This study assessed the acceptance of e–mental health interventions among patients with obesity and explored the factors influencing acceptance. First, it is important to note that all hypotheses (1-5) were confirmed in this study. The overall acceptance of e–mental health interventions among people with obesity was moderate, with 29.7% (133/448) of participants indicating high acceptance, 44.4% (199/448) indicating moderate acceptance, and only 25.9% (116/448) indicating low acceptance of e–mental health interventions. Regarding the second hypothesis, the data yielded evidence for small but significant differences in acceptance depending on the obesity grade, with the highest acceptance in the grade II obesity group. Participants with obesity grade I differed significantly from those with obesity grades II and III in terms of their acceptance

of e–mental health interventions, with patients with obesity grade I exhibiting significantly low acceptance. Employed participants had a significantly higher acceptance of e–mental health interventions than unemployed participants, and participants with a mental disorder also showed significantly high acceptance; however, these differences were mostly slight. Regarding the third and fourth hypotheses, the following can be reported. In the extended regression model, the acceptance of e–mental health interventions was significantly predicted by depressive symptoms (PHQ-8). In addition, the stress caused by permanent availability via mobile phone or email was found to be a significant predictor of acceptance. Moreover, in the second step of the hierarchical regression, we used psychometric data that already explained a small part of the variance. This was different in previous research, which neglected the inclusion of psychometric data and only included eHealth-related data [21]. In addition to the 3 UTAUT predictors, confidence in using digital media was identified as a significant predictor in the regression model. Regarding the fifth hypothesis, the evidence is that the UTAUT predictors (restricted model with UTAUT predictors only) reached a high level in explained variance, whereas the extended UTAUT model (16 predictors) clarified slightly but with significantly more variance in patients with obesity (Table 2).

Comparison With Previous Work

Although previous studies have highlighted the mental health burden among patients with obesity, research regarding the acceptance and use of specific e–mental health interventions, especially with validated measures (eg, UTAUT), is still very scarce for the examined patient group [19]. The general acceptance of e–mental health interventions shown by participants was higher in this study than in previous studies [21,47,48], which also did not exclusively survey patients with obesity, who are a special patient group owing to their psychological and physical problems. We conducted a well-powered study comparable with previous research efforts, which often had a small sample, lacked valid measurement instruments, and captured very few variables that could be important for the acceptance of e–mental health interventions. We aimed to rectify these shortcomings, especially by using the validated measurement of acceptance of e–mental health interventions using the UTAUT model; adding sociodemographic, psychometric, and eHealth-related variables; and recruiting a substantial sample.

Studies that have previously examined the acceptance of e–mental health interventions in general or in specific patient groups have been able to identify the following variables to be significantly associated with acceptance: in addition to age [21,37,48], there is evidence of sex [37,48], anxiety [38], internet anxiety [38], experience with e–mental health interventions [21,37,47], education [21,37,48], experiencing a mental illness [37], and duration of type 2 diabetes [48]. Similar to previous research, the acceptance ratings in this study were significantly associated with sex. However, contrary to previous research by Hennemann et al [21] and Roelofsen et al [49], the acceptance ratings in this study were significantly higher for women than for men. We attribute this finding particularly to the topic of losing weight, dealing with their own bodies, and the

psychological factors in this regard, which more often plays a major role in the lives of women [50]. Age was also significantly associated with acceptance [21,49], whereby the middle-age group (35-44 years) differed significantly from the oldest group (55-69 years) in their acceptance, which could be because older people are less familiar with the internet and digital media. In addition, this study was successful in detecting the associations of the grade of obesity and experiencing a mental disorder with the acceptance of e–mental health interventions. According to previous research, it can be assumed that patients with a high BMI are more psychologically burdened; thus, it can be hypothesized that patient's acceptance of digital interventions also increases with higher weight (eg, owing to the immobility of the patient group), as these patients are more likely to be searching for psychological interventions and experiencing high levels of distress [51-53]. In this study, the level of distress and associated openness to psychological interventions among people with mental disorders also could possibly lead people who are currently experiencing a mental disorder to report high acceptance of e–mental health interventions. This could be in part because people with mental disorders are directly affected by the lack of psychosocial treatment possibilities and are more likely to be grateful to receive any low-threshold interventions to improve their symptoms. A practical implication that arises from this is the tailoring of specific eHealth interventions, especially to the psychological distress of these patients. Previous studies have used the UTAUT model to identify predictors of acceptance and use of internet-based interventions so that the following significant predictors could be identified: *PE* [21,48,54,55], *EE* [21,48,54,55], and *SI* [21,54,55].

The fourth core predictor of UTAUT has been named as *FCs* and is supposed to significantly predict the actual use. However, it does not predict the BI (or acceptance), which is why it was not included in our regression model [33]. The results of this study supported the viability of UTAUT in determining the acceptance of e–mental health interventions. The three UTAUT predictors, *PE*, *EE*, and *SI*, achieved a total of 71.8% at the variance explanation of the acceptance of e–mental health interventions, and this is comparable with those of the original UTAUT validation study (70%) [33]. This study found that *PE* was the key predictor of acceptance [21,33,54-56], which is consistent with previous research suggesting that *PE* is also a predictor of treatment outcome in psychotherapy [57]. The implications of the strong relationship between *PE* and acceptance of e–mental health interventions are that there must be transparent eHealth education in which misunderstandings or false expectations are openly addressed.

Beyond the 3 UTAUT predictors, previous research has identified the following factors as predictors of e–mental health acceptance: *perceived reliability* [55], *stress owing to permanent availability* [21], *perceived security* [48], *technology anxiety* [54], and *resistance to change* [54]. The overall model in this study (with 16 predictors) was significantly better than the restrictive UTAUT model, but ultimately explained only slightly more variance in acceptance. In this study, complementing previous research on this topic, we could also find the *sum score of the psychometric instrument PHQ-8* (indicator for symptoms of depression), the *confidence in using digital media* as

predictors of acceptance, and the *perceived stress through permanent availability*. In contrast to previous research, the regression coefficient of *perceived stress through permanent availability* in the overall model has a positive sign, which means that greater the stress perceived owing to constant accessibility, higher the acceptance was of e–mental health interventions. We explain this result as follows: people who report a high level of stress owing to permanent availability through their mobile phone use it very frequently, appreciate it, and use it for many different things in their everyday life. We assume that people who report a high level of stress from their mobile phone are particularly familiar with the functions and possibilities of their smartphone owing to the daily use. Therefore, they presumably exhibit a low inhibition threshold in the use of additional apps via smartphone and are more willing to use such technology for newly developed interventions or apps. People who reported low levels of stress from being available on their smartphone in the survey would also be unlikely to use their phone for e–mental health interventions because the smartphone does not have a significant role in their lives. This is a discovered difference from previous research, as, for example, Donkin and Glozier [58] identified technology fatigue as an important barrier to acceptance of e–mental health interventions and other findings, which also highlight that digital communication load is associated with psychological disorders such as burnout, anxiety, and depression [59]. *Confidence in using digital media* can be an influential variable concerning the acceptance of e–mental health interventions, as already shown by several studies related to internet use and internet literacy [60,61]. Again, the sign of the regression coefficient of *confidence in using digital media* is unexpected (negative), which, in interpretation first means that the more confident people are in using digital media, the less accepting they are of e–mental health interventions. However, when considering the entire regression model, it is noticeable that the sign of the regression coefficient for the predictor changes, which means that suppression effects might have occurred in the last step owing to the inclusion of the UTAUT factors. A practical implication resulting from this is to make as many patients as possible from different vulnerable patient groups familiar with the use of digital media and eHealth interventions so that they will be more widely accepted and used in the future.

Another new and important finding of this study is that psychometrics also contributes significantly to the variance explanation of acceptance of eHealth interventions among patients with obesity. Therefore, as a theoretical implication, this result should be included in the analysis of future research. The depression score (PHQ-8) is a significant predictor of the acceptance of e–mental health interventions in the overall regression model. As discussed above regarding mental disorders, we can assume that people with high depression scores and more prominent psychological symptoms generally experience more distress. This can lead to the finding that the acceptance of e–mental health interventions seems to be high among patients who are currently experiencing psychological distress.

The evaluation of the psychometric data (EDI-2–B, EDE-Q8, and PHQ-8) shows that the current sample of patients with obesity is noticeably psychologically burdened. The two kinds of psychological symptoms are eating disorders, such as binge eating, and depressive symptoms. A large review of obesity and psychiatric disorders from 2017 shows a very strong association between obesity and depression, especially in longitudinal studies, where the correlation was stronger for women. In addition, multiple studies have also shown an association between eating disorder symptoms and obesity [8]. This leads to the practical implication that eHealth interventions should be particularly targeted at restoring mental health, especially in patients with obesity.

In general, this study confirms recent findings (owing to high variance explanation of the 3 UTAUT factors in the acceptance of e–mental health interventions) and supplements them with further predictors (*depression, stress caused by permanent availability,* and *confidence in using digital media*).

However, it can be assumed that further factors influence the results of acceptance, especially the use of e–mental health interventions, and these must be taken into account when looking retrospectively at the results of previous research. In the evaluation of previous findings on acceptance and use of e–mental health interventions, we should consider whether the researchers used the UTAUT model or another measurement instrument to describe acceptance, the type and duration of the patient's illness, the type of eHealth service, and whether patients or health care workers were surveyed.

Limitations

The following limitations should be considered when interpreting the results of this study. As our study was exclusively web-based, it was mandatory that participants had internet access. As the spread of internet access varies, particularly between age groups, our sample of patients with obesity tends to be younger than the average in the general population (only 5 people older than 65 years). Moreover, the sex distribution is not representative of the overall population. As we recruited participants widely through social media groups (obesity surgery–related groups, which are almost exclusively composed of female members), a large number of women participated (403/448, 89.9% women and 45/448, 10% men), which restricts the generalizability of the results. In addition, we had varying numbers of patients in each obesity grade group: obesity grade I (82/448, 18.3%), obesity grade II (88/448, 19.6%), and obesity grade III (278/448, 62.1%). Thus, a significantly high number of persons are in obesity grade III, which also does not correspond to the distribution in society [62]. The BMI bias in this study (with 278/448, 62.1% of the participants with a BMI >40 kg/m^2) is particularly important, as eHealth interventions often have preventive functions and could be valuable for patients in obesity groups I or II. Owing to these sampling biases, the generalizability of our results may once again be reduced. In addition to the unbalanced distribution of participants from the different obesity groups, we recruited a very high number of participants who had already undergone bariatric surgery (200/448, 44.6%) or were in the process of planning to undergo the surgery (170/448, 37.9%), which could

also limit the generalizability of our results. Similarly, a considerable number of participants did not have a diagnosed mental health disorder at the time of the survey (which makes comparability difficult), whereby acceptance of e–mental health interventions was high among individuals with a mental health disorder. Nevertheless, the general psychological distress of the participants in this study was high, as measured by the valid psychometric instruments.

Owing to the recruitment of participants via the internet (in particular, via social media), we can assume that they might already have been more willing and interested in internet-related topics than random participants from different social backgrounds; therefore, we cannot rule out a selection bias. It is important to note that all the data collected were self-reported. Thus, accuracy of the results may be limited by the fact that participants may respond in a very socially elicited manner. Self-reporting can lead to a phenomenon known as common method bias [63]. To counteract this limitation, the instruments used in the study had sufficient reliability, the survey had a defensible length and was anonymous and web-based, and the patients were well educated, as these points are known to mitigate common method bias.

It is important to mention that this study, similar to most of the previous studies, determined the acceptance of e–mental health interventions among patients with obesity only by using the BI. A direct inference from the intention to use an e–mental health intervention to the actual use is not possible owing to the intention–behavior gap. However, further research should take the limitations of this study into account and include the actual use (behavior) of e–mental health interventions in patients with obesity and not focus only on acceptance.

As a theoretical implication for future research that also focuses on capturing the acceptance of e–mental health interventions, it would be particularly important to observe the distribution of sex, age, and the different obesity groups, to keep it as representative as possible. In addition, it would be beneficial to conduct a longitudinal study in which barriers and predictors for the actual use behavior of e–mental health services would be identified because no causality can be determined by cross-sectional studies. In addition, it would certainly be conceivable to survey other special patient groups, who, similar to patients with obesity (owing to stigma, physical illness, comorbidities, and immobility), have specific barriers that make the implementation of e–mental health interventions particularly important. This would facilitate the identification of the specific needs and demands of these patient groups and, as a practical implication, the development and implementation of e–health interventions that specifically target the improvement of mental and physical health.

Conclusions

Although the measured acceptance in patients with obesity could be determined as moderate, this study highlights that the acceptance of e–mental health interventions differs significantly depending on the following variables: age, grade of obesity, occupational status, sex, and mental health status.

The UTAUT model with its three core predictors (*PE*, *EE*, and *SI*) has proven to be a valuable instrument to predict the acceptance of e–mental health interventions in patients with obesity. The variance explained by acceptance in the restrictive UTAUT model (the 3 core predictors) was high, but the extended UTAUT model is slightly but significantly better in comparison and highlighted three additional significant predictors (depression, stress owing to constant availability via mobile phone or email, and confidence in using digital media). Owing to the close association between acceptance and use, acceptance-facilitating interventions should be fostered to enhance the establishment of effective e–mental health interventions for patients with obesity. Low-threshold, location-flexible, and efficient e–mental health interventions are more important than ever before, especially with regard to the ongoing pandemic and in light of the high psychological vulnerability of patients with obesity. Especially because many patients with obesity decide to undergo bariatric surgery, such interventions could be very relevant in the preoperative phase (for psychological support) and in the postoperative follow-up. In addition, further research should be conducted to determine the detailed expectations, needs, and demands of patients with obesity regarding such tailor-made interventions to further increase motivation and acceptance.

Authors' Contributions

AB, MT, EMS, and MN initiated and conceptualized the study. LCS was coresponsible for the recruitment of the participants. VR, MD, JS, and AS performed the statistical analyses and interpretation of the data, and VR wrote the first draft of the manuscript. VR, MD, and AS performed the data acquisition and statistical analyses. AB, MT, and EMS contributed to the design of the study. All authors contributed to the further writing of the manuscript and approved the final version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Health care delivery continues to evolve, with an effort being made to create patient-centered care models using patient-reported outcomes (PROs) data. Collecting PROs has remained challenging and an expanding landscape of digital health offers a variety of methods to engage patients.

Objective: The aim of this study is to prospectively investigate two common methods of remote PRO data collection. The study sought to compare response and engagement rates for bidirectional SMS text messaging and mobile surveys following orthopedic surgery.

Methods: The study was a prospective, block randomized trial of adults undergoing elective orthopedic procedures over 6 weeks. The primary objective was to determine if the method of digital patient engagement would impact response and completion rates. The primary outcome was response rate and total completion of PRO questionnaires.

Results: A total of 127 participants were block randomized into receiving a mobile survey (n=63) delivered as a hyperlink or responding to the same questions through an automated bidirectional SMS text messaging system (n=64). Gender, age, number of comorbidities, and opioid prescriptions were similar across messaging arms. Patients receiving the mobile survey were more likely to have had a knee-related surgery (n=50, 83.3% vs n=40, 62.5%; *P*=.02) but less likely to have had an invasive procedure (n=26, 41.3% vs n=39, 60.9%; *P*=.03). Overall engagement over the immediate postoperative period was similar. Prolonged engagement for patients taking opioids past postoperative day 4 was higher in the mobile survey arm at day 7 (18/19, 94.7% vs 9/16, 56.3%). Patients with more invasive procedures showed a trend toward being responsive at day 4 as compared to not responding (n=41, 59.4% vs n=24, 41.4%; *P*=.05).

Conclusions: As mobile patient engagement becomes more common in health care, testing the various options to engage patients to gather data is crucial to inform future care and research. We found that bidirectional SMS text messaging and mobile surveys were comparable in response and engagement rates; however, mobile surveys may trend toward higher response rates over longer periods of time.

Introduction

Health care delivery continues to evolve, with an effort being made to create patient-centered care models. Learning health systems engage patients and elicit patient-reported outcomes (PROs) data to continuously improve and drive clinical practice [1,2]. Incorporating PROs into clinical decision-making has led to improvements in patients' quality of life, improved communication, and reductions in unscheduled care [3-5]. Collecting PROs has remained challenging and their integration into clinical decisions remains understudied [6].

The use of mobile technology (cell phones, smartphones, tablets) continues to increase in society and health [7,8]. Engaging patients to capture PROs may provide clinicians with additional understanding to support care and motivate behavior remotely [9,10]. As digital strategies continue to expand, there has been limited research on the optimal ways to reach patients and capture PROs. Research using mobile health has grown in the past decade [11-13]. Clinicians have attempted to use mobile technology to track medication adherence [14,15], encourage healthy behaviors [16], improve home monitoring [17], and institute automated "hovering" to track chronic diseases [18]. However, less is known about the various mobile methods of engaging with patients and collecting and monitoring patient-reported data.

Within the context of the opioid epidemic and in an effort to promote opioid prescribing stewardship, surgical studies have collected PROs focused on pain intensity and opioid prescribing and use through surveys to reduce excessive prescribing [19-22]. These studies have revealed a mismatch between prescribing and patient-reported use, but are limited by their retrospective design, recall bias, and limited response rates. PROs have been used in orthopedic surgery to help guide preoperative decision-making and improve patient satisfaction [9,23]. To overcome the limitations of prior research, the existing gap regarding prospective PRO data on pain, function, and opioid consumption must be addressed. The rapid evolution of mobile technology may provide an opportunity for clinicians to assess trends in patients' self-reported pain and use of prescription analgesics, test methods to support safe and effective pain management, and translate data into clinical protocols [24].

The purpose of this study was to prospectively investigate two mobile patient engagement strategies to collect PRO data. Surgeons seek PRO data on acute pain management to inform safe opioid prescribing and to effectively manage acute pain. We compared response and completion rates of postoperative PROs among patients using bidirectional SMS text messaging versus mobile hyperlink surveys. To our knowledge, this is the first study to compare two distinct mobile engagement approaches in this context. The hypothesis of this study was that conversational SMS text messaging would result in higher response and completion rates as compared to mobile survey hyperlinks.

Methods

Overview

This was a prospective, block randomized trial of adult patients (aged 18 years or older) undergoing elective orthopedic procedures (ClinicalTrials.gov NCT03532256). The study took place over 6 weeks between July 1, 2019, and August 12, 2019. The primary objective was to determine if the method of patient engagement would impact response and completion rates. The primary outcome was response rate and total completion of PRO questionnaires.

Eligible patients included adult patients undergoing an elective outpatient orthopedic surgery (including knee, hip, shoulder, and elbow) and prescribed an acute opioid for postoperative pain. Acute opioid pain medications included oxycodone, oxycodone/acetaminophen, hydromorphone, or hydrocodone. Exclusion criteria included no access to an SMS-capable device or no opioid prescription. These inclusion and exclusion criteria were consistent with prior published research protocols using an established automated postoperative messaging program [24,25]. All patients were recruited from the University of Pennsylvania Health System Department of Orthopedics, which performs approximately 13,000 surgeries per year. In addition to general procedures (~3500 annual surgeries), the department consists of the following divisions: (1) Sports Medicine (~1700 annual surgeries), (2) Hand (~1900), (3) Joints (~4500), and (4) Trauma (~1500).

The research team had previously worked with the institution's legal, privacy, and patient safety departments to obtain remote, SMS text message–based consent for data collection [25]. This was an intentional design of a larger institutional program aimed at improving acute opioid prescribing. The approach allows for remote consent in an attempt to reduce clinical providers' workload and improve the scale of engaging eligible patients.

Following an elective outpatient surgery within the Department of Orthopedics, patients who underwent surgery received an initial SMS text message on the second day after the procedure. This message informed the patient of safe SMS text messaging data practices, provided links to further information regarding the follow-up research study, and offered the ability to opt in or opt out of further messaging. Patient were asked to consent via a simple SMS text message response of "yes." Consenting patients were then sent SMS text messages on postoperative days number 4, 7, 14, 21, and 28. Patients were block randomized in groups of 2 or 4 to receive either (1) a hyperlink to a web-based mobile survey or (2) automated bidirectional SMS text messaging in a conversational format. Mobile survey questions and conversational questions were identical and included PROs related to self-reported pain intensity, ability to

manage pain, use of prescribed medications, and ability to control pain. Block randomization was used to achieve balance in the two groups across demographics, procedure date, and dates of mobile engagement.

Individuals who either did not respond, opted out, or self-reported no further planned use of acute opioid medications were not subsequently messaged. For example, if a participant completed the mobile survey or replied to the bidirectional SMS text messaging on postoperative day 4 and indicated they were no longer planning on using their opioid prescription, no further messaging was sent on day 7, 14, 21, or 28. Participants who did not respond to any messaging would receive a reminder message within 30 minutes; if participants did not respond, then no further messaging was sent. The follow-up intervals were determined with input from a key clinician and surgeon and were in line with prior studies that evaluated PROs at 1 or 2 weeks postoperation.

Descriptive summary statistics were used to characterize the study population, using mean and standard deviation for age, and frequencies and percentages for categorical variables including gender, type of surgery, opioid tablet quantity, comorbidities, and invasiveness of the procedure (open surgical approach vs laparoscopic). To determine differences in the primary outcome of response rate at day 4 between the messaging arms and categorical demographic variables, Fisher exact test was used. To determine the difference in response at day 4 by age, Student t test was used. To determine if there were differences in secondary outcomes such as opioid use over time, Kaplan-Meier product-limit method with a log-rank test was used. A 2-sided α of .025 was considered statistically significant. All opioid prescription types were converted to equivalent doses of 5 mg oxycodone tablets [26]. All analyses were performed using SAS statistical software (version 9.4; SAS Institute).

Ethics Approval

The Institutional Review Board of the University of Pennsylvania approved this study (number 827461).

Results

Over 6 weeks, 127 participants were block randomized into either receiving a mobile survey (n=63) delivered as a hyperlink or responding to the same questions through an automated system—a chatbot using bidirectional SMS text messaging (n=64). Overall, 57.4% (n=73) of participants were male, the mean age was 38.5 (SD 13.9) years, and 70.8% (n=90) had had a knee procedure. Gender, age, number of comorbidities, and number of opioid tablets prescribed were similar across arms (Table 1). Patients receiving the mobile survey were more likely to have had a knee procedure (n=50, 83.3% vs n=40, 62.5%; P=.02) but less likely to have had an invasive or open procedure (n=26, 41.3% vs n=39, 60.9%; P=.03).

Overall engagement over the immediate postoperative period was similar between the messaging arms (Table 2). Using automated bidirectional SMS text messaging, the overall response rate was 45.3% (29/64) versus 49.2% (31/63) using a hyperlink to a mobile survey. For those patients using opioids in the past 4 days, prolonged future engagement was higher in the mobile survey arm at day 7 (18/19, 94.7% vs 9/15, 60%). Among nonresponders, the majority of patient drop-off occurred at day 4. Patients with more invasive or hip procedures showed a trend toward being responsive at day 4 as compared to those not responding (Table 3).

Discussion

Principal Findings

This study has two key findings within the context of mobile patient engagement and data capture. First, immediate postoperative patient engagement and research consent are feasible using digital methods. Second, there were no significant differences in the overall response rates between the modalities of bidirectional SMS text messaging and mobile surveys. We deployed a direct-to-patient approach in obtaining mobile consent to prospectively capture PROs for postoperative pain and pain management. Prior studies aiming to understand patients' pain and use of prescription opioids following surgeries have been limited by retrospective design, telephone or paper surveys, and recall bias [19,22,27]. We worked collaboratively within the health system to develop an approach that offloads clinical providers from obtaining written consent during preoperative visits and reaches out to patients following their procedure through SMS text messaging. This mobile consent process may be further studied to decrease in-person time, allow for researchers to link important research and other patient information, and offer patients the ability to opt out.

Second, the method and approach used to capture patient-reported data may not significantly impact initial response rates and overall completion rates. The ways in which patients use digital technology and mobile apps continue to change [28]. This study begins to analyze direct-to-patient methods that capture patient-reported data [29]. These early results indicate mobile methods can be used to engage postoperative patients and may provide a scalable approach for engaging larger patient populations. Traditional paper-based surveys rely on mail services and may introduce time delays and recall bias, whereas digital methods allow patients to respond in the moment [30]. Though not statistically significant, we found that patients undergoing more invasive procedures (ie, open surgeries and nonlaparoscopic surgeries) or any procedure on the hip were more likely to respond and remain engaged. This suggests an opportunity to provide tailored content and messaging as more procedures become outpatient and more recovery is based in the home. Ultimately, we describe similar and consistent completion rates as the weeks passed following patients' surgeries.

Limitations

This study has limitations. First, the study and data collection were performed at a single academic medical center and thus the study is not generalizable. Second, selection bias may be

present as patients needed to have a mobile device and opt to answer questions through either the mobile survey or the bidirectional SMS text messaging system. Those patients receiving a mobile link to the survey must have a smartphone and may represent a select population. Third, patients were undergoing elective outpatient procedures and may represent a population that is not generalizable to all procedures. This study compares two techniques that have been rapidly adopted; it does not compare these directly to paper methods, which have more traditionally been used.

Conclusion

This study demonstrates the early feasibility of PRO capture using two methods of patient engagement following orthopedic surgery. The findings suggest no major differences between bidirectional SMS text messaging and mobile surveys to collect PRO data. In an increasingly digital era, clinicians and researchers may employ digital surveys as a tool for rapid collection of PROs, which can inform research and a learning health system. Future studies will need to investigate larger scale programs and generalizability outside of surgical settings and for broader populations.

Authors' Contributions

AKA and MKD researched the literature and conceived the study. ZSA, JH, FS, RX, DAR, and ES were involved in protocol development, gaining ethical approval, patient recruitment, and data analysis. AKA wrote the first draft of the manuscript. All authors reviewed and edited the manuscript and approved the final version of the manuscript. MKD, ZSA, and AKA are the guarantors.

Abstract

Background: Chronic obstructive pulmonary disease (COPD) affects millions of Americans and has a high economic impact partially due to frequent emergency room visits and hospitalizations. Advances in digital health have made it possible to collect data remotely from multiple devices to assist in managing chronic diseases such as COPD.

Objective: In this pilot study, we evaluated the ability of patients with COPD to use the Wellinks mHealth platform to collect information from multiple modalities important to the management of COPD. We also assessed patient satisfaction and engagement with the platform.

Methods: A single-site, observational, prospective pilot study (N=19) was conducted using the Wellinks platform in adults with COPD. All patients were aged over 30 years at screening, owned an iPhone, and were currently undergoing a treatment regimen that included nebulized therapy. Enrolled patients received a study kit consisting of the Flyp nebulizer, Smart One spirometer, the Nonin pulse oximeter, plus the Wellinks mHealth app, and training for all devices. For 8 weeks, participants were to enter daily symptoms and medication use manually; spirometry, nebulizer, and pulse oximeter data were automatically recorded. Data were sent to the attending physician in a monthly report. Patient satisfaction was measured via a 5-point scale and the Net Promoter Score (NPS) captured in interviews at the end of the observation period.

Results: Average age of the patients was 79.6 (range 65-95) years. Participants (10 female; 9 male) had an average FEV_1% (forced expiratory volume in 1 second as % of predicted for the patient) of 56.2% of predicted (range 23%-113%) and FEV_1/forced vital capacity of 65%. COPD severity, as assessed by the Global Initiative for Chronic Obstructive Lung Disease (GOLD) classification, was mild in 2 patients, moderate in 6, and severe/very severe in 11; 9 patients were on home oxygen. During this 8-week study, average use of the spirometer was 2.5 times/week, and the pulse oximeter 4.2 times/week. Medication use was manually documented 9.0 times/week, nebulizer use 1.9 times/week, and symptoms recorded 1.2 times/week on average. The correlation coefficients of home to office measurements for peak flow and FEV_1 were high (r=0.94 and 0.96, respectively). Patients found the app valuable (13/16, 81%) and easy to use (15/16, 94%). The NPS was 59.

Conclusions: This study demonstrates that our cohort of patients with COPD engaged with the Wellinks mHealth platform avidly and consistently over the 8-week period, and that patient satisfaction was high, as indicated by the satisfaction survey and the NPS of 59. In this small, selected sample, patients were both willing to use the technology and capable of doing so successfully regardless of disease severity, age, or gender. The Wellinks mHealth platform was considered useful and valuable by patients, and can assist clinicians in improved, timely decision making for better COPD management.

Introduction

Chronic obstructive pulmonary disease (COPD) is a respiratory disorder characterized by persistent symptoms such as shortness of breath, coughing, excess mucus production, and irreversible expiratory airflow obstruction. It primarily affects people aged 65 and over and is often a result of exposure to risk factors such as tobacco smoke or air pollutants [1]. In 2018 in the United States, 16.4 million people reported having a diagnosis of COPD, chronic bronchitis, or emphysema, according to the Centers for Disease Control and Prevention's National Health Interview Survey [2] and COPD was the fourth leading cause of death in the United States [3].

COPD has a high financial impact. COPD-related costs in the United States were projected to be US $49.0 billion in 2020, including direct health care expenditures and indirect morbidity and mortality costs [4]. COPD exacerbations, during which symptoms of coughing and shortness of breath acutely worsen, are a significant driver of these expenditures, due to emergency room visits, hospital admissions, relapses, and readmissions [5]. COPD has a 30-day readmission rate of approximately 20% and is a target condition in the Medicare Hospital Readmission Reduction Program [6]. Frequent COPD exacerbations can lead to a decline in lung function and quality of life and may significantly affect a patient's prognosis [7,8].

The current standard of care for COPD includes medications, smoking cessation, oxygen supplementation (when indicated), and pulmonary rehabilitation [9]. At each office visit, patient biometric data are collected (eg, pulse oximetry and spirometry) and the COPD care plan is communicated. Between office visits, however, it is difficult for the physician to gather insights into patient behavior and adherence to the care plan; significant clinical deterioration or noncompliance can go undetected. Furthermore, many patients with COPD have limited mobility due to the debilitating nature of their lung disease, making office visits challenging or not possible at all. Currently there are few comprehensive and reliable tracking solutions to assess patient adherence to the care plan or the impact of medication and other interventions on a more frequent basis [8,10,11].

Advances in digital health have now made it possible to share medical information in real time, thus enabling more immediate management of chronic diseases. Remote patient monitoring solutions have been successfully developed in other chronic diseases, such as congestive heart failure and diabetes [12,13]. During the COVID-19 epidemic, patients of all demographic groups quickly adopted some form of technology to access medical care [14,15]. Monitoring modalities are now being evaluated for factors such as ease of integration into existing clinician workstreams, correlation with traditional diagnostic measures and treatment modalities, and overall patient acceptance [16].

For patients with COPD, effective remote monitoring should include information on medication adherence and symptoms, plus biometric data including spirometry and pulse oxygen [17]. However, the ability to monitor data streams from different digital sources has presented some challenges, such as accuracy, measuring adherence, and ease of use for both the patient and the clinician, including incorporation into existing electronic medical records [8,11,17].

In this pilot study, we evaluated the Wellinks mHealth platform in a small cohort of patients with COPD. Our objective was to, within a trial setting, determine the feasibility of the platform to track information important to the management of COPD, collected via Bluetooth from multiple modalities including spirometry and pulse oximetry, medication adherence, and patient input of symptoms and medication use. This small-scale study was performed to obtain feedback on patient satisfaction and engagement with the platform, and to inform modifications needed for larger clinical studies.

Methods

Study Design

This prospective observational pilot study of the Wellinks mHealth Platform was conducted from January to May 2021 at a single outpatient pulmonary practice. A sample size of 20 patients was planned. Monitoring data were collected over an 8-week-per-study-patient observation period. Informed consent was obtained from each participant, and the study was conducted according to the principles stated in the Declaration of Helsinki (2013). Patients were deidentified of protected health information according to the Safe Harbor method of the Health Insurance Portability and Accountability Act (HIPAA). Each patient was assigned a unique study ID number and the principal investigator maintained sole access to reidentification codes.

Ethical Approval

This study was approved by the Institutional Review Board (IRB) (IRB#:20-WELL-101) with respect to the scientific content and ethical treatment of human research participants.

Recruitment

Participants were recruited by the principal investigator within the clinical setting. Inclusion criteria specified male or female patients with COPD over 30 years of age with English language literacy who were prescribed a treatment regimen that included nebulized therapy. All patients had access to an iPhone running iOS version 13.4 or later.

Exclusion criteria were acute or chronic conditions that might interfere with patients' ability to participate in the study, or comorbidities that might interfere with data collection and interpretation (eg, renal, cardiac, hepatic, central nervous system, or psychiatric conditions).

Participation in this study was completely voluntary. Participants were permitted to keep the items in the study kit. No additional financial inducements were offered, and no patient recruitment materials were used.

XSL•FO

RenderX

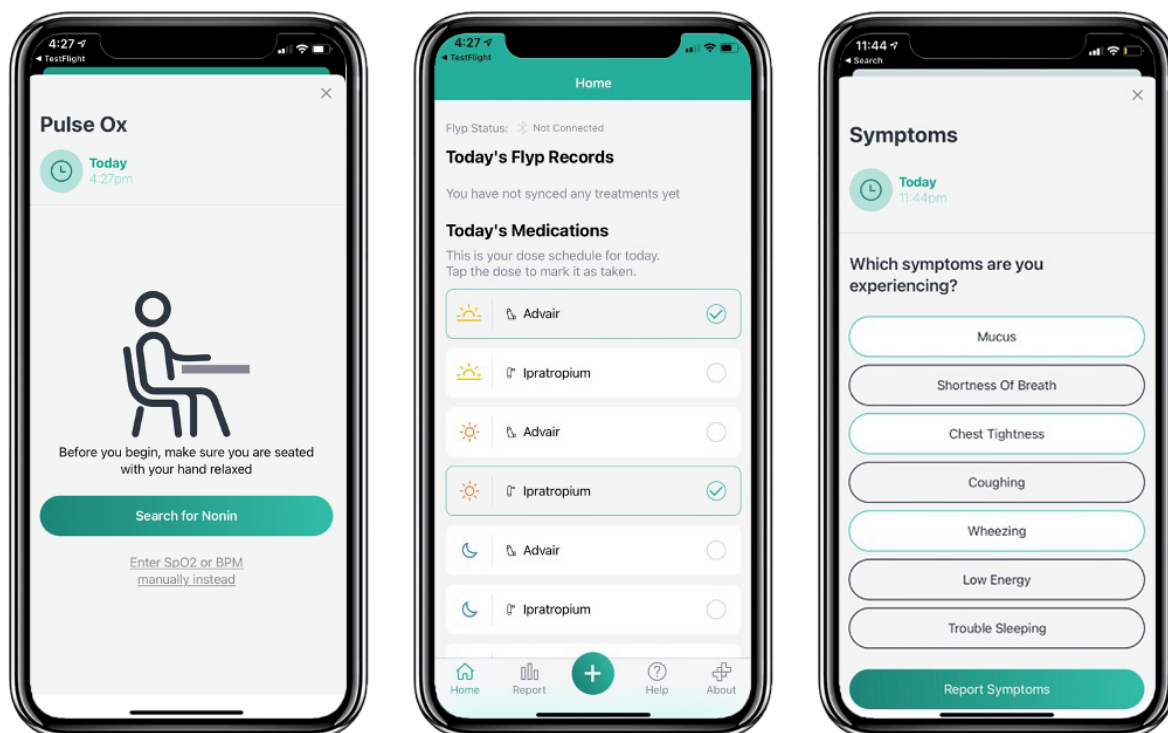
Patient Use of the Intervention

After informed consent was obtained, participants received the study kit, which consisted of 3 devices: the Flyp nebulizer, MIR Smart One spirometer, and Nonin pulse oximeter, plus instructions for use (Figure 1). In addition, participants received instructions for downloading the Wellinks mHealth iOS app. The physician or another member of the research team explained the function of all devices and the app. Participants were considered enrolled once the app was downloaded and the participant had logged in.

Figure 1. Components of the Wellinks mHealth Kit, including the Flyp nebulizer, MIR Smart One spirometer, and Nonin pulse oximeter, are pictured here from left to right. Patients used their own phones to download the Wellinks mHealth App.

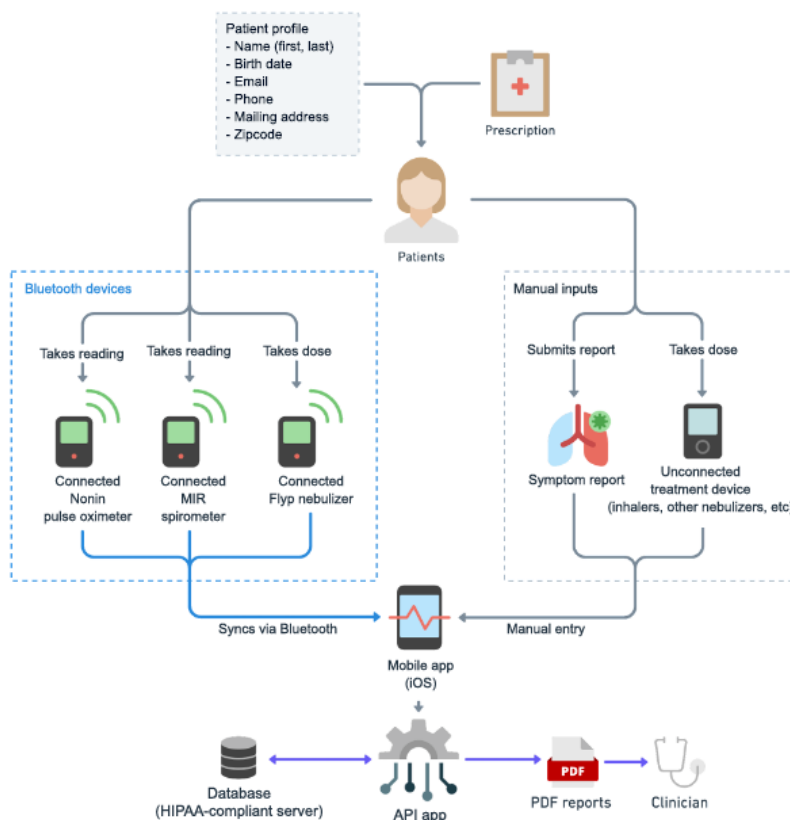
Patients were asked to perform forced expiratory volume in 1 second (FEV_1) and pulse oximetry measurements (peripheral oxygen saturation or SpO_2) at least once weekly; these data were automatically recorded in the app via Bluetooth. Patients' use of the Flyp nebulizer was also automatically recorded; most patients were prescribed nebulizer treatments as rescue therapy only.

Daily medication usage and symptoms were entered into the app manually by the patient (Figure 2). The app was prepopulated with a customized list of medications prescribed to each patient for COPD, including dosing intervals; patients were able to check off when the dose of each prescribed medication was taken. Patients could also enter the use of additional medications, such as rescue inhalers or nebulizer treatments. A list of symptoms (mucus production, shortness of breath, chest tightness, wheezing, coughing, low energy, and trouble sleeping) allowed patients to either check the symptom boxes or to check a "no symptoms" box if they were not having symptoms. Patients were not prompted by the app or the clinical research team to use the devices or to enter information into the app.

Figure 2. The app displays content that guides the patient while recording pulse oximetry, or inputting medications taken and symptoms experienced from a list. The medication list was prepopulated with each patient's prescribed medications.


The Wellinks app collects and stores data related to treatment and respiratory status of the patient on a secure, HIPAA-compliant, cloud-hosted database. Monthly reports containing a summary of the collected medication adherence data, FEV_1 and SpO_2 measurements, and symptoms or notes were sent to the clinician via secure email. Any subsequent visits or treatment were to be consistent with current standard of care (Figure 3).

Figure 3. The Wellinks mHealth platform recorded spirometry, pulse oximetry, and nebulizer use automatically by bluetooth. The patient manually input medications taken and symptoms experienced (if any) using the app. Data were stored securely and compiled into a summary Portable Document Format (PDF) report for the clinician monthly. API: application programming interface, HIPAA: Health Insurance Portability and Accountability Act.



Patient Engagement and Satisfaction

Patient engagement was evaluated by assessing how often patients used the various features of the Wellinks mHealth platform over the 8-week study period. For spirometry and pulse oximetry, the baseline case was 1 use/week. Use of the medication and symptoms recording feature was left to the patient's discretion.

At the end of the observation period, patients' overall attitudes about and perception of the Wellinks mHealth solution were assessed using a 9-question 5-point Likert scale (responses ranged from 1=strongly disagree to 5=strongly agree). In addition, patients had the opportunity to provide qualitative feedback to the interviewer regarding their experience and the intervention.

The Net Promoter Score (NPS) was used to gauge patient satisfaction overall with the Wellinks mHealth solution. The NPS is derived from the answer to just 1 question: "On a scale of 0-10, how likely is it that you would recommend using the Wellinks app to friends, family members, or associates also living with COPD?". The score is determined by subtracting the percentage of "Detractors" (those who gave a score of ≤6) from the "Promoters" (those who gave a score of 9 or 10). The "Passives" (those who gave a score of 7 or 8) are thought to be satisfied with the product, but not to the point of recommending the product or "promoting" it to others [18,19]. With the methodology used here, the total score (tallied from all responses) will fall between –100 and 100, with –100 being the worst outcome and 100 being the best. This survey was administered to the patient by video call or telephone by a member of the Wellinks research team.

The Wellinks mHealth platform generated a physician report monthly (Figure 4). Each report was customized for each patient, and provided the following summary of that patient's activity in the preceding month:

- Scheduled medications (name and dosage): adherence percentage and medication most commonly missed;
- As-needed (pro re nata [PRN]) medications (name and dosage): how often and how much taken;
- SpO_2% over time;
- Pulse (beats/minute) over time;
- Spirometry (peak flow and FEV_1) over time; and
- Symptoms: list of symptoms experienced and when entered (date and time).

Figure 4. The physician report supplied monthly summarizes prescribed scheduled medications, PRN medications and adherence, pulse oximetry and spirometry readings over time, and symptoms. PRN: pro re nata.
Adverse Events

Adverse events occurring during the study period were documented by the investigator; these were not reported to the device manufacturer unless they were considered serious and related to the device. Serious adverse events were to be reported using an unanticipated device effects form and were to be reported to the sponsor and to the IRB.

Analysis

Data were summarized with means and ranges for quantitative variables with normal distribution (eg, age, spirometry values). The Pearson correlation coefficients were calculated to compare concordance between home and office spirometry; mean values from the Smart One spirometer were compared with FEV_1 values collected at the closest patient visit date (office spirometry was performed on a Vyaire Vmax Encore).

Correlations between office and home pulse oximetry were not conducted because of the narrow range of values. The *t* tests were performed to compare differences between subgroups using Microsoft Excel. *P* values are given for subgroup analyses, with a threshold of .05 considered statistically significant.

Results

Demographics

A total of 19 patients were enrolled in the study. The average age was 79.6 years, and the patient group was almost equally divided by gender (10 female, 9 male). Patients' $FEV_1\%$ (forced expiratory volume in 1 second as % of predicted for the patient) at study entry averaged 56.2% of predicted (range 23%-113%), and FEV_1/forced vital capacity averaged 65%. The majority of patients (n=10, 53%) fell into the severe disease category, as indicated by the Global Initiative for Chronic Obstructive Lung Disease (GOLD) criteria [9]. A total of 6 patients (32%) were in the GOLD 2, or moderate category, and 2 (11%) were in the mild category; 1 patient (5%) was categorized as GOLD 4, or very severe. This distribution is not surprising as patients were required to be using nebulizers, which are not typically prescribed for mild disease. A total of 5 patients had a caregiver assist them with many of the activities, including equipment use and symptom/medication input (Table 1).

Table 1. Demographics and baseline characteristics of the study population.

Demographic characteristic	Value (N=19)
Age in years, mean (range)	79.6 (65-95)
Gender, n (%)	
Male	9 (47)
Female	10 (53)
GOLD[a] category, n (%)[b]	
GOLD 1: mild (FEV_1[c] ≥80% predicted)	2 (11)
GOLD 2: moderate (FEV_1 ≥50-79%)	6 (32)
GOLD 3: severe (FEV_1 ≥30-49%)	10 (53)
GOLD 4: very severe (FEV_1 <30%)	1 (5)
$FEV_1\%$[d], mean (range)	56.2 (23-113)
FEV_1/forced vital capacity, mean	65.3
Home oxygen use, n (%)	9 (47)
Pack years, mean (range)	51.6 (10-100)
Independent versus assisted use of Wellinks mHealth solution, n (%)	
Independent use	14 (74)
Assisted use (with help from a caregiver or home health aide)	5 (26)

[a]GOLD: Global Initiative for Chronic Obstructive Lung Disease.

[b]All patients with FEV_1/forced vital capacity <0.70.

[c]FEV_1: forced expiratory volume in 1 second.

[d]$FEV_1\%$: forced expiratory volume in 1 second as % of predicted for the patient.

Patient Use of the Intervention

Participants used the pulse oximeter 4.2 times/week and the spirometer 2.5 times per week on average (Table 2). All 19 patients achieved the weekly goal of at least one pulse oximetry reading per week over 8 weeks, and 15 patients met or exceeded the goal of 1 spirometry reading per week. On average, patients' medication use was entered into the app 9 times/week, and symptoms entered 1.2 times/week.

Differences in participation did not significantly differ by COPD severity, age, or gender (Table 3).

There was a strong correlation between the FEV_1 (r=0.96) and peak flow (r=0.94) measurements recorded by the spirometer compared with the measurements recorded by the physician during the office visit closest in time to the at-home collected information (Figure 5).

Table 2. Study participant interaction with the mobile health platform.

Data collected	Mean number of app entries/week (range of number of app entries/week)
FEV_1[a] by spirometer	2.5 (1-7)
Blood oxygenation by pulse oximeter	4.2 (1-12)
Medication use	9.0 (1-25.1)
Nebulizer use	1.9 (0-11.9)
Symptoms	1.2 (0-5.6)

[a]FEV_1: forced expiratory volume in 1 second.

Table 3. Participation by gender, age, and COPD[a] severity.

Demographic characteristic	n	Spirometry[b]	Pulse oximetry[b]	Medications[c]	Symptoms[c]
Gender					
Male	9	19.3	35.2	10.3	6.5

[a]COPD: chronic obstructive pulmonary disease.

[b]Data are presented as mean number of uses/week.

[c]Data are presented as mean number of times reported.

Figure 5. The correlation of home versus office assessments of (A) peak flow and (B) FEV_1. FEV_1: forced expiratory volume in 1 second.
Patient Engagement and Satisfaction

The average number of recordings for spirometry, oximetry, and medication usage declined over the 8-week interval by varying degrees (Figure 6). Medication use entries fell from 7.8 times/week to 3.7 times/week (a reduction of 52.3%), oximetry recordings from 5.5 times/week to 2.5 times/week (a reduction of 54.2%), and spirometry recordings from 3.4 times/week to 1.8 times/week (a reduction of 45.4%).

Figure 6. Engagement, measured in app uses or recordings/week, fell over the course of the 8-week study, but remained above the baseline requested of 1 use/week for spirometry and oximetry recordings.
The satisfaction survey administered is presented as Multimedia Appendix 1. A total of 16 patients were available to take this survey. Most patients (15/16, 94%) either agreed or strongly agreed that the Wellinks app was easy to use and valuable (13/16, 81%). Most (15/16, 94%) found that it was valuable to be able to take spirometry and pulse oximetry measurements at home. The symptom logging function was found to be moderately valuable (11/16, 69%) as was the medication schedule (10/16, 63%). Patients expressed interest (12/16, 75%) in adding a physician or care team messaging component to the app. In general, the patients did not feel that the app enhanced their knowledge of COPD or the connection with their doctor. The NPS generated by the patients in this study was 59.

Adverse Events

There were no issues reported by either patients or the principal investigator related to the safety of the patients or the performance of the devices.

Discussion

Principal Findings

COPD is a chronic condition where the potential for rapid deterioration due to exacerbations is an ever-present danger [6,7,9]. For this reason, it can be a very difficult condition to manage as adjustments in care are dependent on the patient recognizing and reporting changes from baseline. While various devices exist to enable monitoring of specific individual parameters, an app that allows patients and physicians to track multiple modalities simultaneously, and remotely, would result in the most complete clinical picture available from the patient's daily life.

In this pilot study, we observed that study participants were both willing to use the Wellinks mHealth solution and able to do so effectively, performing both spirometry and oximetry measurements far more often than requested, and logging

medication use and symptoms frequently without being prompted. Patients engaged with the Wellinks platform regardless of disease severity, gender, or age. Notably, the correlations of peak flow and FEV_1 measurements taken by the patient at home and those performed in the office were very high. This has been a technical failure in prior studies, where use of the spirometer in an outpatient setting and without the assistance of a health care practitioner has resulted in inaccurate results [20,21].

Age may be a concern in the adoption of an mHealth system in patients with COPD, as COPD is largely a disease of the elderly who may have a lower digital literacy level, less access to smart devices, and overall, a lower comfort level with technology. A 2018 study of 638,330 Medicare beneficiaries found that 40.9% lacked a smartphone with a wireless data plan, and 26.3% lacked any type of digital access (either a smartphone or a home desktop or laptop computer with a high-speed internet connection) [22].

However, the COVID-19 pandemic has changed the way the elderly view technology. In a recent study conducted by the American Association for Retired People (AARP), 45% of individuals over 60 years viewed technology far more positively than they did prior to COVID. Among those 70 and over, 73% reported having high-speed internet access at home. Ownership of smart technology, including smartphones, continues to increase among those over age 70, and accessing health care services and health information is among the top 10 activities conducted on their smartphones. This represents a significant increase over 2019 [15].

When surveyed in this study, patients found the Wellinks platform to be both easy to use and valuable. These 2 factors have been found to be among the highest predictors of intent to use a medical app within a senior population, as found in a recent study of 364 older adults with an average age of 75 years [23]. In our study, the 2 factors with the lowest scores were the

ability to learn about COPD via the app, and enhanced connection to the physician. While access to educational content and 2-way communication are planned for the next-generation Wellinks platform, the study version of the app did not provide any educational material, nor was there any provision for direct communication between the patient and the physician. Patients or their caregivers had the opportunity to give the interviewer feedback about the Wellinks Platform at the end of the study period. Some patients reported technical difficulties, or the need for more clear instructions; others suggested ideas for improvement, such as integration of educational content to teach patients about the device readings and what the numbers meant. Several patients expressed an appreciation for the ability to track spirometry and oximetry values in real time.

NPS has proven to be a remarkably powerful assessment of customer satisfaction across multiple industries [24] and is now increasingly used in the health care setting due to its ease of administration and higher response rates. NPS surveys can be readied more quickly than email or phone surveys and are less time-consuming for patients, and thus more likely to garner a response [25]. NPS methodology is based on research that cross-references survey responses with actual consumer behavior, demonstrating that a strong personal recommendation of a company or a service to one's family and friends was a key measure of satisfaction [26], and directly correlated with uptake in the market [19]. An NPS of 59, as seen with the Wellinks platform, indicates a very high level of patient satisfaction [19].

Limitations

First, it must be noted that mobile and eHealth innovations are often subject to a high rate of attrition, for various reasons; for example, the novelty wears off over time, or patients have difficulty fitting the technology into their everyday lives. This can make it difficult to assess these types of technologies [27,28]. In the case of the Wellinks platform, the base requirement for spirometry and oximetry was only 1 use/week. Therefore, we believe the decline in usage for these 2 parameters is more reflective of hyperutilization toward the beginning of the study which then reverted to the anticipated baseline. The reduction in use of the medications feature may be reflective of the high medication burden for patients with COPD in general. Yet, even the reduced usage rate represents more information than would normally be available to clinicians.

