their written consent [43].

Conspiracy Narratives of Food Misinformation

The spread of malicious or accidental rumors online, particularly regarding food in real-world emergencies, can have harmful effects on the society. Thus, 8 highly publicized narratives of food risks were officially identified as rumors before implementing the HINTS-China. The veracity of food rumors comprised a range of food additives, fraudulent activities, adulterant substances, GMFs, and food contamination. For example, suspected rumors of food narratives were as follows: "seaweed (nori) is made out of black plastic," "big and sweet strawberries are with excessive swelling agent," and "seedless grapes are covered with contraceptives." A list of food fraud narratives with English translations is displayed in Textbox S1 in Multimedia Appendix 1.

Health Risks of Food Fraud

Eleven heated food safety incidents in 2016 were exposed. These were included in the HINTS-China to measure consumers' awareness and perception of health risks. The veracity of negative food exposure comprised the food-origin story, food additives, adulterants, authenticity, crime, contamination, integrity, quality, and food security. For instance, the narratives regarding food safety were as follows: "seafood from radiated areas in Japan were smuggled into China," "more than 100 tons of expired milk powder from New Zealand was illegally repackaged and sold in Shanghai," "A Vietnam yogurt brand with three-no yogurt (low-quality product with no manufacturer name, no production site, and no production hygiene license code) entered the market in many cities in mainland China, and the product was seized by the China Food & Drug Administration (CFDA)," and "A food ordering platform was accused of partnering with an unlicensed restaurant with poor sanitary conditions by a government-owned television program." A list of health risks of food incidents with safety concerns is shown in Textbox S2 in Multimedia Appendix 1.

Detection and Verification Mechanism

Many food risk concerns and incidents in China were initially reported by central official surveillance and then by local media. The state-owned news media detected food fraud and adulteration in news content and also delivered information concerning food authenticity and integrity. The salient features of rumors and food safety were identified from the following 2 official sources: People's Daily Online (人民網) and Xinhuanet (新華網) [4,44]. People's Daily is supported by the Central Committee of the Chinese Communist Party, while the XinHua Press Agency is an official agency and is the largest news agency in the world.

Two more sources joined the verification mechanism of food rumors and incidents, namely, Chinese Health Daily News (中国健康报) and CNPharm.com (中国食品药品网). Online media provide professional and reliable information under the supervision of the National Health Commission. It has been

confirmed that all of the 8 popular rumors in Textbox S1 in Multimedia Appendix 1 are false, while the narratives of the 11 food scandals in Textbox S2 in Multimedia Appendix 1 reflect the facts in 2016, though 2 of them are not accurate.

Measurements

We measured the conspiracy narratives of food fraud, rumors, incidents, safety issues, characteristics of media sources, and scale descriptions. In particular, the measurements of the narratives of food rumors and incidents were to learn whether the media sources that people searched for on hearing about a statement were trustworthy.

The established measures included a dichotomous answer of yes/no for having heard about each food rumor or incident. It was followed by a 5-point Likert scale for the measurement of the degree of trust, ranging from 1 (completely trust) to 5 (completely distrust), with a higher score indicating a higher distrust of the food rumor and a lower score indicating a lower distrust of the food rumor. The socioeconomic information measured included gender, age, ethnic group, occupation, marital status, highest level of education, and monthly income.

Regarding the media source, the HINTS-China measured the media use behavior regarding seeking general information and health information. The first question focused on 12 media characteristics, either general purpose or health/medical-related information in the past 12 months. A dichotomous question checked people's active information seeking process regarding health/medicine. Moreover, a total of 25 media sources were provided to learn their impact on food rumors and incidents. In order to merge the media sources, the following 5 categories were established for analysis: (1) interpersonal media, (2) public organizations, (3) traditional media, (4) internet portals, and (5) social media (Multimedia Appendix 2). One media option was excluded from the analysis because it appeared that none or very few people had accessed it (less than 1%).

Descriptive and correlation analyses were performed using SPSS 24 (IBM Corp). For any accessed media that connected with food misinformation and food safety issues, analysis of variance (ANOVA) was employed, which determined whether the influence of media use mediated the conspiracy narratives of food rumors and incidents.

Results

Descriptive Analysis

As of May 2017, we conducted the survey and data collection, which was funded by CFDA and Chinese Health Media Group in January 2017, and approved by the institutional review board at the School of Journalism and Communication, Beijing Normal University in March 2017. After 16 dates of data collection (May 9 to 24), 3090 samples were collected, and the number of valid questionnaires was 2584, including 1462 in Beijing and 1122 in Hefei, after list-wise deletion of missing values. The preliminary description was made in August 2017, and further data analysis was performed in May 2020.

The response rate was 42.65% for Beijing and 57.35% for Hefei (out of 3090 participants). The dominant ethnic group was Han Chinese, ranging from 98.0% (1433/1462) in Beijing to 99.5% (1116/1122) in Hefei. Respondents' ages ranged from 18 to 60 years (mean 38.02 years, SD 11.16) in Beijing, but the respondents were younger on average in Hefei (mean 32.26 years, SD 11.23). In Beijing, respondents were predominantly female (920/1462, 62.9%), married or in cohabitation (1199/1462, 82.0%), and high school educated (553/1462, 37.8%). In comparison, Hefei's respondents were predominantly female (677/1122, 60.3%), married or in cohabitation (696/1122, 62.0%), and college educated with a bachelor's degree (351/1122, 31.3%). Table 1 displays the sociodemographic findings of respondents in Beijing and Hefei in 2017.

Table 1. Sociodemographic findings of respondents in Beijing and Hefei in 2017.

Characteristic	Beijing (N=1462), n (%)	Hefei (N=1122), n (%)
Gender		
Male	542 (37.1)	445 (39.7)
Female	920 (62.9)	677 (60.3)
Occupation		
General staff in the organization	342 (23.4)	82 (7.3)
Worker or self-employed	307 (21.0)	289 (25.8)
Business service staff	229 (15.7)	45 (4.0)
Retiree or unemployed	267 (18.3)	151 (13.5)
Government administrator	15 (1.0)	29 (2.6)
Professional technician	95 (6.5)	101 (9.0)

5000-9999	413 (28.2)	210 (18.7)
10,000 or above	49 (3.4)	60 (5.3)

[a]1 RMB = 0.158 USD.

Overall, interpersonal communication was observed to be the most favorable first choice of media use for accessing food risk information (n=1466), followed by internet portals (n=464) and traditional media (n=425). A chi-square test of independence showed that there was a significant relationship between media use and media category in Beijing (χ^2_8=68.223; P<.001) and in Hefei (χ^2_8=78.529; P<.001). The rank of media preference greatly impacts food information outcomes. The additional insight shows that merging use of media sources mimics the way we now consume content across devices and platforms. Table 2 outlines the ranking of media sources for accessing food information in Beijing and Hefei.

Table 2. Ranking of media sources for accessing food risk information in Beijing and Hefei.

Media source	Choice of media in Beijing				Choice of media in Hefei			
	1st (n=572), n (%)	2nd (n=571), n (%)	3rd (n=572), n (%)	Subtotal, n	1st (n=426), n (%)	2nd (n=373), n (%)	3rd (n=410), n (%)	Subtotal, n
Interpersonal communication	385 (39.3)	331 (33.8)	263 (26.9)	979	209 (42.9)	155 (31.8)	123 (25.3)	487
Internet portals	69 (29.7)	65 (28.0)	98 (42.2)	232	98 (42.2)	72 (31.0)	62 (26.7)	232
Traditional media	75 (25.5)	111 (37.8)	108 (36.7)	294	34 (26.0)	24 (18.3)	73 (55.7)	131
Public organizations	34 (22.7)	47 (31.3)	69 (46.0)	150	63 (24.7)	90 (35.3)	102 (40.0)	255
Social media	9 (15.0)	17 (28.3)	34 (56.7)	60	22 (21.2)	32 (30.8)	50 (48.1)	104

Specifically, in Beijing, seeking doctors' or health specialists' advice concerning food risk information was presented most frequently (264/362, 72.9%), followed by a family member (197/324, 60.8%) and television (57/162, 35.2%). However, in Hefei, seeking doctors' or health specialists' advice remained the first option (112/151, 74.2%), followed by a family member (85/169, 50.3%) and friends and colleagues (69/167, 41.3%). Multimedia Appendix 3 displays the preferred media for accessing food risk and related information in Beijing and Hefei.

An average of 83.6% (n=2584) of Chinese respondents heard at least one food rumor, which included 95.7% (n=1462) from Beijing and 71.8% (n=1122) from Hefei. The respondents in Beijing were confronted more frequently by food rumors (range 346-1253) than those in Hefei (range 155-946). Interpersonal connection was the most frequent communication source (698/1253, 55.7%), followed by traditional media (325/1253, 25.9%) and internet portals (144/1253, 11.5%).

The K-means cluster identified 2 groups of users for learning narratives regarding food rumors. To be specific, in the high conspiracy belief group in Beijing, the category of interpersonal connection had the highest frequency of learning food rumor (130/275, 47.3%), followed by traditional media (72/275, 26.2%) and internet portals (49/275, 17.8%). A chi-square test of independence examined the conspiracy belief and media sources, and showed statistical significance (χ^2_5=20.08 [n=1253]; P=.001). A similar trend was also observed for the respondents in Hefei. For high conspiracy belief respondents, the category of interpersonal communication was the most frequent media source (182/346, 52.6%), followed by traditional media (113/346, 32.7%) and internet portals (31/346, 9.0%). However, there was no statistical significance for the high and low conspiracy beliefs in Hefei. Table 3 displays the crosstab comparison of conspiracy beliefs with access to the different categories of media sources in Beijing and Hefei in 2017.

Table 3. Crosstab comparison of conspiracy beliefs with access to different media sources in Beijing and Hefei.

Media source	Beijing, n (%)			Hefei, n (%)		
	Total (N=1253)	Low conspiracy belief (n=978)	High conspiracy belief (n=275)	Total (N=946)	Low conspiracy belief (n=600)	High conspiracy belief (n=346)
Interpersonal media	698 (55.7)	568 (58.1)	130 (47.3)	534 (56.4)	352 (58.7)	182 (52.6)
Public organizations	12 (1.0)	10 (1.0)	2 (0.7)	8 (0.8)	5 (0.8)	3 (0.9)
Traditional media	325 (25.9)	253 (25.9)	72 (26.2)	280 (29.6)	167 (27.8)	113 (32.7)
Internet portals	144 (11.5)	95 (9.7)	49 (17.8)	82 (8.7)	51 (8.5)	31 (9.0)
Social media	72 (5.7)	51 (5.2)	21 (7.6)	32 (3.4)	16 (2.7)	16 (4.6)
Others	2 (0.2)	1 (0.1)	1 (0.4)	10 (1.1)	9 (1.5)	1 (0.3)

The top publicized food rumor in Beijing was counterfeit seaweed (mean score 2.98, SD 1.05), followed by GMF involving chicken with 6 wings (mean score 2.69, SD 0.83) and seedless grapes with contraceptives (mean score 2.62, SD 0.96). In comparison, the most highly publicized rumor in Hefei was counterfeit seaweed (mean score 2.86, SD 0.98), followed by

seedless grapes with contraceptives (mean score 2.65, SD 0.86) and GMF involving chicken with 6 wings (mean score 2.62, SD 0.90). Table 4 outlines the analysis of food fraud with rumors and its correlation with consumer conspiracy beliefs in Beijing and Hefei.

Table 4. Correlation analysis of food fraud with rumors and consumer trust in Beijing and Hefei.

Food rumors and related terms	Beijing (n=1462), mean score (SD)	Hefei (n=1122), mean score (SD)	Correlation
1. Food counterfeit: seaweed	2.98 (1.05)	2.86 (0.98)	0.044
2. Addictive: strawberry	2.12 (0.82)	2.49 (0.79)	−0.012
3. Safety: microwaved food	2.45 (0.93)	2.60 (0.84)	−0.050
4. Implicated food: instant noodles	1.98 (0.84)	2.28 (0.84)	−0.103[a]
5. Contaminated: crayfish	2.45 (1.03)	2.47 (0.96)	−0.013
6. Safety: hookworm in pork	2.32 (0.97)	2.62 (0.99)	−0.076

8. Authenticity: seedless grapes with contraceptives	2.62 (0.96)	2.65 (0.86)	−0.004

[a]$P<.01$.

[b]GMF: genetically modified food.

The K-means cluster identified 2 groups of distrust levels for learning narratives regarding food rumors. All of the narratives regarding food fraud with rumors showed a statistical significance between users with a low level of distrust and their counterparts with a high level of distrust in Beijing and Hefei.

Specifically, more users with a higher score indicated a high distrust of food rumors, such as "counterfeit seaweed" (202/638, 31.7%) and "implicated food of instant noodles" (275/1253, 21.9%) in Beijing. In comparison, a low distrust of food rumors, such as the implicated food narrative "instant noodles are junk food" (600/946, 63.4%) and another narrative "crayfish are genetically modified crops which deals with corpses and grows in unsanitary water with exceeded heavy metals" (266/296, 89.9%), was prevalent in Hefei. Interestingly, much more users in Hefei distrusted the rumor narrative "big and sweet strawberries are with excessive swelling agent" (235/547, 43.0%) than their counterparts in Beijing (27/800, 3.5%). Another rumor regarding the use of genetically modified chicken with 6 wings by KFC also had contrasting trust levels in the 2 cities, with lower distrust in Beijing (94/794, 11.8%) and higher distrust in Hefei (182/449, 40.5%). Table 5 presents the findings of univariate ANOVA comparing the food items in frauds and rumors perceived by users with different levels of distrust.

Table 5. Comparison and analysis of distrust levels of rumors among users in Beijing and Hefei.

Food fraud and related terms	Beijing users				Hefei users			
	Low, n (%)	High, n (%)	F test (df)	P value	Low, n (%)	High, n (%)	F test (df)	P value

[a]GMF: genetically modified food.

The terminology within the domain of food fraud and rumors included the following: food authenticity, food additive, food safety, food contamination, implicated food, and questionable GMF sources. The most significant misinformation of food fraud in rumors included "seaweed is made out of plastic" ($\chi^2_4=29.26$; $P<.001$), "instant noodles are junk food" ($\chi^2_4=20.08$; $P<.001$), "crayfish are GM crops" ($\chi^2_4=29.87$; $P<.001$), "hookworm in pork" ($\chi^2_4=40.18$; $P<.001$), and "seedless grapes were sprayed with contraceptives" ($\chi^2_4=19.95$; $P<.001$) in Beijing. In comparison, only 1 issue regarding the rumor "seaweed is made of plastic" with different levels of distrust attitudes showed statistical significance in Hefei ($\chi^2_4=17.66$;

P=.003). Multimedia Appendix 4 shows the comparative analysis of the groups (low and high distrust) for learning about food rumors by accessing different media sources in Beijing and Hefei.

The top publicized food incidents perceived in Beijing were branded contaminated yogurt from Vietnam (mean score 4.08, SD 1.27), followed by suspected tainted tap water (mean score 4.02, SD 1.29) and expired milk powder from New Zealand (mean score 3.99, SD 1.31). In comparison, the most highly publicized news exposure in Hefei was the use of poppy shells in a chain restaurant in Beijing (mean score 4.12, SD 1.09), followed by a tainted sesame product (mean score 4.02, SD 1.12) and branded contaminated yogurt from Vietnam (mean score 4.01, SD 1.16). Table 6 outlines the analysis of food fraud items in scandals correlated with measuring consumer conspiracy beliefs between Beijing and Hefei.

Table 6. Food items and incident types involving consumer trust in Beijing and Hefei.

Food incident and related terms	Beijing (n=1462), mean score (SD)	Hefei (n=1122), mean score (SD)	Correlation
1. Implicated foods/abnormal conditions: fish out of shelves	3.67 (1.34)	4.03 (1.04)	−0.033
2. Food quality/security: delivery	3.19 (1.46)	3.53 (1.22)	−0.073[a]
3. Food adulterant: beef with duck meat	3.73 (1.37)	3.96 (1.13)	−0.060[a]
4. Food crime: poppy shells	3.74 (1.40)	4.12 (1.09)	−0.080[b]
5. Food authenticity: fake milk powder	3.86 (1.34)	3.49 (1.29)	−0.040
6. Food contaminant/security: radiation in seafood	3.65 (1.39)	3.47 (1.31)	−0.040
7. Food quality: expired dairy products	3.99 (1.31)	3.95 (1.13)	−0.049
8. Food contaminant: tainted sesame	3.86 (1.35)	4.02 (1.12)	−0.046
9. Food quality: frozen meat	3.90 (1.37)	3.81 (1.24)	−0.068[a]
10. Food quality/contaminant: yogurt	4.08 (1.27)	4.01 (1.16)	−0.019
11. Food contaminant: suspected tainted water	4.02 (1.29)	3.95 (1.16)	−0.022
Subtotal	3.79 (1.00)	3.85 (0.80)	−0.082[b]

[a]*P*<.05.

[b]*P*<.01.

The food fraud incidents and related terminology included food authenticity, food additive, food adulterant, food contamination, implicated food, food quality, and concerned sources with GMFs. The K-means cluster also identified 2 groups with distrust levels (low vs high) against negative food reports. All of the narratives regarding food fraud with scandals showed a significant difference between low-level distrust users and their high-level distrust counterparts in Beijing and Hefei.

Overall, responses to the food fraud and incident risks were lower in Beijing than in Hefei (*r*=−0.082; *P*=.006). The following 4 scandals reflected different perceptions between dwellers in Beijing and Hefei: food hygiene on an online food ordering platform (*r*=−0.073; *P*=.014), food adulteration by mixing beef with duck meat (*r*=−0.060; *P*=.046), food crime by using poppy shells (*r*=−0.080; *P*=.007), and food quality in problematic frozen meat (*r*=−0.068; *P*=.02). Multimedia Appendix 5 shows the comparative analysis of the groups (low and high distrust) for accessing media sources in learning about food in fraud and negative reports in Beijing and Hefei.