Second, this study was a small pilot with all patients selected by 1 physician at 1 pulmonology practice. Certain study parameters limited our study population, for example, the requirements of access to an iPhone and of patient nebulizer

use. The fact that the study recruited from 1 small geographic area limits its generalizability as it may not reflect a diverse population.

Third, patient engagement may be artificially higher than expected in a real-world situation due to the Hawthorne effect (where individuals modify their behavior because they are being observed) [29]. In this study, patients were recruited by the principal investigator and were aware that their use of apps and monitoring devices was being recorded. This may have motivated the patients to use the app more consistently than if they were not aware that they were being observed. The slow decline in usage over 8 weeks may reflect that effect over time.

Lastly, while useful data regarding patient health status were provided via the patient report, there was no formal requirement for ongoing physician assessment of the data provided. The study was not designed to show improvement in COPD, only that patients would utilize the Wellinks system. Consequently, there were no interventions taken, and the study was not powered to show improvement in clinical outcomes or pharmacoeconomic impact.

Future Directions

This important pilot study proves that the multimodal nature of the Wellinks Platform is feasible and that appropriate utilization and engagement by the target population is possible. The information collected will direct the continued development of the Wellinks Platform, including features such as virtual pulmonary rehabilitation and health coaching, and has the potential to create value for patients and the health care system. Important questions remain: can this platform improve the quality of care for patients with COPD? Can it improve clinical outcomes such as a reduction of hospital readmissions and cost and improving patient quality of life? These questions will be addressed in a planned future clinical study.

Conclusions

The Wellinks platform is a novel platform designed for patients with COPD that consolidates multimodal biometric data and patient entries into a single, streamlined source of data including trends over time and is intended for use by both patients and providers. Patients were eager to engage with the platform and found it to be useful and valuable. Patient engagement was high across disease severity, age, and gender groupings. Given the difficulty of managing this complex, chronic disease, the Wellinks platform has the potential to improve patient engagement and outcomes, ultimately reducing COPD-related events and expenses.

Abstract

Background: Patient-centered measurement (PCM) aims to improve the overall quality of care through the collection and sharing of patient values, outcomes, and perspectives. However, the use of PCM in care team decisions remains limited. Integrated knowledge translation (IKT) offers a collaborative, adaptive approach to explore best practices for incorporating PCM into primary care practices by involving knowledge users, including patients and providers, in the exploratory process.

Objective: This study aims to test the feasibility of using patient-generated data in team-based care; describe the use of these data for team-based mental health care; and summarize patient and provider care experiences with PCM.

Methods: We conducted a multi-method exploratory study in a rural team-based primary care clinic using IKT to co-design, implement, and evaluate the use of PCM in team-based mental health care. Care pathways, workflows, and quality improvement activities were adjusted iteratively to improve integration efforts. Patient and provider experiences were evaluated using individual interviews relating to the use of PCM and patient portals in practice. All meeting notes, interview summaries, and emails were analyzed to create a narrative evaluation.

Results: During co-design, a care workflow was developed to incorporate electronically collected patient-generated data from the patient portal into the electronic medical record, and customized educational tools and resources were added. During implementation, care pathways and patient workflows for PCM were developed. Patients found portal use easy, educational, and validating, but data entries were not used during care visits. Providers saw the portal as extra work, and the lack of portal and electronic medical record integration was a major barrier. The IKT approach was invaluable for addressing workflow changes and understanding the ongoing barriers to PCM use and quality improvement.

Conclusions: Although the culture toward using PCM is changing, the use of PCM during care has not been successful. Patients felt validated and supported through portal use and could be empowered to bring these data to their visits. Training, modeling, and adaptable PCM methods are required before PCM can be integrated into routine care.

Introduction

Background

Seminal work in the 1960s and 1970s, supporting the combination of the concepts of a medical home with attributes of patient-centered care [1], provided the foundation for research that demonstrated the benefits of this care model (eg, comprehensive, coordinated care within a primary care team). Benefits linked to patient-centered medical home models include improved health-related quality of life, self-management, and depression; reduced hospital admissions; and improved clinical measures such as blood pressure and glycated hemoglobin [2]. However, the concept of patient-centeredness has been poorly theorized and operationalized, although several papers have identified key attributes such as patient and family being respected; given complete health information; being involved in decision-making; and supported in their physical, psychological, and social needs [3,4]. Newly realized in British Columbia (BC), the patient's medical home is a community practice that operates at an ideal level to provide longitudinal patient-centered, team-based primary care [5].

To assess these attributes, measures are needed to capture patient-centered care in a form that can be used to rate care quality and quality improvement (QI). Patient-centered measurement (PCM) has the potential to capture data to improve patient care experiences, care quality, communication, and trust. To this end, the BC Ministry of Health and the 7 health authorities established the BC PCM Steering Committee [6] in 2021 to implement scientifically rigorous approaches to collect and report patient-generated data (PGD). Examples of sources of these data include patient-reported experience measures (PREMs) and patient-reported outcome measures (PROMs).

However, the integration of PCM into regular care visits and decisions presents major conceptual, methodological, and logistical challenges in translating this body of knowledge into routine clinical practice [7-9]. A systematic review found that PGD improved patient health awareness and communication with providers but that difficulties arose when patients wanted greater provider involvement with their data during clinic visits [10]. Lordon et al [10] found that providers had difficulty accommodating patient requests for engagement with PGD because of the perceived lack of value, time constraints, and lack of workflow integration. Even with access to patient portals for data entry, the ability to incorporate and track these data varies across systems because of organizational, practice, workflow, resource, and technological challenges [11-13].

There is an unprecedented opportunity to develop and test best practices for incorporating PCM into clinical care because of the rapid uptake of virtual care and enhanced digital literacy for both patients and providers during the COVID-19 pandemic. This requires planning to determine which strategies to use, selection considerations about which patient populations to target for PREMs and PROMs, choice of specific measures, and engagement considerations, including how clinical care teams will incorporate and act on the data [14]. Given the complexity of implementing PCM in clinical practice, multilevel implementation science frameworks are effective, with the choice of framework or theory based on *fit for purpose* [15,16]. Iterative knowledge sharing, or integrated knowledge translation (IKT), was identified for our research, whereby planning, implementing, and evaluating team-based care performance could be optimally developed through the lens of providers, patients, and the research team [17]. Synergies derived from this IKT approach enhance the understanding of patients' and providers' context and needs, thereby enhancing the relevance of the generated research and increasing user knowledge and understanding of the research process, awareness of the research, and appreciation for how and when it can be applied [18].

For this research, we partnered with the regional district of Kootenay Boundary (KB) Division of Family Practice [19], whose mission is to help rural practitioners meet patient and practice needs and lead change as part of a province-wide initiative to strengthen health care in BC. The focus on people living in rural and remote communities is critical to address limited access to providers and services, and the resulting health disparities of higher chronic disease multimorbidity and all-cause mortality [20-22]. In this context, digital health solutions have great potential to address these health disparities [23]. The study team assessed priority areas for rural clinical care and identified mental health care as a high-needs area based on BC Community Health Data [24]. Mental illness is a common and disabling health problem in Canada, affecting 1 in 5 Canadians, and has become of even greater importance during the COVID-19 pandemic [25]. Care team–based patient-centered planning strategies have important potential in the treatment of mental illnesses, such as anxiety and depression [26]. Mental health concerns have worsened during the pandemic; based on the 2019 Community Health Survey, almost 5 million Canadians aged ≥12 years (16%) had seen or spoken to a health care professional in the previous year about their mental health, an increase of 2% since 2015 [27].

Objectives

The overall research aim was to develop new methods to incorporate patient-generated mental health and experience data for team-based in-clinic and virtual care. The new methods for PCM that emerged from this study are reported in another publication (M Antonio et al, unpublished data, December 2021). This paper reports on the IKT approach that was used in the multi-method study with the following objectives: (1) to explore the feasibility of integrating PGD using a patient portal in team-based care; (2) to describe the use of these data for team-based mental health care; and (3) to summarize patient and provider care experiences with PCM.

Methods

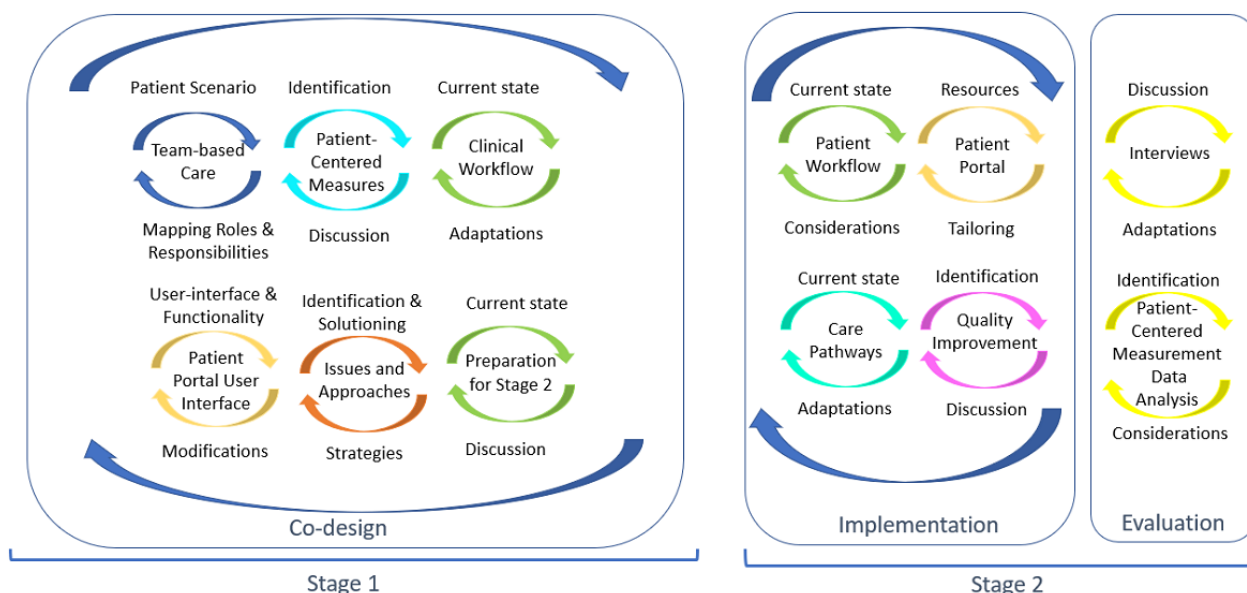
Setting

The study took place in a rural team-based care practice in the southern interior of BC, Canada, between February 2020 and April 2021. The private, multi-provider primary care clinic served as the patient's medical home [5]. The study received institutional ethical approval (protocol number: BC H19-03855). Notably, the first stage began at the onset of the COVID-19 pandemic, and the study was completed during the pandemic. As such, the research was conducted virtually, including regular interactions with providers, patients, and the research team.

Study Design

The research used a multi-method, IKT approach with interconnected stages of study (Figure 1). In line with the

directive in a scoping review on IKT in health care [28], we created a protocol, timeline, and IKT plan to guide our efforts, and the analysis of continuous and documented feedback offered the research team the ability to report findings with sufficient detail to reveal how IKT was associated with outcomes. Stage 1 of the study involved co-design during which the research team worked with the care team to identify relevant PCMs and optimize the use of the patient portal in the context of the team's clinical needs, roles and responsibilities, and workflow. Stage 2 included the implementation of the portal and care workflows with adaptation based on feedback and evaluation of its use and impact on clinical care. Implementation and evaluation occurred concurrently so that feedback could be incorporated and further evaluated.

Figure 1. Multi-method, integrated knowledge translation approach for the integration of patient-generated data.


The research team included patient partners, researchers, subject-matter expert scholars, and our industry partner. The patient partners (PB and MS) and two researchers (MA and SD) met regularly with clinic staff and care providers recruited to the study and with other knowledge users at various points within the study, including local professionals from our study collaborators, KB Division of Family Practice and General Practice Service Committee Practice Support Program [29]. Monthly research meetings were held with the entire research team to discuss and apply what we had learned to date.

Recruitment and Composition of the Provider Practice

A pragmatic approach and convenience sampling were used to recruit a community team-based clinic. The KB Division of Family Practice invited one of the early adopter clinics of a patient medical home care model to participate in both study stages. The enrolled clinic included 2 physicians, 2 medical office assistants, and a newly hired social worker and registered nurse (RN). The practice used an electronic medical record (EMR) but had no experience with the use of a patient portal, and their EMR did not have an embedded portal. The practice

had an identified patient panel within the EMR and received summary patient data from the KB Patient Experience Survey (a questionnaire currently in use by the Divisions of Family Practice to understand patient experience with care) and the Canadian Primary Care Sentinel Surveillance Network [30], a primary care research network that offers a web-based data presentation tool to improve primary health care delivery outcomes across the country. However, these data were not used to practice QI.

One of the initial joint decisions was the identification of the clinical domain of study for this intervention—mental health care. The factors considered in this decision included the limited number of mental health providers in rural primary care, the high prevalence of mental illness [25], and the providers' current familiarity with and routine use (including at the point of care) of two patient-generated mental health measures—the Patient Health Questionnaire-9 (PHQ-9) depression measure [31] and the Generalized Anxiety Disorder 7 item (GAD-7) [32].

Co-design Stage 1

Overview

This stage involved coproducing the implementation and evaluation plans. The components are shown in Figure 1. Methods for data collection included team mapping, care workflow, portal development, emails, and summary meeting notes. Outputs of this stage included mapping the care team's roles and responsibilities, identifying relevant PCMs, detailing the office and clinical care workflows to enable PCM use, optimizing the use of the patient portal, and documenting learnings to understand issues and generate solutions.

Team-Based Care Mapping

Team roles and responsibilities were mapped using the team mapping method, a facilitated cocreation workshop designed to help groups explore how to work together in a primary care team [33] and informed by the circle of care modeling [34], an analytical technique to develop the PCM adoption methods and create and validate patient use cases. A 2-hour–long team mapping session, using patient personas focused on mental health concerns, was held over Zoom (Zoom Video Communications) with all providers and staff from the clinical practice and members of the research team. The mapping session explored and defined team roles and responsibilities in caring for the simulated patients and how PCMs could support care decisions. This exercise also explored the use of technology, such as patient portals outside of regular visits to engage patients, and workflow associated with monitoring the data. Following the session, facilitators generated a summary report that included images of the patient-centered maps that were created, as well as summaries of the PCM gaps and potential solutions, categorized for discussion with the care team.

Patient-Centered Measurements

Discussions with providers led to the following selected PREM and PROMs: (1) a multipart question from the KB Patient Experience Survey that contained subitems about whether someone from the care team talked with patients about difficulties taking care of their health, main health goals and priorities, stressors, needed support, medication review, and offer of preventive care; (2) Patient-Reported Outcomes Measurement Information System Item Bank (version 1.0)—General Self-Efficacy Short Form 4a—a general population measure with demonstrated good convergent validity, internal consistency reliability, model fit, and sufficient unidimensionality [35,36]; (3) PHQ-9 depression measure; (4) GAD-7; and (5) self-action plan for depression [37]. The PHQ-9 and GAD-7 are validated measures already in use by the practice at the point of care.

Care Workflow

A group session, held with the clinic after the team mapping exercise, focused on reviewing the mapping report and how PCM gaps could be addressed through alternative workflows [38]. An electronic patient-reported outcomes toolkit [39] guided discussions related to improvements in office efficiency and integration of electronic PGD. Iterations of care workflow were brought forward as a flow diagram for feedback at the next meeting. In consultation with patient partners and co-designed

with the care providers and clinic staff, an initial workflow was identified for the implementation stage.

Patient Portal

The research team selected a commercial vendor portal that had a patient-centered perspective (eg, patients could select who they want to share data within their care team). The web-based portal was used as a stand-alone system during the study (ie, was not interoperable with the clinic's EMR system) as no current tethered or interoperable patient portal was available for use in this study, and the industry partner was amenable to adding selected PCMs and tailoring to study needs (eg, education and resources). Ongoing adjustments to the user interface were gathered and provided to the industry partner for implementation.

The portal had a user interface for patients and a separate one for the clinic staff and care providers. The researchers had access to both the interfaces. Of the 7 functionalities assessed in a recent Cochrane review on patient access to EMRs [40], this portal provided for PCM, including tracking, education, and a reminder feature that was sent if a requested patient questionnaire was not completed within 3 months. The portal did not provide the ability to request other information, bidirectional communication and sharing, or the ability of patients to manage their care. The materials provided in the portal included selected PCMs and educational resources.

Preparing for Implementation and Evaluation

Preparing for stage 2 encompassed patient recruitment, change management support, portal deployment, and development of the evaluation.

Recruitment of Patient Participants

Clinic staff and care providers contacted patients who had been living with a mental health diagnosis for many years to inform them about the study. Interested patients were provided with a flyer that included contact information for a researcher (MA) who provided study information and a consent form before enrollment. Four patients agreed to participate in the study. Participation involved using the patient portal over 4 months and interviews to discuss how PCM and educational materials within the portal were used during their care. Owing to the COVID-19 pandemic, most clinical visits between patients and providers were held over phone.

Implementation—Stage 2

This stage comprised activities to operationalize the intervention and adapt design components based on iterative feedback. The components of this stage are shown in Figure 1.

Patient Workflow and Portal Use

The use of the portal was presented to patients at the start of the intervention as a part of their workflow. Iterative patient workflow adaptations were made based on patient feedback during the implementation and evaluation stages.

One researcher (MA) provided training in portal use for all patients, clinic staff, and care providers. The patient user interface allowed patients to see messages from their provider, complete the PREM and PROMs, and explore educational

materials. The portal was set up to send an email to inform patients that there was an invite in their portal account. Both patient and provider portal interfaces allowed completed PCMs to be viewed on the computer device screen or downloaded as a document that clinic staff could upload into the patient's record in their EMR. Patients and providers could also view data trends of these measures (eg, scores on PHQ-9) if more than one was completed.

Care Workflow for Providers

The care workflow, finalized in the previous stage, was used as the initial care workflow for the study implementation. Individual discussions with providers and clinic staff during the intervention focused on changes to the care workflow specific to care pathways such as screening, monitoring, and follow-up resulting from the addition of PCM to team-based care processes. For example, the RN took responsibility for sending PROMs and educational materials to patients biweekly to complete through the portal. The PREM was sent at the beginning and end of the portal-use period.

We recognized that because of the lack of interoperability between the portal and EMR, we would have to simulate some embedded portal functions, such as sending reminders and data entry. For example, the portal-completed PROMs were intended to be reviewed during clinic visits. To achieve this, the RN and a researcher (MA) shared responsibility for checking for upcoming appointments, deploying the PROM and checking for completion and transferring the PROM score into the EMR encounter notes section, attaching the document, and entering the score into the existing PROM sections of the EMR. The researchers met periodically with the RN to adjust the implementation efforts.

Evaluation Plan—Stage 2

Interviews

A general interview guide approach was used for the patients (Multimedia Appendix 1) and providers (Multimedia Appendix 2). Patient interview questions included interactions with the portal, use of questionnaire results and educational materials by themselves and with the provider, and how other tools could be used to complement communication with the portal. Interviews were scheduled within 1-5 days after a virtual or phone visit with their provider. A total of 13 patient interviews with 4 patients were conducted, and the number of interviews with each patient was dependent on the number of care visits (2-4 visits) during the study period. Provider questions included

visit information, use of patient questionnaires during the visit, whether educational materials prompted discussion, and whether the questionnaire results/educational materials influenced the visit or team interactions. An individual interview was conducted with all 4 care providers and 2 clinic staff members at a convenient time following a patient visit (timing varied between 1 week and 1 month). To gain immediate insights, a web-based survey was provided to physicians immediately after a patient visit (Multimedia Appendix 3).

All interviews were conducted virtually (phone or video) by two researchers (SD and MA) and lasted 10 to 30 minutes. Both researchers had experience with qualitative research. Notes were taken by both interviewers and combined as summary notes. The summary interview notes were coded by one researcher (MA) using ATLAS.ti (ATLAS.ti Scientific Software Development GmbH), and the coding reports and original data were reviewed by 2 additional team members with experience in the analysis of qualitative data (MS and SD). The final interview coding reports were confirmed by the research team.

PCM Data Analysis

The framework method for the analysis of qualitative PCM data was used. The framework method applies a matrix structure to facilitate the recognition of patterns and has been used effectively under the leadership of experienced qualitative researchers [41]. Data analyses involved looking across interview coding reports, team mapping reports, portal use, and care workflow diagrams to determine areas of convergence or divergence and develop a narrative of the evaluation of the implementation. Our reflective practice comprised the development of new care workflow diagrams, iterative writing, and discussion among the research team at monthly analysis meetings.

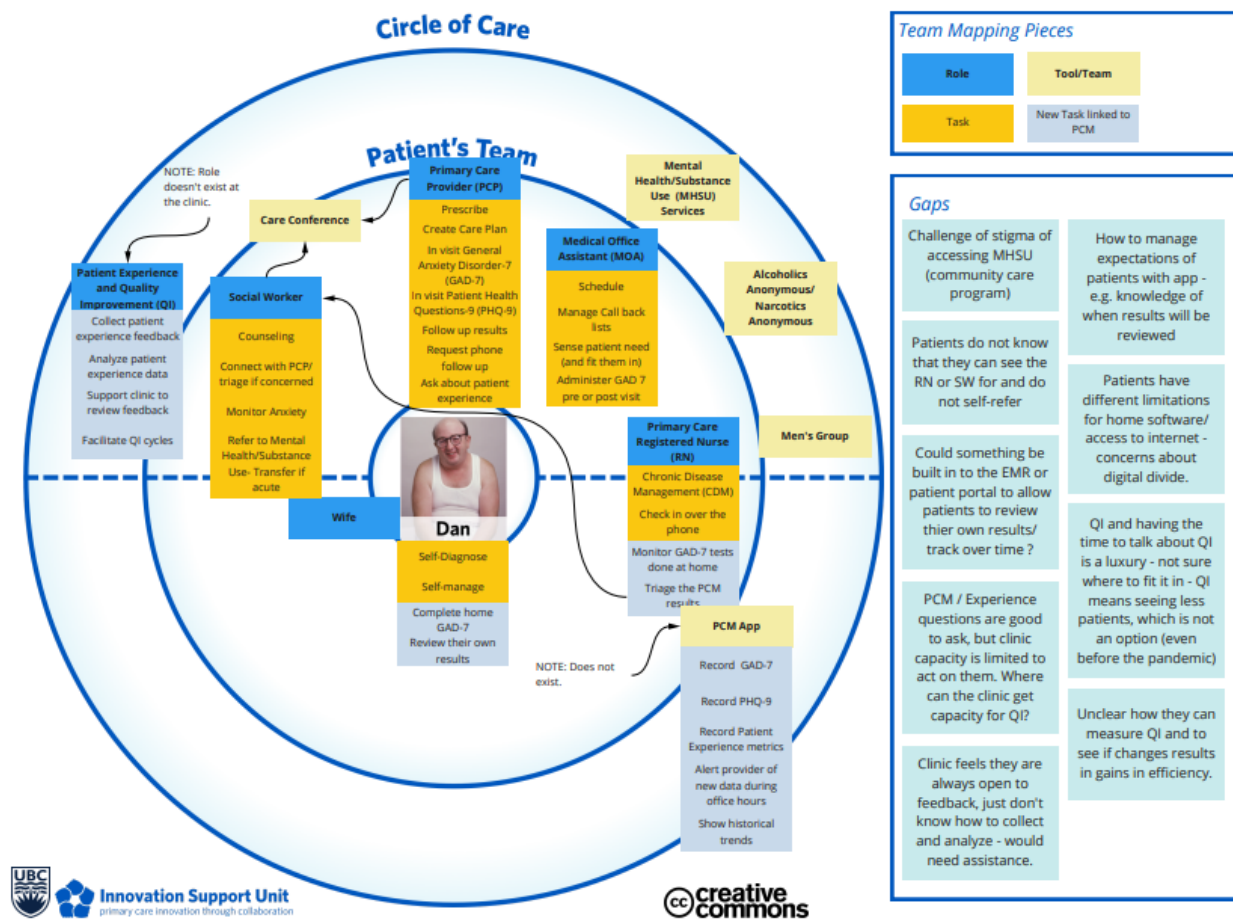
Results

Co-design—Stage 1

The collective results of stage 1 were used to inform stage 2.

Team Mapping to Inform Care Workflow

The team mapping exercise focused on two areas: care of patients with mental health concerns and how PCM could be used in practice. The session produced *circle of care* maps with defined team roles and responsibilities in caring for the simulated patients (Figure 2). The session's discussion focused on PCM integration and how PCM could influence care.

Figure 2. Mapping team-based care for patients with mental health issues.


Supplementary File 5: Team Map- Completed team map of persona "Dan", an accountant with history of anxiety and alcohol mis-use. Note the different roles in Dan's circle of care from himself, family, primary care team, as well as other external groups. Team mapping allowed participants to collaboratively discuss features for integrating patient-centred measurement.

Following the mapping session, co-designing efforts produced an initial care workflow for incorporating PREM and PROMs into routine care, before, during, and in between a patient's clinic visits, using a patient portal. Five key activities were identified: (1) deploying PCM, (2) collecting electronic patient data, (3) tracking completion, (4) reviewing data, and (5) documentation. Workflow changes were then designed to incorporate these activities, and a final workflow diagram was developed (Figure 3 [42]). Before the visit, the patient or clinic staff may initiate a visit appointment, the care team may tailor resources and PCM questionnaires in the portal, the patient would receive notifications and review the resources, and then complete the questionnaires. The nurse would track and triage the PCM scores and initiate urgent responses if needed. During the virtual or in-person visit, the physician might review the PCM scores with the patient, document appropriate actions, and refer the patient to other providers as needed. In between visits, the care team would comanage the patient.

Figure 3. Final team-based care workflow with electronic patient-generated data [42]. GAD-7: Generalized Anxiety Disorder 7-item; PHQ-9: Patient Health Questionnaire-9; PROM: patient-reported outcome measure; PROMIS: Patient-Reported Outcomes Measurement Information System.
Strategies and Concerns About Integrating PCM

On the basis of team mapping and care workflow sessions, we constructed Table 1 with learnings and potential solutions to care gaps and team limitations, strategies needed to allow the use of PCM, constraints in the current workflow including restrictions because of the COVID-19 pandemic, and modifications needed to the patient portal to enhance care. Providers commented that the mapping and workflow sessions mirrored clinical practice well. The major concerns expressed included the practice's limited capacity for incorporating PCM gathered outside the clinic visit (both electronic and paper-based), patient expectations for review of their data, and the provider's knowledge and clinic capacity that limited engagement in QI. Providers expressed concerns about the rural context with lack of access to high-speed internet, insufficient resources to manage practice workload, and current fee-for-service structures that did not provide an allowance for the collection and use of PCM.

Table 1. Stage 1—gaps, learnings, and potential solutions before implementation.

Co-design step	Learnings	Potential solutions
Team roles and responsibilities	• Patients do not know about roles or access to a RN[a] or social worker • No individual was trained in using data for QI[b] • The stigma around mental health care and access to community program • No ability to track medications or change in PGD[c] scores	• Information about staff and other resources in portal • Engage with training resources (eg, future staff training) • Improve connections so these are part of team • Expand team: pharmacist
Strategies (what needs to be in place to use PGD)	• Patients and providers need access to data and tracking; best if integrated • Patients may need reminders: bring data or trigger discussion • Increase the level of patient engagement	• Make PGD available through the portal; EMR[d] linkage; explore ways to document • Consider reminders in the portal • Provide resources in the portal
Care workflow	• No capacity or training to use patient experience data for QI • COVID-19 pandemic restrictions prevent hallway conversations • There is no way to trigger follow-up (eg, significant change in PGD score)	• Begin with joint selection of an experience measure • Schedule brief virtual work huddles at the start of each day • Plan to explore options in stage 2
Patient portal	There was concern regarding limited digital literacy • There was concern regarding patient expectations for review of data • Patient knowledge gaps around depression and anxiety	• Patient interview data to understand needs • Careful use of language and messages to patients on expected follow-up • Add educational resources to portal and delivery plan

[a]RN: registered nurse.

[b]QI: quality index.

[c]PGD: patient-generated data.

[d]EMR: electronic medical record.

Customization of the Patient Portal

The patient portal was collaboratively prepared with selected mental health questionnaires, patient experience measures, depression self-action planning tool, and educational resources, and comprised a feature for trending data such as the anxiety questionnaire, GAD-7, in Figure 4. An appraisal guide was created to select the educational and resource material to ensure that the material was evidence-based, used patient-oriented language, and was adaptable to local contexts (eg, local community resources). Examples of the educational materials are provided in Multimedia Appendix 4.

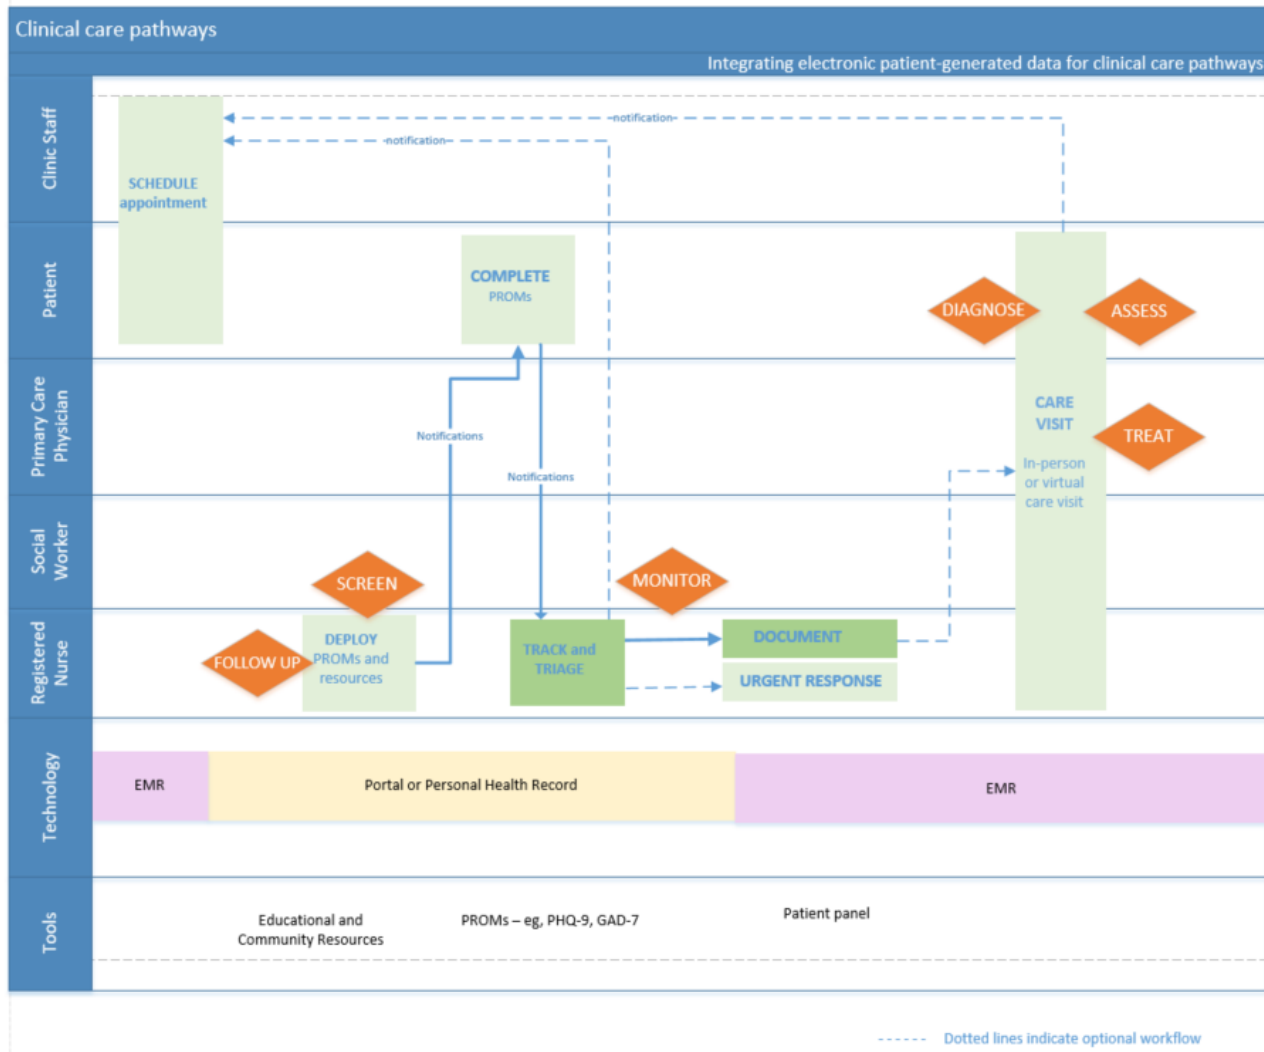
Figure 4. The patient portal—patient-centered measurement questionnaires, resources, and functions.

Before deployment, the portal underwent initial testing by patient partners and an undergraduate student who simulated the role of the patient. Through discussions with the practice and research team, the type, timing of deployment, quantity of educational material, messaging, and notifications within the portal were determined before launching portal use.

Implementation and Evaluation—Stage 2

Care Pathways and Portal Use

On the basis of workflow discussions with care providers and patient partners, a clinical care pathways diagram was produced (Figure 5 [42]) to identify the opportunities for care team members to integrate PCM (eg, asynchronous screening or follow-up or during an encounter). There are 7 PCM-related clinical care activities performed by different care team members to screen, triage, assess, diagnose, treat, monitor, and follow up with the patient, which can be guided by their PCM data. Nurses and social workers may initiate screening, monitoring, and triage of patients, or when triggered by web-based notifications and reminders from the portal. Physicians may refer to PCM data when assessing, diagnosing, and treating the patient during an in-person or virtual visit. In between visits, the nurse could follow up with the patient to provide resources and PCM questionnaires within the portal, monitor for completed PCM data, and schedule notifications as reminders to complete them.

Figure 5. Clinical care pathways with electronic patient-generated data [42]. EMR: electronic medical record; GAD-7: Generalized Anxiety Disorder 7-item; PHQ-9: Patient Health Questionnaire-9; PROM: patient-reported outcome measure.


A patient workflow based on patient feedback was created to incorporate real and potential actions related to PCM (Figure 6 [42]). PCM-related activities for patients are to review resources in the portal and evaluate their relevance, respond to notifications, complete PCM questionnaires indicated by the provider or on their own initiative, and take actions in response to new learnings. These actions include reflecting on their condition in response to new information, initiating self-care, tracking trends over time, sharing information with family or care network, reviewing additional resources, following up with the care team, and preparing for a visit. Considerations included delivery-method notification, the timing for completion of questionnaires and resources, tailoring efforts of educational materials, and visit type (in-person or virtual). A video was created [43] to illustrate study results relating to the use and integration of PGD into clinical care from the patient's perspective.

Figure 6. Patient workflow with electronic patient-generated data [42]. PHR: personal health record; PREM: patient-reported experience measure; PROM: patient-reported outcome measure.

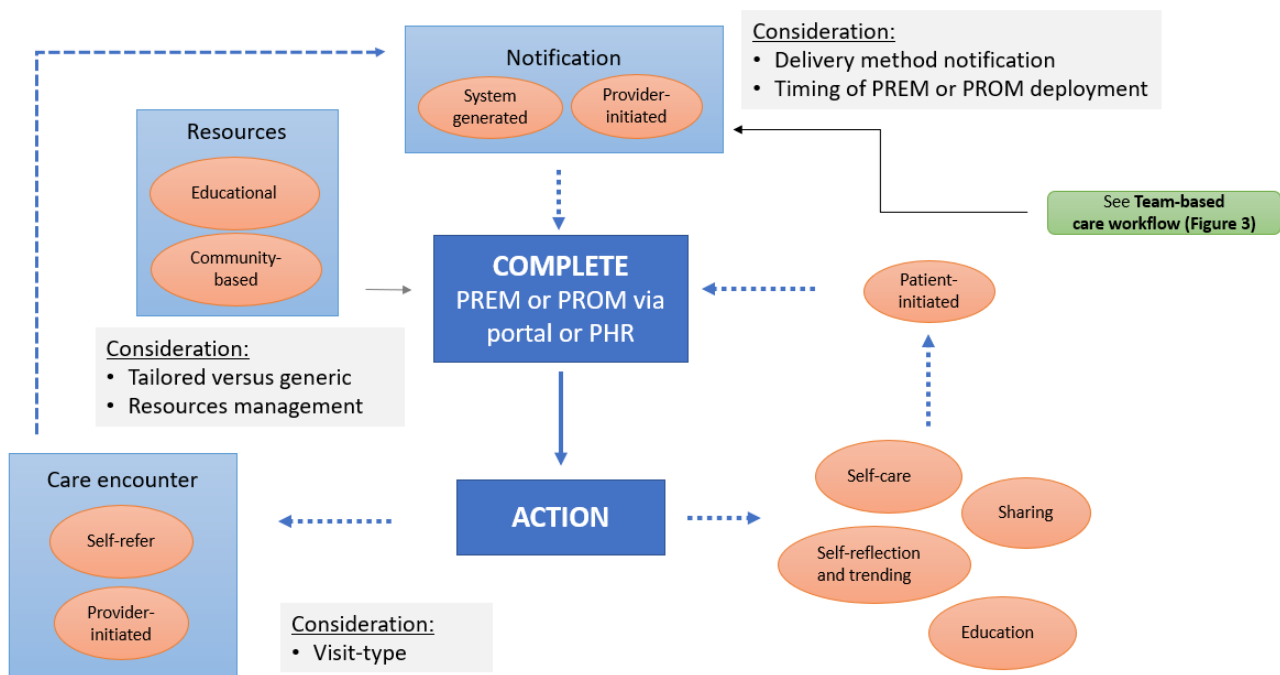


Table 2 provides excerpts from the summary notes that demonstrate our key learnings from stage 2. The qualitative synthesis of 13 patient interviews indicated that the portal was easy to use and valued. Two patients noted the inability to use the portal during times of severe depression and fatigue. Providers saw benefits in patients' use of the portal for information and to give them a sense that care was nearby. The major problems identified with provider use of the portal were lack of portal integration with the EMR and lack of alerts for changes in questionnaire scores that should trigger action. For providers, to limit the extra work across the team, 1 team member (RN) oversaw the PCM data in the portal and transferred it into the EMR. Even with the simulated integration of data transfer into the EMR by the RN, the process of reviewing those data elements in the EMR was often overlooked during a care visit.

All patients read at least some of the educational material provided, with skill-building workbooks being the most appreciated. One patient stated that "knowledge of our illness is vital to taking steps to live with illness and attain victory as often as possible." Getting information over time rather than all at once was useful to avoid overwhelming the participant. Most patient participants had been living with a mental health diagnosis for many years and reported that the initial educational materials offered would have been helpful earlier in their diagnosis and illness. At their request for more advanced information, patient-friendly abstracts of scientific papers were added to the portal. Patients also wanted the ability to rate articles for their usefulness. Providers appreciated the potential for educational resources to be tailored to the patient's stage and needs. However, they recognized that they would not have the resources or domain expertise needed to sustain ongoing educational material development or deployment in the portal.

Table 2. Stage 2: learnings from patient-centered measurement (PCM) and portal implementation.

Learnings	Patients	Providers
Use of patient portal (not used during visits)	• View educational and community resources and complete PROMs[a] and PREMs[b] • A way to overcome isolation and focus on self • Unable to use during times of severe depression or fatigue	• Ways to provide information to the patient and impart "a feeling that care is nearby" • A lack of integration with EMR[c] • Resulted in use by a single nurse to manually transfer patient-generated data, which were rarely reviewed during a care visit • Lack of alerts to trigger action reduced portal usefulness
Value of educational resources	• Knowledge is vital to overcoming illness • Provide credible information and avoid getting "lost in the abyss" • The initial educational materials provided would have been helpful earlier in their diagnosis and illness. Personalized material would be valuable	• Appreciated the potential for educational resources to be tailored to the patient's stage and needs • "Not able to sustain ongoing educational material development or deployment"
Use of PCMs	• Completing PROMs was extremely "validating" • Sense of being heard and capturing more of the relevant information about their mental health • Tracking and trending scores using a portal "painted a picture of where I am" • Frustration that their providers were not asking about or reviewing PROMs during care visits • Unclear who was to bring up the PROM	Did not use within portal because of the following reasons: • Lack of integration of portal with EMR (only total score of PROMs were manually entered into the EMR) • Lack of alerts for changes in questionnaire scores that should trigger action • Belief that the PCM did not add to the existing relationship
Optimizing completion and use of PROMs	• Timely reminders for PROM completion • PROMs needed that address function to aid "what created my responses" as part of the interpretation of a measure	• Timely customizable reminders for PROM completion • Interoperability of systems • Additional training on use of PROMs

[a]PROM: patient-reported outcome measure.

[b]PREM: patient-reported experience measure.

[c]EMR: electronic medical record.

PCM Use in Team-Based Mental Health Care

Three patients reported that the process of completing PROMs was extremely *validating* in that they learned more about themselves and gained confidence in reaching out for support. As one patient noted on reviewing the PHQ-9 with a resident physician, the experience was "unexpectedly rewarding and validating (same page together) and resulted in a treatment change." Several patients noted that clinic visits in their current form are often used to revisit past appointments or begin with general questions that may not relate to a patient's current status. As 1 patient, who was hesitant to talk with the physician about anxiety, noted, completing the questionnaire ensured that all pertinent aspects were covered, preventing communication disconnect. In addition, tracking scores were appreciated; 1 patient stated that the weekly trend "painted a picture of where I am." However, 1 patient noted difficulty in interpreting depression scores in that they did not provide insight into "what created my responses." Suggested additions by patients for PROMs included functional measures (eg, what is working now for or against you), more sophisticated graphics for tracking scores and more specific questions in the action plan based on depression scores. Patients wanted to be able to complete PROMs on their own and trend data over multiple years.

Patients expressed frustration that their providers did not review PROMs and did not ask about PCM at visits. One patient

reported that she thought she was doing something wrong in not having questionnaire data at her visit. Providers noted that although PCM collected before a visit could make visits more efficient, they did not review them for reasons noted in Table 2.

As PGD in the portal was a new activity, there was also a lack of clarity when the PROM scores would be viewed and discussed. Patients were used for in-person visits and thus did not consider opening the portal during their virtual visit. Each provider had different preferences for where to view these data but had not established a practice of viewing them. The limited-time for visits meant that providers prioritized the purpose of the visit and planned to look at the PROM scores during the patient's annual mental health check-up.

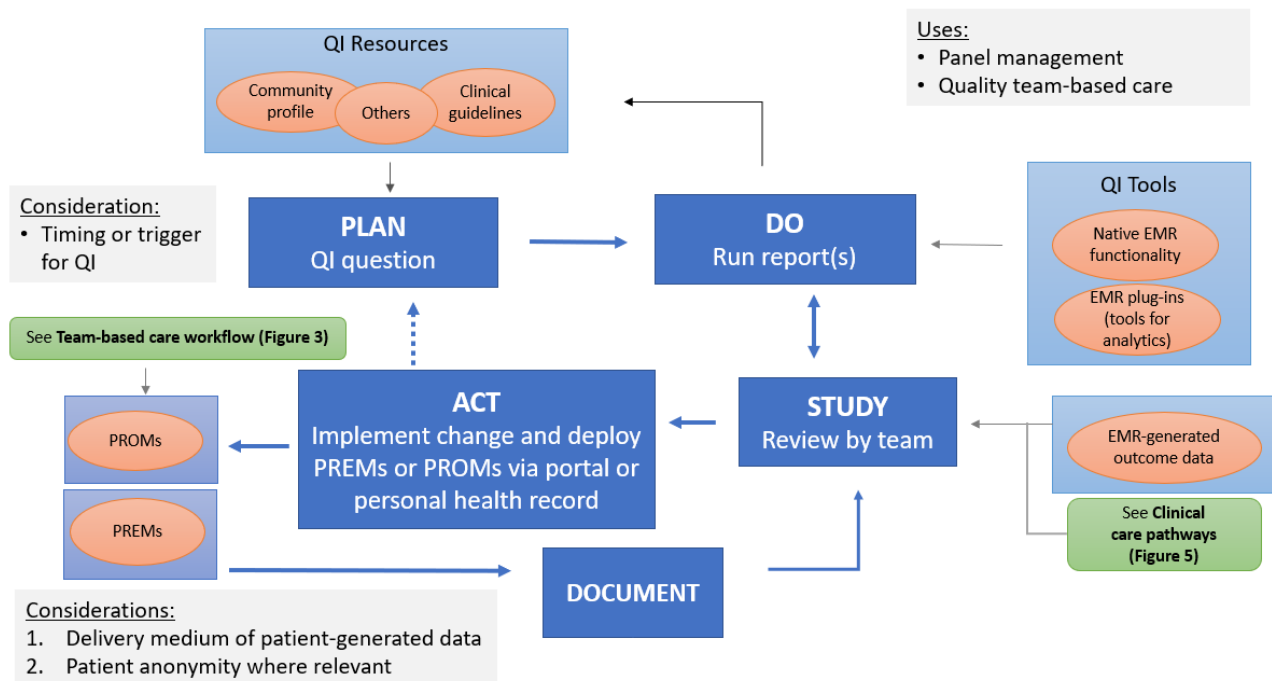
Concerning optimizing the use of PCMs, both patients and providers wanted to be able to set timely reminders for PROM completion. Patients sometimes logged into the portal to see an invite and start completing a PROM, and then realized that they wanted to return when they could give more focus or were less fatigued. The lack of reminders meant that patients often forgot to return and complete PROM. Similarly, providers wanted the ability to customize reminders (eg, 24 hours before a visit or a week after the initial invite). Providers also noted that they lacked education and training on PROMs' limited use, including

interpretation of a PCM score and what constituted a significant change.

Quality Improvement

Although QI activities were never completed, discussions were held to explore opportunities within workflow and care processes to carry it out. Examples of mental health care included PHQ-9 completion, counseling, and medication prescriptions for patients with a diagnosis of depression. The resultant QI process workflow is displayed in Figure 7 [42]. PCM-related QI activities for the care team are based on the plan-do-study-act cycle and documentation processes that can

be informed by PCM. Planning is driven by clinic priorities and capacities and is further guided by community health profiles and the latest clinical practice guidelines. Doing involves running patient panel queries using the clinic EMR and related external databases or applications to identify areas for attention. Studying, acting, and documentation involves a detailed review of the panel query outputs, implementing specific actions, and documenting the actions and results when available. The PCM focus brings awareness to specific groups of patients that may require action depending on their health situation and PCM scores.

Figure 7. Quality improvement (QI) in team-based care workflow with electronic patient-generated data [42]. EMR: electronic medical record; PREM: patient-reported experience measure; PROM: patient-reported outcome measure.


To date, most QI efforts have been focused at the regional level, and the clinic does not know how to apply PREM results to clinical processes with multiple providers. An agreement was received around its value, but resistance was observed, and one provider commented on the lack of medical school training in QI. There was also a sense of technology overload, where providers had to remember multiple login codes and how to view data across more than 4 different systems. QI tools and resources available, delivery medium and type of PCM, timing and triggers for QI, and maintenance of patient anonymity when using PREMs were discussed.

Additional Learnings

Knowledge sharing (or IKT) throughout the study was invaluable to our process and learnings. Specifically, during all interactions and interviews with knowledge users, the researchers received productive feedback to questions like *how we are doing* and whether *we hit the mark* with iterations of (1) process descriptions; (2) design planning, implementation, and evaluation actions; and (3) documentation of identified issues and solutions.

Although providers noted that it takes a *whole team* to care for patients with mental health disorders, clinical resources were overwhelmed and there were limited community mental health services in this rural area. Multiple patients commented on how their physician was overworked, so they were mindful of what could be done at a visit, although they would have preferred mental health visits more frequently than once annually. The addition to the practice of the social worker was relatively recent, and one patient did not know about the availability of the RN or social worker or how they could fit into their care. Another patient stated that they wanted a physiotherapist to be part of their team. Both patients and providers noted that rural living was associated with fewer specialist resources and longer wait times.

Since the COVID-19 pandemic, virtual care visits have become a routine part of practice. One staff member noted that patients were no longer in the waiting room or available to complete questionnaires on-site. Both patients and providers felt that virtual care was less valuable because of lack of personal contact; one provider stated that "the loss of human connection is devastating." One patient reported that they might have brought up their anxiety if face-to-face and that being virtual

missed the seriousness of their illness. However, patients also preferred to answer PROMs at home, as the answers seemed more honest than completion in a public waiting room. One clinic staff member noted a possible benefit of phone visits in a rural (small population) clinic in that patients could have a degree of anonymity by not having a face to recognize when seen out in the community.

Discussion

Principal Findings

IKT offered the research a continuous and rich understanding of patient and provider needs and current challenges in the context of team-based care and PCM, as well as potential best practices for integrating PGD using a patient portal. Providers were unable to incorporate the use of electronically generated mental health PROMs within team-based care during this study for several reasons including workload, need to prioritize issues to address during an encounter, lack of easy access to the data, lack of value placed on the data, and lack of education about and practice in its use. The absence of established provincial standards for interoperability between systems hampered the integration of electronic PCMs in team-based care. In a review of personal health record functionalities and implementation, Harahap et al [44] identified interoperability as a key implementation issue, as well as security and privacy, usability, data quality, and personalization as other important factors. Digital health transformation at the system level is needed to realize interoperability, providing standard definitions for data exchange and cooperation with the patient, provider, and organizational systems. Using an ontological information model, Plastiras and O'Sullivan [45] demonstrated the feasibility of transferring PGD using common standards from personal health records to EMRs. Interoperability must be addressed to ensure that electronic PROMs and PREMs from patient systems can be fully integrated within provider systems and readily available at the point of care. In addition to the issue of interoperability, the authors perceived that the limited experience of these newly formed primary care teams, and having to shift to virtual care during the pandemic made it less likely that any member could ensure delegation and use of the data provided.

Solutions to learnings from the co-design step that were acted upon (ie, engaging with the local Division of Family Practice around QI, patient reminders for the completion of questionnaires, research assistant tracking, and providing patient education and resources within the portal) were valued and demonstrative of the way forward. Ultimately, the gap in getting data viewed in the EMR and usable at the time of a visit was not accomplished. For digital tools to be successful in addressing provider workload, authors of a systematic review [40] identified a need for training, reducing documentation and task time, expanding the care team, and leveraging QI processes in workflows.

Although QI was an intended part of PCM advancement, it was discovered early in the study that providers felt that the practice could not engage in practice improvement using PREMs. An additional knowledge user with subject-matter expertise in QI was added to the team to present information on EMR panel report analysis, community profile, best practices, and clinical practice QI guidelines using PROMs. Although providers expressed interest in the future use of PCM for QI, because of the COVID-19 pandemic, frustrations expressed over prior poor quality QI data provided, and inexperience with use, the study shifted to provide an opportunity to explore QI and educate the practice on ways PCM could be used for QI. The QI activities were not implemented or evaluated.