Discussion

Principal Findings

The main findings of this study were that around 73.6% (out of 2584) of Chinese respondents preferred to go to their physicians for quarrying food health information first; however, when asked where they actually went and got access to food rumors, up to 36.6% (out of 1462) of Beijing respondents and 55.6% (out of 1122) of Hefei respondents reported going online first. Interpersonal connection had the highest frequency among communication sources (698/1253, 55.7%). There was a significant relationship between media use and media category in Beijing (*P*<.001) and Hefei (*P*<.001). Overall, responses to the food fraud and incident risks were lower in Beijing than in Hefei (*P*=.006). The urban dwellers in Beijing and their rural counterparts in Hefei also differed in terms of perceiving different levels of food risk from different media sources.

Foods or raw ingredients most likely to be targeted for adulteration or fraud are those of high economical value to the diet, which are subject to the vagaries of weather during their growth, harvest, storage, or transport. Food quality and food safety incidents involving criminal conduct are considered as intentional acts, and there is zero tolerance from the food regulators in China. Consumers have to be on guard against not only fake food, but also spreading fake information and rumors about food.

Most Chinese respondents were principally confronted with food rumors through interpersonal connections, followed by traditional media and internet portals. Believing in conspiracies supports alternative views to construct radical beliefs in social uncertainty, and laypeople are now creating new articulations of discourse in the public sphere. This is because of their

innovative and often subversive language. Despite the characterization of conspiracy beliefs as paranoid by some in public discourse, they remain robust sources of skepticism regarding important public health recommendations able to prevent the spread of rumors.

For example, a food rumor regarding seafood products being exposed to radiation has been highly publicized. Many countries, including China, have banned seafood imports from Fukushima and other Japanese prefectures due to contamination of surrounding waters [45]. Further, the massive 2011 Fukushima nuclear disaster led to dramatic price drops in Japanese seafood. Consumers were warned that radiation continues to negatively impact marine life in the vicinity of Fukushima. Thus, many consumers believe that seafood products have high levels of radiation that can cause irreversible damage to human cells. Although 10 years have passed since the disaster, the appetite of many consumers of Japanese seafood has remained low.

In our analysis of the prevalence of food incident–related conspiracy beliefs, we found that acceptance of those beliefs highlighted the narratives of seafood contaminants for Beijing respondents (mean score 3.65, SD 1.39) and the narratives of food crime in adding poppy shells for Hefei respondents (mean score 4.12, SD 1.09). Overall, the level of conspiracy belief acceptance grew over the issues of food quality and contamination in Beijing, while the level of acceptance was increasing over the issues of food crime and contamination in Hefei. As with many conspiracies, these beliefs can be accepted by the same person despite their logical incompatibility. It is argued that the underlying distrust of food supply and chain systems in a local market rather than merely the consistency of the media content appears to motivate their acceptance.

It may be difficult to understand how people could believe the rumor that seaweed is made out of plastic or chickens used by the KFC fast food chain were genetically modified to have 6 wings and 8 legs. Nonetheless, food fraud involving some food category or with specific global brands (eg, KFC, Abbott, and Beingmate) has become an issue influencing conspiracy belief and causing economic loss. The rumors appeared in posts on WeChat, and the defamatory messages were read widely. The rumors are just some of many fake food stories going viral, where fears about the safety of food products have become deep-seated in the wake of major cases of food contamination, and food framed as artificial and dangerous may also function as a counterpoint to promote safe and sustainable food in China [46].

Weibo and WeChat were found to be the most used social media for accessing food information in China. For example, a video clip of news was circulated widely and had morphed into dozens of versions, accruing more than 2 million views on Weibo, China's most popular social media platform. Nonetheless, there is an abundance of social media in China without gatekeepers for polarized communities within which antagonistic spheres are created, although they do foster engagement with food fraud discussion as well.

Limitations

Although the HINTS-China provides evidence of media use in the persistence of conspiracy beliefs regarding food fraud rumors, it is almost impossible to disentangle the actual risks perceived from media exposure by researchers. Concomitantly, because we rely on self-reports of recall behavior, we cannot confirm that those reports reflect actual behavior. We also lack evidence to claim purposeful information-seeking behavior and the scanning use of health risk information on food fraud, since our study solely relied on a self-report method.

Another limitation that needs to be recognized is that it is not feasible to generalize the national probability sample to the Chinese population since the survey is only applicable to changes that occurred in 2017. The types of food fraud incidents in China are underrepresented. The effects of media use on food fraud conspiracy beliefs beyond that period remain to be studied. Finally, despite the ability to observe differences in conspiracy beliefs associated with media use in 2 cities, we cannot make strong causal claims because it still remains possible that characteristics other than those for which we controlled drove the changes in those beliefs.

Conclusion

Passive media information seekers or those with information-scanning behavior were the majority who were exposed to information that was gathered incidentally from sources within their environment. Consequently, majority of respondents in Beijing and Hefei preferred to use interpersonal connection for learning food safety concerns, while very few respondents reported access to media run by public organizations for the same purpose. Nonetheless, the food fraud narratives examined according to the conspiracy belief showed that social media play important roles in influencing the attitude against negative reports, and 9 out of 11 food incidents tended to be perceived with higher conspiracy belief among Hefei respondents.

Food fraud is characterized with the intent to harm and is mainly done for economic gain. Thus, the main events of food fraud that occurred in 2016, specifically those associated with food rumors and incidents, were summarized in this study. The typical food fraud covered food adulteration, authenticity, contamination, crime, integrity, protection, quality, and safety, which were used as prompts for attitudinal and perceptual elicitation. Many food rumors place particular emphasis on compositional aspects of food, such as texture, color, and shape. They also involve food origin, geographical consideration, rearing or production systems, processing, and storage, among others. Food fraud regarding food originating from Japan, Vietnam, and New Zealand implies that the information concerning food fraud in these countries may negatively affect the valuation of import locations.

The food rumor narratives that examined the conspiracy belief of distrust degree showed that consumers with prior knowledge of food fraud incidents decreased the valuation of the sources less when they received further information about food fraud. Fueled by constant access to mobile devices, daily online media consumption has increased steadily since 2017. Chinese adults

tend to spend more time each day listening to, reading, watching, or interacting with online media; however, their voracious appetite for digital content exists alongside a continued fondness for traditional media outlets. Furthermore, the results implied that prior consumer knowledge and later response to fraudulent behavior in a product can spread to other products.

Abstract

Background: Noncommunicable disease (NCD)–related deaths account for 71% of deaths worldwide. The World Health Organization recently developed a global action plan to address the impact of NCDs, with the goal of reducing the number of premature NCD-related deaths to 25% by the year 2025. Appropriate therapeutic adherence is critical for effective disease management; however, approximately 30%-50% of patients with an NCD do not comply with disease management activities as prescribed. Web-based patient communities can represent platforms from which specific information on patients' perception of treatment adherence can be gathered outside of a clinical trial setting.

Objective: This study aims to better understand patients' perspectives regarding therapeutic adherence and iatrogenic risk in 2 major groups of NCDs for which poor disease management can have fatal consequences: cardiovascular diseases and mental disorders. Therapeutic adherence, motivational factors, patients' awareness and perception of iatrogenesis, and treatment tools used by patients were assessed.

Methods: A web-based survey was performed among patients with cardiovascular diseases or mental disorders or both conditions who were registered on the French Carenity platform, a web-based community in which patients with an NCD can share experiences and receive support and information. The study inclusion criteria were defined as follows: diagnosis of cardiovascular disease or mental disorder or both conditions (self-declared), age ≥18 years, residence in France, registration on the French Carenity platform, and ongoing pharmaceutical treatment for the condition. Patients who met the inclusion criteria were then invited to complete a self-administered web-based questionnaire that included questions addressing therapeutic adherence and iatrogenic risk.

Results: A total of 820 patients were enrolled in the study, including patients with cardiovascular diseases (403/820, 49.2%), patients with mental disorders (292/820, 35.6%), and patients with both cardiovascular diseases and mental disorders (125/820, 15.2%). The mean age of the participants was 55.2 (SD 12.7) years. We found that 82.8% (679/820) of patients experienced adverse effects of medication. Patients tended to perceive themselves to be more adherent than they actually were; a significant number of patients disregarded their prescription and stopped or interrupted medication without consulting with a doctor. Patients with cardiovascular diseases were nearly twice as adherent as patients with a mental disorder ($P \le .001$). Adherence was significantly associated with gender ($P \le .001$), age ($P \le .001$), and treatment complexity ($P \le .001$). Finally, for each disease type, 3 patient profiles were identified, which provide interesting insight for improving therapeutic adherence and adjustment strategies specifically according to patient behavior.

Conclusions: This study provides insight into the perspectives of patients receiving therapy for cardiovascular diseases or mental disorders or both conditions, which could help improve the management of NCDs and prevent premature death. Our study also

shows that web-based patient platforms provide new opportunities to improve disease management by understanding patients' experiences.

Introduction

Deaths from noncommunicable diseases (NCDs), also known as chronic diseases, account for approximately 41 million deaths each year and 71% of deaths worldwide [1]. The World Health Organization recently developed a global action plan to address the impact of NCDs, with a goal of reducing premature NCD-related deaths to 25% by 2025 [2]. As premature deaths due to NCDs are avoidable, many policy recommendations have been proposed to prevent NCDs and improve disease management for patients with NCDs.

Cardiovascular disease–related deaths account for the majority of NCD-related deaths and 30% of global mortality [3]. Mental disorders also represent a major group of NCDs and account for approximately 14% of the global disease burden [4]. Cardiovascular diseases and mental disorders are major economic burdens on health care systems in terms of the direct (eg, medical consultations, hospitalizations, rehabilitation services, and medications) and indirect (eg, loss of productivity and short- or long-term disability) costs associated with mortality and morbidity [4-6].

Appropriate therapy management, including medication adherence, is critical for effective disease management and for improving patients' overall quality of life [7,8]. However, approximately 30%-50% of patients with an NCD do not comply with disease prevention and management activities [9,10] such as following treatment as prescribed by a physician, staying up-to-date with medical appointments, engaging in regular physical activity, and making necessary dietary changes [7,11]. Medication adherence is defined as the extent to which patients take medications as prescribed in agreement with their health care provider [12]. Poor therapeutic adherence, which has significant effects on treatment outcome and disease prognosis [13], is driven by many factors such as limited disease awareness, poor understanding of the benefits and efficacy of prescribed regimens, and perceived or actual barriers (eg, adverse effects, financial constraints) [7,9,13,14]. Poor disease management can have fatal consequences, especially in patients with cardiovascular diseases and mental disorders [2,15,16]. Furthermore, patients with an NCD are at risk of iatrogenic disease, which is any pathologic condition caused by adverse medication reactions or complication induced by nondrug medical interventions, including diagnosis, intervention, error, and negligence. Although iatrogenic diseases can have major psychomotor and social consequences, most of these are avoidable with close disease management [17,18].

Few studies have been performed on therapeutic adherence from the patient point of view, which could provide valuable insight into patients' perspectives and experiences for improving NCD management. As patients involved in adherence studies are often not representative of the general patient population for a given disease, bias may limit result extrapolation. However, web-based platforms on which patients can obtain information and share their medical experiences anonymously, without medical supervision, may more accurately represent patients' perspectives and behaviors.

Web-based patient platforms such as registries, forums, social networks, and web-based communities offer patients the opportunity to participate in scientific studies and voluntarily share experiences regarding treatment benefits and burdens outside of the clinical setting [19]. Such information provides researchers with a better understanding of patients' experiences, expectations, and unmet needs [19]. The insight gained from these web-based resources may also enhance clinical decision making, study protocol development, and patient recruitment [19]. The Carenity platform is an international web-based community for patients with chronic diseases and their caregivers. The platform provides an environment for patients to share their experiences, monitor their health, provide support, and contribute to medical research through web-based surveys [20]. Currently, over 400,000 patients (88%), primarily with chronic diseases, and their caregivers (12%) from 6 countries (France, Italy, Germany, Spain, the United Kingdom, and the United States) are registered on the platform.

Most studies on therapeutic adherence have been based on in-person interviews. However, under these conditions, patients may be reluctant to report poor medication adherence to avoid disappointing their physician. As social media networks represent useful and valuable resources for patients to obtain medical information and share their experiences with other patients, a web-based survey of patients with cardiovascular diseases or mental disorders or both conditions was performed to better understand patients' perspectives of therapeutic adherence and iatrogenic risk. An anonymous and self-administered questionnaire was used to understand aspects of therapeutic adherence, including motivational factors, patients' awareness and perception of iatrogenesis, and tools used by patients to facilitate adherence.

Methods

Study Design

A web-based survey of patients with cardiovascular diseases or mental disorders or both conditions was conducted. All patients

were registered on the French Carenity platform, a web-based community in which both patients with chronic diseases and their caregivers can share their experiences, provide support, and share or receive information. A caregiver is defined as a person who provides care to someone with a chronic disease, disability, or other long-term health condition, typically outside a professional or formal framework. The community enhances patient-centered approaches by sharing patients' experiences through web-based surveys, in which members may voluntarily participate. In February 2020, approximately 7600 members with at least one mental disorder and 10,000 members with at least one cardiovascular disease were registered on the platform.

Participant Recruitment

Patients were recruited from February 14, 2020, to May 15, 2020, via invitation and follow-up no-reply emails. The study inclusion criteria were defined as follows: diagnosis of cardiovascular disease or mental disorder or both conditions (self-declared), age ≥18 years, residence in France, registration on the French Carenity platform, and ongoing pharmaceutical treatment for the condition. Patients who met the inclusion criteria and agreed to receive invitations were then contacted to complete a self-administered web-based questionnaire available on the Carenity website and promoted on Facebook. Patients who completed the questionnaire but did not meet the inclusion criteria were screened out, and patients who did not finish the questionnaire were not included in the analysis.

Data Collection

The questionnaire comprised 39 questions regarding sociodemographic and medical information, including questions addressing therapeutic adherence and iatrogenesis risk. The questionnaire was developed and approved by a multidisciplinary board of experts, including a psychiatrist and a cardiovascular specialist. It was also approved by 2 Carenity members to ensure that the proposed questions were appropriate for the target audience. Data collected on the Carenity platform are hosted in France on a secured computer server in accordance with the Commission Nationale de l'Informatique et des Libertés, declaration number no 1484083, dated March 29, 2011.

Demographic and Clinical Characteristics

Information on demographic variables (eg, age, gender, education level, and professional status) and clinical characteristics (eg, disease type, age at diagnosis, comorbidities, and current treatments) was collected.

Treatment Complexity Score

The treatment complexity score was calculated by assigning 1 point for each constraining aspect of the pharmacological therapy, such as "varying number of medications each day," "taking some medications with meals," "taking some medications outside mealtimes," "taking some medications at a set time each day," "taking some medications on certain days and not others," and "doses frequently change for some medications." The treatment complexity score ranged from 0 (simplest treatment) to 7 (most complex treatment), and complexity was then classified into 3 categories based on the score: simple (score 0-1), intermediate (score 2), and complex (score 3-7).

Patient Lifestyle and Risk Level

Information was collected on the following 4 behavioral risk factors most associated with NCDs: tobacco use, excessive alcohol consumption, unhealthy diet, and physical inactivity [2]. Height and weight data were also recorded for each patient to calculate BMI. Nutritional status was classified based on patient BMI (weight [kg]/height squared [m^2]) according to World Health Organization recommendations: underweight (BMI < 18.5), normal weight (BMI 18.5-24.9), overweight (BMI 25-29.9), and obese (BMI ≥ 30) [21].

Patients were then categorized into 3 risk level groups. The risk level of each patient was based on the following 5 risk factors: age ≥65 years, BMI ≥ 30, occasional or regular smoking, daily alcohol consumption or consumption of at least 6 drinks every week, and physical inactivity. The risk level was estimated by assigning 1 point per risk factor as follows: 0-1 risk factor, low risk; 2 risk factors, moderate risk; and 3-5 risk factors, high risk.

Iatrogenesis

To collect data on iatrogenic risk, questions focused on the adverse effects that patients experienced and the worries and fears that they had about their medication. Information was also collected on medications, including any interactions, adverse effects, benefits, and channels used to obtain information.

Medication Adherence

Perceived medication adherence was determined based on the response to the following question: "How well do you think you take your medications?" Patients were prompted to respond on a scale of 0 to 100 (0 corresponded to "I do not take my medications as prescribed" and 100 corresponded to "I take all my medications exactly as prescribed").

Actual adherence was assessed based on the response to the questions considering all medications and not only to those for cardiovascular diseases or mental disorders. Participants were asked the following 4 questions: "Regarding your medications, do you ever (1) take medication late or early, (2) disregard the prescribed dose without medical advice, (3) intentionally stop/interrupt a treatment without medical advice, and (4) unintentionally stop/interrupt a treatment (because you forgot, etc.)?" Respondents were instructed to select the most appropriate response (never, very rarely, sometimes, often), with only 1 response per question. The adherence score was then calculated by assigning points according to the frequency of nonadherent behaviors. For the question about taking medication late or early, points were assigned as follows: 1 point for very rarely, 2 points for sometimes, and 4 points for often. For the questions about disregarding the prescribed dose and unintentionally stopping or interrupting treatment, points were assigned as follows: 2 points for very rarely, 4 points for sometimes, and 6 points for often. Finally, for the question on intentionally stopping or interrupting treatment, points were assigned as follows: 4 points for very rarely, 8 points for sometimes, and 12 points for often. Patients were then grouped into the following 4 compliance categories based on the total points: perfectly adherent (0 points), mostly adherent (1-2 points), partially adherent (3-7 points), and poorly adherent (≥8 points).

Information was also collected on adherence reporting, including frequency of doctor notifications and reasons patients did not consult with their doctors. Finally, data were also collected on solutions implemented by patients to improve disease management, such as tools used and types of assistance received, and additional patient needs.

Statistical Analysis

Descriptive multivariable statistical analyses were performed. Categorical variables are expressed as absolute frequency and percentage. Continuous variable data are presented as the mean (SD) for normal distribution and as the median and interquartile range for non-normal distribution. A chi-square (χ^2) test was applied to determine statistically significant differences for categorical variables, and a one-way analysis of variance or t test was applied to determine statistically significant differences for continuous variables.

A multiple correspondence analysis was performed for each of the 2 disease types to identify profiles of patients with similar therapeutic behaviors. To refine these profiles, 3 unsupervised classification models (ascending hierarchical classification, Kmeans, and partitioning around medoids algorithm) were compared using indicators of similarity and dissimilarity. The method with the best results was the 3-class ascending hierarchical classification model based on 12 variables covering the following 3 categories: demographic variables (gender and age), medical characteristics (eg, number of medications, adherence, adverse effects, treatment adjustment, and complementary therapies), and survey responses (fear of disappointing the physician, fear of risks associated with the therapy, discussions with the pharmacist, awareness of the risks of adverse effects, and risk of experiencing adverse effects). Data processing and analysis were performed using R (version 3.6.1; R Core Team).