PREMs are being collected through population surveys in the geographic area of this study, but QI efforts are still nascent, and there is no single best way to collect or use PCM for QI. Gleeson et al [46] systematically reviewed current QI efforts using PREMs and found that most practices attempted small, incremental changes to services that did not require a change in provider behavior and resulted in unclear impacts. They called for more attention to how PREM data can be used to inform practice changes that have a positive influence on the patient care experience. Translating new ideas into practice among early-career providers requires three considerations—credibility, practicality, and need [47]. Efforts to incorporate QI into routine practice will likely require attention to messaging and creating digital solutions to address these issues. In addition, simply providing PGD, even if entered into the EMR, has the potential to increase provider burnout. A review of health record-integrated PCM found that technostress (technological complexity, uncertainty, overload, insecurity, and invasion [higher patient expectations]), time pressure, and workflow-related issues need to be addressed to accelerate the integration of PCM into clinical care [48]. Therefore, future endeavors will need to consider the human and fiscal resources needed for QI in clinical practice and the integration of PGD into the digital health ecosystem.

To create primary care team-based practices that value and use PCM to improve care, a culture change is needed. This process, in the experience of one of the authors (MS) in teaching evidence-based medicine and research training, takes 3 to 5 years, with time for training and practice through targeted, small-scale projects. For example, the introduction of QI training of multidisciplinary teams in local health departments in North Carolina resulted in small but important changes in organizations' cultures over 5 years, increasing engagement in future QI, and improving overall care and services [49]. Mandating QI may be problematic, with a before-and-after study of Foundation Year 1 doctors in the United Kingdom reporting less motivation to complete QI projects and placing less importance on QI for their professional development despite a significant increase in overall QI knowledge at the end of the year [50]. It remains to be seen if the BC support system approach to practice facilitation for QI is successful in this effort.

However, patients found the process of completing and tracking the results of mental health-related questionnaires on portal validation useful in capturing relevant aspects of their experiences, a unique feature of this study. The importance of portals as a communication tool and limited use of PGD was noted in an umbrella review [51], and lack of bidirectional communication was likely an additional barrier to PCM used in this study. Patients commented on how PROMs could provide a way to focus visits on what is of the greatest value for them

at the moment. PCM may be particularly relevant for patients with illnesses for which there are no biomedical markers. For people living with mental health concerns, these measures can aid in communication when the illness makes it difficult to communicate the severity of their difficulties. Although evidence supports the use of patient medical home care models that include data-driven quality of care and patient engagement [2], what seems to be missing is the value placed on PCM by providers and an understanding and appreciation of ways in which the use of these data can advance communication, care quality and QI. To achieve the patient-centered potential of PCM requires a conceptual shift in workflows, where patients and providers are encouraged to bring PGD, particularly around function, into care discussions.

Study Limitations

As this was an exploratory study within a single clinic, the transferability of the findings to another context needs to be explored further. The study was carried out in a rural, early adopter patient medical home practice with a small care team and few patient participants, which may not be representative of other primary care models, larger clinics, or urban settings. As the study focused on mental health, the relevance of our findings to other health conditions is limited.

The researchers supported transferability by providing a detailed description of the context and location, and trustworthiness by being transparent about our methods for data collection and analysis. The study was conducted during the pandemic, which made recruitment of care teams and patients particularly challenging. We strove to address the limited sample size by adding richness to our data through multiple study methods and

an iterative process of knowledge sharing between researchers, including patient partners and knowledge users. Being a transdisciplinary team of patient partners, providers, and researchers across multiple disciplines enabled us to bring in multiple perspectives during the analysis.

Limitations were introduced during the data collection and analysis. The persona image was selected to reflect how Dan may be dressed in an examination room. Upon reflection, we realize that Dan's appearance would be quite different during a virtual visit and would have selected a persona image that does not reinforce power differentials or stereotyping [52]. Although we did not record interviews, we used 2 interviewers at each session, and summative interview reports were iteratively compared with all PCM study data by the research team. Memos in the summary notes were used to record when the interviewers had different interpretations. Each researcher established their process for reflection, and we did not have a standard way to record and review individual reflections.

Conclusions

The value of PGD and the need for PCM methods to collect, integrate, and use PGD in team-based care remain challenging. Through collaborative and adaptive efforts, this gap was narrowed by demonstrating ways in which PGD can be incorporated into clinical practice within a Canadian team-based primary care setting. The conceptualization of PCM methods to accomplish this goal is well served by an IKT approach. IKT offers a beneficial technique for addressing our knowledge of users' needs related to the collection, integration, and use of PGD, bridging the knowledge to action gap and setting the stage for future success.

Authors' Contributions

FL proposed the research and drafted the initial grant proposal. All authors have contributed to the revised and final grant proposal. SD led the engagement with the provider participants. MA led the engagement with patient participants and industry and academic partners. PB, MS, and SD tested and selected material for the portal, and MA integrated education materials and measures into the portal. SD and MA collected interview data. MA and MS performed the analysis of interview data and theme development with input from SD, FL, and PB. SD created Figure 1 and Figures 3-6. SD and MS created the tables. SD and MS drafted the manuscript. All authors critically revised and approved the submitted manuscript and agreed to be accountable for ensuring its integrity.

Conflicts of Interest

A research team member was an industry partner (Cambian Business Services Inc) for this study, who provided data storage and inclusion of the survey tools and educational resources into the patient portal. The system was provided at no cost to the clinic for the duration of the study.

Abstract

Background: Social media platforms, such as Facebook and Instagram, are increasingly being used to share health-related information by "influencers," regular users, and institutions alike. While patients may benefit in various ways from these interactions, little is known about the types of endometriosis-related information published on social media. As digital opinion leaders influence the perceptions of their followers, physicians need to be aware about ideas and beliefs that are available online, in order to address possible misconceptions and provide optimal patient care.

Objective: The aim of this study was to identify and analyze frequent endometriosis-related discussion topics on social media in order to offer caregivers insight into commonly discussed subject matter and aspects.

Methods: We performed a systematic search using predefined parameters. Using the term "endometriosis" in Facebook's search function and a social media search engine, a list of Facebook pages was generated. A list of Instagram accounts was generated using the terms "endometriosis" and "endo" in Instagram's search function. Pages and accounts in English with 5000 or more followers or likes were included. Nonpublic, unrelated, or inactive pages and accounts were excluded. For each account, the most recent 10 posts were identified and categorized by two independent examiners using qualitative content analysis. User engagement was calculated using the numbers of interactions (ie, shares, likes, and comments) for each post, stratified by the number of followers.

Results: A total of 39 Facebook pages and 43 Instagram accounts with approximately 1.4 million followers were identified. Hospitals and medical centers made up 15% (6/39) of the Facebook pages and 5% (2/43) of the Instagram accounts. Top accounts had up to 111,600 (Facebook) and 41,400 (Instagram) followers. A total of 820 posts were analyzed. On Facebook, most posts were categorized as "awareness" (101/390, 25.9% of posts), "education and research" (71/390, 18.2%), and "promotion" (64/390, 16.4%). On Instagram, the top categories were "inspiration and support" (120/430, 27.9% of posts), "awareness" (72/430, 16.7%), and "personal story" (72/430, 16.7%). The frequency of most categories differed significantly between platforms. User engagement was higher on Instagram than on Facebook (3.20% vs 0.97% of followers per post). On Instagram, the highest percentage of users engaged with posts categorized as "humor" (mean 4.19%, SD 4.53%), "personal story" (mean 3.02%, SD 4.95%), and "inspiration and support" (mean 2.83%, SD 3.08%). On Facebook, posts in the categories "awareness" (mean 2.05%, SD 15.56%), "humor" (mean 0.91%, SD 1.07%), and "inspiration and support" (mean 0.56%, SD 1.37%) induced the most user engagement. Posts made by hospitals and medical centers generated higher user engagement than posts by regular accounts on Facebook (mean 1.44%, SD 1.11% vs mean 0.88%, SD 2.71% of followers per post) and Instagram (mean 3.33%, SD 1.21% vs mean 3.19%, SD 2.52% of followers per post).

Conclusions: Facebook and Instagram are widely used to share endometriosis-related information among a large number of users. Most posts offer inspiration or support, spread awareness about the disease, or cover personal issues. Followers mostly engage with posts with a humoristic, supportive, and awareness-generating nature. Health care providers should be aware about the topics discussed online, as this may lead to an increased understanding of the needs and demands of digitally proficient patients with endometriosis.

Introduction

Endometriosis, defined as the occurrence of endometrium-like tissue outside the uterus, is a chronic, incurable disease affecting about 10% of women [1]. Main symptoms include dysmenorrhea, dyspareunia, chronic pelvic pain, and subfertility. Although it may lead to severe and sustained restrictions in women's private, social, and professional lives, both men and women have little knowledge about the condition [2], and even general practitioners' expertise about the disease is scarce [3]. This dilemma is further aggravated by the high prevalence of dysmenorrhea in adolescents, leading to a trivialization of pelvic pain. These factors mutually reinforce delayed diagnosis, withheld care, and lack of awareness. As women are dissatisfied with the public and medical aid they receive [4,5], it is understandable that they turn to other forms of support.

The internet has become the primary source for health information for people all over the world [6]. In addition to static websites, social media plays an increasing role as a channel for medical information [5]. Platforms such as Facebook and Instagram are used by the majority of US adults [7], and the number of health-focused social media accounts has been skyrocketing, with daily growth rates of up to 28% in 2020 [8]. Patients with endometriosis may benefit from this development in various ways. The process of informing oneself about health topics on social media platforms is private, yet personally tailored, allowing for sharing of personal anecdotes and interactions with others, if desired. Thereby, social and emotional support may be received [5,9]. Support in the form of disease management tips, experiences, and mental health support are valuable subjects among young adults with chronic disease as well as baby boomers and older adults [10,11].

On social media, content can be created by, and shared among, regular users, commercial companies, or nonprofit organizations alike. While any user can share personal or general health-related posts with their friends or with the public via their personal stream, other forms of information sharing have emerged in order to focus on specific topics. Two frequently observed variants are the creation of topic-specific Facebook pages and Instagram accounts. This allows for the promotion and distribution of topic-specific content and the dedicated recruitment of followers.

Regarding endometriosis, several hundred disease-related Facebook pages have been created so far [6]. Recently, "influencers" have increasingly gained importance on most social media channels, blurring the line between user-generated and advertorial content. It has been shown that these digital opinion leaders are able to change the attitudes of their followers, increase acceptance of the information provided, and even influence the intention to buy corresponding products [12].

Even though there is an abundance of endometriosis-related information online, filtering and assessing the quality of information can be challenging, as people make little use of source credibility [13]. Available information on endometriosis is often of low quality, inaccurate, or skewed toward the diagnosis or it conveys negative connotations, while high-quality information is challenging for a lay audience to comprehend [14,15]. These circumstances can induce feelings of fear and helplessness [16].

Nevertheless, internet health information seeking has become increasingly popular, and a growing number of patients with endometriosis can be expected to have acquired considerable knowledge on their condition before a consultation. While this may be challenging at first, it can improve the patient-physician relationship when the patient is able to discuss the information with the physician [17]. Naturally, this requires health care professionals to have an overview of the topics at hand.

While several studies have performed social media content analysis for different gynecological conditions on Instagram and Facebook [18-21], only few focused on endometriosis [5,22,23], and information about popular topics is scarce. Due to this paucity of data, it is unclear which topics prevail on both Instagram and Facebook and whether user engagement differs between platforms.

In this paper, we analyzed the nature of posts shared on endometriosis-related public Facebook pages and Instagram accounts and compared them between platforms, granting an additional tool to improve counseling, address possible misconceptions, and fulfill the patient's expectations to be more engaged in health-related decision-making.

Methods

Design

We performed a cross-sectional analysis of public, endometriosis-related social media posts on Facebook and Instagram between August 3 and 5, 2020. The timing was selected with sufficient time distance from known events such as Endometriosis Awareness Month in March, which could have acted as a confounder. Facebook and Instagram were chosen as data sources for their high popularity [7]. The search was restricted to results in English and those publicly accessible to all Facebook and Instagram users.

Data Selection

In order to identify relevant Facebook pages, we performed a search using the term "endometriosis" in Facebook's search function on August 3, 2020. We deliberately included only Facebook pages, as Facebook groups are often private and require approval by a moderator to gain access.

Additionally, we performed a search on BuzzSumo, a website offering tools and search utilities for content discovery, content research, and identification of influencers across different social media platforms. In contrast to regular popularity ranking by

likes, this website has the capability of ranking relevant Facebook pages by additional metrics such as "engagement," an integrative score including reactions, comments, shares, and likes [24]. Results were structured by relevance and by likes in order to maximize the results.

Of all search results, the *information section* was screened together with the last 10 public posts to assess the scope and aim of each page. Pages were considered relevant when they covered endometriosis as their main topic. When endometriosis was not the main topic (eg, pages focusing on general health or nutrition), a minimum of 10 endometriosis-related posts within the last 2 years were considered necessary to qualify. Relevant pages in English with 5000 or more likes were included for further analysis. This cutoff was defined in order to limit analysis to content with a considerable reach and influence. Pages (ie, accounts) that did not meet the inclusion criteria (ie, endometriosis not the main topic, <10 endometriosis-related posts within 48 months, or <5000 followers) were excluded.

On Instagram, we searched for relevant accounts using the search terms "endometriosis" and "endo." The search was conducted on August 5, 2020. Follower lists of relevant accounts were also screened in order to maximize search results. Account names and number of followers were extracted into a Microsoft Excel spreadsheet and sorted by number of followers. All relevant accounts in English with 5000 or more followers were included.

Of all eligible Facebook pages and Instagram accounts, the 10 most recent wall posts in Facebook or the 10 most recent posts in Instagram were analyzed further.

Content Analysis, Codebook, and Categories

A systematic qualitative content analysis approach was used, as this is a standard process in interactive media content analysis [25,26]. A codebook was developed in order to systematically analyze the content of all relevant posts and to file them into predefined groups. The codebook contained 10 categories or groups together with a short explanation about each category's applicability. For example, the "inspiration and support" category was defined as "all posts containing tips, support (mental, moral, etc), and inspirational texts, quotes, and memes." The 10 content categories were defined as follows: "education and research," "awareness and outreach," "nutrition, food, and diet," "sport and lifestyle," "inspiration and support," "personal story," "patient requests," "scientific inquiries," "humor," and "promotion of product or service." An 11th category (ie, "other") was available if none of these 10 categories seemed suitable. The categories were selected based on a previously published study on social media usage [19]; they were adjusted in order to fit the formulated research questions and to be more aligned with the investigated social media services, since the cited study was performed on Twitter and not Facebook or Instagram. Therefore, the categories "nutrition, food, and diet," "patient requests," "scientific inquiries," and "sport and lifestyle" were introduced to test their occurrence in the data sample, while the categories "celebrity story," "political," and "news" were omitted.

Of all included Facebook pages and Instagram accounts, the 10 most recent endometriosis-related wall posts on Facebook or the 10 most recent posts on Instagram, as of August 5, 2020, were analyzed according to the codebook. Each post was coded as a single topic by two independent coders. Coders received an introduction to the codebook and a training set of 10 posts. If results differed between coders, the content was examined by a third person, and each case was discussed until agreement could be reached. Facebook pages and Instagram accounts were classified as health care professionals or medical centers if (1) their bio or page information section declared this classification or (2) if the content of their posts made this classification explicit. This categorization was conducted by a single reviewer (Reviewer A).

Calculations and Metrics: User Engagement

To measure the impact of posts and the amount of interactions the content earned relative to reach, different metrics were calculated [27]. Total engagement was defined as the sum of all user interactions with a post. Likes, comments, and shares (Facebook only) were added together with equal weighting, as follows:

Total engagement per post = likes $\times$ 1 + comments $\times$ 1 + shares $\times$ 1

As an example, a post with 100 likes, 20 comments, and 10 shares would result in a total engagement of 130. Next, the percentage of account followers engaging with that post was obtained by calculating the engagement rate by reach (ERR) using the following formula:

ERR = total engagement per post / total followers $\times$ 100

Additionally, we calculated the percentage of followers liking, commenting, or sharing a post.

Statistical Analysis: Interobserver Reliability

Statistical analyses were performed with SPSS Statistics for Windows (version 27; IBM Corp). Data were presented as numbers and percentages. For categorical data, chi-square tests and analyses of variance were used. A *P* value below .05 was considered statistically significant.

Chance-adjusted measurement of interobserver reliability was calculated using the Randolph free-marginal multi-rater κ [28], with κ values less than 0.40 considered as "poor," values from 0.40 to 0.75 considered as "intermediate to good," and values above 0.75 considered as "excellent."

Ethical Considerations

According to Swiss law, this is not a research project under the Swiss Human Research Act (Humanforschungsgesetz) and, therefore, no authorization is required.

Results

Pages, Accounts, and Posts

A total of 39 Facebook pages and 43 Instagram accounts were identified, with approximately 1.4 million followers. Top accounts had up to 111,600 (Facebook) and 41,400 (Instagram)

followers, with a median follower number for Facebook and Instagram of 11,800 (IQR 7450-19,750) and 10,200 (IQR 7420-16,900), respectively. Hospitals and medical centers made up 15% (6/39) of the Facebook pages and 5% (2/43) of the Instagram accounts. A total of 820 posts were included for categorization: 390 (47.6%) Facebook posts and 430 (52.4%) Instagram posts. Interrater agreement was 62.8% (245/390) for Facebook, with a free-marginal κ of 0.59 (95% CI 0.54-0.64), showing substantial agreement. For Instagram posts, the interrater agreement was 57.9% (249/430), with a κ of 0.54 (95% CI 0.49-0.59).

Top Categories by Frequency

All pages (ie, accounts) covered more than one topic (ie, published posts in several categories). There was a significant difference in topics between platforms, as shown by categorization frequency. On Facebook, most posts were categorized as "awareness" (101/390, 25.9% of posts),

"education and research" (71/390, 18.2%), and "promotion of product and service" (64/390, 16.4%), with only a few posts addressing "sport and lifestyle" (6/390, 1.5%). As a benchmark, only 1.8% (7/390) of posts were categorized as "other."

On Instagram, the top categories were "inspiration and support" (120/430, 27.9% of posts), "awareness" (72/430, 16.7%), and "personal story" (72/430, 16.7%). Only 0.2% (1/430) of posts were patients asking specific health questions (ie, "patient requests") or calls for scientific study participation (ie, "scientific inquiries"). A total of 6.7% (29/430) of posts were categorized as "other."

Out of 11 categories, 9 (82%) differed significantly in the frequency of their occurrence on Facebook and Instagram, suggesting that different topics were posted depending on the platform. Posts concerning "nutrition, food, and diet" and "sport and lifestyle" were published on both platforms without a significant difference (Table 1).

Table 1. Frequencies of post categories on Instagram as compared to Facebook.

[a]ERR: engagement rate by reach; ERR = total engagement per post / total followers × 100.

[b]The percentage of followers liking a post from a given category.

[c]The percentage of followers commenting on a post from a given category.

[d]The percentage of followers sharing a post from a given category.

[e]ERR values in this row are mean values of the 11 rows above.

[f]N/A: not applicable; P values in this column compare the category frequency between Facebook and Instagram; since the final row includes frequencies of 100% for both platforms, a P value was not calculated.

When combining both platforms, the top three categories were "inspiration and support" (174/820, 21.2% of all analyzed posts), "awareness" (173/820, 21.1%), and "personal story" (118/820, 14.4%). Infrequent categories included "sport and lifestyle"

(13/820, 1.6%), "patient requests" (12/820, 1.5%), and "scientific requests" (9/820, 1.1%). Table 2 shows the combined frequency of all posts on Instagram and Facebook.

Table 2. Combined frequency of categories on Instagram and Facebook.

Category	Posts (N=820), n (%)
Inspiration and support	174 (21.2)
Awareness	173 (21.1)
Personal story	118 (14.4)
Promotion	113 (13.8)
Education and research	102 (12.4)
Humor	44 (5.4)
Other	36 (4.4)
Nutrition, food, and diet	26 (3.2)
Sport and lifestyle	13 (1.6)
Patient requests	12 (1.5)
Scientific inquiries	9 (1.1)

User Engagement

User engagement was assessed based on 430 Instagram posts from 43 accounts (563,500 total followers) and 390 Facebook posts from 39 pages (831,900 total followers).

On both platforms, posts were typically liked, shared, or commented on by less than 5% of the followers, with a higher percentage of users engaging on Instagram than on Facebook. Across all categories, followers were over 3 times as likely to share or like a post on Instagram as compared to Facebook. On average, 3.20% (SD 3.65%) of followers engaged with a post on Instagram (liking a post: mean 3.01%, SD 3.41%; commenting a post: mean 0.19%, SD 0.37%) as compared to 0.97% (SD 8.02%) on Facebook (liking a post: mean 0.53%, SD 3.18%; commenting a post: mean 0.12%, SD 1.23%; sharing a post: mean 0.31%, SD 3.65%). Posts made by hospitals and medical centers generated higher user engagement than posts by regular accounts on Facebook (mean 1.44%, SD 1.11% vs mean 0.88%, SD 2.71% of followers per post), and Instagram (mean 3.33%, SD 1.21% vs mean 3.19%, SD 2.52% of followers per post).

Top Categories by Engagement

Facebook

On Facebook, the top three categories by engagement were "awareness," "humor," and "inspiration and support." Posts in these categories induced 2.05% (SD 15.56%), 0.91% (SD 1.07%), and 0.56% (SD 1.37%) of users to engage with that post, in contrast to only 0.11% (SD 0.13%) of followers engaging with calls to participate in scientific studies (ie, "scientific inquiries"). Of note, certain categories, such as "humor" or "sport and lifestyle," accounted for a low number of posts, yet generated a lot of engagement (Table 1).

Next, we compared the number of Facebook posts in each category with the engagement rate of each category. A weak correlation was found between category frequency and ERR (R^2=39.2%), showing that posts that induced high engagement tended to be posted more often or vice versa. Posts addressing disease awareness not only made up for 25.9% (101/390) of posts but also generated over 3.8 times more engagement than the average posts, performing at 382% of the expected engagement rate. Table 3 shows the engagement-inducing performance of posts for all categories on Facebook.

Table 3. Performance of Facebook posts by category.

Category	Proportion of mean performance (engagement), %[a]
Overperforming posts	
Awareness	382
Humor	169
Inspiration and support	104
Underperforming posts	
Sport and lifestyle	81
Personal story	75
Education and research	73
Promotion	61
Nutrition, food, and diet	46
Patient requests	46
Other	43
Scientific inquiries	20

[a]100% represents the expected mean engagement across all categories.

Instagram

On Instagram, the top categories were "humor," "personal story," and "inspiration and support," inducing mean user engagement of 4.19% (SD 4.53%), 3.02% (SD 4.95%), and 2.83% (SD 3.08%) of followers, respectively. Interestingly, "sport and lifestyle" scored last, with a mean user engagement of 0.46% (SD 0.64%) of followers (Table 1). Of note, the mean user engagement across all categories (0.54%, SD 0.52% on Facebook; 2.26%, SD 0.99% on Instagram) differed from the ERR described in the User Engagement section, as the latter was weighted for post frequency. As noted before, categories generating higher engagement tended to be posted more frequently or vice versa, leading to a higher ERR in pages and accounts that pursued this strategy. For Instagram, this correlation was weaker than for Facebook (R^2=14% vs 39%). For example, even though humorous posts induced the most engagement on Instagram, they only accounted for 8.4% (36/430) of all posts. Table 4 shows the engagement-inducing performance of posts for all categories on Instagram.

Table 4. Performance of Instagram posts by category.

Category	Proportion of mean performance (engagement), %[a]
Overperforming posts	
Humor	185
Personal story	134
Inspiration and support	125
Awareness	121

Education and research	104
Underperforming posts	
Scientific inquiries	96
Patient requests	94
Nutrition, food, and diet	75
Promotion	33
Sport and lifestyle	20

[a]100% represents the expected mean engagement across all categories.

Discussion

Principal Findings

In this paper, we were able to quantify Facebook's and Instagram's popularity with regard to endometriosis. Over 80 pages and accounts with approximately 1.4 million followers were included. By analyzing 820 posts, we were able to specify the diversity of endometriosis-related content that was shared and discussed among Instagram and Facebook users.

Facebook's top three categories—"awareness," "education and research," and "promotion"—may be explained by the intended use of the Facebook pages. Similar to a personal profile, a page enables organizations and other entities to create a public presence, which is visible to everyone on the internet [29]; this makes it a viable tool to generate topic-specific awareness, broadcast educational content, and promote products or services.

Our results are mostly in line with what was recently reported by Towne et al [5]. Even though a direct comparison is limited due to partly different categories, we classified a similar percentage of Facebook posts as "research and education" (18.2%) in our study compared to "education" in Towne et al (21%), and we found a low percentage of posts in the categories "nutrition, food, and diet" (3.6%) in our study compared to "recipe" in Towne et al (0.83%), "humor" in our study (2.1%) compared to "humor" in Towne et al (4.70%), "scientific inquiries" in our study (2.1%) compared to "survey" in Towne et al (0.34%), and "other" in our study (1.8%) compared to "other" in Towne et al (1.10%).

Similarly, Wilson et al [23] found a high percentage of posts on their endometriosis-related Facebook page to have informational content.

As described, certain categories were found to be less common than others; for example, only a few posts contained disease-specific questions from users posed to their followers ("patient requests": Facebook 2.8% of posts; Instagram 0.2% of posts). A possible explanation is that such intimate questions tended to be asked in closed groups and forums or via direct messages rather than publicly. Furthermore, some categories may be underrepresented because of the topics being discussed on different pages: an account's main topic may differ depending on the number of followers. For every account with over 5000 followers, there were numerous accounts with 50 to 500 followers, highlighting that information is spread not only from the top down, but also between smaller groups of peers. Without being fully investigated in this study, these smaller Facebook pages often tended to focus on the personal history or story of a single patient. This may explain a relative underrepresentation of the category "personal story" in the study results.

This is the first study showing that content creators share different topics depending on the platform, as popularity and frequency of topics vary between Facebook and Instagram. While most posts on Facebook were creating educational or promotional awareness, on Instagram, the topics were found to be somewhat more "intimate," with a focus on inspiration and support, awareness, and personal stories. This interpretation may be valid for different reproductive topics as well. When

analyzing fertility-related accounts on Instagram, Blakemore et al [19] found a high percentage of posts containing inspiration and support (24% vs 27.9% in our work) as well as personal stories (32% vs 17.0%), while the topic of education and research appeared less frequently on Instagram posts (11% vs 7.2%). Of note, content may vary due to time or certain events; Gochi et al [22] found significant changes in topics during Endometriosis Awareness Month in March when compared to February in 2020.

Regarding engagement, our results showed that post category had a substantial effect on post engagement, a correlation that had been previously observed [5]. Furthermore, we were able to display major differences in engagement between Instagram and Facebook. It is commonly known that engagement rates vary between social media platforms; content marketing providers assume "good" engagement rates in the range of 1% to 2% for Facebook, and 2% to 3% on Instagram [30].

As expected, we noticed higher user engagement on Instagram than on Facebook throughout all categories. When compared with the benchmarks described above, humoristic posts had exceptional engagement rates of more than 4% on Instagram, while many categories performed in the expected range of 2% to 3% (ie, "personal story," "inspiration and support," "awareness," "other," "education and research," "scientific inquiries," and "patient requests"). Instagram's superiority in this regard has been explained as being caused by its format, as users only see one post per screen, urging them to either engage or scroll past [30]. Different mechanisms apply for Facebook. Due to the fact that posts originating from pages are broadcast to a targeted minority of followers, who are more likely to engage, it has been described that Facebook has reduced the reach of such posts over the last years [30], possibly resulting in reduced engagement. Typically, humoristic or controversial content generates strong engagement, and other authors reported strong engagement with posts about oral contraceptives, intrauterine devices, or cancer [6].

Even though medical professionals only accounted for 15% of the Facebook pages and 5% of the Instagram accounts investigated, some of these physicians were able to connect and communicate with the community, rather than acting as passive bystanders [31]. As shown in our study, posts from health care professionals were able to generate high user engagement on Facebook. Although associated with a significant investment of mostly unpaid time as well as exposure, this additional information shared by medical professionals may lead to a more balanced and evidence-based presence of information.

Strengths

Several strengths of our study are noteworthy. Besides YouTube, which is mainly video based and was, therefore, not investigated, Facebook and Instagram are the two largest social media sites in the world, with around 50% of users being female. The approach of searching within Facebook's and Instagram's own search functions resembles a realistic user scenario when searching for endometriosis-related content on social media. In addition, a large number of posts that were shared with over 1 million followers were examined. By using a codebook, a profound and established method of categorizing posts was

applied, and the employment of two examiners, together with an arbitrator in case of disagreement, provided for additional objectivity. Lastly, analyzing data from two social media platforms with a partially overlapping user base allowed for identification of content-related differences between both services.

Limitations

Social media platforms are dynamic and ever-changing, limiting any attempt of mapping or categorizing their content. In this context, this study must be seen as a snapshot that provides insight but cannot adequately reflect the dynamic changes. Although we included two of the largest social media services, several other well-known social media sites, such as Twitter, LinkedIn, Snapchat, Pinterest, Reddit, and TikTok, have not been investigated. Therefore, no statement can be made about the distribution of topics on these services or on social media as a whole.

Facebook's and Instagram's proprietary search algorithms are noteworthy and have limited capabilities for end users. By presenting different search results depending on the user and location, certain pages (ie, accounts) that met the inclusion criteria may have been missed. On Instagram, sorting the results by the number of followers was not possible; this was addressed by screening the follower lists for further accounts with large follower numbers. On Facebook, sorting pages by the number of likes was possible at the time of data collection, a feature

that has since been disabled. This allowed for identification of the largest Facebook pages down to 5000 followers.

Regarding participation bias, it is arguable that only a certain subgroup of patients with endometriosis, or people interested in endometriosis in general, were actively sharing, discussing, and following endometriosis-related content. Assuming this is the case, this study was a content analysis study that used a subset of available posts on two social media platforms on a given date; therefore, participation or nonresponse bias may influence any study's findings in the first place, but it does not affect the veracity of this study's results.

Conclusions

Instagram and Facebook are being used intensively to share endometriosis-related information with a large number of users. The most common topics varied between platforms. Most posts offered inspiration or support, spread awareness about the disease, or covered personal issues. User engagement was higher on Instagram than on Facebook. Followers mostly engaged with posts with humoristic, awareness-generating, or personal content. Health care providers should be aware of the topics discussed online, as this may lead to an increased understanding of the needs and demands of digitally proficient patients with endometriosis. Future research should focus on topics that are trending as well as the scientific accuracy of social media content, possibly highlighting underlying drivers and interests of endometriosis-related content creators.

Authors' Contributions

JMM was responsible for conceptualization, methodology, investigation, preparation of the original draft of the manuscript, data visualization, and project administration. JMM, DRK, and LB were responsible for the formal analysis and data curation. All authors were responsible for reviewing and editing the manuscript. DRK was responsible for data validation. Abstract

Background: Mobile health strategies for smoking cessation (eg, SMS text messaging–based interventions) have been shown to be effective in helping smokers quit. However, further research is needed to better understand user experiences with these platforms.

Objective: This qualitative study aims to explore the experiences of real-world users of a publicly available smoking cessation program (SmokefreeTXT).

Methods: Semistructured phone interviews were conducted with 36 SmokefreeTXT users between March and July 2014. Of these 36 participants, 50% (18/36) of participants completed the SmokefreeTXT program (ie, did not opt out of the program before the 6- to 8-week completion period), and 50% (18/36) did not complete the program (ie, requested to opt out of the program before the completion period). Interview questions focused on smoking behaviors, quitting history, opinions on the program's content and structure, answering assessment questions, using keywords, reasons for opting out, and perceived usefulness of the program for quitting smoking. A thematic content analysis was conducted, with a focus on themes to increase program engagement and optimization.

Results: The findings highlighted features of the program that participants found beneficial, as well as some elements that showed opportunities for improvement to boost program retention and successful cessation. Specifically, most participants found the SmokefreeTXT program to be convenient and supportive of cessation; however, some found the messages to be repetitive and reported a desire for more flexibility based on their readiness to quit and cessation progress. We also found that program completion did not necessarily indicate successful smoking cessation and that program opt out, which might be interpreted as a less positive outcome, may occur because of successful cessation. Finally, several participants reported using SmokefreeTXT together with other evidence-based cessation methods or non–evidence-based strategies.

Conclusions: Qualitative interviews with real-world SmokefreeTXT users showed high program acceptability, engagement with program features, and perceived utility for smoking cessation. Our findings directly informed several program updates, such as adding an adaptive quit date feature and offering supplemental information on live support services for users who prefer human interaction during the cessation process. The study has implications for other digital tobacco cessation interventions and highlights important topics that warrant future research, such as the relationship between program engagement (eg, opt out and retention) and successful cessation.

Introduction

Background

Although cigarette smoking rates have declined over time, smoking remains the leading preventable cause of death in the United States [1]. In 2019, the prevalence of cigarette smoking among US adults was 13.7% [2]. Although evidence-based approaches, such as smoking cessation counseling and pharmacological cessation aids, can support cessation, they are underused [3,4]. Mobile health (mHealth) smoking cessation platforms (eg, mobile phones, smartphones, and tablets) can be beneficial to the cessation process, as they can reduce barriers (eg, time commitment and access limitations) associated with traditional modalities and have been found to facilitate smoking abstinence [5-9]. mHealth interventions also provide anonymity and real-time support, reaching users from the convenience of their mobile devices at any place or time of day. A type of mHealth intervention with demonstrated efficacy for smoking cessation is an SMS text messaging–based cessation program [5,10,11]. Given the popularity of these programs, pervasive ownership and use of mobile phones in the United States (97% of US adults report owning a mobile phone) [12], and opportunities to reach underserved populations with mHealth smoking cessation programs, it is important to continually optimize these programs.

Despite the demonstrated efficacy of SMS text message–based smoking cessation programs in quantitative evaluations, qualitative studies of user experiences with SMS text message cessation programs are scarce [13-15]. The few qualitative studies that exist on this topic have found high levels of acceptability toward SMS text message–based cessation programs, and participants have reported that they appreciate the convenience and emotional support that these programs offer. However, these studies have primarily been conducted as part of existing cessation trials or with specific populations such as women with pregnancies [13-16]. Moreover, prior studies have been conducted with participants who remained in the cessation SMS text messaging program under study for the entirety of the program, and the experiences of users who opted out of the program before completion were not investigated [13-15].

To address these gaps, we explore the experiences of real-world users of a publicly available smoking cessation program (SmokefreeTXT). Specifically, we conducted qualitative interviews with real-world users (ie, who were not part of an existing research study) of the National Cancer Institute's (NCI) publicly available SmokefreeTXT program to understand perceptions about program structure and content, engagement with specific program features, and perceived utility of the program for smoking cessation. We also investigate potential differences in program experience between users who completed the SmokefreeTXT program and those who opted out of the program before completion.

SmokefreeTXT Program

SmokefreeTXT is a free, publicly available, fully automated SMS text message–based smoking cessation program introduced in 2011 by the NCI [8]. The program was developed by a team of mobile technology specialists and clinical psychologists with expertise in tobacco cessation. In 2020, a total of 32,633 new users were enrolled in the SmokefreeTXT program designed for general adult smokers [7].

SmokefreeTXT comprises 6 to 8 weeks of SMS text messages that provide cessation motivation, tips on preparing to quit, advice on managing cravings, quit smoking facts, and recognition of cessation milestones. SmokefreeTXT also refers program users to Smokefree web resources for more detailed smoking cessation information, as well as to the National Network of Tobacco Cessation Quitlines and the NCI Cancer Information Service. Individuals can enroll in SmokefreeTXT through the Smokefree website or by texting a keyword to a short code (QUIT to 47848). At the time of enrollment, users are prompted to set a quit date within 2 weeks of enrollment. Depending on when users set their quit date, they can receive up to 2 weeks of preparation messages leading up to that date. Starting on the quit date, the 6-week intervention comprises 1 to 5 SMS text messages each day, including behavioral intervention and social support messages that target smoking cessation goals [7]. Messages also contain links to relevant pages on the Smokefree website and promote social support through Smokefree social media pages (eg, Facebook).

Throughout the program, users receive messages that assess their smoking status (eg, "Did you smoke today? Reply YES or NO"), craving level (eg, "What's your craving level? Reply with: HI, MED, or LOW"), and mood status (eg, "How is your mood? Reply GOOD, OK, or BAD"). Users can receive additional messages on demand by texting specific keywords that signify their needs (eg, *MOOD* if they are experiencing a negative mood, *CRAVE* if they have a craving, or *SLIP* if they have smoked a cigarette). Users may also opt out of the program at any time by texting the word *STOP* or reset their quit date at any time by texting the word *NEW* [7]. Completion of the program was defined as not opting out of the program before the conclusion of the 6- to 8-week intervention. See Multimedia Appendix 1 for examples of the program messages.

Methods

Recruitment and Participants

Between January and June 2014, all users who completed the SmokefreeTXT program or requested to opt out of the SmokefreeTXT program before program completion were eligible for the study. Program completers (defined as users enrolled in SmokefreeTXT for the duration of the 6- to 8-week program—depending on when they set their quit date—and not opting out before program completion) and noncompleters (defined as users who texted the word *STOP* to opt out of SmokefreeTXT before program completion) were sent an SMS text message inviting them to participate in a phone interview about the program. Interested participants were asked to complete a web-based screener that inquired about their age, race or ethnicity, sex, education, and location (state). Of the 285 individuals who completed the screener, 84.2% (240/285) were eligible to participate in the study (45/285, 15.8% were ineligible because of being aged <18 years or not including contact information on the screener). Eligible respondents were

contacted to schedule interviews. We purposively sampled an equal number of men and women as there are documented gender differences in smoking cessation [17]. We also purposefully sampled an equal number of completers and noncompleters, as prior studies of SmokefreeTXT showed differences in experiences with the program based on completion status [8,18]. The first 36 participants who met the recruitment goals (ie, half were men and half were women; half were program completers and half program were noncompleters) and were available to participate in the study were selected. The sample size was determined a priori because of timeline and funding logistics, widely cited literature on qualitative sample size [19-21], and project goals of maximizing variety and depth of the findings within each subgroup while also ensuring that the number of participants included met our purposive sampling criteria (equal numbers by gender and completion status).

Interviews were conducted by 2 experienced research associates with training in behavioral science and extensive experience conducting qualitative research. One of the researchers (Sondra Dietz) held a master's in public health, and the other (Bethany Tennant) held a doctorate in health education and behavior. Before the interview, participants were informed that the objective of the interview was to gather their feedback on SmokefreeTXT and that interviewers worked for ICF International Inc, a management consulting firm supporting the NCI. The interview questions focused on smoking behaviors, quitting history, opinions on the program's content and structure, answering assessment questions, using keywords (eg, texting CRAVE to receive additional messages related to smoking cravings), reasons for opting out, and perceived usefulness of the program for quitting smoking. The interview guide was reviewed by subject matter experts in mHealth interventions and smoking cessation but was not pilot-tested with adults who smoked. See Multimedia Appendix 2 for the interview guide. Most interviews lasted 30 to 40 minutes, and all transcripts were recorded and transcribed. Only the participants and members of the research team (ie, an interviewer and a notetaker [Sondra Dietz and Bethany Tennant]) were present on the calls. The interviewers read a consent script by phone and obtained verbal consent before the interview. Participants were compensated for their participation with a US $25 electronic gift card. After the compensation, participants were not contacted again (eg, to review transcripts or study findings).

Ethical Considerations

The study was approved by ICF's institutional review board (IRB), which holds Federalwide Assurance (FWA 00002349) from the HHS Office for Human Research Protections.

Data Analysis

The transcripts were analyzed using thematic analysis, an approach in which themes are extracted from qualitative data by identifying salient portions of the transcripts, codes are applied to salient text portions, and codes are extrapolated into larger themes according to their relationship with the study topics of interest [22]. This process mainly relied on deductive coding [23], which was informed by themes that could potentially guide program optimization, such as feedback on program structure and content, but also allowed flexibility for

additional codes that emerged. The data analysis was conducted by 3 ICF staff members and 1 NCI staff member, all of whom were trained in either health behavior, public health, or both, and were experienced qualitative researchers. To develop the initial codes, 4 transcripts were repeatedly reviewed, notated with analytic memos throughout the coding process, and analyzed to devise a list of codes. The coders then met to discuss the codes and any discrepancies to reach a consensus, after which point, a preliminary codebook was formed [24]. Next, 2 transcripts were coded using the preliminary codebook. The codebook was further refined based on discussions between the coders to clarify definitions and remove duplicative codes. Using the final codebook, all 36 transcripts were coded in NVivo (QSR International). This process was iterative, and if new codes emerged during the full analysis, the coders convened to discuss the code, gain consensus, and update the codebook and previously coded transcripts accordingly. After all transcripts were coded, groups of codes were categorized and interpreted as larger themes [23]. Themes were further refined through a rereview of the transcripts using negative case analysis, wherein the coders discussed findings from *outlier* participants whose reports conflicted with most of the sample [25]. For example, most participants reported opting out of the SmokefreeTXT program as they began smoking again or successfully quit smoking; however, a small number of participants reported opting out for other reasons (eg, technology issues), causing the initial hypothesis that opt out was driven only by smoking status to be reconsidered. Although coders looked for differences in responses between men and women and completers and noncompleters, no substantive differences were found. Thus, results are reported for all participants combined, except for the results from questions only asked to noncompleters.

Results

Overview

A total of 36 adults, of whom 18 (50%) had completed the program (*completers*) and 18 (50%) had not (*noncompleters*), participated in semistructured, in-depth, individual telephone interviews conducted between March 2014 and July 2014. Most participants had some college education or higher (24/36, 67%), were White (29/36, 81%), and were from the Southern or Northeastern United States (24/36, 67%). The participants' average age was 36 years (SD 13.5; range 18-60 years; Table 1).

At the time of the interview, participants were asked about their cigarette smoking status, and 53% (19/36) of participants reported that they were no longer smoking (13/18, 72% of completers and 6/18, 33% of noncompleters), whereas 47% (17/36) reported that they were current smokers (5/18, 28% completers, and 12/18, 67% noncompleters). Half of the noncompleters who reported smoking at the time of the interview (6/12, 50%) smoked a pack of cigarettes or more per day, whereas only one of the completers who reported smoking at the time of the interview smoked a pack or more per day. Some participants also reported the use of other tobacco products (eg, cigars, e-cigarettes, hookah, and smokeless tobacco) during the interviews. Approximately 31% (11/36) of participants

reported current use of other tobacco products at the time of the interview (3/18, 17% completers and 8/18, 44% noncompleters). See Table 1 for tobacco use behaviors in the sample.

Several primary themes emerged during the thematic analysis of participant interviews. Participants discussed their experiences with the SmokefreeTXT program and perceptions of message content, timing, and frequency. Participants also discussed their use of program engagement features, such as on-demand keywords (eg, *CRAVE*) and assessment questions (eg, *How is your mood today?*). Program noncompleters discussed the reasons for opting out of the program before program completion. Participants also discussed the role of SmokefreeTXT in their quitting process and reported the concurrent use of other cessation strategies with SmokefreeTXT.

Table 1. SmokefreeTXT user participants' demographics and tobacco use behaviors (N=36)[a].

Characteristics	Total sample	Completers (n=18)	Noncompleters (n=18)
Gender, n (%)			
Male	18 (50)	9 (50)	9 (50)
Female	18 (50)	9 (50)	9 (50)
Age (years), mean (SD; range)	35.9 (13.5; 18-60)	39.3 (12.4; 19-60)	32.5 (13.7; 18-55)
Race or ethnicity, n (%)			
White	29 (81)	14 (78)	15 (83)
Black	5 (14)	3 (17)	2 (11)
Hispanic	1 (3)	0 (0)	1 (6)
Asian	1 (3)	1 (6)	0 (0)
Education, n (%)			
Less than high school	1 (3)	0 (0)	1 (6)
High school or equivalent	11 (31)	4 (22)	7 (39)
Some college	12 (33)	8 (44)	4 (22)
Graduated college	10 (28)	4 (22)	6 (33)
Postcollege education	2 (6)	2 (11)	0 (0)
Geographic region, n (%)			
Northeast	10 (28)	7 (39)	5 (28)
South	14 (39)	7 (39)	5 (28)
Midwest	6 (17)	3 (17)	4 (22)
West	6 (17)	1 (6)	4 (22)
Smoking status at time of interview[b], n (%)			
Smoker	17 (47)	5 (28)	12 (67)
Ex-smoker[c]	19 (53)	13 (72)	6 (33)
Smoking heaviness at time of interview[d] (n=17), n (%)			
<1 (pack per day)	10 (59)	4 (80)	6 (50)
≥1 (pack per day)	7 (41)	1 (20)	6 (50)
Other tobacco use at time of interview, n (%)			
Other tobacco user	11 (31)	3 (17)	8 (44)
Not other tobacco user	25 (69)	15 (83)	10 (56)

[a]Owing to rounding, some percentages may not add up to 100%.

[b]Asked of each participant during the interview.

[c]Defined as participants who reported that they did not smoke cigarettes; may include people who reported using other tobacco products.

[d]Asked of each participant who reported smoking at the time of the interview (n=17).

Participant Experiences With SmokefreeTXT

Convenience of a Mobile-Based Medium

Participants responded positively to the mobile phone–based delivery of SmokefreeTXT, noting its convenience. Some reported that they appreciated the SMS text messaging format as they had already spent a great deal of time on their phones:

> I like the whole idea because I'm always on my phone and so, you know, consistent text messages were, you know, great reminders of the fact that I am quitting and that I want to quit and I need to quit. So, I liked it. [program completer, female, cigar smoker]

Others similarly noted they could quickly read a text, which was preferable to engaging with more time-consuming cessation resources:

> I like the text messages because it pops up during the day, and the job that I do, that works out better, because I check my text messages every so often. And I can't never answer the phone, and I don't have time to search the web. But I've got time to get a really quick text. [program noncompleter, female, smoker]

Accountability and Social Support

Several participants reported that they liked having the program *check up* on them, especially when messages aligned with cravings:

> ...It's just an excellent reminder for me, especially if I happen to be thinking about doing that [smoking]...all of a sudden...I get this text...it just was an excellent reminder. [program completer, male, smoker]

Approximately half of the participants said they felt that SmokefreeTXT was supportive, and one of the participants said it was "like my pocket buddy" (program completer, male, ex-smoker). Some reported that they felt especially supported by SmokefreeTXT as they lacked social support from family and friends or were hesitant to share their quit attempts with others, as they felt judged by previous failed quit attempts:

> ...None of my friends like here are like smokers, so I can't tell them like "oh my god, I'm craving a cigarette so bad right now"...I guess this might sound weird, but like I could text someone who like understands... [program completer, female, ex-smoker]

Automation and Human Interaction

Many participants reported that they disliked that the program sent automated messages and did not include human interaction, reporting that the messages were repetitive, *too automated*, and like *cookie-cutter lines*:

> Sometimes, I'd get the same message, and it wouldn't be the same messages in a row, but it seemed like sometimes, it was pretty generic...It'd be the same sort of three messages. [program noncompleter, male, ex-smoker]

A participant reported strongly disliking the program, explaining that he did not feel that an automated program that did not directly provide live support gave enough assistance to promote successful cessation:

> Because it was talking to a machine...Some of it was just repetitive. There was no real emotional support there at all. [program completer, male, smoker]

Message Tone and Content

The participants had varying perspectives on the preferred message tone. Approximately half of the participants reported that they preferred the positive tone of the program, with messages focusing on the benefits of quitting rather than the negative aspects of smoking. Participants reported that a supportive tone was particularly beneficial when they were facing struggles during their quit attempts:

> I liked that, like if you did slip, it wasn't like oh, my God, how dare you. It would be like...do you want to start over again? Because like that's happened to me before. It was good. [program completer, female, ex-smoker]

However, some participants wanted a *tougher* tone to encourage accountability:

> Give me the more serious stuff. Don't tell me it's okay to have a slip, because honey, I'll have slips all day then...I need some really butt-kicking stuff. [program completer, female, smoker]

Some participants reportedly preferred a mix of message tones depending on their mood or how confident they felt about their quit attempt:

> I think it would be half and half. If you leave work, you might need a more supportive message if you had a bad day. [program noncompleter, male, ex-smoker]

Finally, some participants reported that the content and tone of the messages may have been an impediment to cessation. A few said that the messages triggered smoking cravings, and some noted that certain messages seemed to *permit* smoking by framing quit attempt failures positively:

> ...One that said, even if you fail, if you smoke, don't give up...like it was ok...I slipped once. I was like, no, don't tell me that it's ok to slip once. [program noncompleter, female, ex-smoker]

Message Frequency, Timing, and Duration

Most participants reported that the number of daily messages received in the program was appropriate; however, some mentioned that they would have preferred either more or fewer messages per day. In addition, several participants suggested that the timing of messages could align better with their personal schedules or typical smoking times:

> If you could set the timing, that would be a plus...I tend to smoke early in the morning and late at night...if you can set the frequency on when you do it, that would be an excellent plus because you're going to get that reminder at the times that you

actually may be smoking. [program completer, male, smoker]

Some participants also wanted to be able to customize message frequency or program duration so that the program could be abbreviated if the user successfully quit or extended if the user was struggling to quit:

> *...I wanted more messages...because I wasn't doing so good in any of my quits. Whereas, like this time next week, you know, maybe I am...doing awesome and it will be the perfect timing...Like maybe there could be some type of...where it says "crave" or "doing good"...just maybe "having a rough time"...and that's a trigger to the system to say..."extend her out for three more weeks."* [program completer, female, smoker]

A few participants noted that having an adaptive quit date (eg, 1 in the past and 1 that could be postponed) would make the program better suited to fluctuating levels of readiness to quit.

Program Engagement Features

Program Keywords

Most participants noted that they liked using the keyword feature when they were struggling with their quit attempt:

> *It responds quickly when you text "crave." I like the instant response when you tell it that you are having a problem. It gives me ideas of how to stay strong.* [program noncompleter, female, smoker]

However, some participants did not use the keywords as they did not remember that this feature was available to them.

Assessment Questions

Most participants reported that they liked receiving and responding to the assessment questions. Participants reported a variety of reasons for liking assessments, including their interactivity, accountability, and utility for smoking trigger recognition:

> *...if I would get the [assessment] message during a particular time of day, it would help then...I would stop and think about the things that were going on around me at that time, and then based on what I replied to the message and what my craving level was...I could say...these are the things that are making me crave.* [program completer, male, ex-smoker]

However, many participants reported barriers in responding to assessments, including not having time to respond, not recalling the messages, or feeling guilty for having smoked or relapsed:

> *I'm smoking, and yet, it thinks that I've been quit for five days. Don't tell. So, I'm not responding to it, but that's because I know I slipped up. But at the same time, I still want the messages to come through.* [program completer, female, smoker]

Program Opt Out (Noncompletion)

Smoking Status and Opt Out

Among program noncompleters, more than half reported opting out because they were not successful in quitting smoking. A few participants expressed guilt about continuing to use the program while they were still smoking:

> *Why did I opt out? Well, I started smoking again...It just would make me feel like I was lying, you know? Even if I typed in "slip," when I throw back a pack and a half a day, that's not a slip. That's a habit again.* [program noncompleter, male, smoker]

Some noncompleters reported opting out as they had successfully quit smoking, and one of these participants reported opting out as the messages were becoming a trigger to smoke after he had quit.