Patients with cardiovascular diseases only were classified into 3 different profiles: at-risk, reporter, and tolerant. Patients with mental disorders only were also grouped into 3 different profiles: fearful, at-risk, and confident.

Ethical Considerations

This survey was conducted in accordance with the Declaration of Helsinki and the principles of Good Clinical Practice. Prior to data collection, all patients provided consent on the Carenity website for the analysis of their anonymous health data for the study and subsequent publication of the findings (patients were informed that their health data would be collected and analyzed uniquely upon explicit consent, which was formalized by clicking the "Start" button at the bottom of the information page of the web-based survey). Participant privacy and confidentiality were guaranteed according to European laws and regulations (General Data Protection Regulation). As informed consent was provided by all patients prior to completing the survey, ethical review and approval were waived for this study.

Results

Respondent Profiles

During the recruitment period, 820 patients with mental disorders or cardiovascular diseases or both conditions were enrolled in the study. Depending on the disease category, the 820 patients were recruited, selected, and grouped according to the risk level, therapeutic adherence, and behavior profiles as shown in Figure 1. Patients who answered being a "patient with cardiovascular disease or a cardiovascular risk factor" in the questionnaire were categorized in the "Patients with cardiovascular diseases only" group. The main diseases indicated by these patients in the questionnaire were high blood pressure (232/403, 57.6%), diabetes (120/403, 29.8%), and myocardial infarction (100/403, 24.8%).

Patients who answered being both a "patient with cardiovascular disease or a cardiovascular risk factor" and a "patient with a psychological disorder" in the questionnaire were categorized in the "Patients with both cardiovascular and mental disorders" group. The main diseases indicated by these patients in the questionnaire were high blood pressure (302/528, 57.2%), diabetes (170/528, 32.2%), and myocardial infarction (112/528, 21.2%). Patients who answered being a "patient with a psychological disorder" only in the questionnaire were categorized in the "Patients with mental disorders only" group. The main diseases indicated by these patients in the questionnaire were bipolar disorder (145/292, 49.7%), depression (135/292, 46.2%), and anxiety (125/292, 42.8%). In the risk level groups, the risk level of each patient was based on 5 determined risk factors and estimated by assigning 1 point per risk factor. Actual adherence was assessed based on the response to a set of 4 questions. The adherence score was then calculated by assigning points according to patients' answers. Patients were then grouped into 4 compliance categories based on the total points. Profiles were identified by using a 3-class ascending hierarchical classification model based on 12 variables.

The study group consisted of 542/820 (66.1%) women and 278/820 (33.9%) men, with a sex ratio (male/female) of 0.5. Patients ranged in age from 18 to 93 years (mean 55.2 years, SD 12.7 years). The demographic characteristics of the patients are summarized in Table 1.

Regarding disease category, 49.2% (403/820) of patients had cardiovascular disease; the most common conditions reported were high blood pressure (302/528, 57.2%), diabetes (170/528, 32.2%), myocardial infarction (112/528, 21.2%), hypercholesterolemia (100/528, 18.9%), and arrhythmia (92/528, 17.4%). In total, 35.6% (292/820) of patients had a mental disorder; the most common conditions reported were depression (199/417, 47.7%), anxiety (193/417, 46.3%), and bipolar disorder (184/417, 44.1%). A total of 15.2% (125/820) of patients had both conditions. The medical characteristics of the patients are summarized in Table 2.

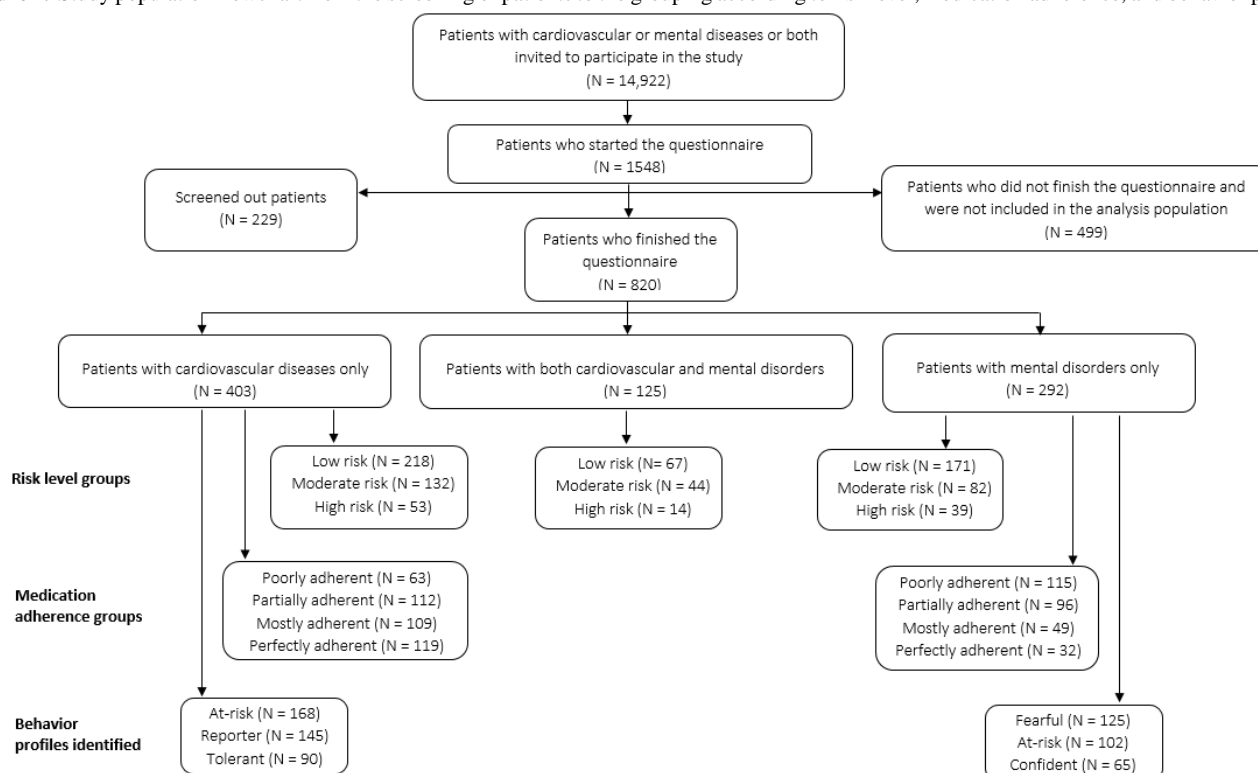
Figure 1. Study population flowchart from the screening of patients to the grouping according to risk level, medication adherence, and behavior profiles.


Table 1. Demographic characteristics of the patients with mental disorders or cardiovascular diseases or both conditions who were recruited for the web-based survey on the French Carenity platform.

Demographic characteristics	Total (N=820)	Patients with cardiovascular diseases only (n=403)	Patients with mental disorders only (n=292)	Patients with both conditions (n=125)	P value
Gender, n (%)					≤.001
Female	542 (66.1)	217 (53.8)	228 (78.1)	97 (77.6)	
Male	278 (33.9)	186 (46.2)	64 (21.9)	28 (22.4)

[a]Cardiovascular diseases vs mental disorders.

[b]N/A: not applicable.

The majority of patients were polymedicated; only 14.1% (116/820) of patients were taking only 1 medication. The average number of medications per day was 4.7 (SD 3.7), with a mean of 6.4 (SD 5.1) pills per day per patient (Table 2). Thus, treatments were very burdensome for some patients who took ≥10 pills (168/820, 20.5%).

Moreover, patients >65 years of age were more often polymedicated and took >3 medications per day (116/189, 61.4%) with an average of 5.1 (SD 3.3) medications per day.

Lifestyle and Risk Level

At the time of the survey, a quarter of patients (210/820, 25.6%) were smokers. Most patients (605/820, 73.8%) consumed alcohol, albeit at frequencies that varied between "a few times per year" (278/820, 33.9%) to "at least 3 drinks per day" (20/820, 2.4%).

The mean BMI was 29 (SD 7) kg/m^2, and 69.1% (567/820) of participants were overweight or obese (BMI ≥ 25). Most patients (582/820, 71%) indicated that they did not adhere to any type of diet.

Iatrogenesis

Regarding iatrogenic risk, 84.7% (695/820) of patients indicated worrying about risks associated with their medication; the main reasons were fear of dependence on treatment (372/695, 53.5%), lack of medication efficacy (373/695, 53.7%), the effect the medication will have on another condition (304/695, 43.7%), and intolerance or allergy to the medication (291/695, 41.9%). Less adherent patients are more likely to worry about dependency on treatment than perfectly adherent patients (89/199, 44.7% vs 36/128, 28.1%; P=.004). Nearly half of patients (432/820, 52.7%) worried about treatment risks and constraints when they started a new treatment; 73.1% (316/432) of these patients anticipated adverse effects.

A large majority of patients (722/820, 88%) worried about at least one treatment risk or constraint. These patients had discussed these issues with their general practitioner (307/722, 42.5%), a health specialist (305/722, 42.2%), or a relative (141/722, 19.5%).

Regarding adverse effects, 82.8% (679/820) of patients experienced adverse effects, and 19.6% (133/679) of these patients disrupted their treatment because of these effects without consulting with their doctors.

In terms of the information on the medications, 73% (599/820) of patients reported having received information from their doctors about treatment benefits, but only 44.6% (366/820) of patients had been informed about possible adverse effects for each medication. Patients with cardiovascular diseases tend to receive explanations on the benefit and health impacts of all their treatments more often than patients with mental disorders (317/403, 78.6% vs 195/292, 66.8%; $P \leq .001$). Furthermore, 35.8% (294/820) of patients had only received partial information regarding the benefits for health and potential interactions and adverse effects associated with their medication. Regarding specific medications, 52.4% (154/294) of patients were informed about most of their medications, 47.6% (140/294) of patients received information about some medications, and 20% (160/820) of patients did not receive any information. Moreover, 26.2% (215/820) of patients were unaware of possible pharmaceutical interactions, and only 40.1% (329/820) of patients were aware of the risks of potential interaction between medications.

Treatment Adherence

Perceived and Observed Treatment Adherence

In this study, the criteria for perfect medication adherence included taking all medication on time and as prescribed, without any interruptions. Overall, patients tended to perceive themselves to be more adherent than they actually were; 70.7% (580/820) of patients perceived themselves to be highly adherent (mean 8.9, median 9.9), 66.3% (544/820) reported taking their medication late or early, and 26.4% (217/820) regularly disregarded the prescribed dose. Patients with cardiovascular diseases perceived themselves to be highly adherent more often than those with mental disorders (320/403, 79.4% vs 173/292, 59.2%; $P \leq .001$). Furthermore, many patients stopped or interrupted a medication either unintentionally (429/820, 52.3%)

or intentionally (254/820, 31%) without consulting with a doctor. The most common reasons provided by the 646 patients who did not take their medication as prescribed were that they had forgotten to take it (335/646, 51.9%) or that they wanted to avoid experiencing adverse effects (188/646, 29.1%). Patients with mental disorders were more likely to intentionally disrupt their treatment than those with cardiovascular diseases (151/260, 58.1% vs 97/284, 34.1%; $P \leq .001$), primarily because they wanted to avoid experiencing adverse effects (84/260, 32.3%). When patients with cardiovascular diseases intentionally disrupted their treatment, they also most often mentioned that they did so to avoid experiencing adverse effects (63/284, 22.2%).

Factors Associated With Treatment Adherence

Factors associated with treatment adherence included demographic characteristics, disease type, treatment characteristics, and patient awareness of treatment and the associated adverse effects (Table 3). Men were more adherent than women (152/278, 54.7% vs 204/542, 37.6% mostly perfectly adherent patients; $P \leq .001$). The older patients (≥ 65 years) were markedly more adherent than the younger patients (112/189, 59.3% vs 244/631, 38.7% mostly perfectly adherent patients; $P \leq .001$). The more complex the treatment regimen (eg, multiple treatments during the day, frequent dose changes), the less adherent the patients were to the treatment regimen (mostly perfectly adherent patients: 75/269, 27.9% simple treatment vs 62/347, 17.9% complex treatment; $P \leq .001$). We also found that patients with cardiovascular diseases were more adherent than patients with mental disorders (228/403, 56.6% vs 81/292, 27.7% mostly perfectly adherent patients; $P \leq .001$).

Patients who were less adherent were more likely to think that they would experience adverse effects when they started a new medication (126/216, 58.3% of poorly adherent patients vs 70/174, 40.2% of perfectly adherent patients; $P \leq .001$). Similarly, the less adherent patients were to the medication, the more likely they were to worry about treatment constraints (160/216, 74.1% of poorly adherent patients vs 90/174, 51.7% of perfectly adherent patients; $P \leq .001$). We also found that poorly adherent patients were less likely to receive information regarding treatment benefits and adverse effects for each medication (74/216, 34.2% of poorly adherent patients vs 102/174, 58.6% of perfectly adherent patients; $P \leq .001$; Table 3).

Table 3. Factors associated with treatment adherence according to adherence level among patients with mental disorders or cardiovascular diseases or both conditions who were recruited for the French Carenity platform study (N=820).

[a]The P value only refers to the comparison of the simple and complex treatment regimens.

Reporting of Adherence Issues

Among the patients who did not always take their medication as prescribed, 59.1% (382/646) did not consult with their physician because they did not think it was necessary (146/382, 38.2%), they forgot (116/382, 30.4%), or they were afraid of disappointing their doctors or of being judged (87/382, 22.8%). Patients with the most risk factors (ie, overweight, smoking, age ≥65 years) seemed least likely to always notify their physician of adherence issues (26/81, 32.1% of high-risk patients vs 162/363, 44.6% of low-risk patients; P=.05).

Solutions and Tools Used by Patients

Just over half of respondents (428/820, 52.2%) used at least one tool to help them properly adhere to their treatment, such as a pill organizer (334/820, 40.7%) or an alarm (80/820, 9.7%). Only 1.9% (16/820) of patients used a smartphone application. Patients with cardiovascular diseases were more inclined to use

a tool than those with mental disorders (224/403, 55.6% vs 136/292, 46.6%; P=.02). A total of 12.2% (100/820) of patients reported that they received help with their medication from a caregiver. Among those who received assistance, the caregiver primarily reminded them to take their medication (60/100, 60%) or purchased the medication for them (43/100, 43%).

Patient Behavior Profiles

Patients With Cardiovascular Diseases Only

Patients with cardiovascular diseases were classified as follows based on 3 identified behavior profiles: at-risk patients, tolerant patients, and reporter patients.

The at-risk patients (168/403, 41.7%) were the least adherent (110/168, 65.5% were not fully adherent). The majority of these patients were women (121/168, 72%). Although these patients perceived themselves to be adherent (123/168, 73.2%), they took ≤3 pills per day (71/168, 42.3%), used complementary

approaches (138/168, 82.1%), and intentionally deviated from initial prescriptions (65/140, 46.4% of these patients did not take their medication as prescribed). These patients were worried about the treatment interfering with their daily routine (55/168, 32.7%) and the frequency of administration (68/168, 40.5%). Moreover, 33.9% (57/168) of the at-risk patients were more likely to worry about becoming dependent on their medication, and 49.4% (83/168) of patients worried about medication efficacy. These patients visited their physician more often (139/168, 82.7%) but did not always notify them of nonadherence (88/168, 52.4%) because of a fear of disappointing them (80/88, 47.86%). Finally, 73.2% (123/168) of these patients did not receive information about medication benefits, and 75% (126/168) of patients had discussed constraints and risks with someone.

The reporter patients (145/403, 36%) were largely adherent (116/145, 80%) and perceived themselves to be adherent (131/145, 90.3% of these patients perceived themselves to be fully adherent). The majority of these patients primarily included older patients (66/145, 45.5% ≥65 years of age) and men (90/145, 62.1%) who took >3 pills per day (118/145, 81.4%). They also believed that they were well-informed (122/145, 84.1%), they used practical tools to manage their medications (91/145, 62.7%), and they were aware of potential adverse interactions between their medication and tobacco (54/145, 37.2%) and alcohol (74/145, 51%).

The tolerant patients (90/403, 22.3%) experienced fewer adverse effects (78/90, 86.7%) and did not adjust their treatment (85/90, 94.4%). These patients were less aware of adverse interactions between their treatment and other medications (66/90, 73.3%) and between their treatment and alcohol (58/90, 64.4%). These patients did not inform their doctors about adherence issues (32/42, 76.2%).

Patients With Mental Disorders Only

Patients with mental disorders were grouped as follows based on 3 identified behavior profiles: fearful patients, at-risk patients, and confident patients.

The fearful patients (125/292, 42.8%) were polymedicated (85/125, 68% of patients took ≥3 pills per day), had experienced treatment adverse effects (125/125, 100%), and anticipated adverse effects when they started a treatment (75/125, 60%). These patients were concerned about treatment risks (101/125, 80.8%) and adjusted their treatment in the event of adverse effects (55/125, 44%); 25.6% (32/125) stopped the medication and 8.8% (11/125) modified the dose. These patients also used fewer complementary approaches such as nonpharmaceutical alternatives (54/125, 43.2%), homeopathy, (16/125, 12.8%), and acupuncture (3/125, 2.4%).

The at-risk patients (102/292, 34.9%) were the least adherent patients (82/102, 80% of these patients were not fully adherent), and the majority of these patients were women (90/102, 88.2%). They took only 1-2 pills per day (57/102, 55.9%) and perceived themselves to be poorly adherent (55/102, 53.9%). These patients worried about treatment risks and constraints (82/102, 80.4%). All patients used at least one other product or an alternative (102/102, 100%); nearly all patients (94/102, 92.1%)

used nonpharmaceutical therapy, 89.2% (91/102) of patients used homeopathy, and 52% (53/102) used acupuncture. They experienced adverse effects (102/102, 100%) and adjusted their treatment in case of an adverse effect (45/102, 44.1%); 17.6% (18/102) stopped the medication and 14.7% (15/102) modified the dose. Of these patients, 75.5% (77/102) reported adverse effects to their physician and 67.6% (69/102) had discussed constraints and risks with their pharmacist.