Program Factors Influencing Opt Out

Some noncompleters reported that they opted out as a result of the volume and content of the SMS text messages. Some reported that the number of texts received per day contributed to opt out, either reporting that the number of texts per day was too high or that the decrease in messages over time was a factor in opting out:

> *They kind of slowed down the texts, and...it kind of made me feel that I didn't need it anymore...The messages weren't as strong.* [program noncompleter, female, ex-smoker]

Some noncompleters also reported that they opted out because the messages on their own were not enough of a motivator to quit:

> *I'd read the text...and then soon as I would close it out light a cigarette within two minutes...I don't think it did a trigger...It just didn't do anything to prevent it...it didn't really help me to say, "okay, I'm not going to."* [program noncompleter, male, smoker]

Other Factors Influencing Opt Out

Along with smoking status and SMS text message–related factors that contributed to opt out, a few participants reported that they had technical issues with their mobile phones that contributed to opt out. One of the participants reported that he no longer needed the program because he had enough social support at the time.

The Role of SmokefreeTXT in the Quitting Process

Several participants reported that they were still smoking at the time they enrolled in SmokefreeTXT, whereas fewer said they had started their quit attempt before enrollment. Several participants reported that they joined SmokefreeTXT during one of the multiple quit attempts, and some reported that they were enrolled in the program multiple times, re-enrolling in the program after completion or opt out:

> *...I was like, you know, I really want to quit. So I thought like maybe this [SmokefreeTXT] will work. And I tried it the first time and I quit for a while and...I had to restart it because I started smoking*

again. And then I was like I quit for a while and then like things just got crazy and I started smoking and then I was like "I'm going to text the [SmokefreeTXT] number again and it's going to be the last time I do it." [program completer, female, ex-smoker]

Approximately half of the participants reported that they felt that SmokefreeTXT had a positive impact on their quitting process, calling the program *helpful* and reporting that it made them feel more confident about quitting. Several participants who were smoking at the time of the study reported that, although they did not fully quit while enrolled in the program, the program helped them quit temporarily or reduce their smoking (fewer cigarettes per day and smoking less frequently).

Other Cessation Support in Conjunction With SmokefreeTXT

Half of the participants reported that although SmokefreeTXT was a useful component of their quit plan, they also relied on other strategies. Notably, several participants reported using strategies that were not evidence-based, such as switching to smokeless tobacco or using hypnosis rather than evidence-based methods such as over-the-counter nicotine replacement therapy (NRT) or prescription cessation medications. Although there are no reports on the implications for SmokefreeTXT on the effectiveness of or adherence to NRT, a couple of participants reported they were motivated to use NRT while they were enrolled in the SmokefreeTXT program, and a few participants reported that they would like SmokefreeTXT to facilitate access to NRT, such as by providing coupons. Several participants also reported using other mHealth cessation resources while enrolled in SmokefreeTXT, such as cessation smartphone apps and social media focused on cessation support (eg, Smokefree Women Facebook page and web-based smoking cessation forum). Some participants who reported using cessation smartphone apps reported that they would like features of cessation apps to be incorporated into SmokefreeTXT, including tracking money saved by not smoking and smoking milestones (number of days since quitting).

Discussion

Principal Findings

Interviews with SmokefreeTXT users showed high program acceptability, engagement with program features, and perceived utility for smoking cessation. Participants provided feedback on program content and functionality, which informed changes to the program. Moreover, the findings provide insights into the complex relationship between program engagement and cessation, which warrants future research.

This qualitative study adds to the limited body of literature that assesses user experiences of smoking cessation SMS text messaging programs. A unique component of this study is its focus on the experiences and perceptions of real-world users of the publicly available SmokefreeTXT smoking cessation SMS text messaging program, which, to our knowledge, has not been explored by other studies of cessation SMS text messaging programs [13-16]. The findings highlighted features of the program that participants found beneficial, as well as some

elements that showed opportunities for improvement to boost program retention and successful cessation. We also found that program completion does not necessarily indicate successful smoking cessation and that program opt out, which may be interpreted as a less positive outcome [18], may occur because of successful cessation. Finally, several participants reported using SmokefreeTXT together with other evidence-based cessation methods or non–evidence-based strategies.

As has been found in prior qualitative studies, participants reported that SmokefreeTXT was easier to use than other live support services that require a more significant time commitment [13,14]. They also noted that the anonymity of the platform provided a source of discrete support without perceived judgment or stigma from family or friends [14]. However, similar to what has been found previously, several participants disliked the automated nature of the program, the absence of human interaction, and what they perceived as generic-sounding messages [14,15].

In terms of program structure, many participants reported that they would like the ability to customize message timing, program duration, and quit date settings, which has been reported in previous studies [13,16]. This underscores the need for mobile-based programs to take into consideration that cessation is a highly individualized and often nonlinear process, which may be optimally supported by programs offering flexible structure and functionality.

Although participants liked that the keyword feature allowed them to receive on-demand support and that the smoking assessment questions provided accountability, in some instances, participants reported that assessments triggered feelings of guilt if they had relapsed, which mirrors previous research [13]. In addition, some participants felt that they could not respond accurately to assessment questions (eg, a question about *slips* may not feel relevant if a user had relapsed). Therefore, as quitting smoking is rarely a linear process, it is important to consider other metrics of program success in addition to abstinence [26]. For example, some participants in our study reported that the SmokefreeTXT program helped them quit temporarily, and participants commonly reported making multiple quit attempts, both of which have been defined as metrics of success in other cessation SMS text messaging studies [13,15]. Participants also noted a reduction in their smoking. Given that many study participants entered the program during one of several quit attempts and that several participants enrolled in the program multiple times, further research is needed to better understand how to meet the needs of smokers who may engage in several quit attempts before being successful. For users who are not yet ready or able to quit, examining intermediate outcomes (potentially through responses to assessment questions), such as the number of quit attempts or cutting back on smoking, may provide valuable information to best support users during different stages of the cessation process.

To our knowledge, this is one of the first qualitative studies of cessation text program users that has explored the factors influencing program opt out. Two existing studies compared the experiences of users who either quit smoking or did not quit

XSL·FO
RenderX

smoking while using a cessation SMS text messaging program [13,15]. As participants of those studies were required to complete the program as part of their participation in an existing clinical trial, the studies were unable to examine the characteristics and experiences of users who would have otherwise opted out of the program. Most noncompleters reported opting out of SmokefreeTXT because of smoking relapse. However, not all participants who opted out did so as they had resumed smoking. Some opted out as they had successfully quit smoking and felt that they no longer needed the program, which suggests a need to reconceptualize the implications of program opt out [27]. Therefore, although certain factors may make opt out more likely, this qualitative work underscores that opt out is more nuanced than previous research suggests. In other words, opt out may not be definitively used as an indicator of either continued smoking or abstinence; rather, it is best seen as an indication that the user no longer finds it helpful to receive messages from an SMS text messaging program.

These findings also suggest that strategies to re-engage users that opt out should not be a one-size-fits-all approach. Although smoking relapse and cessation were the primary drivers of opt out, a few participants cited the number of messages as a reason for opting out, and others reported opting out as they did not find the messages sufficiently motivating to help them quit smoking. This reinforces the need to consider the message volume and tone when developing an automated program [13,14]. Opt out may have also been influenced by the level of smoking dependence and other tobacco use in the noncompleters group, as noncompleters tended to be heavy smokers, and many were poly-tobacco users.

Finally, although most participants reported that SmokefreeTXT was a useful component of a quit plan, approximately half relied on other cessation strategies as a complement to SmokefreeTXT. Notably, many of the strategies used by study participants were not evidence-based, and some participants reported supplementing their use of SmokefreeTXT by switching from cigarettes to other tobacco products, exposing them to further health risks associated with tobacco use. Therefore, it is important to consider how SMS text message programs can be used to encourage participants to both find evidence-based support (eg, NRT and prescription cessation medication) and work synergistically with these other supports.

SmokefreeTXT Optimizations

The results of this study have informed several optimizations to the program. For example, SmokefreeTXT has added messages that provide supplemental information on live support services and has optimized the SMS text message library to ensure that SMS text messages are more varied and less repetitive. Since conducting this study, the SmokefreeTXT program has also been changed to allow users to have a more flexible quit date at the start of the program. Users can set a quit date in the past if they begin their quit attempt before starting the SmokefreeTXT program, and users are also sent a message the day before their scheduled quit date and asked to text *ready* if they would like to keep the quit date they set or *not ready* to postpone the start of their quit attempt and set a new date.

Although we conducted qualitative interviews with users of the SmokefreeTXT program, several findings may also be applicable to the development and optimization of other cessation SMS text messaging programs. First, it may be important to allow users to customize the number of SMS text messages that they receive in the program. Cessation SMS text messaging programs may also be used with other cessation strategies; thus, it may be beneficial for SMS text message content to include messages about evidence-based cessation strategies. Relatedly, live support (eg, tobacco quitlines) is a cessation resource that can be recommended within SMS text message programs to benefit users who prefer human interaction as a component of their cessation process. Finally, program retention versus opt out may have limitations in the ability to predict the cessation *success* of users who opt out or remain in the program.

Limitations

This study had several limitations. First, we conducted in-depth interviews with a small convenience sample of SmokefreeTXT users who were mostly young, White, and had at least some college education. Thus, the results may not be generalizable to a wider population of smokers in the United States. Most current users of SmokefreeTXT are White (11,383/18,510, 61.50%), which demonstrates the need to consider how the program can better reach other demographic groups. In 2016, the SmokefreeTXT program began collecting race and ethnicity data as part of program opt in to track the demographics of the program over time, and future research recruitment efforts may be informed by these data.

SmokefreeTXT users who agreed to participate in the study may have been highly motivated to provide feedback on the program, whether positive or negative, which may have influenced the results. In addition, smoking status was not biochemically verified and relied on the self-reports of the users during the interviews. It is possible that some users stated that they had quit smoking to be more socially acceptable to the interviewer.

This study was conducted in 2014; since then, both mobile phone technology and the SmokefreeTXT program have evolved. However, although there have been changes to message content and quit date flexibility over time, the overarching structure and features of the SmokefreeTXT program (ie, message timing, keywords, and assessment questions) have remained consistent. Furthermore, the results still provide unique data from users who were not part of an intervention trial, and the SmokefreeTXT program continues to be widely used. Thus, the results can still provide actionable information for those developing new or adapting established cessation SMS text messaging interventions. Given the increasing importance of mHealth as an avenue for cessation, data from this study are still relevant today. In addition, some of the findings presented here may have new relevance as improvements to technology enable some of the recommended optimizations, such as the integration of SMS text messages with other digital resources; for example, quitlines or chat applications.

Conclusions

Qualitative interviews with real-world SmokefreeTXT users showed high program acceptability, engagement with program features, and perceived utility for smoking cessation. Our findings demonstrate the importance of allowing customization to the frequency of SMS text messages within cessation text programs, the limitations of measuring cessation *success* through program opt out versus retention, and the importance of recommending evidence-based cessation resources (including live support via quitlines for users who prefer human interaction during the cessation process) to be used with smoking cessation text programs.

Abstract

Background: Diabetes management is complex, and program personalization has been identified to enhance engagement and clinical outcomes in diabetes management programs. However, 50% of individuals living with diabetes are unable to achieve glycemic control, presenting a gap in the delivery of self-management education and behavior change. Machine learning and recommender systems, which have been used within the health care setting, could be a feasible application for diabetes management programs to provide a personalized user experience and improve user engagement and outcomes.

Objective: This study aims to evaluate machine learning models using member-level engagements to predict improvement in estimated A_{1c} and develop personalized action recommendations within a remote diabetes monitoring program to improve clinical outcomes.

Methods: A retrospective study of Livongo for Diabetes member engagement data was analyzed within five action categories (interacting with a coach, reading education content, self-monitoring blood glucose level, tracking physical activity, and monitoring nutrition) to build a member-level model to predict if a specific type and level of engagement could lead to improved estimated A_{1c} for members with type 2 diabetes. Engagement and improvement in estimated A_{1c} can be correlated; therefore, the doubly robust learning method was used to model the heterogeneous treatment effect of action engagement on improvements in estimated A_{1c}.

Results: The treatment effect was successfully computed within the five action categories on estimated A_{1c} reduction for each member. Results show interaction with coaches and self-monitoring blood glucose levels were the actions that resulted in the highest average decrease in estimated A_{1c} (1.7% and 1.4%, respectively) and were the most recommended actions for 54% of the population. However, these were found to not be the optimal interventions for all members; 46% of members were predicted to have better outcomes with one of the other three interventions. Members who engaged with their recommended actions had on average a 0.8% larger reduction in estimated A_{1c} than those who did not engage in recommended actions within the first 3 months of the program.

Conclusions: Personalized action recommendations using heterogeneous treatment effects to compute the impact of member actions can reduce estimated A_{1c} and be a valuable tool for diabetes management programs in encouraging members toward actions to improve clinical outcomes.

(JMIR Form Res 2022;6(3):e33329) doi:10.2196/33329

Introduction

Diabetes is a chronic progressive disease affecting 34 million Americans with 1.5 million newly diagnosed each year [1,2]. Individuals living with diabetes are at greater risk of health complications including increased hospitalizations that result in 1 of every 4 health care dollars spent on diabetes-related care in the United States [3]. An essential factor in successfully living with diabetes is effective self-management, which has shown to improve glycemic control and reduce hospital admissions and the overall lifetime cost of health care [4].

Diabetes self-management efficacy and improved glycemic control is supported by programs that offer education, coaching, glucose monitoring, and physical activity [5-7]. Diabetes management programs have shown to be as or more effective than usual care in providing a significant reduction in hemoglobin A_{1c} (HbA_{1c}) [8-10]. Additionally, structured self-monitoring of blood glucose (SMBG) has been observed to improve glycemic variability and provide greater self-efficacy in management by helping an individual understand lifestyle behaviors' impact on blood glucose (BG) values over time [2,11]. However, while advances in diabetes treatment options, diabetes management programs, new technologies to support self-management, and the rise in digital health are rushing the market, half of individuals with diabetes have an HbA_{1c} value of 7.0% or higher and struggle to obtain consistent glycemic control [1]. This alludes to potential gaps in self-management programs, technology, and delivery to the individual [12].

Personalization has been identified as a key tool in digital health to enhance user engagement for improved outcomes, which is often a missing factor in the development of diabetes digital health programs [12]. Self-management best practices and user preference must be taken into consideration to effectively provide a personalized experience within a diabetes management program. This study has proposed and analyzed the feasibility of using heterogeneous treatment effect models for personalizing action recommendations within a digital remote diabetes monitoring program (RDMP).

Methods

Livongo for Diabetes

Livongo for Diabetes is an RDMP focused on empowering members with education and tools to self-manage their diabetes through mobile technology. The program offers members a cellular-enabled, two-way messaging device that measures BG and delivers personalized insights into their glycemic management; free unlimited BG test strips; real-time support from diabetes response specialists 24 hours a day, 7 days a week, 365 days a year; and access to certified diabetes care and education specialists (CDCESs) for support and goal setting.

Livongo members' glucose meter use was captured remotely through the cellular-enabled device. Members also had access to a mobile phone app that tracked historical SMBG readings and provided reminders for SMBG checking, physical activity, and food log tracking; asynchronous chat with coaches; ability to schedule private coaching sessions with CDCES; educational content for diabetes self-management; and allowed members to send historical reports of SMBG readings to care providers, family members, and friends.

Study Design

A retrospective feasibility study was conducted to compute heterogeneous treatment effect for five different action categories in the reduction of estimated A_{1c} for members enrolled in Livongo for Diabetes with type 2 diabetes and to identify which actions could be most effective for each member. Within each action category, members were classified into a treatment or control group defined by engagement level. The effectiveness of each action category was assessed by computing the heterogeneous treatment effect for each action category for each member.

Population Selection

Members enrolled in Livongo for Diabetes for a minimum of 4 months with a baseline estimated A_{1c} ≥7.5% at 30 days post enrollment were included in the study. Additional inclusion criteria were a self-reported diagnosis of type 2 diabetes at enrollment, ≥5 SMBG measures between 50 and 400 mg/dL in month one and month four of their program, and had not self-reported the use of a continuous glucose monitor (see Figure 1). Member demographics, self-reported preferences around communication and health-related interests, and level of engagement with various program features within 3 months following enrollment were used as covariates for modeling outcomes.

Figure 1. Study population funnel with inclusion and exclusion criteria. HbA$_{1c}$: hemoglobin A$_{1c}$.

Ethics Approval

The institutional review board approval was granted by Aspire IRB (#520160099), and guidelines outlined in the Declaration of Helsinki were followed.

Action Categories

Various program features were categorized and grouped to form five action categories, otherwise known as interventions per the causal inference formulations (see Textbox 1 for action category descriptions).

Textbox 1. Action category name and descriptions.

Monitoring

Number of self-monitoring blood glucose checks a member performed on the device

Coaching

Number of scheduled certified diabetes care and education specialist coaching sessions or asynchronous chat with a coach

Physical activity

Physical activity recorded using synced steps data

Nutrition

Members engagement with nutrition- and meal plan–related nudge recommendations and food log

Content

Members' engagement with educational content nudge recommendations

---

Measures

Estimated A$_{1c}$

Estimated A$_{1c}$ was calculated using the A$_{1c}$-derived average glucose model where estimated A$_{1c}$ = [mean BG over past 30 days + 46.7] / 28.7 [13]. Mean BG was calculated using SMBG values gathered through the member's device.

The intervention outcome, *Y*, is defined as the difference between estimated A$_{1c}$ in month four and month one post enrollment for members with a starting self-reported HbA$_{1c}$ ≥7.5%. Therefore, members with a more negative *Y* have a better clinical outcome.

Model Features

Treatment effect was modelled using self-reported member information and member engagement during the first 3 months post enrollment. The following variables were used as covariates in the model:

- Demographics: age, gender, BMI, race
- Self-reported medical information: self-reported HbA$_{1c}$ at enrollment, diabetes management level of self-efficacy, insulin use, on oral diabetes meds, received flu vaccine, smoking behavior
- Self-reported preferences: preferred channels of communication, interest level in becoming active and healthy
- Engagement: average days between Livongo website use; average days between Livongo mobile app use; number of

days of Livongo mobile app use; average days between SMBG checks; estimated A_{1c} at month two and three; days with SMBG hypoglycemia readings in month one, two, and three; days with SMBG hyperglycemia readings in month one, two, and three

Computing Heterogeneous Treatment Effect

The sample was defined to be composed of members with covariates, X, in treatment or control cohorts, denoted by $T=t_1$ or t_0, respectively, and intervention outcome, Y. Ideally, treatment effect, τ, would be measured for each member as:

$$\tau\,(t_0, t_1, x) = E[Y\,(t_1) - Y\,(t_0)\,|\,X=x\,]$$

However, this was not possible in a real-world data set where a member could only be in one cohort, treatment or control, at a time and not in both. Therefore, observed samples were assumed to be from a joint distribution modeled by the equations:

$$Y = g\,(T, X) \text{ and } T = f\,(X)$$

and the treatment effect was expressed as:

$$\tau\,(t_0, t_1, x) = E[g(t_1, X) - g(t_0, X)\,|\,X=x\,]$$

where $g\,(T, X)$ denoted the likelihood of outcome for a member given an intervention, and $f\,(X)$ denoted propensity of a member to be in the treatment or control cohort of the intervention.

With the assumption that all potential confounders were observed, the heterogeneous treatment effect for each member was computed using the doubly robust (DR) learning algorithm [14-17]. Treatment effect was computed by the DR algorithm using three different models. The first model performed regression on *[T, X]* to predict outcome *Y*. The second model preformed classification on *X* to predict *T*. Lastly, the two models are combined to compute the heterogenous treatment effect where the estimated outcome from the regression model is debiased by adding the inverse propensity weighted model residual. This method provided robust predictions with only one of the two predictive models needed to have a small error to obtain an unbiased treatment effect estimator [18].

Engagement Thresholds for Control and Treatment Cohort Assignment

Engagement level was used to split data into control and treatment groups. The application of the DR learning algorithm enabled intervention outcomes from the treatment and control groups to be representative of the same population because the propensity model, $f\,(X)$, incorporated any differences in population while computing the treatment effect.

Member engagement was measured for each action category during the initial 3 months post enrollment. The level of member engagement with each action category was used to assign members into the treatment or control groups through a defined threshold. If a member had higher engagement than the threshold, then the member was assigned to the treatment cohort, and the members who did not achieve the threshold were assigned to the control cohort. The treatment and control split

only included member's engagement in the action category of the program. Members in the control cohort received communication from Livongo in the form of emails and newsletters.

The engagement thresholds were defined independently for each action category. The threshold value impacted the size imbalance between the control and treatment groups, thereby affecting noise in the data set and consequently the model performance. For this reason, engagement thresholds for each action category were selected that minimize the modelling error while optimizing treatment effect.

Results

Modeling Heterogeneous Treatment Effect for Coaching Intervention

Treatment effect for the five actions categories were modelled independently. The action category of coaching is used to detail the process of selecting an engagement threshold and evaluate the heterogenous treatment effect model. Treatment effects across all action categories are then reported, followed by a proposed method to personalize action recommendations to optimize clinical outcomes.

Members who completed sufficient scheduled coaching sessions or asynchronous coaching chat sessions were assigned to the treatment cohort, with members not meeting the criteria assigned to control. This intervention engagement threshold was observed to have an impact on the DR model performance. As the threshold increases, so does the control-treatment size imbalance and noise in the data. The control-treatment size imbalance for different thresholds is shown in Figure 2.

For a member to be considered as receiving treatment, the data is split into training and validation data sets, which was split by a ratio of 65:35. The treatment effect was modelled with a forest DR learner algorithm using a gradient boosting classifier and a random forest regressor to model the likelihood of the outcome, g, and treatment propensity, f, respectively. The mean squared error (MSE) of the model was a good indicator of confidence in predicting treatment effect. A threshold value that optimizes treatment effect while having lower MSE and sufficient sample size was selected for treatment and control assignment.
The MSE of the heterogenous treatment effect estimator model for different thresholds and computed average treatment effect are shown in Figure 3. Based on Figures 2 and 3, a threshold of at least 3 coaching sessions (scheduled or chat sessions) within the initial 3 months post enrollment was used to assign members to the treatment cohort.

Treatment effect of the coaching action category computed with the DR learner algorithm shows most members having a negative treatment effect, therefore, promoting a greater impact of coaching on estimated A_{1c} (see Figure 4). Members with positive treatment effects were those who the intervention did not improve the outcome.

Figure 2. Control and treatment cohort sample size for different minimum number of coaching sessions defined as engagement threshold.
Figure 3. Top left: MSE of the doubly robust model to predict treatment effect of coaching intervention for different number of coaching sessions threshold. Top right: predicted treatment effect of coaching intervention for different thresholds. MSE: mean squared error.

Figure 4. Distribution of computed treatment effects of coaching intervention.
## Evaluation of Heterogenous Treatment Effect Model for Coaching Intervention

A direct evaluation of causal models cannot be made on observational data where the true treatment effect is not known due to an inability to observe the effect of being treated or not for a particular sample simultaneously. Our causal model performance was evaluated indirectly by comparing the cumulative gain of the outcome when members are ranked by model prediction when compared to random sorting [19].

Cumulative gain is cumulative uplift multiplied by sample size, where uplift is defined as the difference between average outcomes of treatment and control cohorts. A model that performs well will have large uplift values in the first quantiles and decreasing values for larger ones. By comparing the cumulative gain of members sorted by treatment effects and randomly sorted, model performance can be inferred. The higher the area under the uplift curve (AUUC) in prediction when compared to random assignment, the better the model prediction.

The cumulative gain in the outcome for the coaching action category when members are ranked by model predicted treatment effect and when randomly ordered is shown in Figure 5. The cumulative gain curves plotted are the negative of the outcome variables; therefore, the higher gain values reflect better results. The AUUC score for random assignment and assignment using the inferred treatment effect are 0.5 and 1.1, respectively.

Figure 5. Cumulative gain of coaching intervention when members are sorted by predicted treatment effect (solid blue line) and with random sorting (dashed orange line). The cumulative gain plotted is the negative of uplift from intervention outcome variable (change in A_{1c}) so that higher gain values reflect better results.
Modeling Heterogeneous Treatment Effect for Five Action Categories

The control-treatment cohort assignment for each of the five action categories for each member was inferred independently. From these independent analyses, engagement thresholds were defined for the five action categories optimizing treatment effect and sample size while lowering model MSE (see Textbox 2). The treatment and control cohorts vary across interventions depending on if they satisfied the engagement threshold condition for that intervention.

**Textbox 2.** Engagement thresholds within 90 days of enrollment for treatment.

Monitoring

≥70 days with self-monitoring blood glucose checks

Coaching

≥3 coaching sessions (scheduled coaching sessions or asynchronous chat sessions with coach)

Physical activity

≥30 days with 2000 daily steps

Nutrition

≥2 food logs or ≥50% yes responses to nutrition-related nudges

Content

≥50% yes responses to content-related nudges

Action Category Distribution and Outcomes

Figure 6 displays the total number of members within the treatment cohort of each of the five action categories and outcome *Y* related to the action category. Members with insufficient engagement in all action categories are assigned to the "other" category or control cohort.

As shown in Figure 6, the action categories had varying sample sizes. This is a result of engagement rates affected by member preferences or desired support to manage their condition. Members who engaged with coaching and physical activity had better outcomes (ie, more negative change in estimated A_{1c}).

Figure 6. Top: distribution of members in the treatment cohort within the five different intervention categories or other category as a fraction of total data set sample size. Bottom: outcome (difference in estimated A_{1c} level) for the different interventions.

Evaluation of Heterogenous Treatment Effect Model for Five Action Categories

The model performances were evaluated using a common validation data set across interventions. The cumulative gain of the outcome when members are sorted by model predictions compared to random sorting for the five action category outcomes independently is shown in Figure 7. The area under the gain curve was larger when members were sorted by predicted treatment effect compared to random ranking, which confirmed that the model can infer causal effects of all the action categories in the data.

Figure 7. Cumulative gain of outcome for the five different interventions by model predictions (solid blue) and random sorting (dashed orange).

Action/Intervention Recommendation Based on Heterogeneous Treatment Effect

For each member, the intervention with the most negative treatment effect is the action that the model predicted would result in a larger reduction in estimated A_{1c} (ie, optimal intervention). The average change in estimated A_{1c} for members who were part of the treatment cohort in at least one action category in the validation set is shown in dark blue if the received intervention was the same as the predicted intervention and shown in light blue if the received intervention was not the same as the predicted intervention (see Figure 8). Within all five action categories, the outcome is more negative when the prediction matches the true intervention, which indicated that the model was successful in identifying optimal outcomes. Members who participated in interventions that matched their optimal predictions had an estimated A_{1c} reduction of 1.4%, while those that did not participate in their predicted optimal intervention had a reduction of only 0.57%. This 0.8% estimated A_{1c} reduction difference can be attributed to intervention personalization. Members who had a predicted optimal intervention of coaching and received coaching showed the highest change in estimated A_{1c} at 1.7%.

The distribution of predicted optimal intervention for each member with negative predicted treatment effects were coaching

(28%), SMBG checks (26%), physical activity (18%), content (16%), and nutrition (12%). Interaction with coaches and SMBG checks were observed to be the optimal intervention for 28% and 25% of the sample size, respectively, and the most recommended interventions. A balanced distribution of recommendations for optimal clinical outcomes was observed and opens an opportunity to prioritize recommendations based on a heterogeneous causal effect model.

A comparison of average treatment effect with current interventions and with recommended optimal intervention predicted by the model is shown in Figure 9. Treatment effect was larger with the recommended optimal intervention for all action categories. On average, the recommended intervention predicts a treatment effect of 0.07% compared to 0.02%, with the current intervention producing a difference of 0.05% in estimated A_{1c} attributable to personalization.

Figure 8. Change in estimated A_{1c} of members in different intervention treatment cohorts if the member received the model predicted optimal intervention (dark blue) or not (light blue).
Figure 9. Computed treatment effect for members who received different interventions. The light blue bars denote the treatment effect for members who were in the treatment cohort of our data set. Dark blue bars denote treatment effect for members if they received the optimal intervention.
Discussion

This study highlights the feasibility of analyzing the engagement of members in an RDMP to develop a causal inference-based recommender system for predicting actions driving optimal clinical outcomes. Five action categories were identified upon member engagement level, and the causal inference model computed heterogenous treatment effect of each action per member. Model predictions were evaluated by comparing uplift gain when members were ranked by treatment effect to random

sorting, and AUUC of the model predicted gain curves were larger for all actions, validating the method to infer treatment effect. Coaching and glucose monitoring were found to be the most frequently recommended actions for members to achieve optimal clinical outcomes. On average, members who engaged within their recommended actions had a 0.8% higher reduction in estimated A_{1c} than those who did not engage within recommended actions in their first 3 months of the program, with coaching showing the largest reduction in estimated A_{1c} at 1.7% when recommended and used by members.

Machine learning has been used to study precision medicine in diabetes care and complications, variables to predict the development of diabetes, and individual characteristics related to diabetes outcomes [20-22]. However, there is a lack of evidence around practical solutions for real-world implementation, specifically around diabetes self-management behaviors, which are the foundation of successfully living with the chronic condition [23]. It has been well-established that diabetes management programs are effective in helping participants obtain glycemic control, improve HbA$_{1c}$ values, and increase self-efficacy with the support of diabetes coaches and structured SMBG [2,5,7-9]. Therefore, as real-world data has been made available around self-management behaviors through RDMPs, mobile apps, and other technologies, it is immensely valuable to use this data in machine learning techniques to provide personalized recommendations to enhance the future of diabetes care.

Our study observed better outcomes for members who engaged in their recommended actions over members who did not, across all action categories. On average, members who engaged within their recommended actions had a significant improvement estimated A$_{1c}$ than those who did not engage within recommended actions. Therefore, we propose RDMPs develop recommended actions of engagement that are more likely to lead to better outcomes based on computed heterogeneous treatment effects with the most optimal action having the most negative treatment effect. By offering personalized recommendations, members can receive a more effective experience through both digital and human coaching allowing for not only a medical cost saving for the individual through improved health outcomes but also a more cost-effective approach for the RDMP by directing the member to the most valuable program features.

Type 2 diabetes management is complex and dependent upon many factors such as nutrition, physical activity, and medication adherence, which varies widely among this population as a whole; therefore, to generate successful personalized recommendations, all variables must be gathered to match an individual's specific needs [24]. Our study presents one way that treatment effects can be computed from the causal model for recommending future interventions to drive clinical outcomes. Strong evidence around coaching, SMBG, education, nutrition, and physical activity has informed the development of diabetes management programs; however, the individual's education gaps, lifestyle, available resources, and personal priorities get lost in the wide range of program features available. This could lead to overwhelm, burnout, and even distress from not knowing where one should place their focus. By offering our method to develop a recommender system for program feature engagement, we hope that guiding members to program features that are considered most effective in supporting clinical outcomes will lessen any burdens of disease management.

This study has several strengths, including the report of real-world data, as well as insight into the demographics and program engagement of members participating in an RDMP. Members were not provided incentives to participate in the program or study beyond the Livongo for Diabetes program being provided as a benefit through their employer or health plan package. The study also had some limitations, including the retrospective analysis study design. Members in the Livongo for Diabetes program received promotional engagement outreach in the form of mobile app nudges, emails, and text messages; therefore, observational data collected for the study contained a diverse set of engagement behaviors within the program features and did not provide a clean treatment and control cohort split. Improvement in estimated A$_{1c}$ was calculated from participants' SMBG values, which has been successfully correlated with laboratory HbA$_{1c}$ values; however, it does have some limitations and is best used as a population-level tool.

Nonetheless, this study demonstrates how engagement thresholds that minimize modelling errors can be used to create control-treatment samples in observational data and compute treatment effects. The recommended action within the study is based solely on the likelihood of the member attaining a better outcome and member preferences, and propensity to engage in an action during prediction was not considered. Therefore, real-life implementation of the recommender system would have to include the likelihood of engagement and likelihood of outcome while personalizing the action recommendations. Although treatment effects were computed, it was assumed that the interventions were independent of each other and analyzed separately; however, using Bayesian inference of treatment effect would have accounted for dependencies between interventions and is recommend for a future study to further explore RDMP personalization.

Personalized action recommendations using heterogeneous treatment effects to compute the impact of member actions within an RDMP to significantly reduce estimated A$_{1c}$ can be a valuable tool in driving member behaviors toward actions that are more likely to impact clinical outcomes. Future research is recommended to implement and evaluate this model prospectively within an RDMP.

Abstract

Background: Given the interrelated health of children and parents, strategies to promote stress regulation are critically important in the family context. However, the uptake of preventive mental health is limited among parents owing to competing family demands.

Objective: In this study, we aim to determine whether it is feasible and acceptable to randomize digital prompts designed to engage parents in real-time brief mindfulness activities guided by a commercially available app.

Methods: We conducted a 30-day pilot microrandomized trial among a sample of parents who used Android smartphones. Each day during a parent-specified time frame, participants had a 50% probability of receiving a prompt with a message encouraging them to engage in a mindfulness activity using a commercial app, Headspace. In the 24 hours following randomization, ecological momentary assessments and passively collected smartphone data were used to assess proximal engagement (yes or no) with the app and any mindfulness activity (with or without the app). These data were combined with baseline and exit surveys to determine feasibility and acceptability.

Results: Over 4 months, 83 interested parents were screened, 48 were eligible, 16 were enrolled, and 10 were successfully onboarded. Reasons for nonparticipation included technology barriers, privacy concerns, time constraints, or change of mind. In total, 80% (8/10) of parents who onboarded successfully completed all aspects of the intervention. While it is feasible to randomize prompt delivery, only 60% (6/10) of parents reported that the timing of prompts was helpful despite having control over the delivery window. Across the study period, we observed higher self-reported engagement with Headspace on days with prompts (31/62, 50% of days), as opposed to days without prompts (33/103, 32% of days). This pattern was consistent for most participants in this study (7/8, 87%). The time spent using the app on days with prompts (mean 566, SD 378 seconds) was descriptively higher than on days without prompts (mean 225, SD 276 seconds). App usage was highest during the first week and declined over each of the remaining 3 weeks. However, self-reported engagement in mindfulness activities without the app increased over time. Self-reported engagement with any mindfulness activity was similar on days with (40/62, 65% of days) and without (65/103, 63% of days) prompts. Participants found the Headspace app helpful (10/10, 100%) and would recommend the program to others (9/10, 90%).

Conclusions: Preliminary findings suggest that parents are receptive to using mindfulness apps to support stress management, and prompts are likely to increase engagement with the app. However, we identified several implementation challenges in the current trial, specifically a need to optimize prompt timing and frequency as a strategy to engage users in preventive digital mental health.

Introduction

Background

The stressors of parenting are normative and unavoidable. Broadly, stress is viewed in the context of life events (major or minor) that disrupt mechanisms intended to maintain one's physiology, emotion, and cognition [1]. Specifically, parenting stress is a natural experience that arises when parenting demands exceed expected and available resources [2]. Parenting stress may reflect broader contexts to include any number of major life stressors, relationships, or family circumstances [3,4]. Parenting stress can have a negative effect on relationship quality, health, mood, and overall well-being of not only the parent but also the family [3,5,6]. In both children and adults, acute and chronic stress are linked with numerous physiological and psychological disease states [5,7-9]. Thus, strategies to regulate stress are critically important among children and families [2,5-7].

However, few parents seek professional help to manage stress, and few primary care providers counsel on stress management skills [10]. Before the COVID-19 pandemic, 2019 data show that only 9.5% of adults aged ≥18 years reported receiving mental health counseling in the past year [11]. The COVID-19 pandemic took a particularly heavy toll on parents with children aged ≤18 years without much support. Evidence shows that stress management counseling is rarely offered in primary care or is the least common type of counseling provided by primary care physicians relative to diet, physical activity, or smoking cessation [10,12].

Stress management exercises (eg, mindfulness, cognitive reframing, and behavioral modification) are empirically supported strategies to promote self-regulatory skills, stress reduction, and resilience [13-15]. Evidence suggests that mindfulness interventions have the potential to reduce parenting stress and improve psychological functioning in youth [5]. Specifically, mindful parenting (ie, moment-to-moment awareness of the parent-child relationship) may reduce parental stress and promote family well-being [6,16]. However, it is unclear how formal (ie, purposeful or dedicated time) or informal (ie, weaving mindfulness into existing routines such as dishwashing) mindfulness is required to yield positive outcomes [17,18]. Mindfulness intervention dosage has wide variability reported anywhere from 9 to 27 hours [5], 45 minutes to 2 hours delivered over 3 to 12 sessions [19], and 4.5 to 24 hours [20]. Collective findings from systematic reviews and meta-analyses suggest small but beneficial effects of mindfulness interventions [5,19,20].

However, American families are often busy citing time and logistical barriers (costs and transportation) as reasons for attrition or nonparticipation in health-promoting activities. Both before and during the COVID-19 pandemic, families struggled to balance work and life, often feeling tired, rushed, and short on quality time with their children, friends, and hobbies [21]. In 2019, around 51% of mothers and 82% of fathers reported working full-time. In 2015, 26% of children aged <18 years lived with a single parent, and 53% to 73% of parents reported that their child participated in an extracurricular activity in the previous 12 months [21].

Brief mindfulness interventions may be a suitable alternative to more traditional mindfulness programs for populations with limited time or available resources [22]. In contrast to traditional 8- to 10-week mindfulness interventions, brief mindfulness interventions range from 3- to 5-minute guided exercises to 2-week programs [22]. Brief mindfulness interventions have also become increasingly popular with the rise of commercially available mindfulness meditation apps and other technologies [22-25]. Both commercial and research-developed mobile apps that help participants learn, practice, and monitor mindfulness activities [17,18,25,26] may increase opportunities to learn and practice mindfulness or meditation (hereinafter collectively referred to as mindfulness) across diverse audiences compared with traditional face-to-face programs [27], and successful coping strategies may be deployed in real time in real-world conditions to mitigate the deleterious effects of parenting stress [2,5,28].

A critical challenge in digital health, the law of attrition, occurs when digital health study participants drop out before completion or stop using the app [29,30]. Interventions intended to revolutionize stress regulation, including digitally supported health interventions, often fail because they are not used in real-world settings [31-35]. The main users of mental health apps are predominantly younger individuals, of high socioeconomic status, have overall positive health, and routinely engage in preventive health practices [36-39]. Families, particularly of low income, have poor adoption rates of abundant mobile health (mHealth) solutions despite high smartphone ownership and potential for scalability [32,33,38]. Poor engagement with digital health interventions may be mitigated through real-world strategies [31,40,41]. Many mHealth systems lack sufficient effort devoted to their design, development, and evaluation across diverse populations [15,31,34]. A solution-focused approach prioritizes the development of a solution to a practical problem to produce a sustainable solution [40,42].

A critical first step in supporting parental stress regulation (distal outcome) was to identify whether and under what conditions prompting parents to engage in mindfulness is beneficial. Digital prompts (eg, push notifications) are frequently used to promote engagement. Digital prompts are intended to nudge users in a particular direction without limiting the freedom of choice [43-45]. However, an overflow of notifications can be burdensome, leading users to ignore push notifications, increase user inattention, and/or exacerbate disengagement from apps [30,46]. Digital prompts are subject to a myriad of factors such as timing, frequency, sender, content, message framing, mode

XSL•FO

RenderX

of delivery, and theoretical underpinning [43-45]. Previous research on the use of digital health prompts to increase engagement with interventions among parent populations is limited [47,48]. One study conducted with parents found that the timing of prompts to support healthy lifestyle behaviors may be beneficial if delivery coincides with parents' perceived need for support (eg, prompt to practice guided imagery sent when the parent was at home versus while driving) [47]. Parent preference for prompt timing (ie, self-selected time frame of when to receive a prompt) peaked during late afternoon and evening hours when the school or workday ended and the family transitioned to dinnertime and evening activities [47]. With regard to prompt frequency, survey data show that parents desire few notifications (ie, 2 times per week) [48], while intervention data suggest that parents favor frequent messages (eg, daily) [47,48]. As mobile apps evolve, opportunities for meaningful intervention within life patterns may be possible through various mechanisms that sense and capture streams of personal data, giving insight into contextual factors [43,44,49-51].

Just-in-time adaptive interventions (JITAIs) have potential for shaping health behavior, using various data streams to deliver prompts at the *right time* while minimizing user burden and habituation [52]. JITAIs rely on explicit decision rules for when to prompt users with specific intervention components [52]. However, it is uncertain when and under what conditions, interventions should be delivered to engage parents in real-time stress-regulating activities. A microrandomized trial (MRT) is an experimental design that can supplement the use of theory to guide JITAI development. An MRT allows researchers to study the proximal effects of a specific intervention component, change over time, and contextual factors that may moderate time-varying effects [52].

Therefore, before designing a comprehensive JITAI for parenting stress, we conducted a pilot MRT to explore whether it was possible to leverage digital prompts to support real-time parent engagement with stress-regulating activities guided by a commercially available mindfulness app, Headspace. We developed a novel system that, from the front end (parent perspective), leveraged digital prompts containing messages that encouraged brief (<10 minutes) mindfulness activities and were capable of launching Headspace. Parents were able to change the timing of prompt delivery to suit their individual needs through a secondary research-developed app. From the back end (researcher perspective), the system would randomize to send or not send a digital prompt during the parent-specified window. Headspace was used to teach and support mindfulness activities. While adaptability and scalability were facilitated using a commercially available app, proprietary back-end data for Headspace were not accessible by our research team (ie, what content parents accessed on Headspace). Therefore, our system was designed to passively capture relevant smartphone data (eg, when the Headspace app was open; how long the app was open; or smartphone paradata such as silent, ring, or vibrate mode). Finally, our system pushed a daily ecological momentary assessment (EMA). The EMA was used to differentiate engagement with the app versus engagement with mindfulness and to observe for potential benefits on parent mood.

Objective

In this study, we aim to conduct a pilot MRT to determine if it was feasible and acceptable to randomize digital prompts designed to engage parents in real-time brief mindfulness activities guided by a commercially available app (Headspace).

Methods

Trial Design

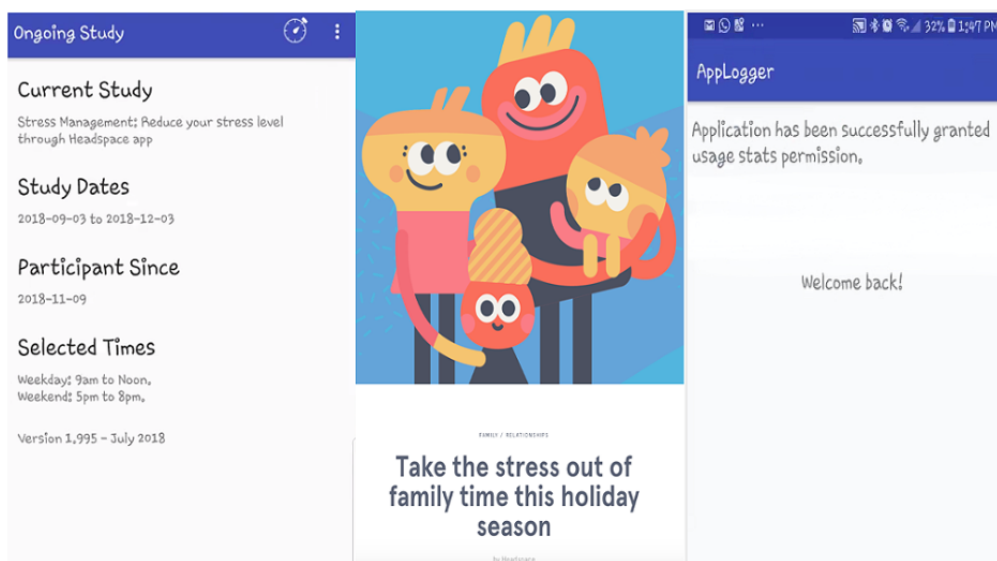
We conducted a 30-day feasibility and acceptability study whereby participants were microrandomized [53] once daily with equal probability to either receive or not receive a prompt recommending engagement in a commercially available mindfulness app (Figure 1). Microrandomizations took place within a time window that each participant prespecified as convenient to receive the prompt. Specifically, during the onboarding session, participants were asked to specify a 3-hour window during the day to receive a prompt encouraging them to practice mindfulness. On the basis of our prior work [47], a 3-hour window was thought to be broad enough but not so restrictive to capture windows of family routines (eg, morning before work or school, work or school lunch or breaks, after work or school dinner, evening activities, or bedtime routines). The time frame can be updated at any point by the user. If a prompt was sent, the participant could either tap the prompt and launch a mindfulness app or dismiss the prompt. Prompt messages were neutral in tone and picked at random from a library developed for the study (eg, "Take your mind to your calm place"; "Use mindfulness to develop your mental toughness"; "10 minutes for yourself can make a huge difference"; and "Give yourself time to recharge"). In the 24 hours following randomization, proximal outcomes of engagement in mindfulness exercises and affect were self-reported via daily EMAs and passively assessed via the smartphone.

Figure 1. Trial design.
Procedure and Ethics Approval

From November 2018 to February 2019, participants were recruited from web-based or social media announcements, word of mouth, and targeted community and workplace recruitment (eg, email notifications via listservs). Announcements included information regarding the study, contact information, and a link to a 3-item eligibility screening survey. Owing to technical aspects of the platform, participant inclusion criteria were as follows: (1) self-identified parent with child or children (aged up to 18 years) at home and (2) an Android smartphone user. The exclusion criterion was non–English-speaking participants. Upon meeting the inclusion criteria, participants provided written informed consent and were enrolled in the study. The setting was the real-world, everyday lives of the participants. Given the formative nature of the proposed work, a convenience sample was used. In appreciation of participant time and feedback, parents were compensated commensurate with participation. Parents were provided compensation for baseline survey completion (US $5), onboarding (US $5), EMA (up to US $15), exit survey (US $5), and a 1-month Headspace Plus paid subscription (valued at approximately US $13). The lead

institution was the Ohio State Behavioral and Social Sciences Institutional Review Board (IRB) with ethical approval from the Ohio State University Office of Responsible Research Practices (IRB #2017B0550).

After obtaining informed consent and completing baseline surveys, participants were provided with onboarding instructions. As part of feasibility testing and formative evaluation, participants were asked to install 3 mobile apps necessary to conduct the research (Figure 2). Two research-developed apps (Beehive and App Logger) were made available to participants through a provided link, while one app (Headspace) was commercially available for download through the Google Play Store. It is worth noting that the research team submitted a request for collaboration with Headspace but owing to timing and resource limitations, the Headspace Health Partnership team was unable to accept our request. However, the principal investigator (PI) communicated with a member of the Headspace team to discuss logistical questions related to onboarding participants. Upon study completion, participants were asked to complete exit surveys and uninstall the research-affiliated apps. Given the commercial availability of Headspace, this app could be continued at the user's discretion.

Figure 2. Research apps Beehive, HeadspaceTM, and App Logger.


Mobile Apps

Beehive

Beehive is a research-developed app that participants installed to guide the delivery of study prompts [54] and the EMA questions. Participants used Beehive to indicate daily wake and bedtime schedules and allowed participants to select the preferred timing for the digital prompts. Specifically, participants were instructed to use the Beehive app to select a 3-hour window to potentially receive intervention prompts encouraging them to practice mindfulness. Parents were informed that they could update the 3-hour window through the Beehive app at any point during the study. The Beehive app also delivered the EMA question at the end of the day and at least one hour before the specified bedtime of each participant.

Headspace App

Prior research has leveraged commercially available tools to support stress regulation and optimize digital health interventions [26,44,55]. We selected Headspace, a commercially available mobile app that includes a wide collection of mindfulness exercises that vary in terms of length and topic [56]. In a review of mindfulness-based iPhone apps and using the Mobile Application Rating Scale [55] to determine app quality, Mani et al [24] found Headspace to have the highest average score. Participants were provided with a code that gave them access to the full Headspace library and were asked to use the app over the course of 1 month. Headspace includes push notifications that participants were asked to disable during the study.

App Logger

App Logger is a research-developed app used to facilitate data collection. It is an unobtrusive mobile app for Android devices that passively records and timestamps smartphone paradata [54]. App Logger was used in prior studies to objectively measure app usage but not content [54,57]. It was used to passively capture smartphone paradata, such as when an app was launched, duration of use (removed from the foreground), and smartphone mode (eg, locked or unlocked). In lieu of a partnership with Headspace, App Logger was used to passively collect relevant smartphone paradata and contribute to a holistic view of engagement.

Measures

Feasibility and Acceptability

Feasibility and acceptability were assessed via participant enrollment and retention rates, satisfaction and acceptability ratings (a benchmark of ≥90%), estimates of use, self-reported engagement with mindfulness exercises (via EMA) and objective engagement with the app (ie, passively collected app usage, patterns, and trends over time), reactions to the intervention, factors affecting implementation ease or difficulty, and the ability of participants to carry out study activities [58]. A research log was used to document the proportion of eligible parents, relative to those who enrolled and subsequently those who enrolled compared with actual attendance. These data were used to inform whether we were able to recruit our target population. We determined whether randomization was feasible

by monitoring software performance and was acceptable by monitoring for aberrant data. Retention rates and reasons for nonparticipation were obtained when possible. A database of prompts sent, date, and timestamps was maintained. Additional smartphone paradata, information regarding smartphone use, were assessed using the App Logger app. App Logger passively records when a prompt is delivered, time from delivery to launching the Headspace app, and duration the Headspace app is open (not content). In addition, App Logger can detect the smartphone mode and setting (eg, on or off or silent, vibrate, or ring mode). We have reported on all study outcomes to determine the extent and likelihood that the intervention was implemented as planned.

Baseline Survey

The baseline survey collected basic demographic information and previous experiences with mindfulness. In addition, we assessed for the personality factor, neuroticism, using the neuroticism subscale of the Big Five Personality Inventory [59,60]. Neuroticism is an indicator of emotional stability, with higher scores suggesting a higher likelihood of vulnerability to stress, anxiety, and nonspecific mental distress [61-63]. The neuroticism subscale consists of 8 items rated on a 5-point scale where 1=disagree, 3=neutral, and 5=agree. To assess depression, anxiety, and stress, we used the Depression Anxiety Stress Scale 21-item (DASS-21) [64]. The DASS-21 has been successfully used in a variety of clinical and nonclinical settings, including parent populations [65-67]. Participants answered each item based on how it applied to them in the past week. Responses ranged from 0=did not apply to me at all to 3=applied to me most of the time. The DASS-21 cutoff values indicate levels such as normal, mild, moderate, severe, and extremely severe within each state; that is, depression, anxiety, or stress.

Ecological Momentary Assessments

Nightly EMAs were scheduled for delivery within 1 hour of participant-indicated bedtimes. We used the Photographic Affect Meter (PAM [68]) to measure the daily affective state. The PAM typically takes users less than a minute to complete, asking users to choose from a grid of 16 photographs arranged in a 4 × 4 grid that most represents their current state. Each image was mapped to the established valence and arousal states. Participants were asked to "touch the photo that best captures how you feel right now." The output of this selection is a positive or negative affect value, which has been validated in multiple trials and shown to be an effective alternative to longer-form surveys [68,69].

Self-reported engagement in mindfulness exercises was measured by asking participants whether they had performed a mindfulness activity. Response options were "Yes, I used the app," "Yes, I practiced on my own," or "No." These options were provided to ascertain how participants engaged in mindfulness exercises, with versus without the app.

End-of-Study Survey

A 14-item survey consisting of both open- and close-ended questions was used to elicit participants' overall thoughts about the study, prompt-specific feedback, and Headspace-specific feedback (ie, prompt delivery, prompt content, and Headspace

app). Survey questions were about general perceived ease of use, usefulness, and satisfaction based on input from prior work with parent populations [47,48], usability [70], and expert recommendations for feasibility and acceptability studies [58,71].

Examples of yes or no questions included the following: (1) Was it easy to get set up and started? (2) Did you dismiss any notifications? (3) Did you find the overall program useful in managing your stress? (4) Would you recommend the program to other parents? Prompt-specific questions included questions such as the following: (1) Was the number of messages sent (frequency) too much, too little, or just right? (2) Was the time when the prompt was delivered helpful, not helpful, or just right? (3) Did you like the wording of the messages: yes or no? (4) Did your feelings toward the notifications change the longer you were in the study? (5) Was there anything that we could have done better? Headspace-specific questions included the following: (1) Did you find the Headspace activities helpful in managing your stress? (2) Did you like the graphics and characters used in Headspace? (3) Can you list one Headspace activity that you liked most and least? (4) Do you think it would be helpful for your kids to use Headspace to learn mindfulness?

Data Evaluation

Feasibility and acceptability were assessed via participant enrollment and retention rates, satisfaction, factors affecting implementation ease and difficulty, patterns of use, and ability of participants to carry out study activities [58]. The proximal outcome, engagement with a mindfulness activity, was assessed in the 24 hours following randomization (when the system would randomize to send or not send a prompt). Engagement in a mindfulness activity was operationalized to disentangle engagement with the app (eg, simply opening the Headspace app) versus engagement with a mindfulness activity (eg, deep breathing with the app or deep breathing on my own without the app). Engagement in any mindfulness activity was assessed along with the affective state (transient emotions) from daily EMAs.

Quantitative data were analyzed descriptively. Benchmarks for recruitment and enrollment efforts were set at ≥50 participants screened and 20 participants enrolled (most studies had a sample of <50 participants; nearly one-third—ie, 6/2, 30%—of studies had a sample of <20 participants) based on a systematic review of similar research [20] and given the pilot nature of the proposed work. Additional indicators of recruitment success

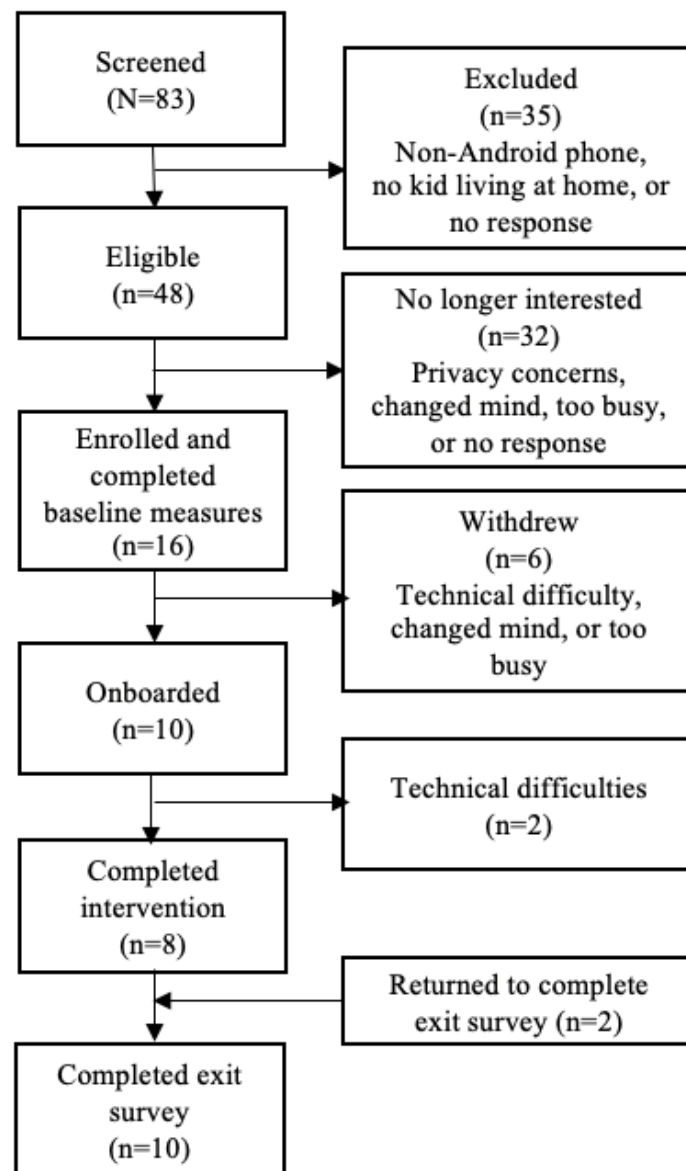
were if ≥24% of the enrolled participants represented racial or ethnic minorities [20]. Owing to limited supporting evidence, we also reported on frequencies of participation from low-income families and fathers (compared with mothers) to help fill the gaps in knowledge. We anticipated 100% success in onboarding and aimed for <20% attrition during the 30-day intervention implementation. We report on response rates to EMAs as we have done in our prior work, with a benchmark for success calculated at 60% or higher (response rate 49% for 35 days [47] and 61% for 30 days [72]).

Qualitative data from free-response questions was narratively summarized by 2 coders representing 2 different disciplines. The study PI (LM) served as the lead coder based on the population and subject matter expertise. The second coder (MS) provided topical expertise on the subject and helped to verify the findings against actual data. Any areas of concern were discussed. The process began with an initial reading of the data before coding. Multiple readings of free-response data were performed to identify key words or phrases. Passages coded similarly were grouped into themes to provide a more comprehensive view of the data.

Results

Sample

Over the course of 4 months, we screened 83 parents who expressed interest in the research. Approximately 42% (35/83) of the parents were excluded before conducting the research, mainly because they were not Android users. Of the 48 eligible patients, 16 (33%) parents were enrolled. Figure 3, the CONSORT diagram, depicts enrollment, participation, and analysis. Most of our sample identified as White and female and were aged between 35 and 44 years. All participants used Android devices as their primary mobile smartphone, with Samsung being the predominantly reported brand (6/10, 60%). At baseline, the sample average score for neuroticism was moderate (approximately 26 out of 40), suggesting a sample not particularly calm nor prone to emotional instability. Similarly, assessments of depression, anxiety, and stress were largely within normal ranges. Although most of the participants reported practicing stress management (13/16, 81%), fewer reported using mindfulness (6/16, 38%) or the Headspace app (1/16, 6%). Table S1 in Multimedia Appendix 1 shows the sample characteristics.

Figure 3. CONSORT (Consolidated Standards of Reporting Trials) diagram.


Feasibility

Recruitment and enrollment were conducted on a rolling basis, but intervention implementation was grouped into waves to prevent overlap with the winter holiday season and to meet logistical needs associated with deploying Headspace bulk subscriptions. As such, most participants were screened and enrolled during the busy winter holiday season (November-December: 12/16, 75%), while efforts slowed after the New Year (January-February: 4/16, 25%). In addition, 12% (2/16) were fathers, 12% (2/16) reported receiving medical assistance, and 6% (1/16) represented a racial or ethnic minority. We were able to meet our recruitment goal but were shy of our enrollment goal and unable to meet our goal to have ≥24% of racial or ethnic minority participation. Enrollment was further aggravated with reductions in sample size occurring during the onboarding process.

Collectively, 50% (8/16) of parents reported technical difficulties during the onboarding process, but 25% (2/8) were

able to overcome these barriers after speaking with a member of the research team. In wave 1, 33% (4/12) of participants were lost during onboarding, and in wave 2, a total of 50% (2/4) of participants were lost during onboarding. Logistical challenges during onboarding can be broadly categorized into two categories: (1) integrating a commercial app into research and (2) using research-developed apps in real-world settings. First, it was necessary for the PI to collaborate with the Headspace team to navigate the logistics of how to purchase and transfer separate Headspace subscriptions to each participant. At the time, Headspace allowed for bulk subscription purchases, akin to a corporate account, but required at least 30 subscriptions to be purchased at once. Furthermore, bulk subscriptions had to be activated on the same day, which was counter to the rolling recruitment research protocol. This was solved in 2 ways. We arranged a small cohort of participants to start the study on the same day using a promo code associated with a bulk subscription. In addition, we provided individual Headspace gift subscriptions to participants via rolling recruitment. Both

strategies allowed parents to download the Headspace app from the Google Play Store and enter a promo code to unlock the premium version of Headspace. Most parents were familiar with the Google Play Store and located the Headspace app for download. In total, 3 of 16 (19%) parents reported that the Headspace promo code did not work when they were onboarding. During these scenarios, the PI helped troubleshoot to resolve the issue. The second challenge was the implementation of the 2 research apps, both available via GitHub. Participants were provided with a direct link to download the research apps. Although the research apps allowed the research team to have greater control, some smartphones triggered a warning during installation. Such warnings may be standard on some Android devices when an app is downloaded from a location other than the Google Play Store. However, parents reported being unfamiliar with downloading apps from outside the Google Play Store:

> I can't download apps from an outside source that isn't Google Play. Unfortunately it looks like I won't be able to participate in the study. [P5]

Similarly, parents voiced concerns regarding privacy and smartphone access, although they were informed that the content was not being monitored:

> I'm fine with it tracking Headspace usage, but I'm a bit concerned if it's monitoring all my app, location, calls or/and keyboard usage. [P7]

> It's like asking someone to put a chair in your living room, even more so it's like asking someone to move in, especially when they are requesting access on your phone. [P4]

Ultimately, 63% (10/16) of the enrolled parents onboarded to the 30-day intervention phase of the study. However, incoming data streams from App Logger were interrupted for 2 of 10 (20%) participants. We were unable to ascertain with certainty whether these interruptions were due to system issues or whether these participants chose to alter or revoke App Logger permissions. Thus, 8 of 10 (80%) parents fully completed the intervention phase and provided the following insights. An average of 10 (SD 5.44) prompts per participant was delivered over the 30 days relative to intended on-average 15 prompts (ie, 50% chance of receiving a prompt × 30 days in the study). Prompt messaging may be found in Multimedia Appendix 2. Across the 8 parents, smartphones were set to the normal ring mode 46% of the time when a prompt was sent (44 observed instances where the smartphone was set to the normal ring mode/95 prompts sent). The average time from prompt delivery to action (eg, either launch Headspace or dismiss notifications) was 185 (SD 303) minutes. A reliable reference point for nonprompt to action was not available; therefore, a comparison analysis was not possible. Figure 4 shows the hour of day (from 0 to 24 hours, after midnight) when a participant opened the Headspace app. The x-axis separates participants, shows the mean as the point, and shows the 95% CI around the mean as error bars. From the 95% CIs, we see visually that the variability in the time of day of opening Headspace differed, with some individuals using Headspace at a more consistent time of day than others.

Proportionally, most prompts were dismissed if the smartphone was in the silent mode (Table 1). The response rate to EMA surveys was 72.4% (ie, 165 EMA responses/228 EMAs pushed).

Figure 4. Distribution of hour of day (from 0 to 24, after midnight) when a participant opened the Headspace app.
Table 1. Smartphone ringer mode when the prompt was sent.

Ringer mode	Value (n=82), n (%)	Was the prompt dismissed?[a]	
		Yes (by mode), n (%)	No (by mode), n (%)
Normal	39 (48)	22 (56)	17 (44)
Silent	12 (15)	9 (75)	3 (25)
Vibrate	31 (38)	18 (58)	13 (42)

[a]The "Value" column was used as the denominator.

Engagement

Engagement With the Headspace App

Over 30 days and across the 8 participants, we counted 298 engagements with the Headspace app from passively collected smartphone data. We noted higher self-reported engagement with the app on days when a prompt was sent (31/62, 50% of days) compared with days without a prompt (33/103, 32% of days). Across the study, most participants (7/8, 87%) in the study self-reported higher engagement with the app on days

with prompts. Engagement with the app was also found to be longer on days with the prompt (mean 566, SD 378 seconds) than on days without a prompt (mean 225, SD 276 seconds). Across the 8 participants, we observed that most engagements with the Headspace app occurred during the first week of the study but subsequently tapered down by week 4. Figure 5 highlights the total duration of engagement with the app by week in the study across the entire sample. The high error bars in weeks 1 and 2 suggest a larger variation in individual use during the first 2 weeks compared with the last 2 weeks.

Figure 5. Total duration of participant engagement with app by week in study across all participants (n=8). Points represent the mean value, and error bars around each point represent a 95% CI around the mean.
The median (IQR) number of engagements with the app per user was 19 (10-55). The median (IQR) duration of each log-in was 45 (15-110) seconds. We discovered 25 discrepancies between reported (yes or no) and observed (yes or no) app usage, where parent-reported data from EMAs indicated app usage, yet we found no recorded Headspace app use on passively recorded data. On exit surveys, 50% (5/10) of parents reported using the app for an average of 5 to 10 minutes per day, and 40% (4/10) reported using the app 1 to 3 days per week.

#### Self-reported Engagement With Mindfulness Exercises (Based on Daily EMAs)

On the basis of when prompts were sent, we observed a multimodal distribution for the time of day when the prompt

was sent, most often during the morning hours, peaking between 9 AM and 10 AM (Figure 6). Proportionally, parent-reported engagement in a mindfulness activity (Table 2) was descriptively similar on days when a prompt was not sent (65/103, 63%) compared with that on days when a prompt was sent (40/62, 65%).

Collectively, parents reported using the Headspace app for mindfulness activity (64/105, 61%) more than engaging in mindfulness activities without the app (41/105, 39%; Table 2).

We observed a change over time. During weeks 1 and 2, parents reported using the Headspace app to support mindfulness activities. However, in weeks 3 and 4, mindfulness activities without the app increased (Figure 7).

Figure 6. Hours from midnight prompts were sent based on the parent-selected time frame. Each bar represents a single hour of the day, and the height of the bars represents the total number of push notifications sent at that specific hour across all participants in the study.

Table 2. Self-reported engagement with any mindfulness activity across all users (n=8).

Parameters	No prompt	Prompt	Total
Ecological momentary assessments collected, n (%)	103 (62.4)	62 (37.6)	165 (100)
Engagements with any mindfulness behavior (with or without the app) indicated by parent report, n (%)	65 (63.1)	40 (65)	105 (100)
Engagements with mindfulness activity using the Headspace app indicated by parent report, n (%)	33 (32)	31 (50)	64 (100)

Figure 7. Self-reported engagement with a mindfulness activity by week in study (n=8). Points represent the average number of ecological momentary assessment (EMA) responses within a week across participants, and error bars represent a 95% CI around the mean value. Each trajectory represents a specific type of EMA response (eg, "Mindfulness without Headspace") as indicated in the legend.
Emotional State or Affect

Across the 8 participants, the top three emotional states captured from the PAM responses were tired, satisfied, and sleepy. We did not observe any patterns or trends in emotional state over the course of the study, nor did we observe any trends between affect and engagement.

Acceptability

Acceptability and parent satisfaction were determined from free-response text on baseline and exit surveys, as well as from communication with parents (eg, during onboarding). Although 2 participants were affected by technology errors impacting EMA collection, they were included in exit surveys (n=10) as their experience could provide additional insight into outcomes. Overall, only 70% (7/10) found the program useful in managing stress, which is below our satisfaction benchmark of 90%. However, 90% (9/10) found the research helpful and would also recommend the program and Headspace app to a friend.

Specifically, most participants liked the wording of the message prompt (9/10, 90%) yet reported dismissing the prompt at some point over the course of the study (8/10, 80%). When specifically asked about the exit survey, 50% (5/10) indicated that the messages could have been more caring (eg, "We care about your health, take a min to manage your stress") or humorous ("funnier"), but not authoritative ("do this now" type of message; 1/10, 10%). The majority (7/10, 70%) did not believe a visual within the prompt (eg, emoji or meme) would be helpful. Participants most often viewed prompts as reminders (9/10, 90%), while some participants (4/10, 40%) reported that

prompts became "more annoying the longer I was in the study." Just over half of the participants reported that both the timing and frequency of prompts were helpful (6/10, 60%). However, responses to open-ended questions highlighted the competing demands for parent attention in the moment:

> I got a notification while I was out running errands. [P9]

> It felt like one more to-do on a long list of to-dos. I occasionally wanted to do mindfulness out and about while waiting for something, but I couldn't download them for offline use. [P3]

> Messages that were trying to be nice felt very tone deaf when circumstances conflicted with them, ie "the stressful part of your day is done" popping up on my phone as my baby is screaming. [P4]

> I had tons of other notifications and I would just delete them all at the same time. [P7]

All participants (10/10, 100%) reported that the Headspace app was easy to use. While the majority (9/10, 90%) liked the *minimalistic and cuteness* of the graphics, 1 parent expressed a strong dislike of the narrator's voice:

> They're simple and kind of cute. [P10]

> They were fun and pretty generic, kind of cute. [P7]

> The voice of the narrator. Not relaxing to be told what to do by a white dude. [P8]

None of the activities emerged as most or least liked. Half of the participants were aware that Headspace had activities for children. While 40% (4/10) thought that using the app would

help their child with stress management, only 1 (10%) parent tried the app with their 3-year-old child and reported that it was not a good experience. At the end of the study, 50% (5/10) reported decreases in stress, 40% (4/10) reported no change in stress levels, and 10% (1/10) reported an increase in stress levels:

> *At the end of the study, I found out I can do mindfulness exercises on my own without the app. The app taught me some tricks which I use a lot.* [P10]

Discussion

Principal Findings

We conducted a feasibility and acceptability study to begin to better understand when, how, and under what conditions a digital health intervention could support parental stress management in real time. The findings of this research demonstrate several areas for refinement before conducting a full-scale efficacy trial. First, in contrast to traditional mindfulness intervention recruitment efforts through mental health centers or community or school settings [20], we were able to meet our screening benchmark solely through efforts taken on the web and word of mouth, which did not include paid web-based advertisements (eg, Facebook advertisements). However, we lost nearly 67% (32/48) of eligible participants during enrollment, just shy of our enrollment benchmark (n=16; the benchmark was 20). This conversion rate is consistent with in-person, family-based health promotion programs, despite our intervention being offered without in-person or telehealth meetings. Parent interest in practical solutions for stress management was reaffirmed by the number of participants screened and eligible. However, subpar enrollment and onboarding (n=10; the benchmark was 16 or 100%) rates highlighted competing demands for parent attention, the need for simplicity in everyday solutions, and the ability to integrate into family routines. For those who completed onboarding, the 30-day intervention delivery was viewed as a success, based on 8 of 10 (80%) participants completing the intervention as intended (the benchmark was 80%) and the 72% EMA response rate (the benchmark was 60%). However, it is important to note that this subset may reflect parents who were highly motivated and technically savvy and may not be generalizable to a larger sample. Furthermore, our sample was predominantly mothers, similar to prior evidence [20], and lacked racial or ethnic diversity (the benchmark was 24%). Recruitment efforts may be strengthened by diversifying recruitment strategies to include both free and paid web-based advertisements, as well as traditional partnerships with the community, schools, and clinics.

Another limitation of the feasibility trial was technology acceptance. Familiarity with the Google Play Store and Headspace brand recognition facilitated onboarding and were viewed as helpful among this sample of parents. While leveraging commercial brands and academic-industry partnerships in research may be beneficial, it is not always possible. Owing to other overwhelming requests for partnership, Headspace was unable to commit to a formal partnership at the time of our request. The formative nature of the proposed work, limited research budget (eg, startup funds), and timing (desire

to align the project implementation with the school calendar when family routines are more stable) likely limited any additional opportunities for partnership. Therefore, we used research-developed apps to capture smartphone paradata that would otherwise be proprietary to gain insight into real-world settings. In addition to passively capturing when and for how long the Headspace app was open, App Logger provided objective smartphone paradata that may have been otherwise overlooked, such as if a smartphone was set to silent when a prompt was delivered. However, technology acceptance of research-developed apps was impacted by concerns about privacy and familiarity, similar to other research [73,74]. The most notable challenge during onboarding was downloading an app from outside the Google Play Store (eg, GitHub). Unfamiliarity with installing apps from a source other than the Google Play Store contributed to inquiries from 50% (8/16) of the enrolled parents. Reliance on only Android devices is a common limitation of many mobile health studies that use open science research-developed apps. The Android operating system allows third-party apps to sample from more sensors and system smartphone logs than apps running on the Apple operating system. Efficient and cost-effective solutions in cross-platform mobile development are needed by industry (eg, Google and Apple) to help streamline resources available to researchers [75,76]. Conversely, in lieu of familiarity or brand recognition, family health researchers need to identify strategies for data collection that reduce participant burden (eg, passive data collection) but are viewed as acceptable.

Owing to variability in the literature, no benchmarks have been established for prompt verbiage, timing, or frequency. We deemed prompt wording acceptable in this population (9/10, 90%). However, both prompt frequency and timing were deemed unacceptable owing to subpar ratings (6/10, 60%), despite parents having control over prompt timing and prompt frequency subject to randomization. In exit surveys, most parents indicated that the prompts came at inconvenient times and were often viewed as reminders. Most dismissed the prompt at least once over 30 days (8/10, 80%). If a prompt was dismissed, most parents reported that it was because they were too busy. Only 1 of 10 (10%) parents reported that the study prompt was one of the *tons of other notifications* and would just delete them all. We found a lag of approximately 185 minutes from prompt delivery to action (eg, either launch Headspace app or dismiss notifications), which is congruent with other studies that found a delay of approximately 163 minutes between notification and action [51]. We observed the time-of-day variability for when the Headspace app was opened, noting that some participants tended to use the Headspace app around the same time each day, more so than others. However, there was insufficient data to investigate whether participants habituated to using the Headspace app during a particular time or in response to a prompt. This hypothesis is worth investigating in future trials to further inform habit formation. The literature is mixed on whether it is beneficial to give participants control over when a prompt is delivered. Prior research shows that both user-designated times to receive a prompt and giving the user control of prompt timing failed to enhance the use of a smartphone stress management app [77]. Intelligent prompts guided by sensor-driven machine learning algorithms that adapt

to the user's context may be beneficial for increasing user engagement [77-79]. It has also been suggested that tools to unobtrusively gauge and manage day-to-day stress may be improved by considering contextual information [34,40,80]. However, other research has shown that after 20 days of receiving machine learning suggestions, participants favored self-selecting their intervention, potentially seeking novelty after the algorithm became too locked in or limited in offerings [78]. However, little has been done to understand the nuanced context of everyday family life. We found that while most parents reported using a calendar to facilitate work and family schedules, family calendars captured the exceptions to everyday family routines (eg, appointments or practice) but did not account for daily family activities such as dinnertime, laundry, homework, crying babies, etc. A needs assessment conducted with a larger, more diverse sample and within the context of everyday family life may help to not only determine opportunities for stress support but may also help to identify how much support is needed based on stress severity.

Across all participants, we observed collectively higher engagement with the app on days when a prompt was sent and for a longer duration compared with days in which a prompt was not sent. However, engagement with apps decreased over time. This parallels other research suggesting that prompts impact near-time engagement with the app [30,77] but are not sustained over time [29,43,77,78]. We did not observe a descriptively higher engagement with any mindfulness activity on days when a prompt was sent. We observed more instances in which mindfulness activities were supported by the app versus without the app. Unfortunately, the Beehive app was only able to timestamp when a prompt was sent and unable to capture and record participant-indicated time frames for when to receive the prompt. On the basis of when prompts were sent, we observed peaks during the late morning and night hours. These findings are consistent with findings from a recent review of objective user engagement with 93 mental health apps [81]. Baumel et al [81] found that mindfulness apps were among the most used, with patterns of use exhibiting two peaks, in the morning (7 AM-9 AM) and at night (10 PM-midnight). We also observed that engagement with Headspace was higher in weeks 1 and 2 than in weeks 3 and 4. By weeks 3 and 4, we observed a potential trade-off, where trends in both self-reported and passively collected data indicated a decrease in app usage, while parent-reported mindfulness without the app increased. These findings suggest that mHealth interventions may help parents to learn or practice stress-regulating skills, to be further practiced or applied independent of the app.

In this study, we objectively observed app usage and self-reported interactions with the Headspace app. Most observed interactions with Headspace were ≤60 seconds in duration, while self-reported interactions averaged 5 to 10 minutes per day. This apparent discrepancy between the observed and reported values may reflect a few different scenarios. Unfortunately, a third EMA option to report using both strategies (mindfulness with the app and on their own) was overlooked during development, which may have contributed to some of the discrepancies. Findings may show a response bias, in which parents responded in a manner perceived as desirable. Alternatively, the discrepancy may reflect parents' perceived time actually spent engaging with the app, such as on days when a prompt was sent. Finally, the prompts were capable of launching the Headspace app. Observations may reflect instances where parents intended to dismiss the prompt but accidentally launched and then closed the app. However, this finding is not necessarily a discrepancy and might reflect the self-reported aggregation of interim engagements throughout the day.

The findings suggest that parents may benefit from flexible interventions, allowing freedom to learn the necessary skills and practice or apply them during more resource-limited times. This is further supported by our findings that although app usage decreased over time, the use of learned skills increased over time. On the basis of this observation, disengagement with the app is not necessarily a negative finding. As suggested in the literature, sufficient versus sustained engagement may be a more useful gauge of engagement [34,41]. More research is needed to understand how much exposure to intervention content is necessary to support stress regulation. Despite the brief duration of app engagement, parents in this study reported that Headspace was easy to use and helpful in managing stress. Although the evidence favors a reduction in negative affect following a mindfulness intervention [22,82,83], we did not observe any patterns or trends. In a pilot study by Champion et al [26], participants who used Headspace showed improvements in self-reported life satisfaction, resilience, and perceived stress after 10 days, with medium to large effect sizes found in self-reported life satisfaction, resilience, and perceived stress after 30 days of use. However, participants in that study reported engaging with the app for at least 10 minutes per session and averaged 6.2 days use out of the first 10 days [26]. Other mHealth stress research examined the effects of microinterventions (eg, using a text prompt that instructs the user what to do along with a link to support the skill) [78]. They found benefits for interventions lasting >60 seconds, but those benefits diminished with usage time greater than approximately 200 seconds [78]. Morrison et al [77] found the average participant log-in to a smartphone stress app to be 4 minutes (240 seconds). They concluded that the timing and frequency of push notifications may increase the exposure to intervention content, but not necessarily use [77]. Prior research suggests that a few days of quick log-ins may be sufficient to enable users to learn new skills to practice without continued guidance from the app [41,47,77]. Breathing exercise apps have one of the lowest 30-day retention rates relative to apps that incorporate mindfulness, trackers, and peer support [81]. However, mindfulness apps often design guided meditations for repeated use [81]. Headspace activities favored by parents in this study focused on breathing, tips on how to make mindfulness a part of their day, and restlessness and sleep. Another strategy to consider in future work is to use a stealth health approach, where the intervention is woven into existing routines and the target (eg, stress management) is a side effect but not a primary motivator for participation [47,84].

Limitations and Future Directions

This was a pilot MRT feasibility study designed to address the following question: *Can it work?* [58] Despite a myriad of

recruitment strategies, it was challenging to recruit parents. Participants self-identified as parents who experienced stress and were interested in learning more about how mindfulness might help manage stress. Parenting stress, as evidenced during the pandemic, comes with unique challenges that differentiate this population from the general public. Our sample was predominantly White and female. This is similar to data on the characteristics of paid subscribers to the Calm app, another consumer-based mindfulness app [27]. Calm app users are also predominantly female (8778/10,981, 79.94%). It was difficult to recruit men or fathers compared with women or mothers and diverse populations, which is similar to several other family-based studies [47,85,86]. However, we strongly recommend conducting a needs assessment among diverse groups in future research efforts to include fathers, low-income populations, and racial or ethnic minorities who are often underrepresented in this literature. Finally, more research is warranted among pediatric populations, given the interrelated health between the parent and child. We found that parents did not use or find the Headspace kid pack useful. This differs from recent findings among a sample of parents who use the Calm app [87]. Just over half of the parents who use Calm (1537/2944, 52.21%) reported that older children used Calm to reduce stress, whereas younger children used Calm to improve sleep. A recent review of preventive digital mental health interventions for children and young people (n=21 interventions) found a need for more (1) research among children aged ≤10 years, (2) co-design processes with children, and (3) research among children from vulnerable and underserved backgrounds [88].

Conclusions

Preliminary findings suggest that parents are receptive to using mindfulness apps to support stress management, and prompts are likely to increase engagement with the app. However, we identified several implementation challenges in the current trial, specifically the need to optimize prompt timing and frequency as a strategy to engage users in preventive digital health. Commercially available mindfulness apps appear acceptable among this sample of parents and may provide an opportunity to expose parents to mindfulness skills that may be later practiced without the app. More research is warranted to understand how much time is necessary to spend using a stress management app for parents to learn the necessary skills and translate those skills into everyday life. As the field of mHealth evolves, strategies to engage users in preventive digital mental health interventions must also evolve to increase the likelihood of intervention success.

Authors' Contributions

LM, MS, and DAA wrote the original manuscript. MS, LM, FO, and INS designed the study. LM served as the lead principal investigator and led recruitment, study implementation, and data collection efforts. FO and MS designed and implemented research-developed mobile apps for this study. DAA, MS, and LM conducted all the statistical analyses. All authors edited and reviewed the final manuscript.

Conflicts of Interest

Headspace gifted the study with 10 30-day trial subscriptions free of charge. DAA is co-employed by United Health Group outside of the submitted work.

Abstract

Background: In Egypt, the shortage of mental health services, particularly for adolescents and young adults, is apparent. Electronic mental health (EMH) has been proposed as a solution to bridge the gap and better address the needs of young people. However, EMH is new to Egypt and its acceptability among target populations is crucial to its implementation and success.

Objective: The objective of this study is to explore the interest of Egyptian youth in EMH, identify perceived barriers to EMH, and inform the design of EMH tools to best address the needs of youth.

Methods: A web-based cross-sectional survey was distributed among medical students at Tanta University in Egypt. Chi-square and one-way analysis of variance tests were performed for inferential analyses using a significance level of .05.

Results: Of the 707 individuals who completed the survey (90.9% response rate), 60.5% (428) were female, 62% (438) lived in urban and suburban areas, and the mean age of the sample was 20.5 (SD 1.8) years. The vast majority of participants (522/707, 73.8%) had already used the internet to find information about mental health problems, but the information was unsatisfactory for about half of them (386/707, 54.6%). Almost all students reported that they would prefer web-based therapy if EMH were available through a trustworthy national web-based platform for youth mental health (601/707, 85%). Students believed that emotional difficulties, social support, and coping strategies were the main topics that EMH should help with. The most common perceived barriers for EMH use in Egypt were concerns about privacy (382/707, 54%) and a lack of technology literacy and unfamiliarity with EMH (352/707, 50%).

Conclusions: EMH is a promising strategy for addressing gaps in the mental health care for young people. To construct and implement a digital system of care that addresses the unique needs and preferences of youth, adolescents and young adults should be involved in the co-development and design.

Introduction

Globally, mental illness is the most common health problem among postsecondary students [1]. Moreover, without access to appropriate treatment services, mental health problems often worsen throughout an individual's adult life [2]. It is well established that mental health services are extremely scarce in low- and middle-income countries, estimated to be 200 times lower than that in high-income countries [3]. Youth in low-income countries who struggle with mental illness therefore

represent a particularly vulnerable population [1,4]. The aim of this study is to explore electronic mental health (EMH) as a promising strategy to address gaps in the mental health care of young people in the low-income world, by specifically interacting and engaging with students in Egypt.

Though half of the Egyptian population is under the age of 25 years, health care structures are not well equipped to handle mental illness in youth [5]. In a national study of 13,000 high school students in 3 different regions of Egypt, 20%-30% of students had mental health problems, with similar rates reported in several other studies [6]. In Egyptian universities, the prevalence of mental illness is even higher, with up to 37% of undergraduate students fulfilling the criteria for moderate depression [7]. However, there are only 1.44 psychiatrists and 0.11 psychologists per 100,000 people in Egypt [8], and the shortage of mental health services is particularly apparent for youth [5]. Within the government's mental health workforce, only roughly 3% work in child and adolescent services [9]. Moreover, only around 1% of health care professionals who work in schools are trained in mental health [8].

To provide care, improve access, and build capacity, web-based resources have become increasingly necessary tools, especially during the COVID-19 pandemic [10,11]. EMH interventions have proven effective in providing mental health services to different vulnerable youth populations and have been increasingly used across the world [12]. EMH domains include web-based resources for mental health, such as information, risk assessments, professional and peer counselling, group therapy, cognitive behavioral therapy, and telepsychiatry, that address the plethora of mental illness comorbidities. Implementation of these tools is an iterative process that includes co-development for specific youth populations. Successful EMH platforms for youth mental health services have been developed in different jurisdictions, including Australia, Ireland, and the United Kingdom, with varying designs and methods [12,13]. Such technology-based interventions are also more accessible and cost-effective [14]. According to recent evidence, many Arabs would rather use EMH services than visit a mental health provider, which would help them overcome some preexisting barriers such as stigma, cost, and physical distance [15]. Interestingly, the use of EMH in conjunction with medication-assisted treatment has proven more effective than standalone treatment for substance use disorders in youth [16]. A major strength of web-based interventions is the ability to provide youth with a continuum of care, starting from early diagnosis to continued peer and professional support [17].

EMH is especially relevant to the Egyptian health care system given the high burden of mental health problems, low access to available resources, and high internet accessibility and mobile phone ownership [18]. Existing studies have investigated the implementation and use of platforms such as electronic medical records in Egypt, but no studies have evaluated how youth perceive these technologies [19]. Psychiatrists in Egypt have agreed that EMH could be the solution to building necessary capacity for youth mental health care, especially given the scarcity of resources for this demographic and familiarity with technology among youth [20]. Despite the ubiquity of smartphones and internet access in Egypt and in other Arab

countries, EMH is largely an untapped resource [21,22]. Attempts have already been made using Arabic mobile apps for depression and anxiety, but clear gaps are evident given the low quality, lack of engagement, and absence of evidence-based resources [23]. Crucial to the development and implementation of EMH in Egypt is the opinion of target populations, namely adolescents and young adults. Little is known about the types of mental health information sought by young people on the internet, how EMH can address their needs, and their perceived barriers to using EMH.

The objectives of this study are to gauge the level of interest of Egyptian youth in EMH approaches, highlight features of web-based interventions that are most appealing to students, and identify the perceived barriers to using EMH in this population. Responses were analyzed by gender and living region to best determine the mental health needs of particular target groups among youth. The findings of this study aim to help inform the development and design of EMH tools that best address mental health issues among youth not only in Egypt but also in other Arabic countries. More broadly, this formative research is an integral part of program development, as it explores the feasibility and acceptability of EMH among Egyptian youth before large-scale summative evaluations such as randomized controlled trials.

Methods

Survey Design

The survey instrument was initially developed by researchers and health care providers from Tanta University, Tanta, Egypt, and the University of British Columbia, Vancouver, Canada, as part of an ongoing collaboration regarding student mental health. Following its design, 11 students from Tanta University (6 females and 5 males; mean age 20.4 years) were invited to participate in a preliminary analysis of the survey instrument in two 1.5-hour sessions. After revising the instrument based on comments from the students in the workshops, the survey was piloted with a sample of 60 students from Tanta University. Some questions were again modified based on student feedback to improve the overall quality of the instrument. The final version of the instrument was then distributed within the student body of the Faculty of Medicine at Tanta University. Medical school students from Tanta University were selected as the target sample because of their high health literacy level and their ability to address broad issues related to health and well-being and to understand the culture, etiquette, and customs of the general Egyptian public [24].

The survey consisted of 28 questions and included multiple choice questions, dichotomous questions, and Likert scales. The survey was in English since medical education in Egypt is also delivered in English. The survey consisted of both quantitative and qualitative questions meant to explore patterns of internet use and EMH strategies, thereby giving youth a platform to voice their attitudes toward and perceptions of EMH.

Recruitment

The survey was distributed within the entire student body in October 2019, thereby including students from all 6 years of

medical school. Participants were recruited by nonrandom sampling via the student council. The student council of the Faculty of Medicine at Tanta University was provided with a hyperlink to the consent form and questionnaire; the council then sent this link to all students within the student body. When respondents clicked on the link, they were first asked if they were interested in participating in the study. Only those who ticked "yes" could access the survey. Participants were reminded that they could withdraw at any time without giving any justifications and without any negative consequences. Participants were permitted to skip any question they were unwilling to answer and could change any answer over the course of the entire survey. Participation was voluntary and students did not receive any reimbursement.

The following description of EMH was provided to the participants: "E-Mental Health refers to the delivery of mental health services (treatment, information and support) via the internet or mobile phone. This can be through websites, web applications, video conferencing, chat or email. Some of these services, such as video conferencing or online counselling, involve direct one on one contact with a mental health professional. Other e-mental health services, such as web applications or information websites, involve less or no contact with mental health professionals" [25].

Data Collection and Analysis

Responses were collected electronically using the Qualtrics platform. To eliminate the possibility of duplicated responses, students were allowed to access the survey only once. All data gathered by this study are confidential and anonymous. Chi-square and one-way analysis of variance tests were performed for inferential analyses using a significance level of .05. Descriptive and inferential statistical analyses were executed using SPSS 25 (IBM Corp, 2017) [26]. The results from the web-based survey have been reported according to the Checklist for Reporting Results of Internet E-Surveys [27].

Ethical Considerations

The study received approval from the Tanta University Ethics Board (31674/07/17). All participants provided informed consent.

Results

Participant Demographics and General Internet Use

The web-based survey link was opened by 778 Egyptian medical school students, of which 707 consented and completed the survey (90.9% response rate). More than half the number of participants were female (428/707, 60.5%), and the mean age was 20.5 (SD 1.8) years (Table 1). All academic years, from first to sixth, were represented in our sample. The majority of participants were living in urban and suburban areas (438/707, 62%), while only 38% (269/707) were living in rural areas (Table 1).

When asked about their internet use, almost all the participants (652/707, 92.2%) said that they used the internet several times a day. Participants mainly accessed the internet using their smartphone (689/707, 97.5%) and mostly from their homes (692/707, 97.8%). The main reasons for using the internet included communication and social media (622/707, 88%) as well as information gathering (611/707, 86.4%; Table 1).

Table 1. Participant demographics and internet use (N=707).

Demographics	Value, n (%)
Gender	
Female	428 (60.5)
Male	279 (39.5)
Age (years)	
18	66 (9.3)
19	215 (30.4)
20	116 (16.4)
21	82 (11.6)
22	125 (17.7)
23	64 (9)
24	15 (21)
25	24 (3.4)
Region	
Urban and suburban	438 (62)
Rural	269 (38.1)
Frequency of internet use	
Several times per week	23 (3.3)
Once per day	32 (4.5)
Several times per day	652 (92.2)
Device	
Computer	247 (34.9)
Smartphone	689 (97.5)
Another device	67 (9.5)
Place of internet use	
Home	602 (97.9)
University	351 (49.7)
Public areas or transport	306 (43.3)
Other	96 (13.6)
Main reasons for internet use	
Information (content)	611 (86.4)
Support (community)	215 (30.4)
Communication (social media)	622 (88)
Electronic commerce (e-commerce)	52 (7.4)
Gaming	276 (39)
Others	156 (22)

Internet Use for Health Information

The vast majority of participants used the internet to find information about physical and mental health problems (595/707, 84.2% and 522/707, 73.8%, respectively), but the information found on the internet was satisfactory for only about half the number of participants (386/707, 54.6%; Multimedia Appendix 1). Use of the internet to find information about mental health problems was not significantly different between genders and living regions, but significantly more women than men used the internet to find information on physical health problems (373/428, 87.2% vs 222/279, 79.6%; P=.007; Multimedia Appendix 1; Table 1). Significantly more individuals from rural areas preferred Arabic to English, in terms of the language of information on the internet (P=.001).

Participants revealed that the main reasons for using the internet as a source of web-based mental health help was convenience, user-friendliness, and privacy (696/707, 95.6%, 604/707, 85%, and 594/707, 84%, respectively; Figure 1).

Figure 1. Advantages of web-based interventions. Participants were asked whether they agreed with, disagreed with, or were neutral (neither agreed nor disagreed) toward various advantages of web-based interventions.
Knowledge of and Interest in EMH

Over half the number of participants (388/707, 54.9%) did not know that mental health websites and mobile apps existed, and about half the number of participants (359/707, 50.8%) said that web-based mental health services would be an attractive option for them (Table 2). About half the number of participants (366/707, 51.8%) said that they would prefer web-based therapy to conventional psychotherapy. Almost all students (601/707, 85%) reported that they preferred web-based therapy if EMH were available through a trustworthy national web-based platform for youth mental health (Table 2).

Table 2. Knowledge of and interest in web-based mental health services (N=707).

Characteristic	Value, n (%)
Knowledge of preexisting mental health websites and applications	
Yes	319 (45.1)
No	388 (54.9)
Web-based mental health services as an attractive option	
Yes	359 (50.8)
No	107 (15.2)
I don't know	241 (34.1)
Preference for web -based therapy over conventional psychotherapy	
Yes	366 (51.8)
No	341 (48.2)
Preference for web-based therapy if available through a trustworthy national platform	
Yes	601 (85)
No	106 (15)

Knowledge about EMH services was significantly different between genders and living regions (*P*<.001 and *P*<.007, respectively; Multimedia Appendix 1; Table 1). Males (149/428, 53.4%) and individuals living in urban areas (215/438, 49.1%) knew more about existing mental health websites and apps than females (170/279; 39.7%) and individuals living in rural areas (104/269, 38.7%), respectively. There were no significant differences in terms of interest in EMH between genders and living regions (Multimedia Appendix 1; Table 1).

Priorities for and Barriers to EMH Development

Participants believed that emotional difficulties, social support, dealing with stressors, and coping strategies were the main topics that EMH should help with (Table 3). When asked about how participants wanted the information on an EMH platform to be delivered, most participants suggested videos explaining mental health topics (539/707, 76.2%); skills training for improving coping strategies, time management, and self-care (381/707, 53.9%); and web-based mood and behavior assessments (351/707, 49.6%). The most common perceived barriers to EMH use were concerns about confidentiality and privacy issues (382/707, 54%), uncertainty toward and unfamiliarity with EMH (352/707, 50%), and technical difficulties (242/707, 34%).

Table 3. Priorities for and barriers to electronic mental health development (N=707).

Characteristic	Value, n (%)
Priorities for EMH[a]	
Emotional difficulties	431 (60.1)
Social support	424 (60)
Dealing with stressors	420 (59.4)
Learning coping strategies	403 (57)
Mental health	365 (51.6)

[a]EMH: electronic mental health.

There were many significant differences between genders and living regions (Multimedia Appendix 2; Table 2). More women thought that web-based platforms should help in dealing with stressors (*P*=.03) and self-harm behaviors (*P*=0.03), whereas more men were interested in seeing web-based platforms help with coping strategies (*P*<.001), sexual education (*P*<.001), and

substance use (*P*=.02). Individuals living in urban areas reported coping strategies (*P*=.01), sexual education (*P*=.001), and cultural- and religious-sensitive topics (*P*=.003) as priorities.

Discussion

EMH

Among Egyptian university students between 18 and 25 years of age, the vast majority report using the internet mainly for social media and general information gathering, which are findings similar to those of previously reported surveys in the same age group from different countries such as the United States, England, and Spain [28-30]. Moreover, Egyptian youth use the internet to find information about mental health, which was also seen among European students [31]. The internet is certainly a popular source of information for youth around the world and seems to be an accessible medium for mental health information.

In Egypt, there is high demand for EMH services that are safe and reliable, and which may be well addressed by a nationally supported platform. A notable example of such a trustworthy and nationally implemented EMH program is eheadspace in Australia, which provides web-based and phone support services to vulnerable youth [32]. eheadspace includes 3 different tools, including group chats, web-based interactive dashboards, and private chats. Group chats increase communication and better enable web-based discussions facilitated by mental health professionals between students and like-minded individuals. The dashboard allows vulnerable youth to collect and manage resources that they find helpful for their daily routines [32]. Private chat sessions accompanied by health professionals can provide youth with intimate conversations that help meet their own individual needs [33]. Since its launch in 2012, eheadspace has created a fully operational eMental health digital ecosystem with an eMental health portal that provides funded services to Australian youth. eheadspace has proven to be an effective solution and has been a key part of the infrastructure addressing mental health among Australian youth [34]. Countries in the Middle East could follow suit to create effective and much needed EMH platforms across the region.

Web-based therapy relative to conventional therapy would be preferred for many Egyptian students if they were diagnosed as having mental illness. This is consistent with findings of an Iranian study showing that students were more willing to use EMH services if available [35]. Conversely, a majority of Irish university students reported preferring face-to-face support rather than web-based support for a mental health problem because it was more reliable and allowed better communication [25]. This discrepancy between youth of different countries, mainly European and Middle Eastern countries, is likely due to several different factors such as stigma around mental health and accessibility to in-person mental health services. Indeed, the scarcity of face-to-face services and resources in Egypt could push students toward web-based solutions if those are most available to them. Students in Egypt reported accessibility and convenience among the main reasons for preferring EMH as a solution for mental health support along with other important benefits such as anonymity and mitigating stigma. More

generally, individuals with mental health issues tend to be less resistant to the use of EMH programs if these are effective, and they report willingness to pursue services if these are made easily accessible to them [36].

Differences in EMH Needs

As expected, women and men reported different perceived needs and opinions regarding web-based services. For instance, women seemed more interested than men in searching the internet for physical health problems possibly because of a higher prevalence of stigma experienced by women with mental illness that leads to the somatization of psychological symptoms, which is common in Arab countries [37]. In terms of priorities for EMH, women expressed more interest in interventions that could help address self-harm behaviors and that could help deal with stressors. Conversely, men seemed to want EMH interventions to provide education on coping behaviors, sexual education, and substance use. Moreover, individuals living in rural and urban areas also reported varying needs. For instance, rural populations seemed to prefer the language to be Arabic on the internet, whereas urban populations preferred English. This highlights the importance of considering language in the provision of web-based resources. The different needs of the various subpopulations demonstrate the importance of providing mental health information that is as individualized as possible. In general, it seems that the relationship between patients and physicians has become less hierarchical and more client-provider oriented [38]. EMH solutions can address a wide variety of issues in this regard and offer functionalities to tailor content to the needs of the individual, for example, by gauging a user's need through in-app assessments [39].

Barriers to EMH

The most important perceived barrier for Egyptian students was confidentiality and privacy of personal information. This is in agreement with the results of a web-based survey that examined consumer expectations and potential challenges of EMH services across several countries such as Australia, Iran, the Philippines, and South Africa [35]. Interestingly, the highest rates of participant willingness to try EMH services are seen in low-income countries such as Iran and Egypt, which also reported a high number of barriers and concerns with patient confidentiality and the protection of personal information [35]. It is important for program developers to recognize the functional and technical assistance that individuals may need to use such services [35]. In high-income countries, there seems to be less concern with how data are handled, possibly because of past positive experiences in dealing with sensitive information on already developed web-based health platforms [40]. Another common concern among Egyptian students was their unfamiliarity with the range of functionalities in EMH as well as technical approaches. These findings were similar to those of another cross-sectional study of university students in the United Arab Emirates, in which half the number of participants had never heard of mobile mental health care apps and 75% had never used these kinds of apps even during the COVID-19 pandemic [41]. Considering that the survey sample consisted of medical school students, familiarity is likely even lower in the general young population and thus the barriers to EMH use

could be greater. These findings highlight the need for increased discussions around the use of EMH in the Middle East. EMH should be a topic in the curriculum for all Middle Eastern students to increase their comfort with it, thereby furthering its implementation and acceptability. Increasing the presence of EMH resources in the everyday lives of youth would also allow for better co-design and collaboration between developers and students. This would help address concerns on the validity and reliability of the available content, which was also highlighted as a perceived barrier by the youth in our sample [42].

Limitations

The findings are not completely generalizable to the general young population because the sample comprised well-educated and technologically savvy students. Moreover, the questionnaire was web-based, and all participants had to use the internet to complete the questionnaire, which demonstrated at least some degree of digital literacy. It must also be considered that all students at this particular university are expected to use the internet as a way of staying up to date on courses. Future studies should examine perceptions about EMH in other subpopulations in Egypt, such as in university students from other specialties (not health care related) and youth not enrolled in postsecondary educational programs.

Conclusions and Implications

The findings of this study highlight that young people attending university are active users of the internet and are willing to use the internet for mental health information and support. EMH is therefore a feasible strategy for addressing gaps in the mental health care for young people in Egypt. Moreover, target populations (eg, males vs females, urban vs rural) as well as topics of interests (eg, self-harm, substance use) must be considered when implementing web-based solutions, given the different needs and preferences of these populations as outlined by this study. Finally, EMH platforms should prioritize informational videos and skills training modules as a way to display content while also addressing privacy and confidentiality issues, which were identified as barriers to EMH use among Egyptian students.

Based on the results of this survey, a virtual mental health clinic is being developed for the students at Tanta University, which will be the first web-based and evidence-based intervention designed specifically for university students in Egypt. The clinic, which will be developed in collaboration with international and local experts, will provide support to students and begin to address gaps in the mental health care for young people in Egypt. Nevertheless, further studies in this area are needed to better understand the feasibility of EMH in the broader Egyptian population and in other Arabic countries. Researchers and mental health clinicians in the Middle East must work together with the youth in their countries to develop and implement web-based interventions that are accepted and used by this population. Students should strive to develop and use EMH platforms to provide compassion and love for the generations to come.

Abstract

Background: Older adults are at an increased risk of falls with the consequent impacts on the health of the individual and health expenditure for the population. Smartwatch apps have been developed to detect a fall, but their sensitivity and specificity have not been subjected to blinded assessment nor have the factors that influence the effectiveness of fall detection been fully identified.

Objective: This study aims to assess accuracy metrics for a novel fall detection smartwatch algorithm.

Methods: We performed a cross-sectional study of 22 healthy adults comparing the detection of induced forward, side (left and right), and backward falls and near falls provided by a smartwatch threshold-based algorithm, with a video record of induced falls serving as the gold standard; a blinded assessor compared the two. Three different smartwatches with two different operating systems were used. There were 226 falls: 64 were backward, 51 forward, 55 left sided, and 56 right sided.

Results: The overall smartwatch app sensitivity for falls was 77%, the specificity was 99%, the false-positive rate was 1.7%, and the false-negative rate was 16.4%. The positive and negative predictive values were 98% and 84%, respectively, while the accuracy was 89%. There were 249 near falls: the sensitivity was 89%, the specificity was 100%, there were no false positives, 11% were false negatives, the positive predictive value was 100%, the false-negative predictive value was 83%, and the accuracy was 93%.

Conclusions: Falls were more likely to be detected if the fall was on the same side as the wrist with the smartwatch. There was a trend toward some smartwatches and operating systems having superior sensitivity, but these did not reach statistical significance. The effectiveness data and modifying factors pertaining to this smartwatch app can serve as a reference point for other similar smartwatch apps.

Introduction

The risk of falling increases with age. Approximately 30% of people older than 65 years and living in the community have a fall at least once a year, with an increase of 5% each year [1]. The incidence is even higher in those living in aged care facilities [2]. This is a major public health problem leading to injuries [1,3], loss of quality of life [1,3], loss of independence [1], placement in assisted-living facilities [4,5] and premature mortality [3]. Fall-related injuries represent 21% of the total health care expenses due to injuries [3] and between 0.85% and 1.5% of the total health care expenditure [6]. Lying on the floor

for a long time after a fall has been associated with serious consequences, with a greater likelihood of hospitalization, decline in activities of daily living, placement into long-term care, and mortality [4,5].