The confident patients (65/292, 22.3%) were more adherent (27/65, 42%) and the majority of those who were adherent were men (44/65, 67.7%). Few patients experienced adverse effects (44/65, 67.7% did not experience adverse effects); these patients did not adjust their treatment in the event of an adverse effect (60/65, 92.3%) and they were less likely to use complementary approaches (27/65, 41.4%). These patients worried less about the risks associated with their medication (22/65, 33.8%). They were less informed about risks (21/65, 32.3%) but well informed about treatment benefits (50/65, 76.9%). Finally, among the confident patients who did not always notify their doctors in the event of therapeutic nonadherence, 42.8% (15/35) did not think it was necessary to do so.

Discussion

Principal Findings

Web-based communities represent an increasingly popular and accessible platform for patients to learn about their condition and participate in clinical studies [22]. These web-based patient communities also provide researchers access to data about specific patient populations that are demographically representative. These tools enable the assessment of data concerning patient behavior, experiences, and well-being in all aspects of their lives (medical, professional, and personal), which are difficult to observe using other methods [22].

The current study focused on perceptions of iatrogenic risk and treatment adherence in patients with cardiovascular diseases, mental disorders, or both cardiovascular diseases and mental disorders. All patients were registered on the largest web-based Carenity patient community in France. We found that 82.8% (679/820) of patients experienced adverse effects associated with their medication. While the majority of patients (492/679, 72.4%) informed their doctor about adverse effects, many patients took steps to address adverse events on their own, with 30.8% (209/679) disrupting their treatment without medical advice. These results indicate that adverse effects present an understandable challenge for patients [23] and represent a major barrier to medication adherence [24]. We also found that well-informed patients were more likely to report adverse effects to a health care professional and are less likely to disrupt their treatment on their own. The frequent report of adverse events likely explains why most patients anticipated adverse effects when they started a new medication and worried about treatment risks and constraints such as dependence, lack of efficacy, effects on another condition, and intolerance.

Regarding therapeutic adherence, patients tended to perceive themselves to be more adherent than they actually were. Medication adherence is often overestimated by patients [25].

In this study, more than half the number of patients (426/820, 52%) unintentionally stopped or interrupted treatment at least once, often because they forgot or wanted to avoid experiencing adverse effects.

The results are consistent with those of previous studies that have indicated that approximately 50% of patients undergoing long-term therapy were nonadherent to their treatment [9,11]. A separate study has also indicated that forgetting to take medication and having limited awareness were the most frequently cited reasons for treatment nonadherence [14,26]. Previous studies have also shown that several factors are associated with adherence, including patient characteristics (gender, age, ethnicity, marital status), symptom intensity, medication type, route of administration, and severity of adverse effects [27,28]. In this study, the factors associated with treatment adherence included gender, age, treatment complexity, and disease type. Men were more adherent than women, and patients ≥65 years of age were significantly more adherent than the younger patients. Moreover, patients with a simple treatment regimen and those who had received information about treatment benefits and potential adverse effects tended to be more adherent. The degree of adherence also varied between the 2 disease groups, as patients with cardiovascular diseases tended to be more adherent than those with mental disorders. Less adherent patients were less aware of potential drug interactions, although they were more likely to anticipate adverse effects when they started a new treatment. They also worried more about risks of treatment dependency, lack of treatment efficacy, and the constraints that therapy may impose on their daily routine.

It is important to emphasize that the study was performed during the ongoing COVID-19 pandemic. To date, limited research is available on how the pandemic has specifically affected therapeutic adherence in NCD patients, but it is well known that the COVID-19 pandemic has disrupted health care services around the world, which has possible implications on therapeutic adherence in patients. One systematic review reported a significant failure of patients with inflammatory bowel disease to adhere to therapies during the COVID-19 pandemic [29]. However, as shown in a pharmacoepidemiological study conducted using data from the French National Health Data System, the COVID-19 pandemic did not seem to lead to a shortage of treatment for patients with cardiovascular diseases. For example, a significant number of hypertensive patients overstocked their medication when the lockdown was announced. On the other hand, the study demonstrated a decrease in consumption of nonprescription drugs and products needed for examinations, such as colonoscopies, or contrast agents. Therefore, the combination of factors related to social restriction (lockdowns, difficulty in accessing health care or treatments) and patient-related factors (fear of infection, decision to take or not take the drug, treatment dosage adjustment) may have impacted therapeutic adherence in NCD patients, even though this impact seems to be more nuanced in France than in other countries [30].

The 3 patient profiles identified for each disease type provide significant insight for improving therapeutic adherence and adjustment strategies specifically according to patient behaviors.

With respect to the cardiovascular disease profiles, the at-risk patients, who were less adherent and worried about treatment risks and adverse effects, should be better informed about treatment risks (especially adverse effects) and treatment benefits. The tolerant patients, who were polymedicated, more adherent, and less worried about risks and adverse effects, should be better informed about tools they can use to properly manage their medication. The reporter patients, who did not discuss adverse effects with their pharmacists and were unaware of treatment interactions, should be better informed about the risks of treatment interactions and encouraged to notify their doctors when medications are not taken as prescribed.

Regarding the mental disorder profiles, the at-risk patients, who were not adherent, rarely communicated with their doctors, and overestimated treatment risks and constraints, should have access to specialized therapeutic educational programs to improve awareness and medication adherence (eg, shared decision making) [31]. The fearful patients, who were polymedicated, experienced adverse effects, and were better informed about drug interactions and adverse effects, should be closely monitored by their doctors so that advice focused on their specific needs can be provided. Finally, the confident patients, who tended not to seek assistance when needed and did not present major challenges, should be encouraged to build a better relationship with their doctors and seek assistance when necessary.

Limitations

A few study limitations should be mentioned. As the study was based on data collected via a web-based survey, it may exclude patients who are not comfortable using or do not have access to internet or a computer or who are non-French speakers living in France. The underrepresentation of older patients in the Carenity community and the overrepresentation of patients who are actively concerned about their health may have also led to selection bias. Moreover, patient characteristics and medication adherence were assessed using self-reported measures, which may have led to recall bias. Finally, the group of patients with both cardiovascular diseases and mental disorders could not be included in the statistical analysis because of the small number of patients in the group. Patients with multiple NCDs should be included in future studies because they are at an increased risk of iatrogenic disease [18].

Patients completed the questionnaire without the guidance of their physicians, so desirability bias was greatly limited. As individuals registered in patient communities may likely be heavily burdened by their condition, our study population may overrepresent highly symptomatic and polymedicated patients. Nevertheless, it has been shown that characteristics of patients in Carenity communities reflect the main characteristics of web-based users willing to share their medical experience but with an overrepresentation of female patients aged 25-54 years [32]. This study exclusively included patients registered on the French Carenity platform and did not include other relevant sampling procedures and methods. Despite the fact that study recruitment focused on a homogeneous population of patients through the Carenity platform, the results of the study are not

generalizable to the larger population of patients with these disorders.

Conclusions

Overall, the results of this web-based survey study provide important insight into patients' perspectives and behaviors because the anonymous nature of the survey allowed patients to respond openly and honestly. These findings emphasize the importance of involving patients in medical decisions and providing patients with information about treatment benefits, treatment adherence, potential adverse effects and risks of treatment, and potential drug interactions. Therapeutic alliance significantly helps patients to understand both the disease aspect and the therapeutic options, thereby improving medication adherence and overall disease management [11,18]. Integrative and comprehensive patient care that considers the complementary therapeutic approaches used by patients could also improve medication adherence [26]. Our results also show that caregivers and pharmacists should be empowered to proactively support and better educate patients with an NCD who require multiple medications. Practical tools should be developed to remind patients to take their medication as prescribed, and additional studies should assess improved support strategies for patients with chronic diseases.

Classical adherence studies are often biased and do not accurately represent the patient population for a given disease. Web-based platforms on which patients can share their medical experiences in an anonymous manner may provide unique insight into the perspectives of patients undergoing therapy for an NCD, which could help to improve disease management and eventually prevent premature deaths.

Conflicts of Interest

PC is the Head of the Department of Psychiatric Emergency and Acute Care at Centre Hospitalier Universitaire de Montpellier. PC has received fees for occasional consultation for Janssen, Exeltis, and Pfizer. CP is a Medical Director at Viatris and discloses stock holdings from Pfizer and Viatris. AFLP is a Quality Manager at Pfizer PFE France, a Viatris company. CA is an employee of Carenity, and MC is the President and Founder of Carenity; CA and MC have no conflicts of interest to declare. Abstract

Background: To address the current COVID-19 and any future pandemic, we need robust, real-time, and population-scale collection and analysis of data. Rapid and comprehensive knowledge on the trends in reported symptoms in populations provides an earlier window into the progression of viral spread, and helps to predict the needs and timing of professional health care.

Objective: The objective of this study was to use a Conformité Européenne (CE)-marked medical online symptom checker service, Omaolo, and validate the data against the national demand for COVID-19–related care to predict the pandemic progression in Finland.

Methods: Our data comprised real-time Omaolo COVID-19 symptom checker responses (414,477 in total) and daily admission counts in nationwide inpatient and outpatient registers provided by the Finnish Institute for Health and Welfare from March 16 to June 15, 2020 (the first wave of the pandemic in Finland). The symptom checker responses provide self-triage information input to a medically qualified algorithm that produces a personalized probability of having COVID-19, and provides graded recommendations for further actions. We trained linear regression and extreme gradient boosting (XGBoost) models together with F-score and mutual information feature preselectors to predict the admissions once a week, 1 week in advance.

Results: Our models reached a mean absolute percentage error between 24.2% and 36.4% in predicting the national daily patient admissions. The best result was achieved by combining both Omaolo and historical patient admission counts. Our best predictor was linear regression with mutual information as the feature preselector.

Conclusions: Accurate short-term predictions of COVID-19 patient admissions can be made, and both symptom check questionnaires and daily admissions data contribute to the accuracy of the predictions. Thus, symptom checkers can be used to estimate the progression of the pandemic, which can be considered when predicting the health care burden in a future pandemic.

Introduction

Background

The rapid spread of the SARS-CoV-2 virus leading to a pandemic presented challenges for nationwide assessment of the progression of the COVID-19 pandemic [1]. The virus was first discovered in Wuhan, China, in December 2019, and COVID-19 was declared a pandemic by the World Health Organization in March 2020 [2-4]. In Finland, cases started to appear in late February 2020, and the Finnish government announced a national lockdown in mid-March 2020 to slow the viral spread and protect risk groups [1].

Digital health technology tools such as symptom checkers have been used in different countries (eg, Finland, France, Israel, Italy, the Netherlands, the United Kingdom, and the United States) as self-triage tools for possible SARS-CoV-2 infections [5-11]. In Finland, a COVID-19 symptom checker was added to a preexisting national Conformité Européenne (CE)-marked medical symptom checker service, Omaolo [5-12]. The web-based symptom checker provides the user with advice on further actions based on a medically approved algorithm. Although there have been studies about how well symptom checkers perform as clinical tools [13], to our knowledge, the potential of these data for predicting epidemic progression has not yet been studied. Having real-time comprehensive data on reported symptom trends could provide an earlier window into the viral spread and help predict the burden of professional health care.

To study if the data collected by the Omaolo service and the national care notification registers could be used to predict pandemic progression in Finland, we used the methods of machine learning. Perhaps the best potential of machine learning over more traditional methods lies in its ability to better adapt to the data, and thus to the evolution of the underlying phenomenon. With large data sets such as the Omaolo COVID-19 symptom checker responses, machine learning may also uncover more complex associations between the factors contributing to the predicted outcomes. Machine learning models can also be trained and retrained along the way to reveal how the significance of the individual input variables for making the predictions will change over time and to become a more accurate predictor as more data are collected.

Objectives

The study objective was to assess if a nationwide symptom checker can be used as a predictive tool in estimating the national progression of the COVID-19 pandemic and health care admissions by utilizing machine learning methods.

Methods

Data

Omaolo

The COVID-19 epidemic in Finland started in mid-March 2020. On March 16, 2020, the Finnish government announced a state of emergency due to the COVID-19 epidemic, and consequently implemented several physical distancing measures aimed at slowing the spread and protecting risk groups [1]. Part of the national response was the Omaolo COVID-19 web-based symptom self-assessment tool, a CE-marked medical device [5,12]. Omaolo was launched for use March 16, 2020, and was published in the two national languages (Finnish and Swedish) and later also in English. The COVID-19 symptom checker functioned as any other symptom checker in Omaolo, and was jointly developed by DigiFinland Oy, Duodecim Publishing Company Ltd, the Finnish Institute for Health and Welfare (THL), Solita Oy, and Mediconsult Oy.

In the symptom checker, the user answers a set of predefined, expert-validated questions. As a result, it returns self-triage information on how to proceed with one's situation. The progress of filling in the questionnaire from start to finish is recorded to the log files of the service. The respondent has a choice to answer anonymously without including one's personal information in the process. The questionnaire itself includes several background questions such as age, postal code, gender, and reason for filling in the questionnaire; existing medical conditions; whether the respondent has had close contact with a COVID-19–positive person; whether the respondent or close contacts have been ordered to quarantine by a physician; where the respondent thinks they may have caught the virus; and what kind of work the respondent does in regard to contacts with others (the full Omaolo questionnaire is provided in Multimedia Appendix 1). The questionnaire has been updated several times during the pandemic to better coincide with the latest COVID-19 research [5].

During the study period, a total of 547,428 responses were submitted to Omaolo. Of these, the contents of 132,951 responses were unsaved due to technical reasons. Almost all of the unsaved responses were submitted prior to March 28, 2020, when Omaolo was yet not configured to save the anonymous responses. A small number of the anonymous responses were not saved during short maintenance breaks throughout the period. Accounting for these losses, a total of 414,477 responses were available for analyses. Care reminders, the self-triaged recommendations for care as given by the Duodecim Evidence-Based Medicine Electronic Decision Support service [5], were available for all submitted responses, including the unsaved responses. The data were pseudoanonymized prior to the analyses.

National Registers: Hilmo, Avohilmo, and Paavo

We used the established national care notification registries Hilmo and Avohilmo [14] of the THL to estimate the demand of COVID-19–related care. These registers contain structured inpatient (Hilmo) and outpatient (Avohilmo) records from all public and private specialist care hospitals in Finland. These records were combined in the data preprocessing stage and are hereafter referred to collectively as "Hilmo." The data were anonymized of all identifiers before use.

As a supplementary source, we used the publicly available version of the Paavo register maintained by Statistics Finland [15]. Among other variables, Paavo contains basic demographics of Finnish citizens based on the postal code of their residence. We used these data to identify and rectify the regional bias in age distribution of the Omaolo users. These data were anonymous at the source.

Predicting the Daily Use of Health Care Resources

We chose our study period to be from March 16, 2020, corresponding to the release of the COVID-19 symptom checker, to June 15, 2020, as the approximate beginning of a period of low activity in the pandemic following the first wave. For the predictions, we used two regressors: linear regression [16] and extreme gradient boosting (XGBoost) regression [17]. The reasoning behind selecting two regressors was to compare a simple and traditional method (linear regression) to a modern option (XGBoost regression) with many hyperparameters that can be learned from the data. Both methods were implemented with three feature preselection strategies: a human expert (KA), F-score [16], and mutual information [18]. All regressor feature selector combinations were tested separately resulting in six different machine learning models.

We chose a scenario where the number of daily COVID-19–related health care admissions, as extracted from the Hilmo register, was predicted 1 week ahead, every week on Wednesdays. This follows a hypothetical scenario where the resources for the following 7 days would be decided midweek (on Wednesday) to give 2 full days to prepare for the weekend, for example by reassessing the need for extra resources and personnel.

For training, testing, and validation of the models, we used time-series nested cross-validation [19]. This strategy was chosen to ensure that the model is trained and tested with samples independent from the validation set; thus, no information from the samples past the prediction point was used. During cross-validation, the set of features (and other hyperparameters in the case of XGBoost), with which the regressor best generalizes its predictions to unseen data in terms of average prediction error on different validation sets, is selected for a given regressor.

We also chose to train the classifiers with Hilmo and Omaolo data first separately and then combined. This was to test how much, if any, the results would improve if the data from both sources were used.

Profiling the Motives of Omaolo COVID-19 Symptom Checker Users

The Omaolo COVID-19 symptom checker achieved considerable popularity immediately after its release. Tens of thousands of responses per day were submitted during the first week. The submission activity showed clear peaks during infomercials and other major media mentions. To distinguish the users that were truly suspecting a COVID-19 exposure from the users that were visiting Omaolo just out of curiosity, a question about this matter was added to the questionnaire in the form of a simple tick-box on March 28, 2020. After this update, it was found that approximately 40% of the responses had the out-of-curiosity option checked. We then investigated whether it was possible to distinguish the two response profiles (out-of-curiosity or not) and which questions were the best predictors of this behavior. We used a naive Bayes classifier [20], logistic regression [16], and XGBoost binary classifier [17]. We chose naive Bayes and logistic regression because they are widely used in medicine and other fields. XGBoost was included since it is based on a different approach (an ensemble of trees) and thus provides an interesting comparison to the two established methods.

All three models were tested with 5-fold random cross-validation, and the sensitivity and specificity for each fold were computed and finally averaged over all folds. The size of the majority set (not out-of-curiosity) was balanced by undersampling to the size of the minority prior to cross-validation.

All analyses, both the predictions and profiling, were performed using Python version 3.6 [21] with the feature selectors, classifiers, and regressors from Scikit-learn module version 1.0 [22].

Ethical Consideration

Our study data are based on statistical register data at the national level. These register data contain no personalizing identifiers. Therefore, this study does not fall under the purview of laws regarding medical research. The study protocol does not violate any ethical considerations or standards, according to a statement from the Medical Ethics Committee of the Hospital District of Helsinki and Uusimaa in Finland (June 2013).

Results

Predicting the Daily Use of Health Care Resources

Women used the web-based symptom checker more often than men; approximately two-thirds of the filled-in forms were completed by women (Table 1). People of working age were also using the symptom checker more than other age groups. Most of the questionnaires (approximately half) were completed in Southern Finland. Cough was the most common symptom, followed by sore throat, fever, headache, and difficulty breathing.

Table 1. Distribution of age, employment status, symptoms, and region of the filled-in Omaolo questionnaires.

Characteristic	Total, n (%)	Men, n (%)	Women, n (%)
Age (years)			
0-9	8652 (2.08)	4291 (2.81)	4361 (1.66)
10-19	30,805 (7.41)	10,689 (6.99)	20,116 (7.68)
20-29	93,511 (22.50)	30,241 (19.77)	63,270 (24.10)

Total	294,984	106,685	188,299

For the analyses, we chose two regressors, linear regression and XGBoost, with three feature preselection strategies for each, and compared their performance. To predict the COVID-19–related admissions for each day, 7 days ahead of the prediction point, the features given to the model were extracted from the responses and the Hilmo register on the 7 and 14 days prior (lag variables). The use of lag variables essentially means that two sets of the time-dependent features

were formed, with the first delayed 7 days and the second delayed 14 days. This was to ensure that no data from any of the sources, Omaolo or Hilmo, were leaked past the point of prediction during feature selection, model training, or testing. The regressors were first trained with 5 expert-selected features: how many of the questionnaires were filled-in by people over 60 years old, how many reported lengths of symptoms were greater than 10 days, and how many were assigned the urgency code P1 (the most urgent) in the care recommendations, in addition to the number of COVID-19–related admissions. The feature preselectors F-score and mutual information were added later.

The predictions made by both models for data gathered between March 16, 2020, and June 15, 2020, were compared to the true admission count (Figure 1). The first 4 weeks were reserved for training the models before predictions were made in the week starting on April 16, 2020. For the consecutive weeks, the models were retrained with the data from the previous weeks. Both models made predictions with a similar error (linear regression: mean absolute error [MAE] 138, mean absolute percentage error [MAPE] 31; XGBoost regression: MAE 135, MAPE 31). The predictions become more accurate toward the end of the study period, since the models had more data to learn from, which reduced the sampling bias. May 22, 2020, was a public holiday in Finland, explaining a similar drop in the true admission count as on weekends.

To check that the Omaolo questionnaire data are relevant for the predictions, we compared the error of both models with and without the questionnaire data, and only with the questionnaire data (Table 2). Both models achieved the lowest error when the registry and the questionnaire data were combined, indicating that the questionnaire data are relevant for making accurate predictions compared to the registry data alone.

In addition to expert-selected features, we tested automated feature selection methods that select the top 8 features based on the F-score or mutual information of the feature with the predicted variable (number of admissions on a given day) (Table 3). The F-score and mutual information are measures of dependence between the feature values and the values of the predicted variable in the historical data. Different feature selection strategies worked better for the two models: linear regression was the most accurate with the mutual information criterion, whereas XGBoost was the most accurate with the expert-selected features.

Older age groups, who are more likely to have a severe form of COVID-19 and hence be admitted to hospital, are underrepresented in the Omaolo questionnaire data. This could affect the performance of the models, as it is more difficult for the models to learn from imbalanced training data. To assess the problem, oversampling of the underrepresented age groups was performed to see if it would decrease the error of the models (Table 4). Resampling gave the linear regression model slightly smaller error, whereas the XGBoost regressor performed worse with resampling. These results indicate that it is not essential when minimizing the prediction error to oversample the questionnaire answers of the underrepresented age groups to match the age distribution of the population.

Figure 1. COVID-19–related admissions predicted by linear regression and extreme gradient boosting (XGBoost) regression models, together with the true admission count during the first wave of the pandemic in 2020.
Table 2. Comparison of the effect of Omaolo[a] and Hilmo[b] data on the error of the models on expert-selected features.

Features	Mean absolute error	Mean absolute percentage error
Linear regression		
Omaolo+Hilmo	137.79	31.33
Omaolo	175.38	44.60
Hilmo	184.37	34.98
Extreme gradient boosting regression		
Omaolo+Hilmo	139.11	31.78
Omaolo	165.18	46.94
Hilmo	178.92	46.63

[a]Omaolo: A web-based, CE-marked symptom self-assessment tool and medical device.

[b]Hilmo: National administrative register on hospital admissions.

Table 3. Comparison of the effect of different feature selection methods on the error of the models.

Feature selection	Mean absolute error	Mean absolute percentage error
Linear regression		
Expert-selected	137.79	31.33
F-score	141.40	30.46
Mutual information	112.16	24.23
Extreme gradient boosting regression		
Expert-selected	139.11	31.78
F-score	150.07	36.40
Mutual information	146.12	33.33

Table 4. The effect of oversampling on the error of the models with expert-selected features.

Resampling	Mean absolute error	Mean absolute percentage error
Linear regression		
No resampling	137.79	31.33
Oversampling	131.13	30.47
Extreme gradient boosting regression		
No resampling	139.11	31.78
Oversampling	153.35	35.22

Profiling the Motives of the Omaolo COVID-19 Symptom Checker Users

The three different models produced the following sensitivity and specificity for detecting users that answered they were using the service out of curiosity: 0.622 and 0.367, respectively, for the naive Bayes classifier; 0.665 and 0.332, respectively, for logistic regression; and 0.607 and 0.388, respectively, for the XGBoost binary classifier. These results were acquired by maximizing the number of correct classifications.

Discussion

Principal Results

In this study, we examined whether it is possible to predict the national epidemic progression and the burden of health care using machine learning methods with real-life data on symptoms and usage of health care. The main finding of this study is that it is possible to predict national health care admissions related to COVID-19 using a symptom checker combined with register data by using machine learning methods with considerable accuracy (small MAPE error). These methods were tested in a scenario where the predictions were made 1 week ahead, once per week. The best model was achieved using the symptom checker data combined with register data (MAPE 24.23%). This result was reached by using linear regression with mutual

information as the feature preselector. All tested models and combinations of feature preselectors and models were able to produce predictions that followed the true epidemic progression (Figure 1). Overall, linear regression was better than XGBoost, although only marginally. This suggests that in our research scenario, there was no benefit in using a model that has many trainable hyperparameters (XGBoost regression) over a simple model (linear regression). All tested models seemed to improve toward the end of our study period as more data were available for training. Additionally, the differences in accuracy between the models were more visible at the start of the period and seemed to diminish toward the end. Based on the results, the F-score and especially mutual information appear to improve the results for linear regression. Feature preselection may improve the predictions by, for example, reducing the risk of overfitting. This is relevant in our data set since the feature set used in the classification was rather large and likely suffers from multicollinearity. Using the preselectors did not improve XGBoost regression. This suggests that we were not able to find a suitable preselection strategy for the method.

Finally, predictions that can follow the progression can be made using either Omaolo symptom checks or historic Hilmo counts separately. However, the best results were achieved by combining both. Adding Omaolo to Hilmo counts reduced the MAPE of linear regression from 34.98% to 31.33% and that of XGBoost from 46.63% to 31.78%. These results suggest that Omaolo contains information of the pandemic progression that is not present in Hilmo alone.

Oversampling the data to balance the regional differences between the Omaolo users and general population seemed to produce conflicting results: marginal gain with linear regression but loss of accuracy with XGBoost. Oversampling leads to added complexity in the analysis pipeline, and without a clear benefit, its use is hard to justify.

Profiling the Motives of the Omaolo COVID-19 Symptom Checker Users

The answer profiles of those using the COVID-19 symptom checker out of curiosity were very similar to those of the other users, and no reliable classification between the groups could be made by any of the tested models. Neither of the groups reported longer or more serious symptoms over the other. The only striking difference between the groups was that there appeared to be more out-of-curiosity responses during high service utilization such as after television infomercials.

Consideration of Other Sources

We also considered using the daily number of phone calls received at the 116117 Medical Helpline service. The 116117 Medical Helpline provides professional assistance on health care–related topics in urgent, but nonemergency cases to over 4 million Finns in extended business hours. However, since it was not possible to extract the topic of the call, whether they were COVID-19–related or not, and since the calls could be localized with much poorer resolution than with the rest of the sources, this data set was eventually dropped from the analyses.

The Google Trends [23] of popular COVID-19–related search terms was another potential data source considered for analyses.

However, it was found that the publicly available Finnish trends only covered major cities. Additionally, the overlap of trending search terms between cities was found to be small, making the data very sparse. For these reasons, this data set was not used in the analyses.

Strengths and Limitations

This study had several potential limitations. A considerable number of responses (132,951) were not saved during the study period. Nearly all of these were submitted during the first 2 weeks of the study, complicating the analysis for the first month. This may have contributed to the relatively poor prediction accuracy for the related weeks by delaying the convergence of the regressors to the true admission count.

The true admission count showed a strong diminishing trend toward the end of our study period. During the last weeks of the period, there were days when only a few dozen new admissions were recorded nationally. Because our error metric, MAPE, is relative to the true values, if these values are small, error values will appear high even though the absolute error between true and predicted counts remains low. Despite this, we decided to use MAPE for its intuitiveness, wide use, and easy comparability of the error between the days, weeks, and methods.

At the beginning, the survey did not include an item about the motive to fill in the survey (ie, whether it was due to actual symptoms or out of curiosity). This adds some additional forms to our data that do not reflect the situation at hand. The proportion of responses filled-in out of curiosity remained remarkably stable at around 40% throughout the study period. Moreover, the results of trying to separate the responses filled-in out of curiosity from the rest with binary classifiers (naive Bayes, logistic regression, XGBoost classifier) failed to reveal any meaningful differences between the answer profiles of these groups. Thus, we did not find a justification to remove these responses from the analyses or handle them differently than the rest of responses (not filled-in out of curiosity).

The data available for this study contained COVID-19–related admissions data with a steady downward trend, and it would have been interesting to see if the models could predict a reversal of the trend before it occurs. However, there is weekly variability in the admissions and the models learned this pattern well. An interesting deviation from the weekly pattern was Ascension Day on Thursday, May 21, which was a public holiday in Finland. The models did not have enough training data on admissions on public holidays on a weekday to predict a similar dip in the admissions as on weekends, although longer data sets could allow the models to learn this pattern as well.

Much of the prediction errors took place during days that showed sharp peaks of increased or decreased demand that were not immediately explainable with the data available. Some of these errors may be due to technical reasons such as a major care provider suffering an error on one day and reporting higher counts on the following day. Naturally, these kinds of special events cannot be learned from the admission count data alone. On a positive note, the developed models appear robust and thus not susceptible to these kinds of anomalies.

One could also question if biological tests make other monitoring redundant. While in many countries biological tests are performed to follow the pandemic, it is important to note that online symptom checking does not replace the need for biological testing but provides a different and valuable perspective. In many countries, including Finland, the testing services are saturated, and only some population groups get tested, making our picture of the pandemic progression biased. Biological testing further comes with an immense cost, particularly with an exponential rise in cases.

The symptom checker, in turn, can be filled in anytime and by large numbers. Furthermore, it can be continuously updated to include the most relevant questions. It is possible that the health care burden is going to change even quite rapidly, and we can see that using Omaolo surveys, even without an indication from the time-series data. Additionally, the machine learning models are trained every week, allowing adaptability to changes in the statistical relationship between the predictors and the predicted variable as the pandemic progresses.

Furthermore, while our data only cover the first wave of the pandemic, the results remain important from the perspective of early decision-making against a new threat, and overcoming the challenge on modeling a novel phenomenon from the start with no history. Additionally, we do not only validate the data, but our approach further enables the prediction and modeling of the pandemic. Emergence of vaccinations, new variants, new policies, and restrictions will all affect the progression of the pandemic. These changes have also affected Omaolo, which has been continuously updated (eg, including questions about vaccination status). Our prediction models are also upgradeable continuously; thus, the drift in data and concept can be mitigated on the go, and features that will drop or rise in importance can be monitored along with the actual result of the prediction.

Finally, the lack of reported anosmia could suggest a lack of specificity. In our data, anosmia is a rarely reported symptom. It is also a known problem that without a specific test, COVID-19 is notoriously hard to distinguish from a common flu. Despite the relatively small number of reported anosmia cases, we have other features that have been shown to be highly significant in predicting International Classification of Diseases-10– and International Classification of Primary Care-2–coded admissions. These include features such as how many of the questionnaires were filled-in by people over 60 years old, how many reported lengths of symptoms were greater than 10 days, and how many were assigned an urgency code P1 (the most urgent) in the care recommendations.

Alternatively, if anosmia is important for specificity, it is likely that we have more false positives and our final models are less accurate. In other words, with the key symptoms, the precision of the model is improved and the error is smaller. The consequence of such a lack depends on how the results are used. If the burden of health care were solely estimated based on these models, we might underestimate the need for health care. However, it is unlikely that the model would be used to define any absolute health care need, whereas it can provide an indication to prepare for an increased health care burden.

The study also has several strengths. We had access to a nationwide online symptom checker data source, Omaolo, which is a CE-marked medical device complying with the Medical Device Directive, used by health care and social service professionals [24]. We also had data on all hospital admission records from public or private hospitals in Finland on a weekly basis. Such data are rarely available anywhere in the world and provide unique opportunities to produce new information about the possibilities of using such real-life data in predicting a subsequent health care burden. Similar symptom checkers could be adopted for use in many other countries, and they could provide an opportunity to collect data on symptom development very rapidly and at a relatively low cost at a national level. These symptom checkers and the findings are not restricted or solely applicable to the current pandemic or its first wave, but could be applied in any other future epidemic or pandemic or for the collection of other types of symptoms as well.

In addition, a clear advantage of machine learning methods is that both the model section and fit are automatized. This means that the prediction method adapts in the face of any new data and attempts to make as accurate predictions as possible with the data in use at any given time. However, in case the phenomenon in question changes notably, changes in data use and sources and machine learning methods are also required.

Conclusions

Our study shows that COVID-19–related health care admissions in the short term can be predicted with considerable accuracy using symptom checker data combined with register data based on machine learning methods. This type of approach could help health care providers better assess the burden of the health care system in advance, which would make resource allocation more predictable. Furthermore, we consider that this type of approach could also be implemented in different stages of the pandemic and in future pandemics as well.

Abstract

Background: While there is a strong association between adhering to a healthy dietary pattern and reductions in blood pressure, adherence remains low. New technologies aimed to help facilitate behavior change may have an effect on reducing blood pressure among individuals with hypertension.

Objective: This study aims to evaluate characteristics of participants with stage 2 hypertension who used Foodsmart and to assess changes in systolic blood pressure (SBP) and diastolic blood pressure (DBP).

Methods: We analyzed demographic, dietary, and clinical characteristics collected from 11,934 adults with at least two blood pressure readings who used the Foodsmart platform. Stage 2 hypertension was defined as SBP ≥140 mmHg or DBP ≥90 mmHg. We calculated mean changes in blood pressure among participants with stage 2 hypertension and stratified by length of follow-up and the covariates associated with achieving blood pressure levels below stage 2 hypertension. We compared changes in diet quality and weight between participants with stage 2 hypertension at baseline who achieved stage 1 hypertension or below and those who did not.

Results: We found that 10.63% (1269/11,934) of participants had stage 2 hypertension at baseline. Among Foodsmart participants with stage 2 hypertension at baseline, SBP and DBP decreased, on average, by 5.7 and 4.0 mmHg, respectively; 33.02% (419/1269) of participants with stage 2 hypertension at baseline achieved blood pressure levels below stage 2 hypertension (SBP <140 mmHg and DBP <90 mmHg). Using a multivariable ordinal logistic regression model, changes in Nutriscore (*P*=.001) and weight (*P*=.04) were statistically significantly associated with changes in blood pressure categories for users with stage 2 hypertension at baseline. Using a multivariable logistic regression model, we found that baseline Nutriscore, change in Nutriscore, and change in weight were associated with greater likelihood of users with stage 2 hypertension at baseline achieving a lower blood pressure category.

Conclusions: This study evaluated changes in SBP and DBP among users (with hypertension) of the Foodsmart platform and found that those with stage 2 hypertension, on average, improved their blood pressure levels over time.

Introduction

Almost half of all adults living in the United States have hypertension, with only 1 in 4 having their condition under control [1]. Hypertension occurs when the body's blood vessels narrow, which results in blood exerting a greater pressure on the walls of one's blood vessels and the heart working harder [2]. Uncontrolled hypertension can also lead to a myriad of

XSL•FO

RenderX

health complications as it can result in narrow, weak, or thick blood vessels, which prevent organs from functioning normally. Notably, it can cause aneurysm, heart disease, or stroke, with heart disease and stroke being the leading causes of death in the United States [1,3]. Consequently, this condition costs the US health care system about US $131 billion annually [4].

A healthy diet is an important part of an individual's toolkit to reduce their blood pressure. Previous studies have shown that a healthy dietary pattern can reduce hypertension to controlled levels. For example, the Dietary Approaches to Stop Hypertension (DASH) diet is composed of fruits, vegetables, and low-fat dairy products. Filippou et al [5] found in a systematic review of studies that the DASH diet resulted in significant reductions in blood pressure both for those with hypertension and those without. After such success in these trials, DASH is now recommended by the National Institutes of Health (NIH) to reduce hypertension [6]. Despite robust evidence supporting the relationship between healthy eating and lower risk of hypertension, barriers related to time, finances, information, and accessibility in obtaining healthy foods prevent people from starting and sustaining such changes over their lifetime.

Foodsmart, a digital nutrition platform, is a potential solution to address these barriers. The platform helps its users improve their health by providing them information about their current diet and pinpointing areas of improvement, while also providing personalized recipes and meal planning options to achieve target goals. The platform also assists in purchasing healthier foods with direct integration from meal plans to grocery lists to retailers through an ad-free environment. Consequently, Foodsmart is able to create sustainable behavior change for its users by making the process easy, quick, and affordable. Previous research has shown that this sustained behavior change has resulted in sustained changes in biometrics as well. Hu et al [7] found that Foodsmart members with obesity have been able to achieve sustained weight loss over the time during which they have used the platform.