Assistive technologies such as call alarm systems and personal emergency response systems are increasingly available. This also holds true for wearables, defined as devices that can be worn or are in contact with human skin to continuously and closely monitor an individual's activities without interrupting or limiting the users' motions [7]. These are cost-effective in reducing hospital admissions when used within emergency response systems [8,9]. However, these systems are not always used by consumers, in part, due to difficulties activating them, including cognitive impairment at the time of, or prior to, the fall [5].

There is an increasing interest in using sensor systems embedded in smartwatches for health care purposes [10,11]. This is particularly the case with falls detection. Although there are several fall detection devices and apps, none to our knowledge have been subjected to a blinded study to evaluate effectiveness, particularly with a variety of smartwatches and smartphones using different operating systems. This study aims to address these issues.

Methods

Ethics Committee

The procedures followed in this study were conducted according to the principles of the World Medical Association Declaration of Helsinki and were approved by the University of New South Wales and St Vincent's Hospital Human Research Ethics Committee jointly (16/229). The study was independently audited.

Study Design

This is a cross-sectional blinded study comparing the fall detection classification provided by a smartwatch algorithm with a reference standard's classification, in this case, a video record of induced falls.

Participants

A total of 22 volunteer participants deemed to be medically healthy were recruited after satisfying all the inclusion and exclusion criteria. Participants were recruited by distribution of a leaflet on the university campus and compensated for their time. The inclusion criteria were males/females older than 18 years willing and able to provide written informed consent prior to initiation of any study-related procedures. Participants were excluded if they had any of the following: disability that may prevent them from completing the study (eg, severe illness), being suspected of or having a known allergy to any components of the smartwatch, having any injury or medical condition that would be adversely affected by an induced fall, and being pregnant.

Smartwatch Threshold Algorithm

This study used a threshold-based algorithm programmed for different smartwatches. The threshold-based algorithm running on the smartwatch app uses threshold values, or settings, to automatically detect a fall. The frequency of the smartwatch accelerometer is 2 kHz with the algorithm of the app collecting data every 0.01 seconds. The algorithm follows strict rules for the three phases of a fall, as shown in Figure 1. The algorithm was supplied by My Medic Watch.

T1 is defined as the time during which the smartwatch is moving toward the earth (fall time) recording a low acceleration, lower than 1G. T2 is the time during which the smartwatch hits the ground, recording a very high positive acceleration for a short period of time. T3 is the time during which the smartwatch is "almost" immobile on the ground for a long period of time. These threshold values are optimized in the app according to the particular smartwatch and body morphology, including body weight and height. Optimization was performed during the test falls.

A near fall can be recognized when all, or one, of the accelerometer data are close to one of the thresholds, as depicted in Figure 2. We have arbitrarily defined "close" as 20% lower than the fall threshold value.

Figure 1. The threshold-based algorithm settings for fall detection. 1G: force of gravity 9.8 m/s^2; accel: acceleration; T1: time of phase 1 of the fall; T2: time of phase 2 of the fall; T3: time of phase 3 of the fall.

Protocol

Participants were randomly assigned to have either smartwatch model A or model C on one wrist and model B or no device on the other wrist. Model A and C were running one operating system, while model B was running on a different operating system. Every smartwatch contained the fall detection app that was programmed to detect and record falls paired with a smartphone located at the study site. The same app was used for each model. The smartwatches and smartphones used one of two operating systems: android or iOS. Two smartwatches were connected to iOS and one to Android. The versions of iOS and Android were the latest available at the time of the test. The version of the operating system on the smartphone and smartwatch were the same for all participants. The smartphones were linked to the smartwatch (according to the operating system) to communicate stored data of the time-stamped recorded episodes to secure cloud servers that were then compared to the video-recorded events.

Before starting the trial, participants were placed in a crash mat protected area, the smartwatches were placed on the participants' wrists, and a helmet was provided to be used during the tests; no other safety devices were used. Once the trial started, the smartwatch app was set up in monitoring mode and two rounds of four falls were induced in the blindfolded participants. A fall was defined as an event that results in a person coming to rest inadvertently on the ground, floor, or other lower level. A nonfall was defined as any event occurring while both the smartwatch app and the video record were active but excluding a fall or near fall (defined later). In every round, a frontward fall, a right side fall, a left side fall, and a backward fall were induced. These were induced by pushing the participant while standing. The method of fall induction was the same for all participants, executed by the same person. The participants were told of the impending direction of the push. Each assessment took approximately 5 minutes with 8 falls: 2 backward, 2 forward, 2 right, and 2 left. Additionally, up to 3 test falls were performed before the first round to ensure the participants were feeling comfortable with the procedure. Test falls were not included in the analyses. Further, prior to the test falls and between the falls, the participants wore the smartwatches and walked around freely. Near falls where the participant took one or more steps in the direction of the push without falling were also recorded, as there is some evidence that they may presage a fall [12]. This definition is in accord with the traditional definition as applied to this experimental scenario: "a stumble event or loss of balance that would result in a fall if sufficient recovery mechanisms were not activated" [12]. Importantly, the fall-triggering settings were optimized for each participant during the test falls. A non–near fall was defined as any event occurring while both the smartwatch app and the video record were active but excluding a fall or near fall.

During the fall, the algorithm was collecting the acceleration data and the time of the fall. The data collected were in three phases: "prefall" (preparation and walking to the crash mat, several minutes) as soon as the smartwatches were on the participants wrist, "induced fall" (8 falls around 5 minutes), and "post fall," walking back from the crash matt to the area to remove the smartwatches. In addition to this, the falls were recorded by built-in motion-detecting cameras (recording at 50 frames/second) available at the study site, the National Facility for Human Robot Interaction Research, University of New South Wales. Motion detection data were used to indicate when a fall was observed. The video of the falls also contained a timestamp that was used to compare it with the falls detected by the smartwatch app. In this case, the video recorded event was used as a reference standard, and the falls detected by the smartwatches were compared against it.

After all the falls had been induced, the smartwatches and safety equipment were removed, and participants were observed for

approximately 10 minutes: the heart rate, blood pressure, and symptoms (if any) were assessed.

Data Analysis

To perform the analysis of the falls, data were first retrieved from video records of the built-in motion-detecting cameras and coded as a fall or near fall by the authors and a person independent of the conduct of the study. Where there was disagreement, a majority opinion was taken. These were then compared independently by an external person with data retrieved from a fall detection database built to register the falls detected by the smartwatch algorithm. Each fall was classified as a true positive if the smartwatch app detected a fall at the time when the event was recorded on the video, a false positive if the smartwatch detected a fall event that was not recorded on the video, a false negative if the smartwatch did not detect a fall event recorded on the video, and a true negative if neither the smartwatch nor the video recorded a fall. Near falls were similarly analyzed. Results were computed for sensitivity, specificity, positive likelihood ratio, negative likelihood ratio, positive predictive value, negative predictive value, and accuracy. CIs for sensitivity, specificity, and accuracy are "exact" Clopper-Pearson CIs. CIs for the likelihood ratios are calculated using the "Log method." To compare fall and near fall detection by smartwatch model and direction of fall only, sensitivity data were used with chi-square tests and a significance value of $P<.05$. Further data are available on request. Sample size calculations were not formally performed beyond an approximate anticipated number of 20 to 25 participants that could be accommodated for the study given the constraints of the availability of the study site and personnel time.

Results

Characteristics of the Participants and the Falls

A total of 22 participants were enrolled in the study: 14 (63%) females and 8 (36%) males; 20 (91%) completed the whole procedure. Two (9%) females abandoned the study during the process: one after a soft tissue injury and the other for unstated reasons. An average of 7.2 falls was performed for each participant; however, one of the participants withdrew from the study after having performed 5 sets of 8 falls, and another after having performed 1 set of 8 falls. Of the induced 226 falls, 64 were backward, 51 were forward, 55 were left sided, and 56 were right sided. Two participants reported postfall self-limiting symptoms associated with soft tissue injuries, 1 required medication and physiotherapy, and their symptoms resolved after 6 weeks.

Demographic characteristics of the participants are shown in Table 1. With regard to BMI, 1 (6%) female was classified as underweight, 1 male and 1 female were classified as overweight (9%), and 1 (6%) male was classified as obese.

Table 1. Demographic characteristic of the participants.

Gender	Age (years)	Height (cm)	Weight (kg)
Female	25	160	58
Female	24	167	57
Female	24	170	62
Female	28	153	48
Female	21	164	50
Male	18	177	68
Female	19	164	47
Male	19	175	65
Female	19	164	53
Male	21	174	62
Female	25	170	60
Female	24	163	53
Female	23	168	49
Female	18	174	60
Male	18	180	63
Male	38	171	86
Female	33	163	55
Male	23	184	110
Female	45	160	50
Female	52	163	64
Male	32	160	65
Male	42	178	70

Overall Performance of the Algorithm

A total of 12 participants were wearing two smartwatches, model A device on one wrist and model B on the other wrist; 10 participants were wearing only one smartwatch, model C, on one wrist. The overall performances of the algorithm, disregarding the model of the smartwatch, are detailed in Tables 2 and 3. There was no difference in the performance of the algorithm according to which wrist if both were used. Tables 4 and 5 represent the results of near fall detection and the associated statistics. The overall test outcomes are summarized in the following section.

In general, the direction of the fall or near fall did not significantly influence sensitivity. Nonetheless, there was a trend for better detection of backward falls: of the 64 backward falls, 11 were false negatives, giving a sensitivity of 82%, versus forward falls, of which there were 51 with 12 false negatives, giving a sensitivity of 76%. Further, there was a significant difference in fall detection if the fall was to the same side versus opposite side of the wrist that had the smartwatch (left sided and right sided sensitivities combined: 92.5% vs 76.3%; $P=.009$). The same held true for near falls. If the fall was to the same side as the wrist with the smartwatch, there was a 95% sensitivity for left sided falls (55 with 3 false negatives) and 89% sensitivity for right sided falls (56 with 11 false negatives) versus if the fall was on the opposite side as the wrist with the smartwatch, there was 84% sensitivity for left sided falls (55 with 9 false negatives) and 80% sensitivity for right sided falls (56 with 11 false negatives).

Table 2. Fall detection results.

True fall status	Test result, n		Total, n
	Negative (nonfall)	Positive (fall)	
Nonfall	265 (true negative)	3 (false positive 1.7%)	268
Fall	52 (false negative 16.4%)	174 (true positive)	226
Total	317	177	494

Table 3. Statistics for fall detection.

	Value (95% CI)
Sensitivity (%)	76.99 (70.95-82.31)
Specificity (%)	98.88 (96.76-99.77)
Positive likelihood ratio	68.78 (22.27-212.39)
Negative likelihood ratio	0.23 (0.18-0.30)
Positive predictive value (%)	98.31 (94.95-99.44)
Negative predictive value (%)	83.60 (80.05-86.61)
Accuracy (%)	88.87 (85.76-91.50)

Table 4. Near fall detection results.

True near fall status	Test result, n		Total, n
Non–near fall	343 (true negative for all falls, normal falls, and near falls)	0 (false positive)	343
Near fall	43 (false negative when near fall 11.1%)	206 (true positive)	249
Total	386	206	592

Table 5. Statistics for near fall detection.

	Value (95% CI)
Sensitivity (%)	88.86 (85.29-91.82)
Specificity (%)	100 (98.23-100)
Positive likelihood ratio	N/A[a] (no false positives)
Negative likelihood ratio	0.11 (0.08-0.15)
Positive predictive value (%)	100
Negative predictive value (%)	82.73 (78.33-86.39)
Accuracy (%)	92.74 (90.34-94.69)

[a]N/A: not applicable.

Performance by Smartwatch Model

The number of responses for each smartwatch model were A=186, B=186, and C=122. Model A was used 173 times on the left wrist and 13 times on the right wrist. As per Table 6, there were differences among the models according to sensitivity and specificity, but none were significant. This was also true of the operating system. Similar results were found for near falls.

Table 6. Fall detection results by smartwatch models A, B, and C. The direction of the fall did not significantly influence sensitivity in any of the models.

	Value (95% CI)
Model A	
Sensitivity (%)	78.8 (68.6-86.9)
Specificity (%)	99 (94.6-100)
Model B	
Sensitivity (%)	71.8 (61-81)
Specificity (%)	98 (93-99.8)
Model C	
Sensitivity (%)	82.1 (96.6-91.1)
Specificity (%)	100 (94.6-100)

Discussion

The primary goal of this study was to evaluate the validity of an algorithm programmed in commercially available smartwatches to detect induced falls. Our study found that the algorithm had an overall sensitivity of 77% and specificity of 99%. The false-positive rate was very low at 1.7%, while the false-negative rate was 16.4%. The positive and negative predictive values were 98% and 84%, respectively, while the accuracy was 89%. Falls were more likely to be detected if the fall was on the same side as the wrist with the smartwatch. Similar results were found for near falls. There was a trend toward some smartwatches having superior sensitivity, though neither this nor the operating system reached statistical significance.

Several studies have been conducted to assess the performance of wearable devices for fall detection, mostly by using smartphones or other specialized self-created wearable devices [13-15]. However, only a few of these studies have been performed using commercially available smartwatches [16-19]. In addition, this study is the only one to assess the performance of a fall detection algorithm in different commercially available smartwatches with different operating systems using a video recording system as a gold standard and using blinded data analysis.

The fall detection algorithm was threshold based—programmed to send an alert once a predetermined threshold had been breached. Threshold-based algorithms, as opposed to pattern recognition methods, are preferred on smartphone operating systems due to the restrictions on computing and storage capabilities of the devices [16]. Indeed, pattern recognition methods are costly and need massive analyses of data, access to databases, and long training periods.

Casilari and Oviedo-Jimenez [16] tested different algorithms with an LG W110 smartwatch model R, finding that the fall detection performance depends on the algorithm used. However, there were only 4 participants with a total of 40 falls. Sensitivity ranged from 70% to 100% and specificity from 80% to 100% depending on the type of fall. Mauldin et al [18] have studied three different pattern recognition algorithms based on Naive bayes (NB), support vector machine (SVM), and deep learning models by using a Microsoft band 2 smartwatch. In this context, the algorithm tested in our study performed better than their NB and SVM models in sensitivity and precision, and when compared with their deep learning model, our algorithm performed better in precision but not sensitivity. Mauldin et al [18] also declared in their study that they tested an Android wear-based commercially available fall detection app (Rightminder) released on the Google Play store. The sensitivity was only 50%, and no technical details of this app are publicly available.

Further, these studies have used small groups of participants (3-7) performing several falls each (up to 10 per side). From our experience in laboratory settings, the dynamics of the falls are affected by repetition, as participants tend to fall in the same way. We minimized this effect by having a high number of participants (N=22) repeating each fall only twice per side.

Furthermore, the previous studies asked the participants to fall rather than having them fall as a result of being pushed unexpectedly by another person as was done in our study. This approach more accurately reflects a true fall given the spontaneity. The differing protocol designs in these studies make it impossible to accurately compare one against the other.

Our findings suggest that the performance of the algorithm differs among various brand devices. Indeed, the combined performance of brand A and C smartwatches on sensitivity and false-negative rates was higher than the brand B smartwatch. However, the brand B smartwatch precision and thus the false-positive rate is better than brands A and C devices. This is probably related to the differences in the operating systems. Medrano et al [20] explain that in current smartphone operating systems such as Android and iOS, it is difficult to configure specific sampling rates. As the sampling frequencies in both systems are different, the performance of the algorithm will likely be influenced by the operating system used. Moreover, Fudickar et al [21] have investigated the impact of the sampling frequency of the accelerometer on the performance of different threshold-based algorithms in smartphones, concluding that a detection system must deal with the polling frequency of the accelerometer sensors embedded in the device. No studies have been performed regarding this issue on smartwatches; however, it is likely that the situation is the same.

Additionally, our study has found that the performance of the algorithm could be strongly dependent on the smartwatch model. According to Silva et al [22], the performance of a fall detection algorithm could be affected by the quality of the sensors embedded in the device. Additionally, as the manufacturer can change the sensors over time, the performance of the algorithm will also rely on the smartwatch model [16]. This situation could explain the differences we have found between the smartwatch models tested, making it difficult to compare with other studies if they have not used the same smartwatch device and model.

It has been previously reported that the direction of the fall affects the performance of the algorithm used in smartwatches [16,18]. In this context, the performance of the algorithm is largely dependent on which side the fall occurred in relation to the smartwatch. Our algorithm performs better when the fall occurs on the same side of the wrist wearing the smartwatch than when the fall occurs on the opposite side. This is a tendency observed regardless of the smartwatch model. Mauldin et al [18] found a similar performance in the three pattern recognition models they tested. Casilari and Oviedo-Jimenez [16] reported an overall result for side falls; therefore, it is not possible to know if they have found the same tendency.

Regarding the back falls, Mauldin et al [18] found their different algorithm models had poor performance indices in this direction. This was thought to be a consequence of less wrist movement in back falls as compared to other directions of falls. However, our algorithm performed the best on back falls, suggesting that the intensity of the wrist movement or the impact is not affecting the algorithm in this fall direction.

Finally, another factor that could affect the performance of the algorithm in detecting falls in different directions is the participant's body habitus. It has been proposed that height and

weight could affect the performance of the algorithm [23]; thus, implementing personalized settings according to participants' characteristics is a way to improve the algorithm sensitivity. To address these issues of body habitus and smartwatch model, we deliberately adjusted the algorithm settings during the test falls. This likely contributes to the positive results and should be considered in future studies.

Our study has some limitations. First, there was a relatively small number of participants though not in comparison with other published studies. Second, not all participants wore a smartwatch on each arm, potentially influencing the results. However, only 1 participant was wearing one smartwatch; the results were essentially unchanged with that participant's data removed. Third, our participants were healthy in contradistinction to the older adult population who would most likely be using the app. Nonetheless, inducing falls in such participants would expose them to considerable risk.

Despite these reservations, the smartwatch app performed well in comparison to studies of other apps and under more rigorous conditions with more stringent analyses, yielding an accuracy of 89%. Indeed, the field of physical activity sensors generally accepts an accuracy of 70% to 80% [24]. Our future research will be focused on investigating the performance of the algorithm in different smartwatch models by using personalized settings. Moreover, head-to-head studies of fall detection devices in smartwatches using real-world participants and settings are likely to improve available evidence concerning the effectiveness of these devices for consumers such as older adults and regulatory or licensing bodies.

Abstract

Background: Video consultations (VCs) were rapidly implemented in response to COVID-19 despite modest progress before.

Objective: We aim to explore staff and patient experiences with VCs implemented during COVID-19 and use feedback insights to support quality improvement and service development.

Methods: Secondary data analysis was conducted on 955 patient and 521 staff responses (from 4234 consultations; 955/4234, 22.6% and 521/4234, 12.3%, respectively) routinely collected following a VC between June and July 2020 in a rural, older adult, and outpatient care setting at a National Health Service Trust. Responses were summarized using descriptive statistics and inductive thematic analysis and presented to Trust stakeholders.

Results: Most patients (890/955, 93.2%) reported having *good* (210/955, 22%) or *very good* (680/955, 71.2%) experience with VCs and felt listened to and understood (904/955, 94.7%). Most patients accessed their VC alone (806/955, 84.4%) except for those aged ≥71 years (23/58, 40%), with ease of joining VCs negatively associated with age (*P*<.001). Despite more difficulties joining, older adults were most likely to be satisfied with the technology (46/58, 79%). Patients and staff generally felt that patients' needs had been met (860/955, 90.1% and 453/521, 86.9%, respectively), although staff appeared to overestimate patient dissatisfaction with VC outcomes (*P*=.02). Patients (848/955, 88.8%) and staff (419/521, 80.5%) felt able to communicate everything they wanted, although patients were significantly more positive than staff (*P*<.001). Patient satisfaction with communication was positively associated with technical performance satisfaction (*P*<.001). Most staff members (466/521, 89.4%) reported positive (185/521, 35.5%) or very positive (281/521, 53.9%) experiences with joining and managing VCs. Staff reported reductions in carbon footprint (380/521, 72.9%) and time (373/521, 71.6%). Most patients (880/955, 92.1%) would choose VCs again. We identified three themes in responses: barriers, including technological difficulties, patient information, and suitability concerns; potential benefits, including reduced stress, enhanced accessibility, cost, and time savings; and suggested improvements, including trial calls, turning music off, photo uploads, expanding written character limit, supporting other internet browsers, and shared online screens. This routine feedback, including evidence to suggest that patients were more satisfied than clinicians had anticipated, was presented to relevant Trust stakeholders, allowing for improved processes and supporting the development of a business case to inform the Trust decision on continuing VCs beyond COVID-19 restrictions.

Conclusions: The findings highlight the importance of regularly reviewing and responding to routine feedback following digital service implementation. The feedback helped the Trust improve the VC service, challenge clinician-held assumptions about patient experience, and inform future use of VCs. It has focused improvement efforts on patient information; technological improvements such as blurred backgrounds and interactive whiteboards; and responding to the needs of patients with dementia, communication or cognitive impairment, or lack of appropriate technology. These findings have implications for other health care providers.

Introduction

COVID-19 is a global health concern [1] that has resulted in the rapid implementation and digitalization of many health care services [2,3]. As a result, video consultations (VCs), also referred to as remote or virtual consultations [4], now form an integral part of both primary and outpatient (ambulatory) care. Although limiting viral exposure and reducing the potential risk of infection for patients and staff [4,5], VCs may also enable additional visual cues beyond the capabilities of telephone consultations, helping further facilitate therapeutic relationships and experiences of care [2].

Although there is guidance on how to deliver VCs [6-8] and growing evidence exploring the rapid implementation of VCs in various areas of health care [4,9-17], there are relatively few empirical studies on VCs. For example, Doraiswamy et al [16] reviewed 543 articles related to telehealth (including telephone, VC, and other communication methods) during COVID-19, and only 12% of articles presented empirical work, with few studies conducted in the United Kingdom focusing on VC [16]. Similarly, other research has focused on a single service, such as orthopedics or mental health [4,13,14]. Although the research by Dhahri et al [15] focuses on feedback across a range of outpatient services from 45 patients and 79 clinicians, this was only over a 3-week period.

The emerging research on remote health care and VC implementation seems to show some benefits. For example, VCs are seen as useful for social distancing [12], may provide quicker consultation times [4], reduce travel time for patients [14], and allow for safeguarding and risk assessment [13]. However, the research to date also shows areas of concern, such as technology limitations (impairing video and sound) [4,9,15], additional burden, lack of physical examination [9], low technology confidence and limited setup support [4], and impaired therapeutic interactions and reduced depth of clinical encounters [14].

However, the sample size of VC respondents in studies to date is limited, and no studies to our knowledge have been reported from a British rural and deprived region with an older population [18]. Documented implications of routine feedback on practice have also been lacking in previous literature. Thus, our study aims to investigate National Health Service (NHS) staff and patient experiences with the Attend Anywhere VC in Cornwall using routine feedback from a large sample and to explore the impact of insights shared when presented to key stakeholders in the service.

Methods

Design

This study consists of a secondary analysis of routinely collected, anonymized survey data following a VC that was designed and distributed by the partner health care provider (NHS Trust) and subsequent follow-up to disseminate results and assess the impact of feedback with the Trust.

Setting

The Cornwall Foundation Partnership NHS Trust provides mental health and community services for Cornwall and the Isle of Scilly, a geographically isolated peninsula in the South West of England that experiences higher than average levels of deprivation [19]. By UK definitions, Cornwall and the Isle of Scilly are very rural, with 40% of the population living in remote areas [19], an older age profile [20], and a single acute hospital located in the center of the county. The Trust's services include children and adolescent mental health, adult mental health, and physical health, including but not limited to learning disabilities, cardiac services, bladder and bowel, complex care and dementia, eating disorders, personality disorders, psychiatric liaison, palliative care, stroke nursing, speech and language therapy, diabetes, epilepsy, minor injuries, musculoskeletal care, neurorehabilitation, physiotherapy, podiatry, and respiratory nursing. This study was carried out by an independent research team using anonymous data provided by the Trust.

VC Service

The Trust started using Attend Anywhere, a telemedicine platform for outpatient care [21,22], on April 6, 2020. The platform facilitates video calls between clinicians and patients for scheduled appointment times. The video calls can be conducted over internet-connected computers, phones, or tablets. The implementation process followed guidance provided by NHS England and NHS Improvement [23]. Some appointments were still carried out face to face, but many patients were offered VC or telephone contact during the study period.

Data Collection

The Trust set up a system of routine feedback using a web-based survey (Multimedia Appendix 1) based on the standardized feedback survey questions provided in the national guidance [23]. Immediately after participating in a VC, all staff and patients were invited to complete the web-based survey regardless of whether they had completed one before. The survey was presented via the Meridian surveying platform at the end of a VC. To our knowledge, the survey was not designed with patient or public involvement owing to the rapid implementation process. The rapid rollout of this feedback process may also be responsible for some limitations in the surveys themselves, including limitations in response options and understanding of the sample (eg, number of unique

individuals and complete understanding of the service accessed by the patient). However, we have confidence that the data items used in the analysis are robust based on their recommended use by NHS England and NHS Improvement.

Participants

Participation was voluntary, and the patient participants were patients or their carers. Survey respondents gave consent for their data to be used, but some chose not to have comments publicly shared. Their data were included in the analysis and production of the themes, but their quotes were not included. We used data collected during the early implementation of VCs in response to COVID-19 (June 1, 2020, to July 31, 2020). During this time, 4234 Attend Anywhere appointments were completed. The feedback data used were 22.56% (955/4234) patient and 12.3% (521/4234) staff responses out of the 4234 completed VCs. The sample size was largely pragmatic, using data from as many patients (nearly 1000) as was thought possible to thematically analyze in a timely manner to give feedback to staff during a 2-month period after an initial *settling down* of the system but early enough to have practical use in assessing the utility of the method.

Data Analysis

Descriptive statistics were reported for numerical data, and chi-square and Mann–Whitney *U* tests were used where appropriate. Free-text responses were analyzed by 4 researchers (HB, RB, KE, and SS) using inductive thematic analysis [24]. Initially, staff and patient comments were analyzed separately. A comprehensive coding framework was developed. Patient and staff codes demonstrated high comparability and, thus, are presented as combined themes across the data set, with areas of discordance discussed. Thematic analysis was selected as a useful and flexible method to generate a rich yet detailed and complex account of qualitative data [24]. Adopting an inductive approach also helped ensure that identified themes arose from the data generated as opposed to predefined concepts or ideas.

Documented Impact of Routine Feedback on Real-world Practice

Following analysis of the results, summary presentations were created and presented to relevant stakeholders as rapid feedback between November 24, 2020, and February 21, 2021. Presentations were given in partnership with a service-user consultant to patients, patient representatives, and professionals at an Experiences of Care collaborative meeting within the care system, the South West Outpatient Transformation group, the

region's VC forum, and local web-based research dissemination events, and to national audiences through the Outpatient Transformation regional leads meeting. The results were also shared with interested international health care providers (Finland).

Patient and Public Involvement

The research question and study were informed by patient input (through inclusion of patient experience), and a service-user consultant contributed to reviewing and coauthoring the manuscript.

Ethics Approval

Ethical approval to conduct this secondary analysis was provided by the Health Research Authority and Health and Care Research Wales, Integrated Research Application System ID286543 (27.07.2020). This manuscript was prepared using the Standards for Quality Improvement Reporting Excellence guidelines [20].

Data Sharing Statement

Not all patients consented for their comments to be published; thus, the full data set is not publicly available. However, interested parties may inquire with the authors for further details.

Results

The results are presented in three sections: (1) quantitative results, including participant characteristics; (2) qualitative results; and (3) documented impact of this routine feedback on real-world practice. Multimedia Appendix 1 provides further details on the questions presented to staff and patients in the survey.

Quantitative Results

Patient Age and Device Used

Just under a quarter (955/4234, 22.56%) of the 4234 patient VCs resulted in feedback responses. As the data were anonymous, it was not possible to know if some individuals completed the survey more than once in this 2-month period. Therefore, each data entry was treated as an individual episode. The highest number of survey responses was received from individuals aged 31-50 years (333/955, 34.9%), with the lowest response from patients aged >71 years (58/955, 6.1%). Half of the patients (487/955, 51%) used a laptop to access their VC. Devices used varied by age ($\chi^2_{12}=68.9$; *P*<.001)—patients aged >50 years were much less likely to use mobile devices and more likely to use a tablet (Table 1).

Table 1. Use of devices for the video consultation by age group, showing numbers (percentages; N=955).

Item	Device, n (%)				Total, n (%)
	Laptop	Mobile phone	Tablet	Other	
Age group (years)					
<18	82 (50.3)	44 (27)	32 (19.6)	5 (3.1)	163 (17.1)
18-30	76 (52.1)	35 (24)	24 (16.4)	11 (7.5)	146 (15.3)
31-50	167 (50.2)	87 (26.1)	64 (19.2)	15 (4.5)	333 (34.9)
51-71	120 (49.6)	20 (8.3)	70 (28.9)	32 (13.2)	242 (25.3)
>71	36 (62.1)	1 (1.7)	16 (27.6)	5 (8.6)	58 (6.1)
Total	487 (51)	189 (19.8)	209 (21.9)	70 (7.3)	942[a] (98.6)

[a]A total of 13 respondents did not answer regarding age group.

Staff Characteristics

In total, 521 staff responses were received (Table 2), with a response rate of 12.3% (521/4234). The largest number of responses by profession was from Allied Health Professionals (155/521, 29.8%). The largest number of responses by department was from Community Mental Health (188/521, 36.1%). Most staff responses were completed following VCs with a patient for whom staff members had 1-3 previous contacts. Staff data, such as patient data, are episodes rather than individuals.

Table 2. Staff respondents, showing profession and department (N=521).

Characteristics	Participants, n (%)
Profession	
Nurse	81 (15.5)
Psychologist	117 (22.5)
AHP[a]	155 (29.8)
Physician	61 (11.7)

Patient Overall Experience and Future Intention

Most patients (890/955, 93.2%) reported having a *good* (210/955, 22%) or *very good* (680/955, 71.2%) overall experience with VC. A small number of patients had a *poor* (13/955, 1.4%) or *very poor* (17/955, 1.8%) experience. Future intention could also be seen as a measure of satisfaction with VC—9 out of 10 patients were *very likely* (704/955, 73.7%) or *somewhat likely* (176/955, 18.4%) to choose a VC in the future. Very few patients (28/955, 2.9%) suggested they were *somewhat unlikely* (17/955, 1.8%) or *very unlikely* (11/955, 1.2%) to use VCs in the future. Within the results, we were able to look at two aspects of overall satisfaction: satisfaction with the technology (video and sound) and satisfaction with the communication (more related to the clinician's performance in this situation).

XSL•FO

RenderX

Patient and Staff Technical Satisfaction

Three-quarters of the patients reported having a *very positive* experience with sound and video quality (732/955, 76.6% and 728/955, 76.2%, respectively). When combined, 67.6% (646/955) had a very positive experience with both video and sound (Table 3). Three-quarters of staff also reported a *positive* or *very positive* experience with sound and video quality (411/521, 78.9% and 399/521, 76.5%, respectively).

Table 3. The 4 indicators of patient satisfaction with video consultations shown by patient age and device used, showing *P* values from chi-square test (N=955).

Characteristic	Positive overall	Would choose VC[a] again	Positive about technology	Positive about communication	Total patients
Age (years)					
<18, n (%)	153 (93.9)	146 (89.6)	94 (57.7)	137 (84)	163 (17.3)
18-30, n (%)	133 (91.1)	134 (91.8)	92 (63)	131 (89.7)	146 (15.5)
31-50, n (%)	316 (94.9)	313 (94)	240 (72.1)	290 (87.1)	333 (35.4)

Patient and Staff Satisfaction With Communication

Most patients felt that they had been listened to and understood (904/955, 94.7%), had had their needs met (860/955, 90.1%), and had been able to communicate everything they wanted (848/955, 88.8%). Overall, 85.7% (818/955) of the patients rated all 3 aspects positively (Table 3).

Most staff members (419/521, 80.4%) felt able to communicate everything they wanted to, although satisfaction was slightly lower than that of patients (419/521, 80.4% vs 848/955, 88.8%; χ^2_1=19.4; *P*<.001). Staff perceptions of patients feeling their needs were met were generally positive, with 57% (297/521) and 29.8% (155/521) responding *yes* and *yes partially*, respectively. Only 2% (19/955) of patients said their needs were not met, whereas 11.1% (58/521) of staff believed that patients felt their needs were not met, suggesting an apparent discrepancy.

Association Between Patient Satisfaction With Technology and Communication (Combined as Above)

Patient satisfaction with communication was very strongly positively associated with satisfaction with technical performance (χ^2_1=104.0; *P*<.001; Table 4). Only 4.3% (41/955) of patients were less satisfied with the communication despite being satisfied with the technology. Conversely, 22.3% (213/955) of patients remained positive about the communication despite being less positive about the technology.

Table 4. Cross-tabulation of patients being positive about technology with patients being positive about communication (N=955).

Positive about technology	Positive about communication, n (%)		Total, n (%)
	No	Yes	
No	96 (70.1)	213 (26)	309 (32.4)
Yes	41 (29.9)	605 (74)	646 (67.6)
Total	137 (100)	818 (100)	955 (100)

Patient Independence and Accessibility

Most patients (806/955, 84.4%) stated that they could access their VC alone and that it was *very easy* or *easy* to join the VC call (849/955, 88.9%). However, more respondents aged >71 years reported needing help (35/58, 60%), and fewer reported it easy to join compared with those aged <31 years (40/58, 69% vs 286/309, 92.6%; χ^2_3>=28.6; P<.001).

Influence of Patient Age and Device Used on Outcome

The relationship between device used, age, and satisfaction with technology and the VC was complex. On the one hand, older patients were more positive about the technical experience despite being more likely to need help accessing the VC and being less likely to find accessing the VC easy. Mobile users were also more positive (Table 3), and older adults were less likely to be mobile users (Table 1).

Staff Experience With Managing and Joining the Call

Most staff respondents reported a *positive* or *very positive* experience when managing and joining the VC (466/521, 89.4%). A smaller number of staff responses indicated a *negative* or *very negative* experience (49/521, 9.4%).

Patient and Staff Perceived Savings

Two-thirds of patients reported a perceived saving in time (662/955, 69.3%), with more than half of respondents also reporting a perceived saving in money (544/955, 57%). There was no difference by age. Staff respondents most commonly identified carbon savings (380/521, 72.9%) followed by time (373/521, 71.6%). Over one-third of staff reported saving money (187/521, 35.9%). Just below one-quarter of staff respondents reported a perceived saving on missed appointments or *did not attends* (DNAs; 128/521, 24.6%). Approximately 24% (125/521) reported *other* unspecified savings. Savings are explored in greater depth in the qualitative analysis below.

Patient Versus Staff Perception

Overall, there appears to be good concordance between staff and patient feedback, with similar benefits noted for time and money savings. Mann–Whitney *U* tests demonstrated no significant difference between 521 staff and 955 patient ratings of video (P=.15) or sound quality (P=.77). However, significant differences between staff and patient responses were identified when reviewing whether patients had been able to communicate everything needed and felt their needs were met. On both occasions, staff responded more negatively than patients (P<.001; P=.02). This could suggest that staff overestimated patient dissatisfaction with VC outcomes or were not aware of patient experiences. This is a useful finding, which was reported back to stakeholders at the Trust; however, limitations in the survey (as discussed in Multimedia Appendix 1) must also be considered.

Qualitative Results

Number of Comments

Overall, 13.9% (133/955) of patients made 1384 free-text comments in response to one or more of the 16 questions (Multimedia Appendix 1). Patients who rated their overall experience as good or very good were much less likely to comment (105/890, 11.8% vs 28/65, 43.1%; P<.001). Two-thirds (350/521, 67.2%) of staff made 528 free-text comments in response to one or more of the 9 questions asked.

Overall Themes

Overview

Inductive thematic analysis of free-text responses identified three main themes: barriers, benefits, and suggested improvements. Although the overarching themes were the same based on staff and patient analysis, there was some variation in initial codes between the 2 groups, as discussed in the narrative below and shown in Table 5. Unique identifiers are used for each quote.

Table 5. Qualitative patient feedback themes, subthemes, and codes.

Theme and subtheme	Codes
Barriers	
Technological issues	• Equipment, sound or video issues, difficult to communicate, connectivity issues, sound quality, video quality, joining issues (SP[a]) • Impaired therapeutic flow, limited support, poorer-quality interactions, increased staff stress (S[b])
Quality of patient information and administrative support	• Jargon, accuracy, complexity of language (P[c]) • Lack of technical support, human error, patient struggles with VCs[d] and joining (SP)

Accessibility and suitability concerns	• Lack of suitable or compatible devices and up-to-date browsers, support required (SP)
	• Widening inequalities, difficult to risk-assess, no hands-on care, suitability of certain conditions including the following (S):
	  • Hearing-impaired (SP)
	  • Children and attentional issues (S)

Time, resource, and cost concerns	• Increased personal cost for staff, increased staff time, more DNAs[e] (S)
Benefits	
Reduced anxiety and stress	• Comfort, face-to-face element, relaxing and anxiety-reducing, safer, patients better supported, family members present (SP) • Ability to open up more (S)
Continued service delivery	• Allows examination, facilitates contact with patients and staff, higher-quality appointments, nonverbal cues, safety, continued service (S)
Perceived savings	• Travel, money, time, environment, work hours, arranging lifts, childcare (SP)
Enhanced accessibility	• Increased access, affordability of attending, comfort, childcare, arranging lifts (SP) • Fatigue (P)
Suggested improvements	
Information and support improvements	• Notify if appointments are running late (P) • Allow trial VC, provide reminders, simplify or improve patient information, simplify sign-in process, device advice (SP) • Camera positioning guidance (S)
Technological improvements	• Turn off music, allow photo upload before appointment, support use in other browsers, expand character limit, allow document editing (P) • Shared interactive whiteboard, resources or activities, background blur for privacy, allow control by patient (S)

Barriers

The participants related barriers from technological difficulties, quality of patient information, and concerns about accessibility or suitability of using VC.

Technology

Many patients identified concerns of connectivity—"platform glitches" [Patient 94]—or experienced delays between video and sound:

> *The picture kept freezing and pixelating.* [Patient 741]

> *The video quality is so poor it's really hard to get much done.* [Patient 332]

In some cases, technical difficulties meant patients felt that their "needs were not met" [Patient 305]. Similarly, some clinicians reported having to "resort to a telephone" [Staff 14] to supplement VC audio. Some staff members reported that VCs had "a very negative effect on the quality of...therapy we can deliver" [Staff 28] and "limit...the complexity of the conversation" [Staff 29], making it "hard to pick up on body language" [Staff 144]. For some staff members, impairments

caused by technological issues were seen as "detrimental to patient care" [Staff 90], "frustrating" [Staff 197, Staff 409, and Staff 439], and "stressful" [Staff 90]. It is possible that the connectivity issues seen in this study related to the geographical character of the region of Cornwall, with staff reporting the following:

> *The general Cornish bandwidth is the obstruction here.* [Staff 118]

However, staff reported other platforms seemed to encounter fewer issues, suggesting the platform "needs to be improved substantially and quickly" [Staff 22].

Quality of Patient Information and Administrative Support

The quality of patient information, particularly joining instructions, was repeatedly called into question by both patients and staff. A patient described the joining process as "stupidly complex" [Patient 52]. Others described being "directed to a troubleshooting, jargon filled, suggestions page" [Patient 95]. The accuracy of the joining instructions was also questioned:

> *The link doesn't open as the instructions [suggest].* [Patient 236]

Although a video version of the information was provided, this was described by the participants as in need of further development and refinement to ensure inclusivity, particularly for "deaf patients" [Patient 582]. Similarly, staff felt that the "main issues" [Staff 75] for patients involved "logging on" [Staff 71] and that "the process of joining has lots of information to process" [Staff 75]. The consequence being "patients [take] a while to get into the appointment [as] the process [is] complicated" [Staff 150]. Some clinicians needed to "telephone and talk [the patient] through logging on" [Staff 286].

Accessibility

Access to relevant devices, browsers, digital skills, and confidence were also described as problematic by some participants:

> *Unfortunately I was not up to date with technology.* [Patient 319]

Some patients reported needing to download alternative browsers or borrow other people's devices because of "outdated" [Patient 671] models. Staff also suggested the following:

> *It can be hard to engage those with limited IT equipment.* [Staff 106]

Similar to the quantitative findings outlined above, some participants reported needing help from family members or friends as "without [them] it would have been impossible" [Patient 540]. Another "96 year old had to pay for a carer to be present [and] 2 hours of IT help from someone else" [Patient 47], raising further questions and concerns.

Suitability Concerns

Although patient concerns focused mainly on technology and digital exclusion, staff had additional concerns about suitability based on patient illness or requirement. Some staff members felt that VCs were exacerbating "health inequalities" for individuals with learning disabilities or living in residential homes as patients were "often excluded from the review" [Staff 202] as computers were often located "in an office" [Staff 202]. This concern was echoed, as "clients with learning disabilities" [Staff 15] often "need reasonable adjustments to be facilitated to communicate" [Staff 15]. The usefulness of VCs for dementia services was also queried, with the "screen [removing] sensory aspects and visual clues" [Staff 130]. VCs were also seen as unsuitable for dysphagia, where "a hands on approach is required to closely look, listen and feel as the person eats and drinks" [Staff 25]. Patient conditions that may impede VC success as suggested by staff respondents also included "cognitive, speech, language, fatigue, concentration, need for physical...assessments, environmental assessments, safety" [Staff 23]. Other areas described as problematic included family therapy, where the "family had to sit side by side, so parents couldn't see their child's facial expressions" [Staff 278], and VCs with children generally, particularly with attentional needs, which "meant [the] session was longer" [Staff 136] and fewer tasks were achieved than face to face. Patient safeguarding and "environmental assessments" [Staff 23] also appeared to be a key issue for clinicians—"home visits remain hugely important to gather information to ensure patient safety," [Staff 130] providing more information "such as how a person may be living and identify self-neglect, declines in functional skills or poor medication management" [Staff 130]. Staff also suggested some conversations may "be very challenging" [Staff 202] over VC, such as discussing "the risk of dying over the internet and not in person" [Staff 202], as some respondents felt "discussing end of life care" [Staff 29] over video carried "an increased risk of missing cues" [Staff 29]. Patients raised concerns for people with hearing impairments as "face to face is easier" [Patient 457] for lip readers because of video or sound delays and character limitations in the VC chat function.

Time, Resource, and Cost Ineffectiveness

A minority of staff members reported concerns of time, resource, and cost ineffectiveness as, although VCs "saved a few minutes walking to the clinic and tidying the room for the assessment," [Staff 169] they could also "add an extra appointment" [Staff 169] when a face-to-face consultation was needed. Some respondents also suggested that VCs were longer owing to a "longer explanation time" [Staff 279] to talk patients through the process of how to log on, as described above. Technological issues also affected duration, with patients "having to change rooms" [Staff 198], "change to telephone" [Staff 203], or "re-join" [Staff 19] after disconnection. Furthermore, staff felt VCs "take quite a bit of preparation prior to the consultation" [Staff 23], particularly in psychological services where staff may "need to make electronic versions of therapy resources" [Staff 6]. Although 24.6% (128/521) of staff reported reduced DNAs numerically, some staff members suggested DNAs had increased:

> *I've had more DNAs than when most of my visits were by car.* [Staff 413]

However, only 3 such comments were made. Interestingly, patients did not report time or resource ineffectiveness and generally reported savings, as described below.

Interestingly, none of the patients described the therapeutic relationship or quality of care delivered by individual health care professionals as a barrier or limitation of VC use.

Benefits

Overview

The participants identified benefits of continued high-quality service delivery, including reduced anxiety and stress, perceived savings, and enhanced accessibility. Most patients repeatedly described their VC experience as "fantastic" [Patient 558], "excellent" [Patient 579], "amazing" [Patient 153], "wonderful" [Patient 863], "positive" [Patient 600], and "useful" [Patient 667]. The participants also appeared to appreciate being able to have "family members join the appointment" [Patient 15].

Continued High-Quality Service Delivery

For staff, VCs allowed them to "continue to provide care" [Staff 47] and "maintain contact and show patients that we are here, that we are holding them in mind and we are motivated to help" [Staff 24]. Clinicians noted that, without VCs, provision would be "even more reduced" [Staff 47] and that services such as "psychotherapy" [Staff 160] did not need to go "on hold" [Staff 160]. Staff who were "shielding" [Staff 356] also managed to maintain workloads and provide care for "shielding patients" [Staff 394]. Some clinicians reported good "depth of therapy work," which was "less tiring than therapy by telephone" [Staff 60].

Reduced Anxiety and Stress

Both patients and staff felt that VCs were "far less stressful" [Patient 796] than face-to-face consultations. Several patients reported feeling "more relaxed" [Patient 563] and less "rushed" [Patient 392] as a result of avoiding certain stressors, including arranging transport, arriving on time, finding and paying for parking, and traffic. Reduced anxiety and stress were also reported among children, particularly in children who experienced anxiety about appointments or leaving the house. Clinicians noted that child assessments could be supported by the presence of teaching staff in addition to parents alone and noted the following for adults with learning disabilities:

> *Distant parents [were] able to join the review, whereas they wouldn't have previously.* [Staff 202]

Staff also reported that VCs were "less stressful" [Staff 89] for the clinicians themselves, "increasing my wellbeing" [Staff 64] by "saving stress" [Staff 209] and "anxiety and distress" [Staff 519]. Other staff members suggested that VCs "can actually be more therapeutically productive" [Staff 170] with "improved communication" [Staff 110] and "better clinical contact" [Staff 200]. Patients reported that the removal of "so much stress" [Patient 290] meant that they had "more time to focus on what needs talking through" [Patient 290]. Several participants suggested that, as they "didn't feel so stressed" [Patient 695] and were in the comfort of their "own home" [Patient 564], they were "able to open up more" [Patient 695], often feeling more "comfortable" [Patient 564] and "relaxed" [Patient 564]. Similarly, for staff, patients receiving care at home was seen as beneficial, such as for a "post-natal mum" who "felt more comfortable in their own home" [Staff 126]. VCs were also seen as reducing "anxiety for patients concerned about face-to-face

appointments due to COVID" [Staff 29] and allowed for "concordance" [Staff 58] in patient care.

Perceived Savings

Both patients and staff reported time, monetary, and environmental savings. Some patients reported saving "over £20 in transportation costs" [Patient 98] and being able to now "afford" [Patient 153] an appointment as a result of time and cost savings:

> *[VCs] have genuinely changed my life...being accessible for my needs and being able to afford an appointment.* [Patient 153]

Travel and cost savings may be particularly prevalent in "Cornwall," where it "is always difficult to travel for appointments" [Patient 262]. Many staff members also suggested VCs save "time, money and travelling for all concerned" [Staff 324], also reducing "carbon footprint" [Staff 75] by saving "on travel" [Staff 315], "paper" [Staff 242], and "printing resources" [Staff 261]. Many clinicians reported that they could "see patients more intensively" [Staff 7] and "complete an increased number of appointments in a day" [Staff 19] with "increased capacity as a whole" [Staff 17]. Clients who were often "late due to travel" [Staff 81] were now on time. Clinicians reported saving "90 minutes in the car visiting a patient who is just as happy to be seen by video" [Staff 307]. Some staff members also reported that they "rarely get DNAs" [Staff 444] and that VCs "must have saved [The Trust] a lot of money" [Staff 444].

Enhanced Accessibility

Although digital exclusion was thought to reduce accessibility for some, as outlined above, most free-text responses suggested that VCs facilitated service accessibility in a number of ways. First, owing to certain conditions and reduced mobility, some respondents found "trips to the hospital very tiring and difficult" [Patient 20]. VCs removed this experience. Childcare and employment cost savings were also described, helping increase accessibility. For example, a participant suggested that, for a face-to-face appointment, they "would have been dragging all three kids along for what ended up being something that the video call was able to address" [Patient 863]. The "option of video call" [Patient 335] was also considered "useful" [Patient 335] for those who are employed or "working parents" [Patient 335]. Patients could schedule weekly appointments around their employment, something that is not always possible when relying on face-to-face appointments. Furthermore, a number of patients who were "not able to drive" [Patient 307] or "can't drive" [Patient 846] described VCs as "much more convenient" [Patient 307] because of enhanced independence and removal of reliance on others. Similarly, staff reported increased accessibility for numerous patients who ordinarily "cannot travel to appointments" [Staff 77], such as those with "mobility issues" [Staff 201]. The lesser time requirement for patients to attend via VC was considered to increase "availability of services to clients with other commitments" [Staff 274], "work engagements" [Staff 153], or "caring responsibilities" [Staff 280].

As a result of the benefits encountered, many patients expressed a strong desire for VCs to be made available beyond the COVID-19 pandemic:

> I hope that all of our future appointments will be held this way. [Patient 863]

This highlights an important element of patient choice.

Suggested Improvements

Finally, staff and patients suggested improvements in two main areas: information and technology.

Information Improvements

Respondent suggestions included the simplification of patient guidance and information, device-specific advice, and suggested device use for optimum VC experiences. For example, some patients reported positioning their "iPad onto the floor, so I could show...my feet and me walking" [Patient 248]. This would have been less feasible if using "a desktop computer" [Patient 248]. Other participants suggested it was "a bit challenging getting [the] camera in position to demonstrate me doing the exercises" [Patient 809]. Therefore, providing device-specific information and recommending particular devices based on service requirements and availability may be beneficial. Patients also requested some method of notification if the clinics were running late.

Technology Improvements

Related to platform functionality, patients requested the ability to "turn off the music while sitting in the waiting room" [Patient 388] as it was considered "terrible" [Patient 517] and repetitive by some. Patients also expressed a desire to be able to "upload photos or videos" [Patient 20] to the consultation and "change the mobile camera being used" [Patient 145]. Further platform-related improvements suggested included expanding its functionality to "other browsers" [Patient 342] and having the character limit expanded beyond 200 characters for patients who need to use the text function. Other suggestions made by staff included more interactive screen-sharing capabilities as currently clinicians "cannot see [the] client anymore" [Staff 6] when sharing their screen. Others thought it would be useful if the clinician could "allow the client to take control of a particular programme you are sharing," [Staff 6] which could help with "engaging children so you could play games together" [Staff 6]. A similar desire was noted for adult cognitive behavioral therapy, with staff requesting a "white board" [Staff 119] to "draw things out on such as CBT formulations" [Staff 52]. The absence of such functionalities meant that diagrams were completed less "collaboratively" [Staff 107] than if patients were "in the room" [Staff 107]. Finally, related to digital skills and confidence, some patients expressed a desire for a "dummy run" [Patient 74] to be made available so that people could familiarize themselves with the technology before their consultation. Interestingly, no suggestions for health care training were proposed by the participants, although this may reflect the questions asked in the feedback survey. For enhanced security, staff requested a "blurred background" [Staff 3] option "to help protect privacy" [Staff 3] and "improve confidentiality" [Staff 375]. This seemed particularly relevant for clinicians who "work with forensic clients" [Staff 3]. An additional

improvement would be having the ability to "lock the room once everyone is in" [Staff 8] after experiencing "incidents of other staff joining private, confidential therapy sessions uninvited" [Staff 8].