Previous studies have also shown the effectiveness of digital nutrition interventions in helping participants lower their blood pressure. Milani et al [8] provided a digital intervention that consisted of lifestyle recommendations as well as medication management to assist patients in reducing their blood pressure. Participants were asked to measure their blood pressure at least once a week on purchased blood pressure devices. They found that in the digital intervention groups patients saw an average decrease in blood pressure of 14 mmHg in systolic blood pressure (SBP) and 5 mmHg in diastolic blood pressure (DBP) after 90 days compared with those on usual care with a reduction of 4 mmHg/2 mmHg [8]. This study displays what is possible at the higher end of blood pressure reductions over 90 days given that this was a partially medication-guided intervention. Steinberg et al [9] implemented a digital intervention to attempt to increase DASH adherence and thus lower blood pressure more through the use of a mobile diet-tracking app. After 3 months, participants had an average reduction of 2.8 mmHg of SBP and 3.6 mmHg for DBP [9]. Foodsmart, however, does not provide medication management services and differs from the latter intervention in its digital interface, personalized meal

planning, and online food ordering system. Therefore, Foodsmart is well-positioned to help its participants with hypertension make sustainable, holistic changes in their health by both providing them with nutritional information and adjusting their food purchasing environment to facilitate behavior change.

This study aims to characterize Foodsmart participants with stage 2 hypertension, as well as identify what characteristics are associated with returning to stage 1 hypertension levels or lower among those with stage 2 hypertension. It also aims to evaluate changes in blood pressure levels and other biometrics over time among participants with hypertension.

Methods

Study Sample

As of August 2021, 106,816 participants of Foodsmart who were older than 18 years living the United States and enrolled since January 2016 had entered plausible systolic and diastolic readings (SBP between 80 and 300 mmHg, exclusive; DBP between 40 and 200 mmHg, exclusive). Of those Foodsmart participants, 11,934 had reported at least two systolic/diastolic readings, with the first and last reported readings at least 30 days apart. Our final sample size was 11,934 participants with at least two reports of SBP and DBP.

Foodsmart

Foodsmart is a digital nutrition platform that facilitates sustained dietary and behavior change through 2 main components, FoodSmart and FoodsMart. Foodsmart has been described previously [10]. In brief, participants on Foodsmart complete an online dietary assessment, Nutriquiz, to evaluate current diet quality. Based on the results of the Nutriquiz, personalized meal plans, aligned with their dietary preferences, are created that are converted into grocery lists and integrated into online order and delivery of meal kits, prepared foods, and groceries.

Foodsmart is available through health plans and employers and can be accessed via the web or the iOS or Android operating system.

Measurements of SBP, DBP, and Weight

Foodsmart participants were able to input their biometrics such as blood pressure, height, and weight, and were able to report new biometrics at any time. Because of potential errors in participants self-reporting their biometrics, the following values were considered as outliers and removed: SBP ≤80 mmHg or ≥300 mmHg, DBP ≤40 mmHg or ≥200 mmHg, weight ≤27.2 kg or ≥181.1 kg, and BMI ≤15 kg/m^2 or ≥50 kg/m^2. Length of follow-up was calculated as the number of days between the first and last systolic/diastolic measures inputted. We defined normotension as SBP <120 mmHg and DBP <80 mmHg, elevated blood pressure as SBP between 120 and 129 mmHg (inclusive) and DBP <80, stage 1 hypertension as either SBP between 130 and 139 mmHg (inclusive) or DBP between 80-89 mmHg (inclusive), and stage 2 hypertension as either SBP ≥140 mmHg or DBP ≥90 mmHg, as defined by the American Heart Association [11]. These rules were applied to both the first and last systolic/diastolic measures reported. We used the stage 2

XSL•FO

RenderX

hypertension cutoff for the primary analysis, and the stage 1 hypertension cutoff for the sensitivity analysis. Changes in blood pressure were calculated by subtracting the end SBP and DBP readings from the baseline SBP and DBP readings, respectively. Percent changes were calculated for both SBP and DBP readings by dividing the change in SBP/DBP readings by the baseline SBP/DBP measurements.

Baseline BMI was calculated as the baseline weight entered in kilograms divided by height in meters squared (kg/m^2). Participants' baseline BMI was categorized as normal BMI (BMI <25 kg/m^2), overweight (25-29.9 kg/m^2), or obese (BMI ≥30 kg/m^2). Participants were also able to report any conditions they currently had (eg, diabetes, high blood pressure) in the Nutriquiz.

Dietary Assessment

Participants self-reported their food intake and dietary habits in the Foodsmart platform. Participants were asked to fill out a 53-item food frequency questionnaire called Nutriquiz (adapted from the National Cancer Institute Diet History Questionnaire I) when they sign up [12]. Demographic information (age, sex, height), weight, and daily dietary intake (added sugars, fiber, fruits, vegetables, whole grains, fats, proteins, water, and sodium) were collected in the Nutriquiz.

Based on responses from the Nutriquiz and the daily dietary intake, a score (Nutriscore) from 0 to 70 was calculated to assess overall diet quality, with 70 being the highest diet quality. The Nutriscore is based on the Alternative Healthy Eating Index-2010 and the Commonwealth Scientific and Industrial Research Organization Healthy Diet Score [13,14]. Change in the Nutriscore was calculated as a participant's last Nutriscore minus the first Nutriscore. A positive change in Nutriscore indicates the participant improved their nutrition.

Statistical Analysis

We performed exploratory data analyses to assess the baseline demographic characteristics, SBP and DBP levels, and diet quality of the total study population, stratified by whether participants had stage 2 hypertension at baseline or not. We reported categorical variables as number of participants (percentage of study population) and continuous variables as mean (SD). We used chi-square tests to assess whether categorical variables are independent of baseline stage 2 hypertension status, and 2-sample t tests (unpaired) to evaluate differences in continuous variables.

Univariate and multivariable ordinal logistic regression analyses were used to estimate the odds ratios (ORs) and 95% CIs of achieving different blood pressure categories at different thresholds (eg, using the elevated blood pressure category as the threshold, the odds of achieving below stage 1 hypertension and stage 2 hypertension). Four blood pressure categories were considered: normotension, elevated blood pressure, stage 1 hypertension, and stage 2 hypertension. Univariate and multivariable logistic regression analyses were used to estimate the ORs and 95% CIs of achieving blood pressure levels below stage 2 hypertension. The multivariable logistic regression and multivariable ordinal logistic regression models were both mutually adjusted for sex, age category, baseline BMI category, baseline Nutriscore, change in Nutriscore, change in weight, baseline SBP, baseline DBP, diabetes, and high cholesterol.

Among participants who had stage 2 hypertension, we calculated the mean changes in SBP and DBP overall, and by time of follow-up at different thresholds (≥6, ≥12, and ≥24 months). We used paired t tests to evaluate whether the changes in SBP and DBP were statistically significant. In addition, we calculated the mean percentage change for SBP and DBP. In a sensitivity analysis, we used a threshold of stage 1 hypertension or higher (SBP ≥130 mmHg or DBP ≥80 mmHg) to calculate mean changes in HbA1c.

We also calculated the percentage of participants with stage 2 hypertension at baseline who achieved stage 1 hypertension or lower by the end of follow-up, and stratified by follow-up length.

To further explore the impact on SBP and DBP, we examined changes in weight, diet quality, SBP, and DBP, stratified by whether participants with stage 2 hypertension at baseline achieved stage 1 hypertension or lower (SBP <130 mmHg and DBP <80 mmHg) by the end of follow-up.

We considered P values less than .05 to be significant for all tests. R Studio version 1.4.1106 and R version 4.0.5 (R Foundation) were used for all analyses.

Ethical Approval

The study was declared exempt from institutional review board oversight by the Pearl Institutional Review Board given the retrospective design of the study and the less than minimal risk to participants.

Results

Participant Characteristics

Baseline demographics and biometrics of the total study sample stratified by a threshold of stage 2 hypertension status are shown in Table 1. Of participants with at least two blood pressure entries, 47.15% (5627/11,934) were classified as having stage 1 hypertension or higher at baseline, and 10.63% (1269/11,934) were classified as having stage 2 hypertension at baseline.

There were 11,934 participants included in the total study sample; 69.93% (8346/11,934) of the participants were female, 19.44% (2320/11,934) were 60 years or older, 68.46% (8170/11,934) were either overweight or obese, 17.80% (2124/11,934) reported having diabetes, and 37.91% (4254/11,934) reported having high cholesterol. The mean weight was 83.9 (SD 22.1) kg, the mean baseline Nutriscore was 33.8 (SD 8.5) points, and the mean change in the Nutriscore was 1.7 (SD 7.1) points. The mean follow-up length was 8.8 (SD 9.5) months and ranged from 1 to 65 months. Compared with participants who did not have stage 2 hypertension, participants who did have stage 2 hypertension were more likely to be male, to have a higher weight and BMI, to have a lower baseline Nutriscore, to have a longer length of follow-up, and to self-report having diabetes or high cholesterol. Participants with stage 2 hypertension at baseline were also more likely to have a higher increase in Nutriscore compared with participants

without stage 2 hypertension at baseline, although the difference was not statistically significant (*P*=.28).

To better understand what blood pressure category participants attained at the end of follow-up, we used ordinal logistic regression to examine the association of covariates with the end blood pressure categories among participants who had stage 2 hypertension at baseline (Table 2). Threshold 1 indicates the probability of stage 2 hypertension, stage 1 hypertension, or elevated blood pressure versus normotension. Threshold 2 indicates the probability of stage 2 hypertension or stage 1 hypertension versus elevated blood pressure or normotension. Threshold 3 indicates the probability of stage 2 hypertension versus stage 1 hypertension, elevated blood pressure, or normotension. In the univariate ordinal logistic regression

models, participants who were female were less likely to end in the elevated blood pressure or higher categories versus the normotensive blood pressure category on average (OR 0.75, 95% CI 0.59-0.96; *P*=.02). Participants with a higher baseline Nutriscore were less likely to end in the elevated blood pressure or higher categories versus the normotensive blood pressure category on average (OR 0.97, 95% CI 0.94-0.99; *P*=.01). Participants whose Nutriscore increased at the end of follow-up were less likely to end in the elevated blood pressure or higher categories versus the normotensive category (OR 0.96, 95% CI 0.93-0.99; *P*=.008). Participants who gained more weight at the end of follow-up were more likely to end in the elevated blood pressure or higher categories versus the normotensive category on average (OR 1.02, 95% CI 1.01-1.04; *P*=.004).

Table 1. Baseline characteristics of total study sample and by baseline hypertension status.

Characteristic	All participants (n=11,934)	Below stage 2 hypertension (n=10,665)	Stage 2 hypertension (n=1269)	*P* value[a]

Table 2. Association between predictors and likelihood of blood pressure categories at the end of follow-up in the univariate and multivariable ordinal logistic regression models.

Association	Univariate odds ratio (95% CI)	P value	Multivariable odds ratio (95% CI)	P value
Sex (female)	0.75 (0.59-0.96)	.02	0.82 (0.60-1.12)	.22
Age				
<40	1 (reference)		1 (reference)	
40-59	0.76 (0.55-1.05)	.09	0.79 (0.53-1.18)	.24
≥60	0.61 (0.42-0.88)	.009	0.68 (0.42-1.09)	.11
Baseline Nutriscore (0-70; per 2 points)	0.97 (0.94-0.99)	.01	0.96 (0.92-0.99)	.02
Change in Nutriscore (per 2 points)	0.96 (0.93-0.99)	.008	0.93 (0.89-0.97)	.001
Baseline BMI category				
Normal	1 (reference)		1 (reference)	
Overweight	0.96 (0.66-1.37)	.81	0.90 (0.56-1.45)	.67
Obese	0.93 (0.67-1.30)	.69	0.78 (0.50-1.23)	.29
Change in weight (kg)	1.02 (1.01-1.04)	.004	1.02 (1.00-1.04)	.04
Length of follow-up (per 6 months)	0.91 (0.86-0.97)	.002	0.97 (0.90-1.04)	.40
Diabetes	0.91 (0.71-1.18)	.50	1.14 (0.81-1.59)	.46
High cholesterol	0.84 (0.66-1.05)	.13	0.80 (0.59-1.08)	.15
Baseline systolic (per 5 mmHg)	0.98 (0.95-1.01)	.17	1.00 (0.96-1.05)	.96
Baseline diastolic (per 5 mmHg)	1.04 (1.00-1.09)	.07	1.05 (0.99-1.12)	.12

After adjusting for all other covariates in the multivariable ordinal logistic regression model, change in Nutriscore was inversely associated with ending with elevated blood pressure, stage 1 hypertension, or stage 2 hypertension (OR 0.93, 95% CI 0.89-0.97; *P*=.001); for every 2-point increase in Nutriscore, a participant was 7% less likely to end in the elevated blood pressure or higher categories versus the normotensive category on average. Change in weight was positively associated with ending in the elevated blood pressure or higher categories (OR 1.02, 95% CI 1.00-1.04; *P*=.04). For every 1-kg increase in weight, a participant was 2% more likely to end with elevated blood pressure or higher versus normotension, on average.

We further examined the association between baseline characteristics and odds of achieving a blood pressure category below stage 2 hypertension in the univariate and multivariable logistic regression models (Table 3). In the univariate regression models, participants who were female were 30% more likely to achieve an end blood pressure category below stage 2 hypertension than participants who were male (OR 1.30, 95% CI 1.02-1.67; *P*=.04). Participants classified in the age group 60 years and older were 68% more likely to achieve an end blood pressure category below stage 2 hypertension than participants classified in the less than 40-year-old group (OR 1.68, 95% CI 1.15-2.46; *P*=.007). Participants with a higher baseline Nutriscore were more likely to achieve an end blood pressure category below stage 2 hypertension (OR 1.04, 95% CI 1.01-1.06; *P*=.01). Participants with an increase in Nutriscore were more likely to achieve an end blood pressure category below stage 2 hypertension (OR 1.04, 95% CI 1.01-1.08; *P*=.01). Participants with a decrease in weight were more likely to achieve an end blood pressure category below stage 2 hypertension (OR 0.98, 95% CI 0.96-0.99; *P*=.003). Participants with a longer length of follow-up were more likely to achieve an end blood pressure category below stage 2 hypertension (OR 1.11, 95% CI 1.05-1.19; *P*=.001).

Table 3. Odds of achieving blood pressure below stage 2 hypertension for users with stage 2 hypertension at baseline in univariate and multivariable logistic regression analyses.

Variables	Univariate odds ratio (95% CI)	P value	Multivariable odds ratio (95%)	P value
Sex (female)	1.30 (1.02-1.67)	.04	1.16 (0.85-1.61)	.36
Age (years)				
<40	1 (reference)		1 (reference)	
40-59	1.36 (0.98-1.89)	.07	1.34 (0.89-2.03)	.17
≥60	1.68 (1.15-2.46)	.007	1.58 (0.96-2.61)	.07
Baseline Nutriscore (0-70; per 2 points)	1.04 (1.01-1.06)	.01	1.05 (1.01-1.10)	.01
Change in Nutriscore (per 2 points)	1.04 (1.01-1.08)	.01	1.07 (1.03-1.12)	.003
Baseline BMI category				
Normal	1 (reference)		1 (reference)	
Overweight	1.14 (0.79-1.67)	.48	1.21 (0.74-2.00)	.45
Obese	1.19 (0.85-1.68)	.31	1.43 (0.89-2.31)	.14
Change in weight (kg)	0.98 (0.96-0.99)	.003	0.98 (0.96-1.00)	.03
Length of follow-up (per 6 months)	1.11 (1.05-1.19)	.001	1.04 (0.97-1.13)	.26
Diabetes	1.15 (0.88-1.49)	.30	0.92 (0.64-1.30)	.62
High cholesterol	1.21 (0.96-1.54)	.11	1.23 (0.90-1.68)	.20
Baseline systolic (per 5 mmHg)	1.02 (0.99-1.06)	.14	1.01 (0.96-1.05)	.78
Baseline diastolic (per 5 mmHg)	0.96 (0.92-1.01)	.12	0.96 (0.90-1.02)	.23

After adjusting for all other covariates in the multivariable logistic regression model, we found that for every 2-point increase in baseline Nutriscore, a user would be 5% more likely to achieve an end blood pressure category below stage 2 hypertension (OR 1.05, 95% CI 1.01-1.10; P=.01). In addition, adjusting for all other covariates, for every 2-point increase in change in Nutriscore, a participant would be 7% more likely to achieve an end blood pressure category below stage 2 hypertension (OR 1.07, 95% CI 1.03-1.12; P=.003). Adjusting for all other covariates, for every 1-kg increase in change in weight, a participant would be 2% less likely to achieve an end blood pressure category below stage 2 hypertension (OR 0.98, 95% CI 0.96-1.00; P=.03).

Changes in SBP and DBP

Multimedia Appendices 1 and 2 show the mean and percent change in SBP and DBP, respectively, for participants who had stage 2 hypertension at baseline. Changes were calculated overall and by length of follow-up, at ≥6, ≥12, and ≥24 months. The mean changes in SBP for overall and subsetting to length of follow-up ≥6, ≥12, and ≥24 months were –5.7 (SD 14.6), –7.0 (SD 15.7), –8.0 (SD 14.3), and –7.4 (SD 13.3) mmHg, respectively. The mean percentage changes in SBP were –3.5% (SD 10.3%), –4.4% (SD 10.4%), –5.2% (SD 9.4%), and –4.8% (SD 8.6%) for overall, ≥6, ≥12, and ≥24 months, respectively. The mean changes in DBP for overall and subsetting to length of follow-up ≥6, ≥12, and ≥24 months were –4.0 (SD 10.6), –4.4 (SD 10.5), –5.0 (SD 9.8), and –4.3 (SD 10.1) mmHg, respectively. The mean percentage changes in DBP were –3.8% (SD 9.7%), –4.4% (SD 9.7%), –5.1% (SD 8.9%), and –4.3% (SD 8.9%) for overall, ≥6, ≥12, and ≥24 months, respectively. Using paired t tests, all changes between baseline and end SBP

and DBP readings were statistically significant at the P<.05 level. Systolic and diastolic BP for overall, ≥6, ≥12, and ≥24 months were all P<.001.

For participants who had stage 1 hypertension at baseline, the mean changes in SBP for overall and subsetting to length of follow-up ≥6, ≥12, and ≥24 months were –2.0 (SD 9.4), –2.4 (SD 10.1), –3.0 (SD 10.3), and –2.7 (SD 9.9) mmHg, respectively. Mean percentage changes in SBP were –1.3% (SD 6.9%), –1.6% (SD 7.2%), –2.0% (SD 7.4%), and –1.8% (SD 7.1%) for overall, ≥6, ≥12, and ≥24 months, respectively. The mean changes in DBP for overall and subsetting to length of follow-up ≥6, ≥12, and ≥24 months were –1.8 (SD 6.9), –2.1 (SD 6.9), –2.5 (SD 7.3), and –2.4 (SD 7.1) mmHg, respectively. The mean percentage changes in DBP were –1.9% (SD 7.4%), –2.3% (SD 7.5%), –2.7% (SD 8.1%), and –2.6% (SD 7.6%) for overall, ≥6, ≥12, and ≥24 months, respectively. Using paired t tests, all changes between baseline and end SBP and DBP readings were statistically significant at the P<.05 level. Systolic and diastolic BP for overall, ≥6, ≥12, and ≥24 months were all P<.001.

We evaluated the percentage of participants who had stage 2 hypertension at baseline who achieved blood pressure levels below stage 2 hypertension, systolic reading <140 mmHg and diastolic reading <90 mmHg, at the end of follow-up (Multimedia Appendix 3). Across all length-of follow-up periods, 33.02% (419/1269) of participants with stage 2 hypertension at baseline lowered their blood pressure to below stage 2 hypertension by the end of follow-up. Among participants whose follow-up time was longer than 6, 12, and 24 months, 37.6% (238/633), 42.5% (131/308), and 38.4%

(66/172) of participants achieved blood pressure levels below stage 2 hypertension by the end of follow-up.

We examined the change in weight and Nutriscore for participants who lowered their blood pressure levels to below stage 2 hypertension versus those who remained in the stage 2 hypertension category (Multimedia Appendix 4). Participants who changed from stage 2 hypertension to below stage 2 hypertension lost 1.8 more kilograms in weight (0.0 kg versus 1.8 kg lost) and had 1.2 points higher (1.5-point increase versus 2.7-point increase) in their diet quality (Nutriscore) than those who remained in the stage 2 hypertension category.

Discussion

In this study, we found that 10.63% (1269/11,934) of Foodsmart participants had stage 2 hypertension at baseline. Foodsmart participants with stage 2 hypertension at baseline were more likely to be male, older, have a higher weight and BMI, have additional comorbidities (diabetes, high cholesterol), have a lower Nutriscore, and have a longer follow-up. For participants with stage 2 hypertension, blood pressure reduced by 5.7 mmHg/4.0 mmHg on average over a follow-up of 9.8 (SD 10.9) months. Among participants with stage 2 hypertension at baseline, 33.02% (419/1269) lowered their blood pressure to stage 1 hypertension or below. Furthermore, there were greater reductions in weight changes and increases in Nutriscores among those with stage 2 hypertension at baseline who achieved blood pressure levels below stage 2 hypertension. Our findings suggest that participant use of Foodsmart may be associated with reductions in blood pressure for patients with stage 2 hypertension.

Previous research confirms several of our findings. Through Korea's National Health and Nutrition Examination Survey, Noh et al [15] confirmed that, in line with our baseline analysis, those with hypertension are more likely to have additional comorbidities, noting that these comorbidities (obesity, dyslipidemia, and impaired fasting glucose) are also likely to be associated with age and male sex. Additional studies have provided further context to these findings. Weight, in particular, has been long-established to increase the risk of hypertension [16]. Having a BMI greater than or equal to 30 kg/m^2 (categorized as obese) has been associated with a 3.5 times higher likelihood of developing hypertension. In addition, previous research has shown that diabetes and hypertension often occur together because they are mediated by similar physiologic conditions, such as impaired circadian blood pressure rhythm, renin-angiotensin-aldosterone blood pressure system dysregulation, microvascular and macrovascular damage, and more [17,18]. Finally, prior research also suggests that dyslipidemia may be a risk factor for hypertension [19]. Dyslipidemia is known to cause endothelial damage, which results in the constriction of cardiovascular vessels as opposed to their dilation. This damage may consequently result in hypertension. In line with our findings, Neter et al [20] found a dose-response relationship between weight change and blood pressure reduction. They found a reduction in blood pressure of −1.05 mmHg/−0.92 mmHg per kilogram of weight loss. In addition, a meta-analysis on the DASH diet found that improved

nutrition is associated with greater decreases in blood pressure, with the mean difference of SBP and DBP being −3.2 and −2.5 mmHg, respectively, from a systematic review of 30 randomized clinical trials [5].

Individuals with hypertension are estimated to incur US $1920 higher incremental health care expenditures and nearly triple the medication expenditures compared with individuals without hypertension [4]. Drugs such as angiotensin-converting enzyme (ACE) inhibitors and calcium channel blockers account for a large proportion of these expenditures. Given the high cost of medications, prevention and management of hypertension through healthier eating could supplement hypertension drugs and potentially lower its usage. Unfortunately, we do not know whether participants were on blood pressure medications before or during enrollment on the Foodsmart platform. Despite this, we can estimate the difference in costs between prescription medications and Foodsmart. As of 2021, the Foodsmart platform on average costs US $12.30 per eligible member annually. Using the results above, a 5-mmHg reduction in SBP and DBP would cost US $12.30 on average for participants on the Foodsmart platform for at least a year. Using lisinopril (ACE inhibitor), by contrast, would cost US $48 on average to reduce SBP/DBP by 21.4/15.7 mmHg [21]. The Foodsmart platform could be a cost-effective program to complement the use of standard hypertension medications.

There are some important limitations to note for this study. The first is that blood pressure values were self-reported and not clinically validated. Given that only blood pressure values were reported, we do not have information on which blood pressure devices were used or if standard protocol, such as the average of 3 consecutive measurements, was used. We assumed participants inputted their last recorded blood pressure values from a clinical setting. Nevertheless, we have reason to believe these values should still be approximately accurate, because blood pressure is not a required input for the app, and therefore those who did input blood pressure were most likely motivated by personal tracking. In addition, because values were self-reported, follow-up time was based on when the biometrics were entered as opposed to when blood pressure was measured. Therefore, the first measurements of SBP and DBP recorded may not necessarily align with the beginning of Foodsmart enrollment. Another possible issue is selection bias for individuals with hypertension who use Foodsmart. Those with hypertension who use the app may be more likely to make lifestyle changes because they are using the app for the purposes of improving their nutrition. These users may also be working to make lifestyle changes outside of the app that affect their blood pressure. Therefore, we cannot state that Foodsmart caused these changes in blood pressure. To make statements about causation, a randomized controlled trial must be conducted. Next, we were not able to collect data on other factors that might affect hypertension status. For instance, participants' personal or family medical histories may have an influence on hypertension status. We lack information on whether participants were taking blood pressure medications before or during usage of the Foodsmart platform or if participants changed blood pressure medication during enrollment. Finally, we did not have data on socioeconomic

factors, such as education, which may confound the associations. Further research is necessary to understand these additional variables. We also did not examine the frequency of Foodsmart app use, which may affect the associations found in our analyses.

Our analysis also has many strengths. This is the first study to examine the real-life impact of behavioral change as a result of online food ordering, dietary education, and meal planning through a digital intervention and its impact on hypertension. Through analyzing data from Foodsmart's large user base, we were able to gather information about real-world associations between changes in diet and blood pressure levels. Furthermore,

Foodsmart participants had a wide range of enrollment lengths, which allowed us to evaluate changes in blood pressure over different lengths of time, including follow-up time of more than 2 years.

In summary, this study assessed changes in self-reported SBP and DBP for participants using a digital nutrition platform that offers personalized meal planning, food ordering, grocery discounts, and price comparisons. Further research through a randomized clinical trial is warranted to evaluate the causal effect between the use of the Foodsmart platform and changes in blood pressure among participants.

Authors' Contributions

BS acquired data, analyzed the data, interpreted the results, and drafted the manuscript. EAH designed the study, interpreted results, and drafted the manuscript. SB interpreted results and drafted the manuscript. JL interpreted results. All the authors reviewed and approved the final version of the manuscript and take responsibility for the manuscript.

Conflicts of Interest

SB, BS, JL, and EAH are employees of Foodsmart.

Abstract

Background: The rapid increase in the number of people who are overweight and obese is a worldwide health problem. Obesity is often associated with physiological and mental health burdens. Owing to several barriers to face-to-face psychotherapy, a promising approach is to exploit recent developments and implement innovative e–mental health interventions that offer various benefits to patients with obesity and to the health care system.

Objective: This study aims to assess the acceptance of e–mental health interventions in patients with obesity and explore its influencing predictors. In addition, the well-established Unified Theory of Acceptance and Use of Technology (UTAUT) model is compared with an extended UTAUT model in terms of variance explanation of acceptance.

Methods: A cross-sectional web-based survey study was conducted from July 2020 to January 2021 in Germany. Eligibility requirements were adult age (≥18 years), internet access, good command of the German language, and BMI >30 kg/m^2 (obesity). A total of 448 patients with obesity (grades I, II, and III) were recruited via specialized social media platforms. The impact of various sociodemographic, medical, and mental health characteristics was assessed. eHealth-related data and acceptance of e–mental health interventions were examined using a modified questionnaire based on the UTAUT.

Results: Overall, the acceptance of e–mental health interventions in patients with obesity was moderate (mean 3.18, SD 1.11). Significant differences in the acceptance of e–mental health interventions among patients with obesity exist, depending on the grade of obesity, age, sex, occupational status, and mental health status. In an extended UTAUT regression model, acceptance was significantly predicted by the *depression score* (*Patient Health Questionnaire-8*; β=.07; *P*=.03), *stress owing to constant availability via mobile phone or email* (β=.06; *P*=.02), and *confidence in using digital media* (β=−0.058; *P*=.04) and by the UTAUT core predictors *performance expectancy* (β=.45; *P*<.001), *effort expectancy* (β=.22; *P*<.001), and *social influence* (β=.27; *P*<.001). The comparison between an extended UTAUT model (16 predictors) and the restrictive UTAUT model (*performance expectancy*, *effort expectancy*, and *social influence*) revealed a significant difference in explained variance ($F_{13,431}$=2.366; *P*=.005).

Conclusions: The UTAUT model has proven to be a valuable instrument to predict the acceptance of e–mental health interventions in patients with obesity. The extended UTAUT model explained a significantly high percentage of variance in acceptance (in total 73.6%). On the basis of the strong association between acceptance and future use, new interventions should focus on these UTAUT predictors to promote the establishment of effective e–mental health interventions for patients with obesity who experience mental health burdens.

Introduction

Background

The prevalence of people who are overweight and obese has approximately tripled since 1975, resulting in >1.9 billion adults worldwide being obese in 2016 [1]. Taking this figure and the association of obesity with serious health complications into account, obesity is considered to be a global public health crisis [2]. Obesity increases the risk of noncommunicable diseases, such as cardiovascular disease, type 2 diabetes, and even some types of cancer [3,4] and increases the chance of remaining dependent on care in nursing homes [5]. Besides several physical comorbidities, obesity is also associated with psychological distress. It elevates the risk of mental health disorders, including depression, adjustment disorders, and anxiety disorders [6-8]. For instance, previous research found that more than half of the patients with obesity experienced at least one mental disorder, resulting in low quality of life and reduced self-esteem [9,10]. Furthermore, it was shown that a high number of people with obesity have an increased risk of developing depressive disorders [11] and show symptoms of major depression [12]. In particular, discrimination against patients with obesity and weight-related stigmatization play a central role and mediate the connection to negative mental and physical health outcomes and often lead to low quality of life and poor well-being [13]. It is important to note that distress and depression inversely increase the incidence of obesity again. A very central reason for this is that individuals with obesity are often blamed for their weight and a perception among the general population is that weight stigma is justified and can motivate individuals to adopt healthy behaviors [13]. Indeed, and speaking in terms of money, obesity causes large economic burdens for health care systems [14].

However, effective interventions for obesity management are scarce because they are often impractical to implement in the health care system [15]. The social stigma that accompanies obesity and the impediments in mobility of older patients with obesity are only 2 of many barriers preventing good professional patient care [15]. In particular, long-term psychotherapeutic and psychosocial care of people with obesity are often not possible owing to limited health care opportunities. As a result, the development and implementation of cost-effective and low-threshold approaches to handle elevated psychological distress and existing mental health disorders are essential.

E–mental health interventions are an effective and innovative approach that can circumvent the aforementioned barriers hindering the health care system. Especially during the COVID-19 pandemic, the need for contact-free, low-threshold, and easily accessible approaches in health care has become increasingly evident [16]. During this crisis, many institutions in the health care system tried to develop possibilities to serve their patients via videoconferencing or other digital methods [17,18]. Innovative e–mental health interventions offer a low-threshold, time- and location-flexible, and often anonymous alternative to traditional face-to-face therapy. Although the implementation of e–mental health interventions in Germany is in its early stage [19], multiple studies have shown effects comparable with that of face-to-face therapy [19,20]. Existing e–mental health interventions for patients with a variety of mental disorders mostly include psychoeducational interventions and web-based tasks designed for cognitive behavioral, psychodynamic, or acceptance and commitment therapy [21]. Acceptance of participants who participated in such interventions and their satisfaction with such interventions has often been considerable [21,22]. A recent study revealed that patients who had undergone bariatric surgery were very positive about eHealth interventions in their follow-up care [23]. Particularly after bariatric surgery, eHealth interventions can be effective in postoperative weight maintenance and in the reduction of eating disorder symptoms [24]. Although the proven user acceptance for e–mental health interventions [25] and the reasonable assumption that patients with obesity affected by mental health disorders would benefit from easily accessible and effective e–mental health interventions to support their mental well-being, the current opportunities are still in their infancy. Therefore, it is important to explore the patient-specific needs because newly developed interventions need to be tailored to these needs to foster user acceptance and treatment adherence [26].

Besides the advantages and resources described above, there are barriers to using eHealth interventions that should not be neglected, which will now be examined in more detail. In addition, previous research has shown that various predictors seem to influence patient acceptance of e–mental health interventions. A cross-sectional survey in 2016 demonstrated that the acceptance of web-based aftercare among inpatients (groups mentioned below) is low [21]. The highlighted factors that were able to significantly predict acceptance were social influence (SI), performance expectancy (PE), and effort expectancy (EE; 3 predictors of the Unified Theory of Acceptance and Use of Technology [UTAUT] model, which will be described in more detail in the following sections). Although high acceptance correlated with (young) age, (high) education, (high) level of information, and experience, the stress caused by permanent availability was associated with low acceptance; however, the effect was very small. Other factors influencing the acceptance of web-based aftercare were different patient groups (psychosomatic, cardiologic, orthopedic, pediatric, and substance-related disorders) [21] and current employment status [27].

In addition, 2 research studies focusing on the patient's perspective explored the following barriers of e–mental health interventions reported by health care providers: the lack of guidance through therapeutic relationship, limitation of communication, and control or concerns about data security [28,29]. To minimize the supposed disadvantages of e–mental

health interventions for patients and health care professionals and to focus on possible advantages, specific research in this area is necessary. As the implementation and uptake of e–mental health interventions are still low, the acceptance of such interventions and the barriers hindering them make their use less likely and need to be further evaluated [30]. Most studies assessing the acceptance of eHealth interventions are not based on valid measurement constructs [31,32]; therefore, for this study, it is important to determine that the results are evaluated based on solid operationalization and theoretical ramifications. Therefore, the UTAUT is used in this study [33], as it has already been used in research on eHealth to validly identify the determinants of acceptance [33]. The UTAUT model consists of four main predictors: *PE, EE, SI, and facilitating conditions (FCs)* [34]. It can be used to assess acceptance of an eHealth intervention or other technological systems using the first 3 core predictors, whereas acceptance itself is operationalized as *behavioral intention (BI)* to use such interventions on a fifth scale. PE describes the degree to which an individual believes that he or she will benefit from using the intervention. EE is defined as the degree of ease associated with the use of the technology. A person's assessment of the extent to which their relevant social contacts (ie, family and friends) would approve the intervention is indicated by SI. FC is defined as the degree to which an individual believes that an organizational and technical infrastructure exists to support the use of the system [33]. The acceptance (intention to use; Figure 1) is predicted by the three main predictors (*PE, EE, and SI*), whereas actual use behavior is predicted by the intention to use and FCs.

Researchers have pointed out that the UTAUT model needs to be explored and validated in different target groups [21]. A study using the UTAUT model for acceptance measurement conducted by Hennemann, Beutel, and Zwerenz in 2017 [30] revealed that acceptance of e–mental health interventions was quite low and acceptance of web-based aftercare was moderate and did not differ between age groups. Significant predictors of high acceptance are PE, SI, and treatment-related internet and mobile use [30]. A further study in 2019 found that FCs and perceived usefulness were associated with increased eHealth activity, whereas SI was not associated with eHealth use [35]. In 2015, de Veer et al [36] found that 63.1% of elderly people (aged between 57 and 77 years) included in their study would use an eHealth app (moderate acceptance) by using the UTAUT model. In this case, the model showed that PE, EE, and self-efficacy were highly related to acceptance of eHealth intervention, whereas SI was not [36]. Although previous research has focused on the acceptance of e–mental health interventions, it has rarely measured acceptance using validated constructs, making it important to use the UTAUT model in future research. In addition, because of the various findings to date on the different variables that might predict acceptance, more research with the UTAUT model is necessary. Research studies are needed, on the one hand, to establish relationships between the individual components, the use behavior, and the acceptance of e–mental health interventions in patients with obesity and, on the other hand, to validate the UTAUT model in other patient cohorts than the ones studied so far.

Figure 1. Unified Theory of Acceptance and Use of Technology (UTAUT) model and the extended model predictors including hypotheses (H) 1-5.
Objectives

This study aims to assess the acceptance of e–mental health interventions in patients with obesity (grades I, II, and III) and to explore the underlying, influencing factors determining the

acceptance. We use the established UTAUT model and extend it to accomplish the abovementioned goal. Previous studies have already shown that acceptance is associated with sociodemographic variables such as age and sex [21,37]. In addition, there were differences in acceptance depending on the

mental health status of the patients [37,38] and evidence that patients who have already undergone bariatric surgery show high acceptance of eHealth interventions [21]. Previous research has not yet addressed patients with obesity and their acceptance of e–mental health interventions. To identify additional variables associated with acceptance of e–mental health interventions, this study includes several obesity-specific factors (eg, bariatric surgery and the grade of obesity). Previous research has examined acceptance and various predictors in other patient groups, leading us to propose the following assumptions for our study:

- Hypothesis 1: In accordance with previous research in other patient groups [21,30,38], it is assumed that the overall acceptance of e–mental health interventions in patients with obesity is moderate.
- Hypothesis 2: Moreover, we assume that we will find group differences in the acceptance of e–mental health interventions depending on sex, age, grade of obesity, occupational status, mental disorder, outpatient psychotherapy, and previously performed bariatric surgery [21,25,27].
- Hypothesis 3: We postulate a positive relation between the UTAUT factors (SI, PE, and EE) and the acceptance of e–mental health interventions for people with obesity [21,33,35,36] (Figure 1).
- Hypothesis 4: Furthermore, we assume that, in addition to sociodemographic and medical factors, psychometric data and eHealth-related data, for example, internet anxiety (negative) and experience with e–mental health interventions (positive), significantly explain variance in the acceptance of e–mental health interventions among patients with obesity [21].
- Hypothesis 5: In a comparison between the restrictive UTAUT model and our extended UTAUT model, we hypothesize a significant difference in the explanation of variance.