Comparison of Patient and Staff Feedback

Generally, staff and patient responses showed high congruence, as evidenced by the similarity of codes and subsequently combined themes. However, as with the quantitative results, where more staff members responded with concern about patients feeling their needs were met than patients themselves, the qualitative data also demonstrate some evidence of clinicians believing that VCs impaired the therapeutic flow or produced poorer-quality interactions. Patients provided no indication of dissatisfaction with the clinician's communication, outcomes, or care received other than issues resulting from the technology. Although staff concerns on meeting patients' needs also commonly resulted from technical issues, generic concerns were also shared on therapeutic quality and missing cues or body language via VC. In addition, patients regarded highly the increased accessibility of health care and found appointments less stressful. The codes on time, resource, and cost ineffectiveness were provided only by staff, whereas patient data strongly supported perceived savings across time, money, travel, and environmental impact. Staff and patients showed similarity in the reported requirement for improved sound and video quality. In addition, patients requested the removal of waiting room music, expansion of character limits, and trial runs, whereas staff requested blurred backgrounds and interactive shared screens. Both patients and staff requested simplified or improved patient information.

Documented Impact of Routine Feedback on Real-world Practice

Following the initial analysis of the results, the authors presented the above findings to relevant patient and professional stakeholders to provide rapid feedback on barriers and facilitators, possible areas for improvement, and ways to encourage the sustainable use of VCs. The findings were positively received by both clinicians and patients. In particular, clinicians reported underestimating patient satisfaction with VCs and were surprised to see such high levels of satisfaction with the service, particularly patient perceptions of communication quality and feeling their needs were met. The presentations aided in revising clinician perceptions, and some initial changes to VC practice have already been instigated, including the replacement of waiting room music with bird songs and efforts to improve patient information. Thus, the use of routine feedback and its analysis was instrumental in instigating some initial improvements for the use of VCs within the NHS Trust and promoting further conversations around future VC use and improvements. The implementing NHS Trust has now confirmed the procurement of Attend Anywhere for VC service provision to continue beyond COVID-19 restrictions.

Discussion

Principal Findings

This research contributes to the existing literature exploring staff and patient experiences with the rapid rollout of VCs for outpatient care during the COVID-19 pandemic [21], with clear implications for policy, practice, and future research. Specifically, this work contributes to the VC evidence base with a considerably larger sample than previous evaluations, in a rural setting and with a focus on VCs rather than telephone. We also provide documentation on the impact of routine feedback. Unlike existing literature mainly focusing on primary care or specific health services, this research explored the use of VCs across outpatient services more broadly, helping address limitations within the existing COVID-19–response literature [4,10].

Most patients rated their VC experience as *good* or *very good*, felt listened to and understood, were able to communicate everything they wanted to, and felt their needs had been met. Many patients reported saving time and money, and >90% (880/955) would likely choose a VC in the future, although it remains unclear whether this resulted from no perceived *alternative* option owing to the global pandemic or from positive patient experiences and related motivations. Further exploration would be beneficial, including analyzing patient experience over time. Staff also generally supported the use of VCs through positive experiences with joining and managing calls, being able to communicate all that was needed, and feeling the patients' needs had been met, although agreement on the latter issue was not unanimous. Staff also reported savings, mostly in terms of carbon footprint and time. Qualitatively, both staff and patients noted increases in service accessibility and affordability. As a result, this Trust commissioned Attend Anywhere for future (COVID-19 and post–COVID-19) use, and other Trusts should consider making VCs a permanent option beyond pandemic restrictions.

Patients aged ≥71 years (58/955, 6.1%) were the only age group in which a larger percentage of respondents reported needing support accessing their VC than those who were able to access alone. Nevertheless, there was no clear age gradient in satisfaction with VCs. Indeed, older adults were more likely to be positive about the technology than younger people. This may reflect higher expectations among younger people. Although high levels of positive experience were reported across all device types, more users of tablets or mobile devices were positive. The relationship between age, device used, and positive experience with VCs is complex. Research suggests that the small size of mobile phones can pose a barrier for older adults coupled with declining dexterity and vision. Mobile phones are mainly used by older adults for calls and texting [25], whereas tablet computers are more popular for web-based access among older adults than among younger people [26]. Older working age groups may be more likely to prefer technologies they are familiar with at work (often desktops with poor cameras and sound systems), whereas older adults new to computing use tablets as their entry device [27].

Clinical areas of less suitability for VCs were also noted, particularly by staff. Further research is needed to identify when VCs work best, for whom, and in what context. Although Greenhalgh et al [7] have already provided guidance on appropriate and inappropriate use of VCs, a more granular understanding from both a patient and professional perspective may be required. Some limitations were noted for spinal services, neurology, children, attentional issues, and assessing dysphagia. The previous guidance [7] suggested that inappropriate contexts included patients at high risk, patients requiring internal examination, and patients with challenges affecting the ability to use technology. This suggestion is supported by our work, with staff suggesting VC was less appropriate for patients with learning disabilities, communication disorders, fatigue, cognitive issues, or dementia.

Barriers described by staff and patients included technological difficulties, quality of patient information, administrative errors, and accessibility or suitability concerns. Conversely, identified benefits included reduced stress and anxiety for patients and staff, the opportunity to "open up more" for patients as a result of enhanced comfort, cost and time savings, increased sense of affordability, and service accessibility. Finally, the participants suggested a number of improvements, such as simplifying patient information, notifications for late appointments, the ability to turn off waiting room music, a shared interactive whiteboard, blurred backgrounds, and "practice run" opportunities to increase familiarity and digital skill confidence. Other suggested improvements included allowing photo or video upload to the appointment, swapping between cameras used, extending Attend Anywhere to other internet browsers, and expanding the character restrictions of the chat function, particularly important for accessibility of deaf patients. Thus, this study has a number of practical implications. Routinely collecting and responding to feedback is likely to be an integral aspect of service improvement, as demonstrated in this study. Feasible improvements such as those reported here are likely to have important impacts on staff and patient experience.

The need to simplify and improve patient information was highlighted as a key barrier by both staff and patients, and this may be best achieved in co-design with patients. Although the implementation of VCs was a rapid response, actively involving patients and the public and creating digital-related information may improve accessibility, relevance, and understanding. Thus, an implication of this work is an identified need to establish the best practice for rapid co-design when implementation timing is critical. Any future patient information may also include guidance for patients on camera positioning to reduce another barrier identified in this work. Health care services may also benefit from recommending particular devices based on their functionality and service requirements. For example, larger, static screens may be suitable for child therapies or family-based interventions where patients and families need to sit side by side. Alternatively, VCs that include assessment of movement may be better suited to more portable devices such as mobile phones or tablets.

An important consideration for VCs is safeguarding. Bhardwaj et al [13] reported that clinicians were confident in performing safeguarding and risk assessments remotely. Our results indicate

otherwise as clinicians reported that home visits were key for patient safeguarding and to allow monitoring of self-neglect, decline in well-being, or poor medication. Therefore, home visits for patients requiring environmental assessments could be prioritized for face-to-face appointments, as could consultations relating to the identified less appropriate contexts. However, this assumes that environmental assessments are not possible via VC, where perhaps a visual tour of the home environment during a VC would suffice. Thus, an alternative implication is guidance for clinicians in this regard. A further concern was raised by clinicians consulting with patients in residential care with respect to widening health inequalities as patients are often unable to attend consultations where computers are housed in staff offices. In addition, some patients in these contexts appeared unable to appropriately position their camera, suggesting the potential for solutions such as affordable telepresence devices or robotics in residential care to facilitate VCs. This could respond to two barriers: (1) patients being excluded from VCs because of equipment in staff offices and (2) challenges regarding appropriate camera positioning.

As the final practical implication, in response to patients noting administrative and human errors, the collaborative development of checklists and supportive training may be beneficial. Trusts could perhaps include on-screen checklists on patient records to ensure that scheduling of VCs is followed by provision of an appropriate link, patient-facing guidance, and setup support. Clinicians may also consider promoting the benefits of teachers or distant relatives attending a VC.

Our study also raises implications for the collection and use of routine feedback. The clinicians in our sample overestimated patient dissatisfaction with VCs. More clinicians than patients also responded negatively to communication quality. A minority of clinicians reported some impairment of therapeutic flow. Our presentation of these results to Trust stakeholders supported this observation, with clinicians surprised about high patient satisfaction. Some clinicians reported avoiding VCs for fear of patient dissatisfaction. Thus, the provision of this routine feedback aided in addressing staff perceptions. It is possible that low staff expectations for VCs somewhat explains the low documented uptake of VCs in comparison with telephone calls in previous research [10,13,14]. When collecting routine feedback, critically considering the purpose is important. For example, Sibley et al [28] recently likened the increasing collection of patient feedback to an "avalanche...with experience now tracked, monitored and measured to an almost obsessive degree" [28]. However, to what end and for what purpose? Reflecting previously acknowledged concerns around the ethics of collecting patient feedback that leads to minimal direct benefit [29,30], Sheard et al [31] suggested all patient feedback tools must be meaningfully usable by those providing frontline care; otherwise, it becomes "unethical to ask patients to provide feedback which will never be taken into account" [31]. Thus, service providers should ensure that routinely collected feedback (including after an Attend Anywhere appointment) is meaningful for both patients and clinicians, serves a beneficial function beyond mandatory feedback collection, and focuses on care delivery aspects that are most important to patients and clinicians. Future research may consider which feedback

methods are most effective in encouraging responses, particularly in the new *digital norm*, with staff members supported and empowered in acting upon and responding to feedback received.

Limitations

The first limitation of this research is the reliance on a self-selected sample of individuals who attended or facilitated a VC and chose to provide feedback. Experiences or barriers for those unable or choosing not to use VCs currently remain unknown, as do the experiences of those not providing feedback following their VC. Nevertheless, from this study, we know that hundreds of staff members and patients had a positive experience with VCs. Second, owing to the anonymous nature of the data set, we were unable to identify how many individuals completed the survey on repeated occasions; thus, the results may be skewed by repeat respondents. Third, this research relies on secondary data and the subsequent questions or scales used by the Trust. Although informed by the *1-week implementation guide for NHS Trusts and NHS Foundation Trusts* provided by NHS England and NHS Improvement [23], the survey had some limitations—some of the questions were poorly worded, and the questions were not directly comparable between staff and patient questionnaires (a more detailed discussion is provided in Multimedia Appendix 1). Furthermore, to the researchers' knowledge, the survey was not created in co-design with all relevant stakeholders, including patients and carers. Therefore, the questions asked may not reflect the most important aspects of the VC experience for patients.

Future research could explore challenges and barriers for excluded patients, particularly those considered seldom heard or marginalized in the context of digital health [32]. Murphy et al [12] noted previously that digital consultations increase access for those with information technology skills but may reinforce existing health inequalities. There is an important balance required between acknowledging increased accessibility for some patient groups who may encounter difficulties accessing face-to-face services and acknowledging reduced accessibility for others. This aspect needs urgent further work and reiterates the importance of patient choice and availability of multiple media to access health and care services.

The nature of this study meant that we were also unable to conclude on a number of additional factors, highlighting the scope for further research. Apparent efficiency savings in service delivery via VC should be explored to assess the impact of VCs on clinician and patient experience. Although intensive work may aid in meeting growing health care requirements, workforce burnout poses a danger. Related to efficiency, further research should look to establish DNAs before and since the implementation of VCs, with almost a quarter of staff reporting less DNAs using VCs than with usual practice. This is an interesting result, and further work could explore the reasons for the reductions in DNAs compared with in-person consultations. Although the results suggest a reduction in DNAs generally, 3 staff comments suggested increases. It would be interesting to explore if DNAs that do occur are linked to patient inability to access VCs or lack of confidence with technology. Other implications for future research include a need to identify

the mechanisms responsible for the positive patient experiences and high levels of future VC use intentions, as demonstrated by the Trust in this research. By doing so, other Trusts and health care services can engage with acknowledged areas of best practice. Economic evaluations that incorporate clinician, patient, and environmental savings may also be beneficial, although it is important to emphasize that potential cost savings should not take precedence over patient safety, quality of care, and stakeholder experience.

In addition, suggestions made in this research that VCs improve "affordability" of appointments and comfort in sharing personal or clinical information are important areas of future interest. Future research questions could include how and in what ways have VCs affected patient accessibility? Similarly, how, if at all, do VCs affect the therapeutic relationship? Future research could compare patient satisfaction with more conventional face-to-face consultations or other VC platforms. In addition, the range and type of consultations available to patients are currently limited and expressed satisfaction may reflect a lack of choice or alternatives. Future research may review patient experiences over time, particularly during times of heightened and reduced COVID-19 restrictions.

Comparison With Previous Work

Generally, our results continue to demonstrate positive experiences for staff and patients with VCs during the pandemic [4,9,10,16], furthering previous work with smaller samples and narrower focus. For example, congruent with Gilbert et al [4], we found that positively perceived aspects of VCs included reduced travel times and reduced impact of travel on symptoms such as fatigue [4]. Other similarities with previous work include low confidence reported among some participants [4] and the negative impact of technological limitations and difficulties on patient experience [4,9,12,13]. Findings from this research regarding age differences in independent use and family involvement are also congruent with other research [12,33]. However, given the difficulties that many older adults have in traveling to outpatient clinics [34] and the largely high acceptability of VC use reported in this study for older adults, no quick assumptions should be made about the unsuitability of VC for older adults.

Areas of divergence from the existing literature include patients reporting higher levels of satisfaction and willingness to use VCs in the future than in previous work [4]. Previous feedback was collected within an entirely orthopedic service, which could suggest that greater satisfaction and use intentions are seen here owing to the variety of services included, which may better

translate to VC than orthopedics as perhaps a more *hands-on* service. However, this would need further exploration as survey limitations impair our understanding of exactly which service patient respondents accessed. Other contributions of this research include the identification of additional benefits, including enhanced comfort and subsequent ability to "open up more." This contrasts with the results of Liberati et al [14], who reported impairments to depth of conversation and relational quality via remote means. Although this paper reports on a larger sample, Liberati et al [14] also reported on qualitative interviews. Therefore, this incongruence in results is worth exploring further, perhaps across specific psychological therapy services. In contrast to Isautier et al [9], who suggested that telehealth limitations included poorer quality of communication, our results suggest that most patients were satisfied with the VC aspects related to communication, with combined technical satisfaction being lower, congruent with Kayser et al [10]. In addition, in this study, we provide further insight into the influence of patient age and device used in predicting overall VC experience, with implications for targeted consultations in the future. This research also provides interesting insights into both staff and patients reporting an increased sense of accessibility and patient perception of enhanced affordability. Therefore, our work contributes to furthering previous research [4,9-17] that reported on small sample sizes and generally single-service focus, whereas we report on a comparatively large sample across outpatient services in a rural and older adult setting [18,20].

Conclusions

In conclusion, most NHS staff members and patients reported positive experiences with VCs for outpatient care in a rural, older adult, and deprived setting. Patients often felt listened to, able to communicate their needs, and understood, and staff and patients noted resource savings and enhanced accessibility. However, some barriers identified, such as technological difficulties, accessibility of patient information, and accessibility or suitability concerns, require further attention if the potential benefits of VCs are to be realized and their use is to be sustained. The implications of this research include the implementation of patient-suggested improvements, including trial calls, turning music off, facilitating photo uploads, expanding written character limit, and supporting VCs on other browsers. Future work may explore the accessibility and experience of patients excluded from this study through lack of VC access. In addition, this study demonstrated the real-world impact of routine feedback and raises further discussion on the future use of routine staff and patient experience data.

Authors' Contributions

All authors have read and approved the manuscript. HB analyzed and interpreted the results and led in producing the manuscript. RB analyzed and interpreted the results and substantively contributed to the manuscript. KE analyzed and interpreted the results

and substantively contributed to the manuscript. SS reviewed and contributed to the manuscript. KA provided expertise in patient experience and engagement and reviewed and substantively contributed to the manuscript. EW facilitated access to patient experience data, provided contextual data, and reviewed and substantively contributed to the manuscript. AC reviewed and substantively contributed to the manuscript. RJ analyzed and interpreted the results and reviewed and substantively contributed to the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Shift work is associated with sleep disorders, which impair alertness and increase risk of chronic physical and mental health disease. In health care workers, shift work and its associated sleep loss decrease provider wellness and can compromise patient care. Pharmacological sleep aids or substances such as alcohol are often used to improve sleep with variable effects on health and well-being.

Objective: We tested whether use of noise-masking earbuds can improve reported sleep quality, sleepiness, and stress level in health care shift workers, and increase alertness and reaction time post night shift.

Methods: Emergency medicine resident physicians were recruited for a prospective, single-subject design study. Entrance surveys on current sleep habits were completed. For 14 days, participants completed daily surveys reporting sleep aid use and self-rated perceived sleepiness, tension level, and last nights' sleep quality using an 8-point Likert scale. After overnight shifts, 3-minute psychomotor vigilance tests (PVT) measuring reaction time were completed. At the end of 14 days, participants were provided noise-masking earbuds, which they used in addition to their baseline sleep regimens as they were needed for sleep for the remainder of the study period. Daily sleep surveys, post–overnight shift PVT, and earbud use data were collected for an additional 14 days. A linear mixed effects regression model was used to assess changes in the pre- and postintervention outcomes with participants serving as their own controls.

Results: In total, 36 residents were recruited, of whom 26 participants who completed daily sleep surveys and used earbuds at least once during the study period were included in the final analysis. The median number of days of earbud use was 5 (IQR 2-9) days of the available 14 days. On days when residents reported earbud use, previous nights' sleep quality increased by 0.5 points ($P<.001$, 95% CI 0.23-0.80), daily sleepiness decreased by 0.6 points ($P<.001$, 95% CI –0.90 to –0.34), and total daily tension decreased by 0.6 points ($P<.001$, 95% CI –0.81 to –0.32). These effects were more pronounced in participants who reported worse-than-average preintervention sleep scores.

Conclusions: Nonpharmacological noise-masking interventions such as earbuds may improve daily sleepiness, tension, and perceived sleep quality in health care shift workers. Larger-scale studies are needed to determine this interventions' effect on other populations of shift workers' post–night shift alertness, users' long-term physical and mental health, and patient outcomes.

Introduction

Over the last several decades, sleep deficiency has reached epidemic proportions. An estimated one-third of adults in the United States do not get the recommended seven hours of sleep nightly, and at least 50 million Americans have chronic sleep disorders [1,2]. Shift work, including working overnight hours, having variable or rotating schedules, or working extended hours on call uniquely contributes to worse sleep and poor work-related outcomes [3-6]. Health care practitioners and support staff represent occupation groups with some of the highest prevalence of shift work and sleep problems including sleep disturbances (eg, multiple awakenings), and sleep deficiency from either extended wake episodes (ie, acute sleep deprivation) or multiple days or nights of insufficient sleep (ie, sleep restriction or chronic sleep deprivation) [7].

In health care workers, sleep loss impairs alertness, which can lead to poor work performance and medical errors, potentially compromising patient care [4,8-11]. Despite the recognized impact of sleep loss on clinician health and patient safety, workplace interventions to combat sleep loss and improve restful sleep are lacking compared to other wellness initiatives [12]. Accordingly, we assessed the impact of noise-masking earbuds on self-reported sleepiness, sleep quality, stress level, and post–overnight shift alertness in emergency medicine (EM) resident physicians.

Methods

Study Design and Setting

This prospective, single-subject design study was performed at a single urban academic medical center. This facility hosts residency training programs for multiple specialties including a 4-year EM training program.

Ethical Considerations

This work was approved by the institutional review board (IRB), and all participants gave informed consent. This study was approved by the Brigham and Women's Hospital Institutional Review Board (2019p002509).

Participant Recruitment

EM resident physicians working full-time at the emergency department (ED) during the study period were recruited. All EM residents who were not hearing impaired and who owned a smart phone capable of receiving SMS text messages and opening electronic surveys were eligible for inclusion. Participants were recruited via email to the residency listserv and through a text message in a resident-specific group messaging app delivered to their personal devices.

Within this residency training program, each resident works between 18-21 shifts in a rotating schedule comprising day shifts (roughly 7 AM to 5 PM), twilight shifts (roughly 3 PM to 2 AM), or overnight shifts (roughly 11 PM to 8 AM) over each 28-day period. Each participant works 5-7 overnight shifts over a 28-day period.

Interventions

Following consent procedures, participants completed an electronic entrance survey that included questions about their baseline sleep habits, sleep aid use, self-reported sleep quality, daily sleepiness, and daily tension over the prior 28 days (Multimedia Appendix 1). Over the next 14 days (the control period), participants were instructed to continue with their baseline sleep habits. On study day 15, each participant was provided with a pair of Bose SleepBuds (Bose Corp). SleepBuds (hereby referred to as "earbuds") are earbuds worn in both ears all night and function to mask ambient noises by playing various sound tracks selectable from the Bose app, which each target decibels that are specific to common ambient sounds. Participants were given instruction on device functionality including the app for activating the device noise-masking technology, which only occurs when the device is turned on and used in conjunction with the app. Participants were instructed to use the earbuds with the noise-masking technology for their sleep episodes as needed over the next 14 days in addition to their preferred baseline sleep aids. This 14-day period was considered the intervention period. Earbud use was at the discretion of each participant, and study personnel who were not affiliated with the Bose Corporation were available throughout the study period to answer questions about functionality or troubleshoot device function. At the end of the study period, participants completed an electronic exit survey on sleep aid use and earbud functionality over the prior 28-day period (Multimedia Appendix 1).

Measurements

Daily Surveys

Each day of the 28-day study period, participants received an automated SMS text message at 12 noon containing a daily survey asking them to rate the quality of their last sleep episode, current daytime sleepiness, and current level of tension. All measures were reported on 8-point Likert scales of 0 (extremely bad sleep quality, not sleepy at all, and not tense at all) to 7 (extremely good sleep quality, extremely sleepy, and extremely tense). Beginning on day 15, daily surveys also included a question about whether earbuds were used during the last sleep episode (Multimedia Appendix 2).

Psychomotor Vigilance Testing

After every overnight shift, each participant was approached by a trained study research assistant to complete a 3-minute psychomotor vigilance test (PVT, PVT Research Tool, Texas A&M University System CSE) [13]. This test was conducted on portable tablet devices requiring participants to rapidly tap a circle as it appeared on a tablet screen, and the reaction time for each tap was measured. Participants were able to decline

participation in the daily PVT if clinical demands required their attention.

6-Month Follow-up

After the study period, participants were allowed to keep their earbuds for their own personal use. At 6 months after study completion, participants were sent an electronic survey asking about sleep aid use since study completion, including earbud use. For participants still using earbuds, additional questions about when and how they most commonly used the device since the study period were included.

Data Management and Statistical Analyses

Study data were collected and managed using REDCap electronic data capture system sponsored and hosted at our institution. Data were deidentified prior to analysis and analyzed using Stata (version 16; StataCorp). Frequencies and percentages were used to summarize binary and categorical variables. Mean (SD) or median (IQR) values were used to summarize time variables and Likert scale data.

Changes in quality of the last sleep episode, current daytime sleepiness, and current level of tension in control and intervention periods were assessed using a linear mixed effects regression model with a participant-specific random intercept. In the postimplementation period, we only included data collected on days when participants reported using the earbuds. For PVT data, each participant's mean reaction times pre- and postintervention period were directly compared. Six-month follow up responses were qualitatively assessed.

Results

Participant Demographic Characteristics

Of 58 invited participants, 38 participants enrolled in the study. Of these, 6 participants who did not complete any daily surveys and 6 who participated in surveys but never used the earbuds were excluded. The remaining 26 participants completed a total of 655 daily sleep surveys. We further excluded surveys taken on postintervention days when participants reported not using earbuds, resulting in 501 daily surveys being included in final analysis (Figure 1). Participants included in final analysis represented resident physicians from all 4 postgraduate years. In total, 27% of participants included in the final analysis were female, and their ages ranged from 25 to 35 years (Table 1).

Figure 1. Study design flow chart. PVT: psychomotor vigilance test.
Table 1. Participant demographic characteristics (N=26).

Variables	Participants
Sex, n (%)	
Male	19 (73.1)
Female	7 (26.9)
Age (years), n (%)	
20-25	0 (0)
25-30	12 (46.1)
30-35	14 (53.9)
>35	0 (0)
Training year, n (%)	
PGY1	5 (19.2)
PGY2	9 (34.6)
PGY3	7 (26.9)
PGY4	5 (19.2)
Baseline average sleep or tension measures over the 4 prior weeks, median (IQR)	
Sleep quality	5 (4-6)
Sleepiness	4.5 (4-5)
Tension	5 (3-5)
Baseline sleep and aid use, n (%)	
Blackout curtains	16 (61.5)
Eye mask	8 (30.8)
Earplugs	6 (23.1)
Weighted blanket	1 (3.8)
White noise	9 (34.6)
Pharmacological sleep aid[a]	9 (34.6)
Other	1 (3.8)
None of the above	2 (7.7)

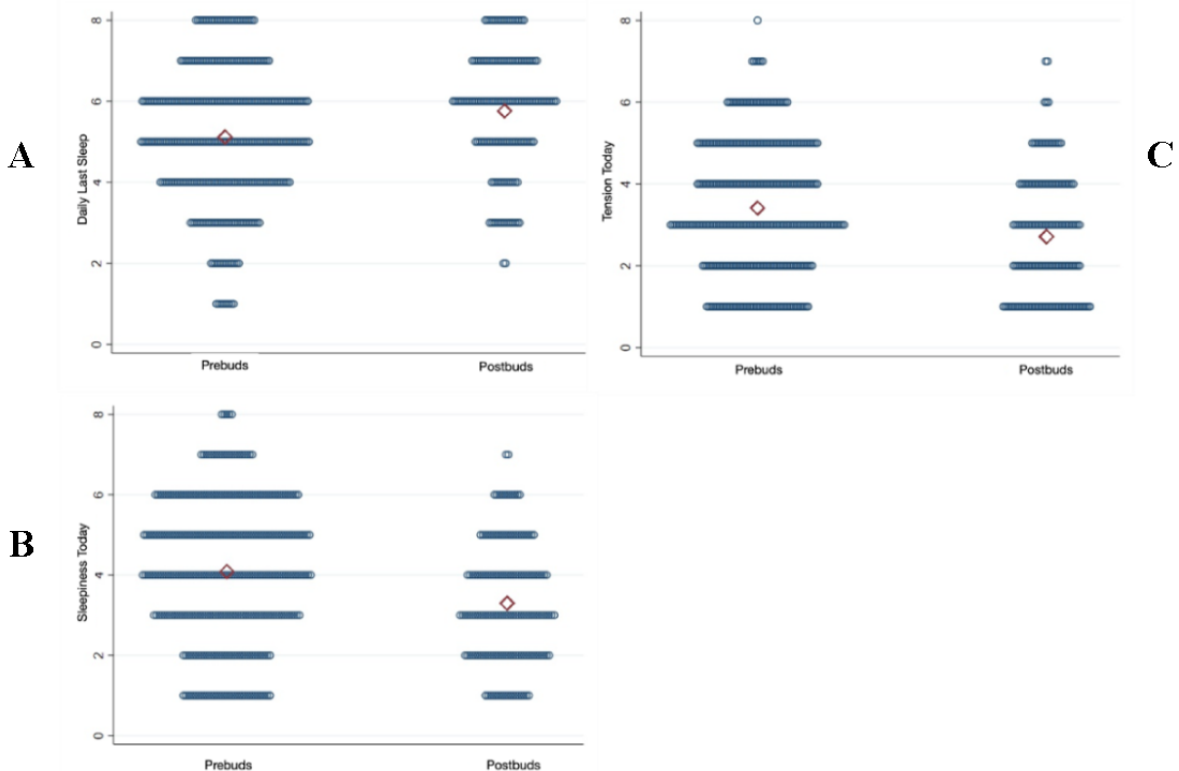
[a]Pharmacological sleep aid refers to oral medications such as melatonin, benzodiazepines, zolpidem, or diphenhydramine.

Earbud Use

Among participants who reported using earbuds at least once, the frequency of use varied. Of 14 days when earbuds were available, participants used earbuds for a median of 5 (IQR 2-9) days. The lowest earbud use occurred on day one of the intervention, with 6 of 26 participants reporting use, trending upward until day 4 when 15 of 26 participants reported using earbuds, and remaining generally stable with a slight downward trend in use toward the end of the study (Figure 2). Participants who reported using earbuds for ≥7 of the 14 days did not have significantly different baseline prestudy 4-week sleep scores than those who reported using earbuds between 1 and 6 days (mean score 5.2 vs 4.8, *P*=.34).

**Figure 2.** Reported earbud use over the intervention period.
Sleep Quality, Daily Sleepiness, and Tension

Participants' self-reported last sleep episode quality, daily sleepiness, and daily tension had improving trends in the postintervention period (Figures 3A-C). On days when residents used earbuds, on Likert scales of 0 to 7 points, previous nights' sleep quality increased by 0.5 points ($P<.001$, 95% CI 0.23-0.80), daily sleepiness decreased by 0.6 points ($P<.001$, 95% CI –0.90 to –0.34), and total daily tension decreased by 0.5 points ($P<.001$, 95% CI –0.81 to –0.32) using linear mixed regression models. In the subset of participants who reported below-median sleep scores before the intervention, the beneficial effects of using earbuds were amplified.

Figure 3. Self-rated last nights' sleep quality (A), daily sleepiness (B), and daily tension (C) on days with earbud use during the prior sleep period.


Post–Night Shift Reaction Time and Alertness

In total, 7 post–overnight shift residents completed a total of 12 PVT tests during the intervention period. A total of 6 completed PVTs were linked to participants who reported no earbud use and were thus excluded from the final analysis. Ultimately, 3 participants both used the earbuds and completed PVTs in both the control and intervention periods. Data from these participants comparing pre- and postearbuds mean reaction time showed no significant differences; however, this study was underpowered to detect an effect of earbud use on PVT.

6-Month Follow-up

We received responses from 12 (46%) participants. Of the 12 respondents, 5 reported ongoing earbud use; all of whom reported use on less than 25% of all sleep episodes since study completion. Participants cited limited sound options, uncomfortable fit, and forgetting to use the device as barriers to further use. There were no notable differences in self-reported baseline sleep aid use and 6-month follow up sleep aid use.

Discussion

Principal Findings

We report that adding a noise-masking earbud, Bose SleepBuds, to a sleep routine can foster significant improvements in shift workers' self-reported sleep quality, sleepiness, and tension over baseline sleep habits. Participants in this sample noted statistically significant improvements following use of earbuds, and minimal safety concerns were identified. In health care providers, poor sleep contributes to decreased alertness and performance, which adversely affects patient care. Sleep-deprived shift workers demonstrate decreased mood, and professional fulfillment, emotional exhaustion, and increased rated of burnout [10,14-18].

Sleep and wake disturbances are common among shift workers and can produce a primary circadian rhythm disorder called "shiftwork sleep disorder" (SWSD) characterized by insomnia, excessive sleepiness, and significant sleep loss [6,19,20]. Sleep problems are associated with debilitating chronic physical and mental health disease. In addition to excessive sleepiness, sleep deficiency and SWSD are associated with critical short- and long-term health concerns. Sleep deficiency in shift workers has been associated with obesity, type 2 diabetes, stroke, multiple types of cancers, and cardiovascular disease [21-24].

To combat shift work–associated sleep loss, shift workers may develop self-designed strategies to assist with sleep. One common approach is to alternate between the use of pharmacological stimulants and sedatives to achieve wakefulness or sleep as needed. Staying awake and alert during shift can require aids such as caffeine or nicotine [25,26]. To accelerate the onset of sleep, over-the-counter supplements such as melatonin, prescription sleep aids such as benzodiazepines, or other sedative-hypnotic medications (eg, so-called "Z-drugs" such as zolpidem) are also often used [26-28]. Despite the fact that alcohol consumption worsens sleep overall, postshift alcohol use is another common strategy among shift workers to achieve sleep, a strategy that has been associated with binge drinking disorder [29,30]. Each of these strategies demonstrate variable efficacy and can have significant off-target, often deleterious, health effects, development of compulsive use consistent with addiction, and poor patient care.

Participant adherence and uptake in the intervention was one challenge faced in this study. When considering wellness interventions, in addition to intervention efficacy, institutions must also consider factors such as participant interest and adherence and cost-benefit ratios of a given intervention. Here, roughly two-thirds of the approached participants elected to enroll in the study in which they were receiving sleep aid devices free of charge. It is possible this number may serve as a proxy for interest in such nonpharmacological sleep aid devices or in sleep interventions in general. Direct assessment of shift worker interest in nonpharmacological sleep interventions, such as this one, are needed. Interestingly, a larger proportion of males than females enrolled in the study despite the fact that the group originally solicited was roughly even in terms of sex. This may suggest that an electronic sleep device such as noise-masking earbuds are more attractive to males than to females as an intervention. Further analysis of the most likely users may be helpful in targeting sleep interventions to users who may benefit from or adhere most to them. Finally, cost-benefit ratio is often a consideration when implementing wellness initiatives. Though the particular noise-masking earbuds studied here have a relatively high price point for the general public, targeting these devices to participants who may have the highest uptake, adherence, and physiological outcomes may result in a favorable cost-benefit ratio for organizations. Further work is needed to more carefully target sleep interventions such as the earbuds studied here.

Shift workers experience striking rates of workplace burnout; yet, occupational interventions targeting sleep problems are often lacking compared to other wellness initiatives [12]. The importance of this work, therefore, is that noise-masking earbuds may improve several metrics of sleep quality without the threat of problematic substance use, medication adverse events, or pharmaceutical misuse. Although we identified several beneficial effects of the noise-masking earbuds on self-reported sleep and tension, alertness testing via PVT was underpowered to detect an effect in our study population. Because health care professionals are particularly vulnerable to the deleterious effects of sleep loss and SWSD is prevalent in up to 30% of the general population, our findings, while limited, have broad therapeutic potential in multiple industries where shift work is common, including medicine.

Limitations

This was a single-arm study with a small sample size, and variable intervention adherence, all of which affected the analytical power of this study. Further efficacy should be evaluated in a randomized controlled trial comparing earbud use to a matched control. Here, we focused on resident physicians as representatives of the health care shift worker population. This population tends to be fairly young (between 25-35 years old), and may be more willing to use new technology than shift workers as a whole. While approximately one-third of resident shifts are overnight, night shifts tend to be clustered and are not evenly distributed over a 28-day period.

Thus, typical resident schedules are somewhat suboptimal for a single-subject design where subjects serve as their own controls across 28-days. The PVT data collection was limited given the smaller number of data points across control and intervention periods for individual participants. Future solutions may include recruiting study participants such as nocturnists, who are physicians who work a higher proportion and more consistent distribution of night shifts, other groups who work exclusively overnight, or participants with clinically diagnosed SWSD. Increasing study population size or extending the study period by multiple months would likely enhance our data points and improve study power.

Variable intervention adherence also affected our findings. Manually filling out daily surveys and PVT testing after overnight shifts can be burdensome to participants. Participants may have forgotten to complete surveys after receiving the SMS text message reminder. Future studies will consider alternative data collection strategies that may present less of a barrier, such as automatic data collection on sleep quality via wearable fitness trackers or cellular telephones. These strategies may also provide more objective measures of sleep quality as opposed to self-reporting. In terms of inconsistent device use, participants cited a desire for additional sound options including selectable music, improved device fit, and needing reliable reminders to improve intervention adherence. Addressing these factors will be crucial to designing maximally effective digital therapies for sleep deprivation in the future.

The potential for sustained adherence is an important consideration in any wellness intervention. Here, at 6-month follow up, <50% of respondents reported ongoing earbud use beyond the study period. Six-month follow-up responses were collected from only 46% of original participants; thus, the limited response rate likely impacts our ability to draw firm conclusions from these data. Subjectively, however, reasons commonly cited for limited ongoing use included poor fit, limited audio tracks, and forgetting to use the earbuds. The fit and audio selection can be addressed by manufacturers to make such products more attractive to users. Habit formation and establishing automated behaviors are key to implementing sustainable health and wellness interventions. Data from nutritional wellness interventions suggest habits can take more than 50 days to reach automaticity [31]. Regarding forgetting to use the device, it is likely our study period was not long enough to promote habit formation. Prolonging the intervention study period with frequent reminders to use the device, or instructing participants to place the device in a convenient, easily accessible location that will remind and reinforce use can be helpful. Further, time-based cues such as reminders on cellular telephones can help establish behaviors while habit formation is taking place [31].

As a pilot study, the aim of this work was to assess uptake, user receptiveness, and perceived effect of a nonpharmacological sleep intervention. Important next steps for future studies include evaluating objective measures of sleep and mood, physician burnout among earbud users, as well as potential changes in clinician performance and patient outcomes such as physician errors or return visit rates. While participant experience is an important component in evaluating the effect of a wellness intervention, objective outcomes studies will help corroborate the utility of implementing such interventions on an institutional level.

Comparison With Prior Work

While electronic devices aimed at addressing sleep problems do currently exist, few have robust data supporting their efficacy. Most common devices addressing poor sleep include fitness trackers or mobile apps to track sleep quality, but these rarely offer therapeutic interventions [32,33]. Existing digital therapies for poor sleep include app-based meditation or relaxation guides, and app-guided cognitive behavioral therapy [34,35]. Though moderately effective in some populations, these interventions are often targeted at addressing chronic sleep loss and insomnia, are subject to intervention fatigue, and do not address acute sleep problems and circadian rhythm disruption common in post–night shift health care workers.

Devices supplying white noise are commonly marketed as sleep aids. Despite broad commercial penetrance, evidence for the efficacy of continuous white noise on sleep onset, latency, or quality is inconsistent [36-39]. Many factors likely play into the effect of ambient sounds on sleep, including but certainly not limited to the type of sound, the ability to block out alternative ambient noises, and sound volume among other factors. The SleepBuds technology used in this study included first-generation devices that provide noise-masking technology to reduce ambient auditory distractions with optional relaxing sounds. Given our promising results, future work can explore the effect of subsequent-generation devices with enhanced functionality targeted at relaxation. This work will both assess the efficacy of this digital intervention, as well as contribute to the existing body of work on the therapeutic effect of ambient noise on sleep overall.

Conclusions

Sleep loss is a public health crisis that disproportionately affects the physical and mental health of shift workers. The recent emphasis on support programs aimed at improving employee wellness and decreasing burnout is not reflected in interventions aimed at improving sleep. Our data demonstrate the efficacy of a digital intervention addressing sleep disturbance. This intervention is of low risk and is feasible in a complex cohort such as medical resident physicians. While our target population was health care shift workers, extension of our findings to other industries and cohorts is reasonable. Our work prepares for additional studies to improve employee health and wellness through effective, generalizable, and scalable sleep interventions.

Acknowledgments

Authors' Contributions

NMD conceptualized and designed the study, wrote and submitted the IRB draft, acquired, analyzed, and interpreted the data, and drafted and revised the manuscript. MAH and GJ oversaw IRB draft submission and data acquisition and management. OB carried out data analysis and interpretation and manuscript drafting and revision. AJG drafted and revised the manuscript. AC and AIL conceptualized and designed the study, wrote and prepared the IRB draft, and revised the manuscript. DA mentored the design of the study and revised the manuscript. EWB mentored the design of the study, analyzed and interpreted the data, and drafted and revised the manuscript. AJE mentored the design of the study, sought funding resources, and revised the manuscript.

Conflicts of Interest

The authors have no conflicts to report.

Abstract

Background: The overuse of antibiotics has rapidly made antimicrobial resistance a global public health challenge. There is an emerging trend where providers who perceive that their patients expect antibiotics are more likely to prescribe antibiotics unprompted or upon request. Particularly, health care providers have expressed concern that dissatisfied patients will provide disparaging online reviews, therefore threatening the reputation of the practice. To better deal with the negative reviews and inform patients, some health care staff directly respond to patients' online feedback. Engaging with patients' online reviews gives providers an opportunity to prevent reputational damage and improve patients' understanding of the antibiotic resistance problem.

Objective: We aim to test the effectiveness of different response strategies to the negative patient online reviews on the readers' perceptions of the health care provider and their perceptions related to antibiotics resistance.

Methods: Two experiments were conducted to examine the impact of message tactics (apologizing, inducing fear or guilt) that can be employed by health care providers when responding to patients' negative online feedback related to not receiving an antibiotic.

Results: Overall, our results demonstrated positive impacts of responding to patients' online reviews. In study 1, we found apologetic messaging and use of emotional appeals in the response were effective in making readers feel more favorable toward the message. Readers also expressed a greater credibility perception toward the provider and willingness to visit the clinic when emotional appeals were used. Findings from study 2 largely supported the effectiveness of a fear-based response in improving the readers' credibility perceptions and willingness to visit the clinic. The fear-inducing information was particularly effective among parent readers.

Conclusions: This paper demonstrated that a strategic response to online patient complaints could prevent reputational damage and minimize the potential negative impacts of the review. The results also glean insight into the step toward developing a novel intervention—crafting a persuasive response to patients' negative feedback that can help improve the understanding of antibiotic resistance problems.

KEYWORDS

Introduction

There are at least 2.8 million antibiotic-resistant infections per year in the United States, and as many as 35,000 people die each year due to such infections [1]. Nearly 1 in 3 antibiotics prescribed at outpatient facilities is found to be unnecessary [2]. Reducing the overuse of antibiotics in such facilities, like urgent care centers, can help to lower risks associated with antimicrobial resistance. While the judicious use of antibiotics has been widely promoted, there are still barriers to antibiotic stewardship practices [3]. The most commonly cited reason for unnecessary prescribing is providers' perception of patient expectation and satisfaction [4,5]. Studies have consistently reported that patient demand greatly influences antibiotic prescribing decisions [6-8]. Likewise, a major determinant of prescribing antibiotics in pediatric care is parents' expectations and pressure [9,10]. Improving communication between health care providers and patients is suggested as one of the ways to reduce overprescribing [11,12].

This perception of pressure from patients can be exacerbated by other external factors. For example, as patients are increasingly behaving as consumers by posting their experiences with health care providers to websites such as Yelp.com [13], providers may fear that their patient will post a disparaging online review of the clinic and provider when requested antibiotics were not provided. In fact, these felt pressures have become so well known that Wired Magazine termed it "the Yelp effect" [14]. A study showed that 65% of Americans are aware of these online ratings and 37% had avoided a physician based on negative reviews [15]. Anxious over potential negative online reviews, providers might be pressured to comply with unrealistic patient expectations such as prescribing antibiotics even when not warranted.

For the clinics of providers, it is important to engage with patient feedback as those reviews can influence future patients' visits [16]. For example, if the complaint is about not receiving requested antibiotics during the visit, providers can think of it as an opportunity to improve the patient experience and inform the patient about the potential consequences of taking unnecessary treatments or antibiotics. Nonetheless, few strategies have been tested to assess how they might positively impact patients' antibiotic perceptions and expectations and ultimately act as a step in stemming the tide of antibiotic resistance. In fact, there are no studies of this ilk in the domain of the so-called Yelp effect, yet there are effective risk and health communication strategies that should be tested in this domain. Scholars have long proposed that in order to garner attention, increase message scrutiny, and change attitudes, emotional appeals can be useful [17,18]. Two emotional appeals that have received attention are fear and guilt.

Fear appeals, which communicate an impending threat coupled with behavioral recommendations to mitigate the threat, have consistently been shown to effectively change attitudes [19]. If the fear appeal effectively communicates the threat and receivers believe the response is an effective measure they can take, then message receivers judge that the risk is dangerous and can affect their lives. A meta-analysis investigated fear appeal's effectiveness for influencing attitudes, intentions, or behaviors and found that fear appeals are effective [20]. In addition, practitioners find that fear appeals can be effectively used to persuade audiences when used appropriately [21]. When communicating antibiotic resistance, fear can be aroused by emphasizing the potential harm or danger that will befall individuals if they take unnecessary antibiotics. In this case, we argue that fear messaging can increase the perception of antibiotic resistance risk. Thus, the reader of a negative review would believe that a provider who did not provide antibiotics was being careful and protecting the patient. This could mitigate unfavorable effects of the negative review.

> *H1: A response from the clinic that features fear-inducing antibiotic resistance information will have a positive impact on (a) message favorability, (b) provider credibility, and (c) increased willingness to visit the clinic in the future relative to no response or a simple apology (ie, apologetic response).*

Guilt appeals, though, work through a different mechanism. Guilt appeals communicate that a harm could be potentially caused by our own actions or inactions and are commonly used in health and risk communication [22-25]. These subtle messages remind audiences of their moral code (eg, do not harm others) and can spark both attitude change and behavior change. Turner's research [22,26,27] revealed that when messages convey a discrepancy between individuals' moral norms and their potential future behavior, they are less likely to engage in the harmful behavior. In this case, people would be reminded that pressuring doctors for antibiotics ultimately affects the antibiotic health crisis. Guilt is seen as a prototypical moral emotion, and it is repeatedly used in persuasion campaigns for its behavioral consequences [24].

> *H2: A response from the clinic that features guilt-inducing antibiotic resistance information will have a positive impact on (a) making readers feel favorable toward the message, (b) increasing the credibility of the reviewed provider, and (c) increase the willingness to visit the clinic in the future relative to no response or an apologetic response.*

As indicated in hypotheses 1 and 2, one type of baseline comparison group we test is a simple apology. Apologies are considered to be the essential response component that service providers can use to handle consumer complaints [28,29]. Health care providers can engage in complaints by apologizing and taking responsibility for patients' negative experiences. This can help them to reclaim a favorable impression as prior research has documented that apologies are effective for reestablishing trust [30,31]. Accordingly, we hypothesized the following:

> *H3: A response from the clinic apologizing for patients' negative experience will have a positive impact on (a) making readers feel favorable toward the message, (b) increasing the credibility of the reviewed provider, and (c) increasing the willingness to visit the clinic in the future relative to providing no response to the review.*

Study 1

Introduction

Based on the vast literature on emotionally framed health and risk communication, we tested strategic communication regarding antibiotic resistance in the form of replies to negative patient online reviews. We test the effectiveness of fear, guilt, and apologetic message strategies used when responding to a patient's negative online reviews complaining about not receiving requested antibiotics during its visit to the local urgent care. We accomplish these objectives by conducting a randomized controlled experiment with the goal of examining the impact of different response message strategies on readers' perceptions of the health care providers and perceptions and knowledge about antibiotics resistance.

Methods

A between-subjects experimental design with 4 message conditions—control (no response), apology messaging, fear-based messaging, and guilt-based messaging—was used. Participants were asked to imagine that they have moved to a new town and need to find a local urgent care. Then, participants viewed a review site (like Yelp, but deidentified) where a patient provides a negative review of an urgent care. The patient arrived at urgent care with a cold and a sore throat but did not receive an antibiotic. The wording of the fictitious online review was based on real online reviews. Participants also saw the urgent care clinic representative's (staff or care provider) response to the negative review based on the experimental condition. See Multimedia Appendix 1 for stimulus. Participants were allowed to view this page as long as they needed to. Afterward, participants were asked to complete a short survey and asked their favorability toward the response; the credibility of the clinic, provider and staff; and willingness to visit the clinic in the future (see Multimedia Appendix 2). Participants were recruited through the Amazon Mechanical Turk platform. A total of 216 adults (55% (119/216) male, 81% (175/216) White) from around the nation were paid to take part in a 15-minute experiment. About 64% (138/216) of the participants were aged 30 to 49 years, and 42% (91/216) had a Bachelor's degree.

Results

To test the effect of response strategies on outcome variables, we ran a series of 1-way analyses of variance (ANOVAs) with Tukey post hoc testing. There was a statistically significant difference in readers' favorability toward the message ($F_{3, 212}=29.81$, $P<.001$), perceived provider credibility ($F_{3, 212}=3.66$, $P=.01$), and willingness to visit the reviewed clinic $F_{3, 212}=4.01$, $P=.008$) across message conditions (see Table 1).

Table 1. Effects of response strategies by messaging condition in study 1 (Note: Means in a row sharing superscripts are significantly different from one another).

Variable	Control (1)		Apology (2)		Fear (3)		Guilt (4)		η^2
	Mean	SD	Mean	SD	Mean	SD	Mean	SD	
Favorability toward the message	2.90[*]	0.78	3.86[#]	0.84	4.44[^]	0.89	4.30[^]	1.00	.297
Provider credibility perception	3.65[*]	1.17	3.71[*]	1.08	4.20[#]	1.06	4.16[*,#]	1.11	.049
Willingness to visit the clinic	3.56[*,#]	0.98	3.36[*,#]	0.98	3.89[*,^]	1.19	3.98[*,^]	1.08	.054

These data support the hypothesis that a fear-inducing message was effective in making readers feel more favorable toward the response (mean 4.44 [SD .89]) compared to the control group (P<.001). This response was also more effective than an apology message (mean 3.86 [SD .84], P=.003). H1a was supported. Furthermore, the fear message increased readers' credibility perception toward the reviewed provider (mean 4.20 [SD 1.06]) compared to the control group (mean 3.65 [SD 1.17], P=.06), and the apology message condition (mean 3.71 [SD 1.08], P=.09). H1b was supported. Respondents' willingness to visit the clinic in the future was only significantly different between the fear (mean 3.89 [SD 1.19]) condition and the apology condition (mean 3.36 [SD .98], P=.04). The mean difference between the fear-inducing condition and the control condition was not significant. Accordingly, H1c was partially supported.

Similarly, guilt-inducing messaging made readers feel more favorable toward the response (mean 4.30 [SD 1.00]) relative to apologetic messaging (mean 3.86 [SD .84], P=.047). Thus, H2a was supported. The guilt message did not increase readers' credibility perception toward the provider (H2b not supported). When a response offered guilt-based antibiotic resistant information, readers were more willing to visit the clinic in the future (mean 3.98 [SD 1.08]) compared to the apology message condition (mean 3.36 [SD .98], P=.01). Nonetheless, a statistically significant difference was not observed when the guilt condition was compared to the control condition (mean 3.56 [SD .98]). Therefore, H2c was partially supported.

We found that the readers who read an apology message (mean 3.86 [SD .84]) from a clinic, which received a negative review from a past patient, felt more favorable toward the response compared to the readers who read the negative patient review with no reply from the clinic (mean 2.90 [SD .78], P<.001). However, there was no significant effect of apology messaging on the credibility perception and willingness to visit the clinic. Thus, H3a was supported, but H3b and H3c were not supported.

The findings from study 1 provide empirical support for the idea that engaging with patients' negative reviews with an effective and evidence-based communication strategy can prevent potential reputational damage and improve the patient-provider relationship. In doing so, our findings suggest that rather than just apologizing for patients' negative experiences (which implies admitting blame), using emotional appeals would further enhance the effectiveness of the message

in building favorable attitudes, credibility, and increasing potential patients' chance to visit the clinic in the future.

Specifically, we found that apologizing for a patient's negative experience can make readers feel more favorable, but it did not increase credibility perceptions or willingness to visit the clinic. If the goal of the communication is to restore credibility and increase patient visits, emotion-based messaging is more effective than not responding or apologizing. We found the fear-inducing information related to antibiotic resistance was particularly effective in increasing the credibility perception of the provider.

These findings can help empower managers, owners, and providers within urgent care clinics to deal with the pressures patients might exert when they want antibiotics. It is critical that providers feel confident that they can engage in clinically sound practices without harming their, or the clinic's, credibility. It is critical to assess the replicability of these findings, though, so we replicated and extended this study with a second national panel of participants.