The results of this study could significantly accelerate the process of implementing and adapting e–mental health interventions for specific patient groups, such as patients with obesity. Especially considering how the current pandemic has caused additional mental health burdens, more efficient and easily available ways to provide psychological support should be developed.

Methods

Study Design and Participants

A cross-sectional approach was implemented to measure the acceptance of e–mental health interventions and its underlying predictors in a sample of patients with obesity based on the UTAUT.

Participants were recruited from July 2020 to January 2021 at the Obesity Center of Alfried Krupp Hospital and via social media platform groups such as Facebook, exclusively directed toward patients who are seeking, undergoing, or have already undergone bariatric surgery and were aged ≥18 years. Other eligibility requirements were good command of the German language, internet access, and BMI >30 kg/m^2 (diagnosis of obesity). The classification of obesity grades according to the World Health Organization is as follows: (1) obesity grade I (BMI 30-34.9 kg/m^2), (2) obesity grade II (BMI 35-39.9 kg/m^2), and (3) obesity grade III (BMI ≥40 kg/m^2) [39]. The processing time of the web-based survey, consisting of 68 items in total, was approximately 18 minutes. No financial compensation was offered. Electronic informed consent was obtained before the survey began, and participation was completely anonymous and voluntary. Of 996 participants who started the survey, 643 (64.6%) participants completed it. A total of 30.3% (195/643) of participants were underweight, normal weight, or overweight but not with BMI >30 kg/m^2; thus, they were excluded from this study. This resulted in a total sample of 69.7% (448/643) of participants, with no one being excluded owing to additional criteria.

Ethics Approval

The survey was conducted in accordance with the Declaration of Helsinki, and the Ethics Committee of the Essen Medical Faculty (19-89-47-BO) agreed to conduct the study.

Measures

Overview

The survey contained items of sociodemographic, medical, and mental health data. In addition, we used a modified UTAUT questionnaire (based on previous adaptations) to assess the acceptance of e–mental health interventions and the resources of and barriers to eHealth use. The exact questionnaire is presented in Textbox 1. To assess the mental health of the participants, we used validated instruments such as the Eating Disorder Inventory-2–Bulimia (EDI-2–B), Eating Disorder Examination-Questionnaire 8 (EDE-Q8), and Patient Health Questionnaire-8 (PHQ-8).

Textbox 1. Scales and adapted items of Unified Theory of Acceptance and Use of Technology and references of original studies (italicized verbalizations have been adapted).

Behavioral intention (acceptance)

- "I would like to try a psychological online intervention." [26,40]

- "I would use a psychological online intervention if offered to me." [26,40]

- "I would recommend a psychological online intervention to my friends." [38]

Social influence

- "People close to me would approve the use of a psychological online intervention." [26,34,40]

- "My general practitioner would approve of a psychological online intervention." [26,40]

- "My friends would approve of a psychological online intervention." [21]

Performance expectancy

- "A psychological online intervention could improve my general well-being." [26,40]

- "A psychological online intervention could help me with stress." [26,40]

- "A psychological online intervention could help me improve my personal (psychological) health." [26,40]

Effort expectancy

- "The use of a psychological online intervention would not be an additional burden to me." (self-constructed)

- "A psychological online intervention would be easy to operate and comprehend." [26,33,40,41]

- "I could arrange using a

  psychological online intervention

  in my everyday life." [21]

Sociodemographic and Medical Data

Sociodemographic and medical data were assessed using items on age, sex, marital status, having children, occupational status, educational level, physical illness, mental disorder, and medication. In addition, there were items on data related to obesity and its management (weight, height, BMI, grade of obesity, comorbidities, and bariatric surgery).

Acceptance, eHealth Use, and UTAUT Predictors

To assess the acceptance of e–mental health interventions and its underlying factors, a modified version of the UTAUT model (Textbox 1) and several items for the measurement of internet use, internet anxiety, and attitudes toward and experiences with web-based interventions were used. The UTAUT questionnaire consists of 12 items and answers are given on a 5-point Likert scale (ranging from 1=totally disagree to 5=totally agree). Three items measure the underlying predictors of acceptance and acceptance itself, which are operationalized as intention to use (BI). Cronbach α values in this study were .88 for acceptance (BI), .84 for SI, .93 for PE, and .82 for EE, proving high internal consistency.

To assess the eHealth use of the participants, items such as the duration of use of media such their smartphone or tablet and previous experiences with eHealth interventions were asked. To record how confident the participants felt in using digital media, they were asked to rate their confidence on a scale of 1 (very unsafe) to 5 (very safe). The perceived stress caused by permanent availability via mobile phone or email was surveyed on a scale of 1 (strongly disagree) to 5 (strongly agree). The participants' internet anxiety was assessed using a set of 3 items (already used in previous studies), of which a mean value was calculated on a scale from 1 to 5, with 5 indicating very high internet anxiety. Cronbach α for this instrument in this study was .76, which indicates a sufficient internal consistency.

Assessment Using EDI-2–B

The EDI-2–B consists of 7 items assessing symptoms of bulimia (especially binge eating) on a 6-point Likert scale (1=never to 6=always) [42]. The sum score has a minimum of 7 points and a maximum of 42 points. Cronbach α in this study was .81, indicating high internal consistency.

Assessment Using EDE-Q8

The EDE-Q8 is a short version of the EDE-Q and comprises four subscales: restraint, eating concern, shape concern, and weight concern [43]. In this abbreviated version, 2 items refer to each scale (8 items in total), thus ensuring optimal internal consistency, one-dimensionality, and even coverage of the EDE-Q subscales. It consists of 5 items assessing eating disorder psychopathology in the past 28 days on a 7-point Likert scale (ranging from 0=not any day to 6=every day) and 3 items assessing the occurrence and frequency of core eating disorder behavior on a scale (from 0=never to 6=every time). Cronbach α in this study was .78, which indicates a sufficient internal consistency.

Assessment Using PHQ-8

The PHQ-8 measures depression symptoms via 8 items on a 4-point Likert scale (0=not at all to 3=nearly every day) [44]. A score ≥10 indicates major depression symptoms. Cronbach α in this study was .85, indicating high internal consistency.

Statistical Analyses

Data analysis was performed using SPSS Statistics 26 software (IBM). First, the sum scores and mean scores for scales PHQ-8, EDE-Q-8, and EDI-2–B were computed. Second, the internal consistencies for the different psychometric questionnaires were calculated and descriptive statistics were performed. Third, the acceptance was computed (mean value) and its distribution was assessed.

Acceptance (BI) of the UTAUT model (scale 1-5) was categorized by mean as low (1-2.34), moderate (2.35-3.67), and high (3.68-5) acceptance. Percentage and absolute count in categories were calculated. To highlight group differences in age, four age categories were formed before analysis: (1) 18-34 years, (2) 35-44 years, (3) 45-54 years, and (4) 55-69 years. The BMI of the participants was calculated by dividing their body weight by their height in meters squared. The means of acceptance (BI) were compared between groups regarding sociodemographic and medical data with 2-tailed t tests and analyses of variance (ANOVAs) to also include variables with multiple categories. The normal distribution of acceptance was examined using the Kolmogorov-Smirnov test, skewness, and kurtosis and graphically via a histogram including a normal distribution curve. All measures detected violations against normal distribution. However, we still used parametric tests for various reasons. According to the central limit theorem, the sampling distribution of the mean of a variable can be safely assumed to be normal if the variable and its mean are normally distributed in the population and the sample size is sufficiently large. We consider our sample size of 448 as sufficient because some studies suggest that such an effect already emerges at the sample size of 30 [45]. Moreover, other researchers found that acceptance distributions in general did not differ from normal distribution, which indicates that the variable acceptance might be normally distributed in the population [38]. In addition, 2-tailed t tests and ANOVAs are considered to be robust against violations, assuming normal distribution [46].

Using multiple hierarchical regression, the predictive model of acceptance was tested by using the enter method. The following predictors were included blockwise: (1) sociodemographic and medical data, (2) psychometric data, (3) eHealth-related data, and (4) UTAUT predictors (Figure 1). In addition, the full model was tested against the restricted UTAUT model with the UTAUT predictors (*PE, EE,* and *SI*) only. No multicollinearity could be detected because all the variance inflation factor values for testing multicollinearity were <5. The QQ plots of the residuals were visually inspected and showed no signs of violations against normality; therefore, normal distribution of the residuals can be assumed. Homoscedasticity was proven based on a scatter plot of the standardized residuals and adjusted predicted values.

For every ANOVA and 2-tailed t test, the level of significance was set at .05. In addition, post hoc tests were used to describe differences between the groups.

Results

Sociodemographic, Medical, and Psychometric Data

A total of 448 individuals participated in this study, of which 403 (89.9%) were women and 45 (10%) were men. The mean age was 44.69 years and age ranged from 18 to 69 years. Marital status for most participants was married (246/448, 54.9%) or living in a partnership (77/448, 17.2%). Of the 448 participants, 67 (14.9%) participants reported being single. Of the 448 participants, 98 (21.9%) participants had graduated from high school, 55 (12.3%) had graduated from college, and 210 (46.9%) had graduated from junior high school. In all, 66.3% (297/448) of the participants were employed at the time of participation and 33.7% (151/448) of the participants were unemployed.

A mental disorder was reported by 37.5% (168/448) of the participants. The diagnosis of depression was mentioned most frequently (58/168, 34.5%). There were 20.5% (92/448) of participants in outpatient psychotherapy owing to a mental disorder. In all, 22.8% (102/448) of the participants reported currently taking a psychiatric medication. The presence of a physical disease (other than obesity) was reported by 64.9% (291/448) of the participants. Frequently mentioned diseases (other than obesity) were diabetes, hypertension, and joint pain (182/448, 40.6%). Of the 448 participants with obesity, a total of 82 (18.3%) participants had obesity grade I, 88 (19.6%) participants had obesity grade II, and 278 (62.1%) participants had obesity grade III. Totally, 44.6% (200/448) of the participants had already undergone bariatric surgery. Of these 200 participants, 80 (40%) participants were part of the grade III obesity group. Of the 448 participants, 170 (37.9%) participants indicated that they planned to have bariatric surgery. Only 17.4% (78/448) participants neither had surgery nor planned to do so. Of the 200 participants who had already undergone surgery, 107 (53.5%) had opted for a gastric tube.

Of the 448 participants, 31 (6.9%) participants reported using the internet for private use for 0-1 hour per day, 94 (20.9%) participants used the internet for 1-2 hours per day, 119 (26.6%) participants reported a use time of 2-3 hours per day, 88 (19.6%) participants reported a use time of 3-4 hours per day, and approximately 116 (25.9%) people used the internet for >4 hours per day for private needs. The mean score for confidence in using digital media in this study was high (mean 4.08, SD 0.97). The stress experienced by the participants owing to permanent availability via mobile phone or email was moderate (mean 2.59, SD 1.24). Internet anxiety among participants in the study was low (mean 1.60, SD 0.76). Experience with e–mental health interventions was reported by 19.6% (88/448) of participants, whereas the remaining 80.4% (360/448) of the participants had no experience with such interventions.

The sum score of the EDI-2–B scale (mean 15.62, SD 0.87) was high compared with the norm values defined by Thiel and Paul [42], with a sample of 40.8% (183/448) of the participants (mean 11.59, SD 4.00) [43]. The sum score of EDE-Q8 (mean

3.89, SD 1.22) was also relatively high compared with healthy control patients from previous study by Hilbert et al [43] with a sample of 91.3% (409/448; mean 1.44, SD 1.22) and indicated eating disorder symptoms [44]. Using the recommended cutoff in the literature of ≥10, analyses of PHQ-8 (mean 10.10, SD 5.64) showed, that 49.6% (222/448) of the participants in this study might experience symptoms of major depression. In a very large random comparison sample (N=198,678) from a study in 2009, 8.6% of the participants experienced depressive symptoms (PHQ-8 sum score >10) [44].

Hypotheses 1 and 2: Acceptance as a Function of Sociodemographic and Medical Data

The general acceptance of e–mental health interventions was moderate (mean 3.18, SD 1.11). We divided the sample of 448 participants into groups by their degree of acceptance, with the results being as follows: 116 (25.9%) participants showed low acceptance, 199 (44.4%) showed moderate acceptance, and 133 (29.7%) showed high acceptance.

Table 1 contains the acceptance scores as a function of sociodemographic and medical data. Acceptance differed significantly between sexes (t_{446}=2.35; P=.02), with higher acceptance among women than among men. In addition, there were significant differences in acceptance by the different age groups ($F_{3,444}$=2.75; P=.04), with the highest acceptance in the middle-age group (35-44 years) and the lowest acceptance in the oldest group (55-69 years). However, the post hoc test of ANOVA showed that only age group II (35-44 years) and age group IV (55-69 years) differed significantly (P=.03). There was a significant difference in acceptance among the 3 obesity groups, with high acceptance level among people with obesity grade II ($F_{2,445}$=6.59; P=.002). The post hoc test of ANOVA revealed that the obesity grade I group was significantly different from grades II (P=.004) and III (P=.003). There was no significant difference in acceptance between grade II and grade III (P=.99). The occupational status (employed) was also significantly associated with higher acceptance ratings (t_{446}=2.40; P=.02) compared with those participants who were currently unemployed. In addition, participants with a mental disorder displayed significantly higher acceptance than those without a mental disorder (t_{446}=2.02; P=.02). There were no significant differences in acceptance regarding the variables such as bariatric surgery and outpatient psychotherapy.

Table 1. Differences in acceptance by sociodemographic and medical data (N=448).

Variable	Values, n (%)	Values, mean (SD)	t test (df)	F test (df)	P value
Sex			2.35 (446)	N/A[a]	.02
Women	403 (89.9)	3.23 (1.09)			
Men	45 (10)	2.78 (1.24)			
Age (years)			N/A	2.75 (3,444)	.04
18-34	86 (19.1)	3.15 (1.12)			
35-44	131 (29.2)	3.39 (1.12)			
45-54	140 (31.3)	3.16 (1.14)			
55-69	91 (20.3)	2.96 (1.03)			
Grade of obesity			N/A	6.59 (2,445)	.002
I	82 (18.3)	2.79 (1.06)			
II	88 (19.6)	3.34 (1.06)			
III	278 (62.1)	3.25 (1.12)			
Occupational status			2.40 (446)	N/A	.02
Employed	297 (66.3)	3.28 (1.11)			
Unemployed	151 (33.7)	3.01 (1.11)			
Mental disorder			2.02 (446)	N/A	.02
Yes	168 (37.5)	3.35 (1.05)			
No	280 (62.5)	3.09 (1.14)			
Bariatric surgery			N/A	1.04 (2,445)	.35
Yes, executed	200 (44.6)	3.11 (1.10)			
Already planned	170 (37.9)	3.28 (1.16)			
No	78 (17.4)	3.19 (1.07)			
Outpatient psychotherapy			0.795 (446)	N/A	.78
Yes	92 (20.5)	3.21 (1.16)			
No	356 (79.5)	3.11 (1.16)

Hypotheses 3 and 4: Predictors of Acceptance

The multiple hierarchical regression analysis revealed that the sociodemographic and medical predictors included in the first step explained 7.1% (R^2=0.071; $F_{5,442}$=6.74; P<.001) of the variance in acceptance. Thereby, sex (β=−0.13; P=.006), BMI (β=.13; P=.007), presence of a mental disorder (β=.16; P<.001), and occupational status (β=−0.18; P<.001) significantly predicted acceptance. The psychometric predictors included in the second step (R^2=0.127; $F_{8,439}$=7.98; P<.001) increased the explained variance significantly (ΔR^2=0.056; $F_{3,439}$=9.431; P<.001), whereby the depression sum score (PHQ-8; β=.12; P=.04) and the EDE-Q8 score (β=.13; P=.02) significantly predicted acceptance. In the third step, when entering the eHealth-related predictors, the explained variance in acceptance increased significantly to 15.4% (R^2=0.154; $F_{13,434}$=6.094; P<.001), but only the stress owing to constant availability on

the mobile phone or via email was a significant predictor in this step (β=.12; P=.02). The UTAUT predictors included in the last step (R^2=0.736; $F_{16,431}$=75.26; P<.001) changed the explained variance significantly by 58.2% (ΔR^2=0.582; $F_{3,431}$=317.28; P<.001), resulting in a total percentage of 73.6% for the explained variance. *PE* (β=.45; P<.001), *EE* (β=.22; P<.001), and *SI* (β=.27; P<.001) significantly predicted acceptance. In the overall model (step 4), in addition to the 3 UTAUT predictors, 3 additional variables from the extended model can be established as significant predictors of the acceptance of e–mental health interventions in people with obesity: *depression sum score* (PHQ-8; β=.07; P=.03), *stress owing to constant availability via mobile phone or* email (β=.06; P=.02), and *confidence in using digital media* (β=−0.06; P=.04). Table 2 presents the regression parameters of the hierarchical regression model of acceptance. Multimedia Appendix 1 illustrates the full model of the hierarchical regression.

Hypothesis 5: UTAUT Versus Extended UTAUT Model

For hypothesis 5, we aimed to determine whether our full model (R^2=0.736) is better in explaining the variance in acceptance of e–mental health interventions than a restricted model (R^2=0.718), including only the UTAUT predictors of acceptance (*PE, EE,* and *SI*). Comparison of both models revealed a significant difference in the explained variance ($F_{13,431}$=2.366; *P*=.005), which means that the extended UTAUT model provides high variance explanation in the acceptance of e–mental health interventions owing to the additional included variables.

Discussion

Principal Findings