Study 2

Introduction

A second study was conducted to test the robustness of some of the key findings from the first study. In a pediatric care setting, parent pressure to prescribe antibiotics for their child is a barrier for working toward a strict adherence of antibiotic prescription [9,10]. Thus, in the second experiment, we test the effectiveness of response strategies when a negative online review is left by a parent who did not get antibiotics prescribed for their sick child. In study 2, we also compare which type of message strategy (control vs apology vs fear vs guilt) is more effective in altering readers' antibiotics expectations and perceptions.

In study 1, we examined if strategic messaging could improve readers' perceptions toward the reviewed provider. To test the robustness of the findings, we suggest the following hypotheses:

> *H1: A response from the clinic that features fear-inducing antibiotic resistance information will increase (a) the credibility of the reviewed provider and (b) the willingness to visit the clinic in the future relative to providing no response or an apologetic response.*
>
> *H2: A response from the clinic that features guilt-inducing antibiotic resistance information will increase (a) the credibility of the reviewed provider and (b) the willingness to visit the clinic in the future relative to providing no response or an apologetic response.*
>
> *H3: A response from the clinic apologizing for patients' negative experience will increase (a) the credibility of the reviewed provider and (b) the willingness to visit the clinic in the future relative to providing no response to the review.*

In study 2, we also test if the clinic's response can be an effective educational intervention that improves people's understanding of the antibiotic resistance problem. We predict that an effective message will lower people's unrealistic expectations for antibiotics and reduce the conception of better to be safe than sorry (BSTS). The latter, BSTS, is the common misperception that even in the cases when taking antibiotics are unlikely to be effective; patients perceive that there is some chance that antibiotics might be effective and have little risk. Patients prefer to take antibiotics since doing so provides the possibility of getting better, and it is often the patients' rationale for requesting antibiotics [32]. Thus, we try to answer the following question:

> *RQ1: Which response message strategy (apology vs fear-inducing vs guilt-inducing messaging) is more effective in (a) lowering people's antibiotics expectations and (b) reducing BSTS misconception compared to the control group condition?*

As the online review used in study 2 features a parent's experience with a clinic, we also evaluate whether there is any difference in the effectiveness of the response strategies between parent readers and nonparent readers with the following research questions.

> *RQ2: Is there any difference in the level of (a) credibility perception, (b) willingness to visit, (c) antibiotics expectations, and d) BSTS misconception between parent readers and nonparent readers?*
>
> *RQ3: Is there any difference in the effects of response strategies on the (a) credibility perception, (b) willingness to visit, (c) antibiotics expectations, and (d) BSTS misconception while controlling for the parental status?*

Methods

Study Overview

A 4 (message type: control, apology, fear-based, guilt-based) × 2 (parental status: parent vs nonparent) between-subjects experimental design was used. Multimedia Appendix 1 includes the stimulus used in the study. Participants aged 18 years and older and living in the United States were recruited. As with study 1, we used the MTurk survey platform for this 10-minute experimental survey. A total of 400 US adults took the survey; after removing incomplete responses, a total of 390 responses were used in the analysis. The median age group of participants was 30 to 49 years, and 62% (242/390) of participants were male. About 58% (226/390) of participants identified their race as White and 58% (226/390) had a Bachelor's degree. A summary of survey measurements is presented in Multimedia Appendix 2.

Data Analysis

A 2-way ANOVA was conducted to determine the effects of message strategies and parental status for each outcome variable. Table 2 reports a summary of test results. An additional simple effect analysis was conducted to probe interaction effects.

XSL·FO

RenderX

Table 2. Summary table for 2-way analysis of variance of the effects of messaging strategies and parental status in study 2.

Variable and source	MS[a]	F score	P value	η_p^2
Provider credibility perception				
Message[b]	5.96	4.02	.008	.031
Parental status[c]	33.24	22.45	<.001	.056
Message × parental status[b]	3.19	2.15	.093	.017
Willingness to visit the clinic				
Message[b]	8.23	19.36	<.001	.033
Parental status[c]	36.57	19.36	<.001	.048
Message × parental status[b]	7.09	3.75	.011	.029
Antibiotic expectation				
Message[b]	0.49	0.56	.640	.004
Parental status[c]	2.34	2.7	.102	.007
Message × parental status[b]	0.625	0.72	.541	.006
BSTS[d] misconception				
Message[b]	1.13	1.28	.281	.010
Parental status[c]	24.66	27.99	<.001	.068
Message × parental status[b]	0.606	0.69	.560	.005

[a]MS: mean squares.

[b]$df = 3, 382$.

[c]$df = 1, 382$.

[d]BSTS: better safe than sorry.

Results

To test H1-H3, we first compared the mean scores of credibility perception and willingness to visit the clinic across the 4 message conditions (Table 3). We found that response strategies have statistically significant effects on readers' credibility perception of the provider and willingness to visit the clinic (see Table 2).

Table 3. Effects of response strategies by messaging condition in study 2 (Note: Means in a row sharing superscripts are significantly different from one another).

Variable	Control (1)		Apology (2)		Fear (3)		Guilt (4)		η^2
	Mean	SD	Mean	SD	Mean	SD	Mean	SD	
Provider credibility perception	2.51[*]	1.13	2.92[*,#]	1.27	3.09[#,^]	1.29	2.82[*,#,^]	1.3	.028
Willingness to visit the clinic	2.61[*]	1.30	2.94[*,#]	1.48	3.26[#,^]	1.42	3.05[*,#,^]	1.5	.027
Antibiotic expectation	3.24[*]	0.94	3.25[*]	0.90	3.11[*]	0.92	3.15[*]	0.97	.004
BSTS misconception	2.91[*]	0.95	2.71[*]	0.96	2.76[*]	0.95	2.71[*]	1.01	.008

These data support the hypothesis that fear-inducing information can increase providers' credibility perception (mean 3.09 [SD 1.29], P=.006) and willingness to visit the clinic (mean 3.26 [SD 1.42], P=.008) when compared to the control group (credibility: mean 2.51 [SD 1.13]; willingness to visit: mean 2.61 [SD 1.30]), but the differences were not statistically significant compared to the apology message condition (mean 2.98 [SD1.27]). Thus, H1 was partially supported. The guilt-inducing response did not increase credibility perception.

Study 1 showed that the guilt message can increase readers' willingness to visit when compared to the apology condition. However, in study 2, which is in the pediatric context, the effect was not statistically significant. Accordingly, H2 was not supported. Regarding H3, there were no statistically significant effects of the apology message on the credibility perception or willingness to visit the clinic (H3 not supported), repeating the findings from study 1.

XSL•FO
RenderX

To answer RQ1, we compared the mean scores of the expectations for antibiotics and BSTS misconception (see Table 3) across the message conditions. We found no significant main effects of message strategies on antibiotic expectation and BSTS misconception.

Two participant groups (parents vs nonparents) were compared to answer RQ2 (see Table 4). Participants' parental status had a statistically significant impact on provider credibility perception, willingness to visit the clinic, and the BSTS misconception. Parents perceived the provider less credible (mean 2.56 [SD 1.19], P<.001) compared to nonparents (mean 3.13 [SD 1.29]). Parents were also less willing to visit the clinic in the future (mean 2.69 [SD1.42], P<.001) than nonparents (mean 3.26 [SD 1.40]). Parent readers exhibited greater BSTS misconception (mean 3.01 [SD .86], P<.001) than nonparent participants (mean 2.52 [SD 1.01]). There was no statistically

significant difference observed in their expectations of getting antibiotics.

Finally, a statistically significant interaction effect between parental status and the message strategy was detected on individuals' willingness to visit the clinic in the future (RQ3, see Figure 1). For the parent participants ($F_{3, 384}=3.51$, P=.02), the response that elicited fear increased their willingness to visit the clinic (mean 3.18 [SD .20]) significantly more than the control (mean 2.52 [SD .20], P=.02) and the apology (mean 2.31 [SD .20], P=.002) message conditions. For the nonparent participants ($F_{3, 384}=3.93$, P=.009), all 3 types of response messages increased their willingness to visit the clinic (apology: mean 3.56 [SD .20], P=.002; fear: mean 3.33 [SD .19], P=.02; guilt: mean 3.49 [SD .21], P=.006) when compared to the control group condition (mean 2.69 [SD .20]). There was no statistically significant difference among the three message conditions for nonparents.

Table 4. Mean and standard deviations for effects of parental status in study 2.

Variable	Parent		Nonparent		η^2	P value
	Mean	SD	Mean	SD		
Provider credibility perception	2.56	1.18	3.13	1.29	.051	<.001
Willingness to visit the clinic	2.69	1.42	3.26	1.40	.040	<.001
Antibiotic expectation	3.26	0.97	3.11	0.88	.007	.11
BSTS[a] misconception	3.01	0.86	2.52	1.01	.065	<.001

[a]BSTS: better safe than sorry.

Discussion

Principal Findings

Emotional appeals can be used to better communicate the information about the risks and consequences of inappropriate

use of antibiotics. Appealing to human emotion has long been known to help garner attention, engage message receivers cognitively, and change beliefs and intentions [18]. This study showed that such emotion-based tactics need not be solely used in public service announcements; rather, such known message strategies can also be used in responses to online reviews.

Providers and clinic owners can and should communicate good clinical practice whenever they can do so. Instead of being worried about negative online reviews, it is possible that these moments can be leveraged as teachable moments, and we believe this paper provides insight into how to develop evidence-based online interventions [33,34].

Study 1 was conducted in the primary care context. This study revealed that fear-based messaging can increase message favorability, provider credibility, and willingness to go to the clinic compared to a simple apology. Given that the apologetic response is the most common response to negative online reviews, this information is critical for clinics. These results can be explained by the studies that showed that when communication of the severity of a health threat is combined with communication of susceptibility to the threat, message receivers are more likely to engage with the message content [17]. Particularly if the message communicates a solution (ie, efficacy), message receivers will engage in a process known as danger control whereby they are fearful of the health threat, understand the threat can be averted, and want to engage in behaviors that would control and prevent it [35].

The findings from study 2 further demonstrated the effectiveness of using a fear-frame when responding to a patient's negative online review. Another important finding was that while different message strategies were equally effective in increasing nonparents' willingness to visit, only the fear-inducing message had an impact on parent readers. Thus, when responding to a pediatrics online review often left and read by parents, fear messaging, demarked by communicating susceptibility to, and severity of a risk, can help to mitigate potential negative consequences of a negative online review.

Moreover, we found that parents were overall more influenced by the negative online review than nonparents. Parents perceived the provider as less credible, and they were less willing to visit the clinic than nonparents. This could be because parents are generally concerned about doing the right thing for their child. When it comes to medical decisions, they experience greater uncertainty and anxiety with their decisions for their ill child [36]. Parents held greater BSTS misperception (taking antibiotics has little risk associated and increases the chance of getting better even when it might not be needed) because they are more worried about missing an opportunity to treat their child's serious illness than a long-term side effects of antibiotics.

Finally, the emotion-based response strategies did not have statistically significant effects on lowering individuals' antibiotic expectations or correcting the BSTS misperception. Although we found limited educational effects of the response messages, as changing patients' perception is critical to reduce the overprescribing of antibiotics, future studies should examine the effects of different message strategies and interventions that can improve people's understanding of antibiotic resistance.

To this point, it is critical that expertise in messaging strategies is sought before clinicians design responses to online reviews (or develop message strategies generally). It is well known that certain messaging strategies can fail when used with the wrong audience or in the wrong context. In this study, we found that while nonparent readers were receptive to various messaging strategies, only fear-inducing messaging was effective among parent readers. Previous studies reported that a persuasive appeal's effectiveness varies by the audience, and aligning message strategies with the recipient's personal traits and emotional status can increase the message's impact [37,38]. Likewise, certain messaging strategies can fail when used with the wrong audience or in the wrong context [39]. Thus, practitioners should critically analyze their target audience and develop the best messaging strategies accordingly.

Limitations

There are limitations to this research. Certainly, these studies did not use probability-based samples (although they did use random assignment), and thus, we should be cautious when generalizing the findings. Additionally, this study only examined one iteration of fear or guilt; but guilt and fear messages vary a great deal in intensity. Overly intense messages can cause anger and perceptions of being manipulated—so such strategies must be used subtly and thoughtfully. We were also mainly interested in the effects of messages in both studies, but the tested outcome variables (ie, favorability, credibility perception, and willingness to visit) are interrelated. For instance, it is possible that the favorability or credibility perception may predict readers' desire to visit the clinic. Thus, future studies could further our findings by investigating a causal model among the outcome variables engaging in mediation analysis. Finally, it may be that clinics are uncomfortable replying to negative online reviews at all. Although we hope that these data provide confidence that replying is a good idea, we recognize that some clinic managers will remain reticent to do so. In those cases, the emotional appeals here could be used to inform in-clinic messages that might change or adjust expectations prior to a negative review happening.

Conclusion

It is imperative that providers feel empowered to follow clinically sound practices. In this case, that means not feeling pressured to prescribe antibiotics when they are not needed. Health communication theories can provide strategies that can be used to assist in these efforts. For example, some clinics have tested the impacts of displaying posters using a commitment strategy [40], as a well-known strategy in communication and psychology, on changing patient expectations [41]. Overall, the strategy has shown promising results in affecting patient perceptions and expectations. Here, we examined the role of emotionally framed messages. Health communication scholars have tested emotional appeals on attitude change for nearly a century, finding that they can have a positive impact at how people perceive health risks. In this case, the key outcomes were to increase the credibility of a provider and willingness to visit a clinic. More studies of this ilk must be conducted going forward so that we can arm providers with efficacious communication devices that help them do their job.

Abstract

Background: Although mental ill-health is more prevalent among people from lower socioeconomic groups, digital mental well-being innovations are often developed for people from higher socioeconomic groups, who already have resources to maintain good mental and physical health. To decrease health inequalities and ensure that available solutions are appealing and accessible to people with fewer resources, new approaches should be explored. We developed the app Wakey!, which focused on creating engaging mental health content that is accessible, particularly among lower socioeconomic groups in the United Kingdom.

Objective: The aim of this study is to assess engagement with the app, investigate initial effectiveness data for 6 well-being outcomes, and explore participants' subjective experiences of using Wakey!

Methods: The app Wakey! was publicly launched on January 20, 2020, and was free to download from Apple Store and Google Play. The app provided its users with entertaining and educational content related to mental well-being. Concurrently, a single-arm mixed methods feasibility trial was carried out from January to April 2020 among people who had downloaded the app and created an account. The primary outcome was engagement, which was collected passively from data logs. Secondary outcome measures were 6 well-being outcomes collected from self-report questionnaires. Individual interviews with 19 app users were carried out in April 2020.

Results: In total, 5413 people fit the inclusion criteria and were included in the final sample—65.62% (3520/5364) women, 61.07% (3286/5381) aged between 25 and 44 years, 61.61% (2902/4710) in employment, 8.92% (420/4710) belonging to the lower socioeconomic group, and 8.09% (438/5413) were engaged users. There was no evidence of a difference in engagement regarding sociodemographic and socioeconomic characteristics. There was evidence that users with a higher average daily sleep score, who joined the study more recently, who had higher baseline self-report of sleep quality, and who found episodes more entertaining were more likely to be engaged users. Among 230 users who provided follow-up data, there was evidence of improvements on four of the six well-being outcomes: life satisfaction ($P<.001$), feeling that life is worthwhile ($P=.01$), ease of getting up in the morning ($P<.001$), and self-efficacy ($P=.04$). The app and its content were well received by those who were interviewed, and several people perceived a positive change in their mental well-being.

Conclusions: This study shows that the app Wakey! could potentially be engaging across different socioeconomic groups, and there is an indication that it could positively impact the mental well-being of those engaged with the app. However, this study was a pragmatic trial with a limited sample, and the selection bias was present in the qualitative and quantitative study. Further work is needed to make any generalizable conclusions.

Trial Registration: ClinicalTrials.gov NCT04287296; https://clinicaltrials.gov/ct2/show/NCT04287296

Introduction

Background

Mental health conditions are a considerable burden for patients and health services and have been shown to have social patterning in severity and incidence [1,2]. People in the lowest socioeconomic groups have mental ill-health at higher rates than those in the highest socioeconomic groups [3,4]. Those in lower socioeconomic groups are more likely to be unemployed, working in jobs with low pay, and have insecure work, which have been found to be detrimental to mental health [3,5-7]. Mental health services are struggling to cope with demands on services, and unequal access to support is further exacerbating health inequalities [8,9]. Prevention and broader determinants of health have a larger effect on mental health than reactive, illness-based treatment [10,11]. In addition, people with higher education and higher socioeconomic background who have good access to resources (eg, time, income, and knowledge) are more likely to use commercial mental health solutions in the market to invest in their self-care [12-14].

Digital interventions have been proposed as a solution to address the high demand for mental health support in the context of the crisis in health care services [15]. During the past decade, there has been an explosion of available apps offering mental health and well-being support [16]. These apps target a variety of needs from habit formation to supporting recovery from mental ill-health [17]. Despite the large number of available apps, most lack evidence of effectiveness (ie, no available data) [18] and long-term engagement [19]. Results from a systematic search by Baumel et al [20] show how most apps see a drop in retention between days 1 and 30, 69% and 3%, respectively, depending slightly on the focus of the app (eg, happiness and meditation). Success in engagement has been shown to be a combination of several factors, such as higher rating in app stores, lower price, more positive reviews, good usability, variety in content and features, personalized experience, credibility, high security, social support, and the use of behavior change techniques (BCTs) [21-24]. McKay et al [17] found that 2 BCTs seemed to be more common to use in mental health apps, allowing or encouraging practice or rehearsal in addition to daily activities and providing instructions on how to perform the behavior.

The role of digital mental health interventions in addressing health inequalities is yet to be determined. On the one hand, they provide the potential to reduce health disparities, by providing personalized, low-cost, infinitely reusable resources that can increase access to health interventions [25,26]. On the other hand, they may increase inequity where there remain barriers to access and usability for disadvantaged groups [27,28]. To ensure that health inequalities are not further exacerbated by digital interventions, there is a need to develop and assess digital interventions that manage to maintain long-term engagement and that are appealing and accessible to people from lower socioeconomic groups who often use entertainment to regulate difficult emotions and for education [29-31].

We developed Wakey!, a mental well-being app that is generally appealing across social groups. However, we also aim to address inequalities in access to mental health and well-being support for lower socioeconomic groups in the United Kingdom, by providing content that is both entertaining and led by theory and evidence. The content was developed using information and techniques from cognitive and third-wave psychotherapies, positive psychology interventions, and mental health interventions [32-37]. The web-based psychoeducational strategies are effective at improving mental health literacy [33], reducing stigma [38], and improving the clinical course in depression [39]. Psychoeducational interventions in general are effective (with a small effect size) in managing stress [40].

Objectives

The purpose of this feasibility study is to explore engagement, assess initial impact, and explore users' subjective experiences with the app, to inform the next steps. Although we measured the app's impact on health outcomes, the study was not intended to be a definitive effectiveness trial.

Methods

Overview of Study Design

A 12-week mixed methods single-arm feasibility trial was conducted to explore engagement with the app Wakey!, initial effectiveness data, and subjective user experiences. Participants were recruited for the quantitative component exploring the engagement and effectiveness of Wakey! between January 17 and March 30, 2020. The qualitative study to explore people's experiences of using Wakey! was conducted between April 9 and 24, 2020.

Ethical Considerations

The trial was approved by the Faculty of Health Sciences Research Ethics Committee at the University of Bristol (reference 98382) and registered in ClinicalTrials.gov (NCT04287296).

Intervention—The App Wakey!

Wakey! is an app that delivers a 9-minute morning edutainment show, designed as an alternative to an alarm clock (ie, where users can set an alarm and wake up to a breakfast show on their phone). Edutainment refers to media where entertainment is combined with education [41]. The initial pilot of the show (10 episodes) was streamed via Facebook from April to May 2019. During this time, both quantitative and qualitative data (such as desired improvements) were collected and subsequently used as input in the development of the show and the app. Approximately 40.37% (44/109) of the sample had an annual household income below £30,000 (US $40,836.40), which suggests that the feedback received reflected the thoughts and

XSL•FO

RenderX

experiences of our target group. In addition, in February 2020, we carried out a think-aloud study among people who lived in a deprived area of London (Southwark and Lambeth). This provided us new insights that influenced usability tweaks in the app, which were implemented before the trial began.

This study focuses on the first 12 weeks after the launch on January 20, 2020, on Apple Store and Google Play. During this time, the show was presented by a comedy drag queen (Ginger Johnson) and a previous cast member from Love Island (Christopher Taylor), who were occasionally accompanied by special guests. Although including a drag queen as a host may turn off some lower socioeconomic group users who may hold more conservative social values, there is evidence that drag queens are seen as an important part in the working-class entertainment in the United Kingdom [42], and people from lower socioeconomic groups tend to watch Independent Television programs, such as Love Island, which is aimed at a less conservative audience [43].

Each week focused on a different mental health–related topic that was discussed by using colloquial language paired with humor in the morning shows (Multimedia Appendix 1). The content was developed (and written by one of the authors (IJ) who is a consultant psychiatrist and psychotherapist) as psychoeducational content designed to communicate the underlying principles from a variety of evidence-based treatments of, and preventative strategies for, common mental disorders. The content was composed of easy-to-understand principles from various cognitive therapies [44], third-wave psychotherapies such as compassion-focused and [45] mindfulness-based therapies [46], positive psychology interventions (such as well-being therapy developed by Fava [34]), and behavioral and lifestyle mental health interventions such as sleep behavior, exercise, and behavioral activation [47]. The content was adapted for the scripts for the show in collaboration with one of the hosts of the show who is a professional writer. Additional content and features were provided on the app to support the theory- and evidence-based techniques, to increase engagement with the app, and to respond to current events (such as the COVID-19 crisis; Multimedia Appendix 1).

Recruitment

The app was advertised in the United Kingdom through partner companies of the *Lost In TV Audience Services*, who have a database of 450,000 people (approximately 10% were targeted). In addition, the app's content was advertised through social media platforms (eg, Facebook and Instagram) and more traditional media outlets (eg, *Marie Claire*, *Sunday Mirror*, *The Sun*, and *Metro*).

As this was a feasibility study and focused primarily on uptake and engagement with an interest in the demographics of the users, a sample size calculation was not performed.

Quantitative Study

Procedures

On downloading the app, users were taken through a registration process. Users were presented with the Terms and Conditions

and the Privacy Policy, which included consent to enter the study and the data to be used for research purposes (Multimedia Appendix 1). Thereafter, users were asked to provide sociodemographic and socioeconomic information: name, email address, age range, gender, and occupation (Multimedia Appendix 1). Users were asked to set their in-app alarm clock time. Baseline data were then collected on the 4 UK Office for National Statistics (ONS) well-being questions [48], one question inquiring about ease of waking up in the morning and one question inquiring about self-efficacy (Multimedia Appendix 1). Following sign-up, users were taken to the home page (Multimedia Appendix 1), where they were presented with the welcome video.

Data Collection

All quantitative data were collected from users via the app. The data on overall engagement were collected passively from data logs on a daily basis (ie, whether users watched that day's episode or not). Other measures were collected by asking users to provide information at baseline (ie, onboarding) and thereafter on either a daily or weekly basis. Sociodemographic and socioeconomic information was collected only at baseline. A total of 6 well-being outcomes were collected at baseline and then weekly until the end of the trial. Engagement outcomes included the number of people who downloaded the app and created an account, number of shows watched over the 12-week period, average time watched, and entertainment value of the episode (self-reported on a scale of 0 [*not at all*] to 10 [*completely*]).

Data Processing

Users were excluded from all analyses if they had not finished creating the account or were aged <18 years. Users whose baseline and follow-up scores were left on the default setting were excluded from the impact assessment. This was 0 for the ONS and sleep questions and *strongly disagree* for the self-efficacy question. In addition, when participants answered *Prefer not to say* to gender (n=49), age (n=32), or occupation (n=703) questions, their answer for a specific variable was treated as missing. Owing to a technical error, 63 users were not able to answer the self-efficacy questions when creating the user, thus missing the baseline assessment and excluded from the analysis about self-efficacy.

Users were segmented into five levels of engagement: never active—had not seen any of the episodes and the welcome video; inactive—had seen only 1 episode or the welcome video or both; became inactive after their first week—saw at least two episodes on their onboarding week and then stopped watching; irregular—had seen at least two episodes on separate weeks but <20% of all the available episodes for them; and engaged users—had seen ≥20% episodes of those available to them. The 20% threshold was a rough equivalent of weekly use—if the user would watch 1 episode per week, then it would equal to 20% of weekly episodes.

The coding of occupational groups is based on two classifications: the Standard Occupational Classification 2010 volume 1 [49] and 2016 ONS National Statistics Socio-economic Classification (NS-SEC) [50]. The 8 NS-SEC

categories provided in Table S1 in Multimedia Appendix 1 were used to provide a more detailed overview of socioeconomic groups within the sample of people who used Wakey! during the 12-week trial in the descriptive analysis and to explore the predictors of engagement with Wakey! and improvements on the well-being outcomes.

Data Analysis

To see if there were any differences in the probability distributions between the active and never active groups and between people who provided follow-up data and those who did not by sociodemographic and socioeconomic characteristics and content use characteristics (ie, number of watched episodes and entertainment value), chi-square tests and independent-group 2-tailed t tests (or Wilcoxon rank-sum tests) were conducted. Wilcoxon signed-rank tests were used to investigate improvements in the 6 ordinal well-being outcomes from baseline to follow-up. To explore predictors of outcomes, binary variables were created, and multiple logistic regression was undertaken, as the parameters were not met for linear regression. For engagement, we explored which variables predicted whether the participant was an engaged user (watched ≥20% of episodes available) or a not engaged user (watched <20% of episodes available). For retention, both the daily (ie, days 1, 7, 14, and 30) and weekly (weeks 1-5) retention were assessed by calculating the proportion of users who created an account and then were active at a specific time. For well-being outcomes, we explored predictors of improvements (≥1 point change) versus no improvement (no change or deterioration). Univariable analysis was conducted using logistic regression to explore predictors of whether the participant was an active user or improved on well-being outcomes. All predictor variables are presented in Table S1 (Multimedia Appendix 2). Repeated-measures multivariable analysis was performed using logistic regression. The initial model inclusion criterion was $P<.05$, with putative predictors entered using backward stepwise selection and retained where $P<.05$. To explore the influence of exposure to Wakey! and to account for different entry times into the study for different participants, we explored associations between improvements in well-being outcomes and user segmentation, the week when they joined the study, if they were an active user, the time between baseline and the last follow-up, and the last week they provided follow-up data.

Qualitative Study

Procedures

The aim was to interview people from lower socioeconomic groups [49,51] and from a diverse range with respect to gender, age range, and user engagement with Wakey! We used purposive sampling [52] and divided people into different groups based on their engagement (to ensure that people from all 4 groups would be represented in the study) and then sent invitations by email (at first) and push notifications to participate

in the study (Multimedia Appendix 1). People who were interested in participating in the study received an email with the participant information sheet and a link to the web-based consent form. The web-based consent forms were hosted on the University of Bristol BOS system, and the data were kept in accordance with the Data Protection Act 2018 [53].

Data Collection, Processing, and Analysis

Qualitative data were collected via semistructured audio-recorded individual interviews conducted by MÖ. All interviews occurred either on the phone or on a video-call platform. Participants were given a £20 (US $27.22) high-street voucher if they were an active user and £5 (US $6.81) if they were an inactive user as a thank-you for their time. The interview topic guide is outlined in Multimedia Appendix 1. The audio recordings were made on encrypted audio-recorders and transferred to Method X Studios secure servers, where they were kept in accordance with the Data Protection Act 2018 [53]. The anonymized transcriptions were kept separately from the identifiable information on the consent forms, so they could not be linked. Transcribed recordings were anonymized (all names or other identifying material removed), and the collected data were analyzed in themes, which were based on the interview topic guide (using a deductive approach). Gender, age range, and user group have been added to all quotes presented in the *Results* section.

Results

Quantitative Study Sample

Between January 17 and March 30, 2020, a total of 5928 people downloaded Wakey! (unique downloads, excluding the Wakey! Team). Of these 5928 people, 515 (8.69%) did not meet the inclusion criteria and were excluded from the study (276 were aged <18 years and 239 had not verified their email address and thus did not finish the registration), leaving a final sample of 5413 users, who were divided into two groups—never active and active. The characteristics of active and never active users are presented in Table 1. Two-thirds of the active users were women (3520/5364, 65.62%) and aged between 25 and 44 years (3286/5381, 61.07%). Approximately 61.61% (2902/4710) of the users were in employment. Approximately 8.92% (420/4710) of the users had an occupation that indicated belonging to a lower socioeconomic group (as defined by the NS-SEC [50]), such as semiroutine and routine occupations (Table S2 in Multimedia Appendix 1). A higher proportion of the never active group was women, in the youngest age group, and not working (unemployed, caregivers, retired, students, looking after family or home, or sickness or disability). In terms of socioeconomic groups, those who were never active were also more likely to have an occupation that indicated them belonging to lower socioeconomic groups.

Table 1. Sociodemographic and socioeconomic characteristics among active and never active users.

	Active, n (%)	Never active, n (%)	*P* value
Gender (active N=3958, never active N=1406)			<.001
Female	2489 (62.89)	1031 (73.33)	
Male	1404 (35.47)	358 (25.46)	
Nonbinary or other	65 (1.64)	17 (1.21)	
Age (years; active N=3972, never active N=1409)			<.001
18-24	643 (16.19)	300 (21.29)	
25-34	1268 (31.92)	459 (32.58)	
35-44	1195 (30.09)	364 (25.83)	
45-54	689 (17.35)	236 (16.75)	
55-64	153 (3.85)	42 (2.98)	
≥65	24 (0.60)	8 (0.57)	
Occupation (active N=3455, never active N=1255)			<.001
Employed	2191 (63.42)	711 (56.65)	
Unemployed	137 (3.97)	56 (4.46)	
Caregivers	241 (6.98)	94 (7.49)	
Retired	53 (1.53)	10 (0.80)	
Students	363 (10.51)	184 (14.66)	
Looking after family or home	301 (8.71)	132 (10.52)

Socioeconomic groups (active N=3455, never active N=1255)			<.001
High	1462 (42.32)	438 (34.90)	
Middle	414 (11.98)	136 (10.84)	
Low	290 (8.39)	130 (10.36)	
Not classified elsewhere	1289 (37.31)	551 (43.90)	

User Retention and Engagement

Among all 5413 users (this includes both active and nonactive users), 1593 (29.43%) were active on day 1, a total of 273 (5.04%) on day 7, 169 (3.12%) on day 14, 126 (2.33%) on day 21, and 108 (2%) on day 30.

As Wakey! was meant to be used during weekdays and people were onboarded during weekends, it was decided to assess the weekly retention as well. Of the 5413 people, 3135 (57.93%) were active on the week they were onboarded, 1454 (26.87%) 1 week later, 635 (11.73%) 2 weeks later, 448 (8.28%) 3 weeks later, and 341 (6.30%) were active 4 weeks later.

The welcome video (length 1 min 26 seconds) was seen by 24.46% (1324/5413) of the users, with a mean watch time of 1 min 6 seconds. The mean number of users watching live streamed episodes was 127 (SD 83.67), and that for archives episodes was 102 (SD 92.22). When combining the unique views of livestream and archived episodes, the mean number of viewers was 219 (SD 131.65). The mean entertainment value of all 60 episodes was 6.80 out of 10 (SD 1.14). Compared with the first week (mean 5.64, SD 0.68), the average score increased by 2.34 points by the last week (mean 7.98, SD 0.43).

When dividing the 5413 users based on the level of engagement, 1420 (26.23%) were never active, 2024 (37.39%) were inactive users, 406 (7.50%) became inactive after their first week, 1125 (20.78%) were irregular users, and 438 (8.09%) were engaged users. The engaged users were divided into those who saw 20%-39% of the episodes available to them (269/5413, 4.97%), 40%-59% (83/5413, 1.53%), and 60% or more of the episodes available to them (86/5413, 1.59%).

In the univariable analysis (excluding the never active users), being engaged users was predicted by a higher average entertainment score (odds ratio [OR] 1.16, 95% CI 1.12-1.20; *P*<.001), a higher average daily sleep score (OR 1.15, 95% CI 1.11-1.20; *P*<.001), joining the study more recently (OR 0.92, 95% CI 0.88-.96; *P*<.001), and a higher baseline report of sleep quality (OR 1.06, 95% CI 1.03-1.10; *P*=.001) (Table S2 in Multimedia Appendix 2). There was no evidence of a difference in engaged users (watched ≥20% of available episodes) versus not engaged users (watched <20% of available episodes) in terms of social characteristics (Table S3 in Multimedia Appendix 2). The results from the multivariate model are presented in Table S4 (Multimedia Appendix 2).

Effectiveness on Well-being Outcomes

When comparing users (N=3993) who had seen at least one episode (or the welcome video) and provided follow-up data with those who had seen at least one episode (or the welcome video) and had not provided any follow-up data, there was a higher proportion of users aged ≥45 years and users who were from middle socioeconomic groups and who provided follow-up data on ONS, sleep, and self-efficacy measures (Table S5 and Table S6 in Multimedia Appendix 2). In addition, users who provided follow-up data had rated episodes with a higher score

(mean=7.5 vs 5.2; $t_{1348}=-8.6134$, $P<.001$) and had watched more live (11 vs 1; $t_{3885}=-36.1515$, $P<.001$) and archived episodes (6 vs 1; $t_{3885}=-26.9019$, $P<.001$).

Users who provided follow-up data demonstrated improvements on 4 of the 6 health outcomes (Table 2). There was strong evidence ($P<.001$) that users experienced improvements on life satisfaction and ease of getting out of bed in the morning (median difference 2 points). There were also improvements in feeling that life is worthwhile (median difference 1, $P=.01$) and in self-efficacy (median difference 0, $P=.04$).

Table 2. Evidence of improvements in outcomes from baseline to final follow-up (N=5413).

	Users whose score improved		Users with baseline data, n (%)	Median at baseline (range, IQR)[a]	Users with follow-up data, n (%)	Median at follow-up (range, IQR)[a]	Difference from baseline to follow-up	P value
	N	n (%)						
Life satisfaction	230	112 (48.7)	3638 (67.21)	6 (0-10, 4-7)	230 (4.25)	7 (0-10, 5-8)	+1	<.001
Worthwhile	230	111 (48.3)	3638 (67.21)	6 (0-10, 4-8)	230 (4.25)	7 (0-10, 5-8)	+1	.01
Happy yesterday	230	97 (42.2)	3638 (67.21)	5 (0-10, 4-8)	230 (4.25)	6 (0-10, 4-8)	+1	.43
Anxious yesterday	230	97 (42.2)	3638 (67.21)	5 (0-10, 2-7)	230 (4.25)	4 (0-10, 2-7)	−1	.73
Easy to get up	230	133 (57.8)	3638 (67.21)	4 (0-10, 2-7)	230 (4.25)	6 (0-10, 4-8)	+2	<.001
Self-efficacy	158	53 (33.5)	3577 (66.08)	4 (1-5, 3-4)	158 (2.92)	4 (1-5, 3-4)	0	.04

[a]Baseline and final follow-up data were collected at different time points for different users, as people were able to sign up at any point during the 12-week trial, and follow-up data were collected each week. Follow-up data were reported as the final outcome data reported by the users.

There was a single variable that predicted improvements in life satisfaction ($P<.05$) in the univariable analysis; therefore, no multivariable analysis was conducted (Table S7 in Multimedia Appendix 2). Lower self-efficacy at baseline was associated with improvement in life satisfaction by the end of the trial (OR 0.63, 95% CI 0.50-0.80; $P<.001$).

There were 2 variables associated with improvements in feeling life is worthwhile by the end of the trial. Those participants who improved on perceiving the life worthwhile were more likely to have a lower baseline sleep quality (OR 0.89, 95% CI 0.81-0.97; $P=.01$) and have had lower self-efficacy at baseline (OR 0.78, 95% CI 0.63-0.98; $P=.03$). The results from the multivariate model are presented in Table S8 (Multimedia Appendix 2).

Four variables were associated with improvements in sleep quality in the univariable analysis: higher number of archived episodes watched (OR 1.04, 95% CI 1.00-1.08; $P=.04$) and lower baseline scores for three of the ONS questions—satisfaction with life (OR 0.83, 95% CI 0.74-0.93; $P=.002$), life being worthwhile (OR 0.77, 95% CI 0.69-0.87; $P<.001$), and happiness (OR 0.85, 95% CI 0.76-0.94; $P=.003$).

A single variable was associated with self-efficacy in the univariable analysis; those with a lower baseline score of perceiving life being worthwhile (OR 0.86, 95% CI 0.76-0.99; $P=.03$) were more likely to show improvements in self-efficacy.

Qualitative Study Sample

In total, 1524 people received an invitation to participate in the qualitative study, and of these 1524 people, 76 (4.99%) were

interested in participating. Ultimately, 1.25% (19/1524) of the users consented, all of whom were interviewed. Of the 19 participants, 9 (47%) were women, 12 (63%) were aged between 25 and 44 years, and 15 (79%) were not in full-time employment (eg, student, caregiver, and unemployed). On the basis of the segmentation of the level engagement, of the 19 participants, 9 (47%) were active users, 5 (26%) were irregular users, 2 (11%) had become inactive, and 3 (16%) were inactive users.

Qualitative Results

Hearing About and Using the App

Participants mainly heard about Wakey! through social media, such as Facebook and Instagram. When asked about what made the interviewees interested in the app, different reasons were mentioned, such as having a drag queen as one of the hosts, having a different approach to waking up, and addressing mental health issues (almost all interviewees reported having mental ill-health currently or in the past).

When asked about how they used the app, most used Wakey! as part of a morning routine after waking up or sometimes later during the day, rather than as an alarm clock. Whereas some people had seen change in their use of Wakey! during lockdown, others had stuck to their routine or way of life.

> *There's not much difference for me, to be honest, because I'm isolated anyway...There are a lot of people with physical disabilities and mental disabilities and illnesses that live like this already.* [Female, aged 35-44 years, active]

XSL•FO

RenderX

The interviewees who were active users said that they watched Wakey! on most mornings or every day (including watching old episodes during the weekend or watching archived episodes if they missed the livestream ones). When asked why they might have missed some of the episodes, the main reasons were the change in their morning routine due to lockdown (eg, change in work times and not having to wake up at a particular time), forgetting to watch the show, and occasionally oversleeping or staying up late. The use of the app varied slightly among the irregular users. Of them, 4 were watching the show at least three times a week, including occasional watch of the archived episodes. Getting late to bed or forgetting about the show were two reasons behind not watching the show more frequently. One of the irregular users felt that sometimes he feels it was too overwhelming to watch the show.

> *To be honest with you, it's how I feel on the day...It is basically about trying to be in the right state of mind...trying to be in the mood to watch Wakey Wakey is one thing because sometimes if you're not feeling too great within yourself, it's like the last thing you want is sometimes to be looking at some people, where everyone's laughing, because it's hard.* [Male, aged 25-34 years, irregular]

Watching Wakey! was usually less regular among people who became inactive after their first week or who had been inactive before the qualitative study. Some of them mentioned that they tend to watch Wakey! a couple of times a week or as often as possible. The reasons behind not watching the show more often were related to the change in their routine during lockdown (as among active users) and work routine.

The Presenters and Content

Interviewees' general impression of the app was positive. They were very satisfied with the presenters, and it was mentioned several times that they seem very friendly and have a great chemistry, which makes the show very enjoyable. Several people pointed out that the content of Wakey! was very well developed, as it covered a variety of useful topics on mental health and provided practical tips that people can relate to and incorporate into their lives, and it was done in a fun and entertaining way that helped keep people engaged.

> *You've wrapped it up in an entertainment bubble, but it's very much about mental health. I think it's brilliant the way it's done.* [Female, aged 35-44 years, active]

> *I think it's really good that they're focusing on a lot to do with mental health because that is a big thing that gets pushed under the carpet. There's so many of us that look okay on the outside but might be suffering.* [Female, aged 35-44 years, irregular]

Use of Features

Several interviewees had used the chat option during livestream episodes, Q and A sessions, or *Brain–aerobics* quizzes. They liked that using the chat created the feeling of a community through interacting with other users. In addition, it was appreciated that people received responses to their questions and comments.

> *I do appreciate the fact that somebody from Wakey! has actually replied to me and had a bit of a conversation with me. I do like the interactive aspect and getting involved with people."* [Female, aged 25-34, active]

By the time the interviews occurred, 8-9 articles were made available on the app. Whereas some people had read the articles and found them useful, most had not yet engaged with them.

There were two types of live events: Q and A and *Brain-aerobics* quiz. Not everyone was aware of the quiz, but those who were viewed it positively, describing it as an opportunity to interact with Ginger Johnson and other users. Only a small number of interviewees had watched Q and A live events (as people had other responsibilities at the time it was broadcast). Of those who had, some found them useful, whereas others did not feel they were relevant to them or found them boring.

Among users who had visited the progress page, the regularity of use varied; however, in general, people found it useful as a tool to track their progress and see improvements.

Data Collection

Daily questions at the end of episodes were perceived, among some participants, as a possibility for self-reflection. Whereas some of them would have liked more daily questions, others found them too frequent. Whereas the majority remembered the daily questions, several struggled to remember if they had answered the weekly ones. Those who had answered the questions commented that the questions can be useful when you are interested in your mental well-being and show how things have changed compared with previous weeks.

> *When you actually put that number in on the score, you think to yourself, "I actually feel a lot better than what I thought," or, "I actually feel a lot worse than what I thought." I think it's a good idea definitely because it helps well, yourself to be able to see how you are feeling.* [Male, aged 25-34 years, irregular]

> *When I joined, I was quite shocked by doing the survey at the end, when you have to give yourself points as to how you feel and things. It shocked me how bad I was feeling. I hadn't realized that that's how I was feeling.* [Female, aged 55-64 years, active]

Perceived Change in Outcomes

When asked about changes in mood, sleep, or other similar aspects that might relate to using Wakey!, almost all interviewees had some positive examples of change that related to improvement in their mood, paying more attention to having a routine (which was perceived as likely to have an effect on sleep quality), finding it easier to getting up from the bed in the mornings, and reduced stress levels.

> *Using the app made me feel better in the morning, got me up, got me alert, got me awake, relatively easy. Whereas I previously tended to snooze my alarm clock frequently.* [Male, aged 45-54 years, irregular]

> *It just gets me out of bed at a proper time. I've noticed that in personally myself, I've been able to smile a*

bit more rather than being a bit down in the dumps. Even if I am in a bit of a mood when I wake up, by the time I've watched an episode of Wakey!, I've giggled me up for a good 10 minutes. [Male, aged 35-44 years, active]

Usability Issues and Future Improvements

Although people had many positives to say about the content of Wakey!, there were things that participants felt could be improved, such as some users feeling that the show felt a bit rushed and too preplanned and some of its content repeating itself. Technical issues mentioned included the following: alarm not going off, videos freezing, issues with chat's functionality, livestream episodes not starting from the beginning, and not being able to save the videos or watch them offline.

When interviewees were asked about three things they would keep if everything else about Wakey! would be changed, the three most popular things were the presenters and the Old News and *Bed-Aerobics* segments from the morning shows (described in Multimedia Appendix 1).

That's a tough one. Things to stay, obviously, first of all, is the presenters. Secondly, I'd say the content...is fantastic. [Male, aged 25-34 years, active]

Several participants found it difficult to answer but instead focused on things that could be improved. Suggestions included addressing different parts of the app, such as the content, survey, chat, live events and challenges, length and frequency of the episodes, and technical issues. One of the interviewees emphasized that the app's objective is not entirely clear and could have an effect on people not using it.

I think one of the main things is it's not entirely clear what the app's meant to do. It's a wake-up alarm clock, and the mental health and well-being side of it's not that clear until you've started using it. [Male, aged 45-54 years, irregular]

Discussion

Principal Findings

This study has three main objectives: (1) exploring engagement, (2) assessing the app's potential to improve mental well-being, and (3) exploring users' subjective experiences with the app. The findings provide insights into the potential an edutainment app can have, from both the engagement and effectiveness perspectives. Fleming et al [19] have shown that the use of digital interventions can be more modest when launched in a real-world setting (compared with a trial setting). As Wakey! was made publicly available to everyone, the findings are more likely to reflect the *real-world* data and to be ecologically valid. Although 8.09% (438/5413) of the users were considered as engaged, it is difficult to compare the level of activity at Wakey! with other apps, owing to differences in definitions and the content [19]. For example, moderate use can be viewed as using an app 1 week after installation, but it can also mean that a proportion of users (7%-16%) have completed at least two modules on the app [19]. In contrast, there are universal indicators such as user retention that enable the initial comparison. Baumel et al [20] showed that, on average, around

70% of mental health apps' users are active on day 1. That number drops significantly and reaches 10% by day 7 and 4% by day 30. When comparing the user retention numbers of Wakey! with the average, the former are around twice as low at each time point. At the same time, Wakey! is a weekday app, with no new content added during the weekend, and as the expectation for an active user was to use the app at least once a week, it was decided to see the weekly retention as well. Although the week 1 retention of Wakey! is still lower than the average day 1 retention, user activity does not drop that rapidly in the following weeks. Although days 1, 7, 14, and 30 retention rates tend to be more common to use [20], the authors would recommend considering using weekly retention as an accompanying metric, especially if the app is not meant for daily use.

Although Wakey! aims to decrease inequalities by increasing access to mental health information and products to people from lower socioeconomic groups, only a small proportion of users were from these groups. In addition, people who had never used the app were more likely to be from lower socioeconomic groups. Taken together, these findings suggest that the version of Wakey! explored in this trial was less accessible or appealing to people from lower socioeconomic groups. Low uptake can be influenced by a variety of factors, such as low digital literacy, lack of awareness of the app, low availability and accessibility, lack of recommendations from other people to use the app, and lack of support to navigate new technology [54,55]. The difference in use has been explored in several systematic reviews, but the evidence regarding socioeconomic characteristics is inconclusive. For example, Turnbull [56] found that people with higher income were more likely to use digital solutions that addressed chronic health conditions, but there were no differences in use regarding education and employment. However, it was highlighted that caution should be taken with conclusions drawn from these findings because the number of studies included in the analysis was small and there was a high risk of bias. Beatty and Binnion [57] investigated the adherence to web-based psychological interventions and found that in 28% of studies reporting education, higher adherence was predicted by higher education. Similar to Turnbull [56], the authors did not find any association between employment and adherence in all studies reporting employment. Perski et al [58] found that higher levels of education and employment were associated with greater engagement with digital behavior change solutions.

On the basis of the responses from a small number of users who provided qualitative data, participants' general experience with the app was positive. This was in agreement with the high average entertainment scores reported in the quantitative data. The latter, in turn, was one of the indicators that predicted higher engagement with the app. The results of this study also indicate that in the small sample (n=158-230) of users who were engaged with the app and provided data for health outcomes, improvement was seen across different mental well-being outcomes, such as life satisfaction, life being worthwhile, ease of waking up and self-efficacy, and users' perception of positive change in their mental well-being. A recent systematic review highlighted that only 2% of publicly available psychosocial

wellness and stress management mobile apps have published peer-reviewed evidence of feasibility or efficacy [18].

Mental health apps vary by different factors, such as the mental health conditions they target [59,60] and the BCTs used [17]. For example, providing instructions on how to perform a behavior and allowing or encouraging practice or rehearsal in addition to daily activities are the two most popular BCTs used in apps that aim to improve mental well-being [17]. The content of Wakey! has influences from different types of therapies and psychology interventions and covers a variety of BCTs shown to have an impact on mental well-being [17,61]. Although the concept that Wakey! uses—mixing entertainment with education—has been used for decades in various forms (eg, *Sesame Street* in the Unites States and *The Archers* in the United Kingdom) [62], its uniqueness largely stems from its format—it is about addressing mental well-being at the start of the day through a breakfast show. However, the app should be more appealing to the target population who already tends to be less likely to use digital health solutions [63-65].

There are several ways to make the app more appealing to people from all socioeconomic groups. Our qualitative findings in this study suggested that not everyone was aware of the app's objective when they downloaded it (ie, a focus on improving mental well-being) and providing a clear description of the app in social media and in the App Store and Google Play is "a key channel to inform consumer choice" [66]. For some people, this led to dissatisfaction and disengagement because they were seeking entertainment, not entertainment and support. We will seek to clarify the description of the app in the App Store and Google Play, to improve clarity of the purpose of the app, and to reduce misunderstanding about its purpose. To make the app more appealing and user-friendly to lower socioeconomic groups specifically (as we did not quite reach the groups expected), further work (eg, cocreation workshops and feedback sessions) is being undertaken with the target group. These methods are evidenced to improve the accessibility of behavior change interventions and to improve engagement in these groups [67,68].

Huang and Bashir [21] investigated how information cues across anxiety apps influence the selection and adoption of the app. They found that users were more likely to select apps that were cheaper and had better ratings and reviews. Schueller et al [69] asked people to rate the importance of health apps' features and found that content, ease of use, and cost were the most important factors regarding uptake and continued use. Alqahtani and Orji [22] found that poor usability, unvaried content, and lack of personalization were the most common reasons why users stop using mental health apps. Although the general experience of the app described by the sample of qualitative study participants (n=19) was positive (eg, easy to navigate, useful, and entertaining content), it was also pointed out that technical issues should be addressed, and the content could be more varied. Although there is a lack of information regarding the main reasons why people stopped using the app, several interviewees mentioned the issue of the alarm not working properly, and similar feedback was also received via emails and morning chat. Thus, our best guess is that functional issues with the alarm could be one of the main reasons why people stopped using the

app (ie, becoming inactive). The app was advertised as an alternative to a traditional alarm clock, and the feedback received implied that it was not fully functional for everyone—the phone had to be unmuted and connected to the internet.

Uptake and ongoing use of apps are influenced by a variety of factors, which are often related to users' needs and resources. To reduce barriers to access for those with lower incomes, Wakey! is designed to be free to use and the entertaining content becomes available as soon as the user creates an account.

Limitations

First, the study lacked the comparator group. It is therefore not possible to know if improvements in the 4 well-being outcomes were related to the use of the app.

Second, the sample size of people who provided follow-up data is small, and this limits the generalizability of the findings. Although there was an indication that these users improved on 4 health outcomes, these results should be interpreted with caution as the data are likely to be not missing at random [70]. Users who provided health data had rated episodes with a higher score and had watched more episodes; a higher proportion were aged ≥45 years and were more likely to be from a middle socioeconomic group. Therefore, this group of individuals was not representative of the whole sample but can be taken of an indication that those engaged with the app can benefit from its use. Using incentives (eg, quizzes and prizes) would be an option to motivate people who do not normally engage in research to provide data.

Third, the app was targeting people from lower socioeconomic groups, but the group was underrepresented in the final sample (420/4710, 8.92%).

Fourth, more than one-third of users (1840/4710, 39.07%) who provided data on their occupation belonged to a group *Not classified elsewhere*. This group included people who were not in employment—unemployed, caregivers, retired, students, looking after family or home, or sickness or disability. It is possible that a proportion of these people who had engaged with Wakey! would have been classified as people from lower socioeconomic groups, as those people who are not in employment may have lower levels of access to resources. However, because we did not have any information about people's income or prior occupations, it was not possible to infer their socioeconomic group in this study. In a future study, prior occupations and other indicators of access to resources would be sought to support the identification of the socioeconomic group.

Fifth, the frequency of follow-up reports varied among the participants, from 35.2% (81/230) of the people whose last follow-up was after 1 week of using Wakey! and 5.2% (12/230) from the 12th follow-up week. To account for this, we explored the influence of study entry dates and the dates of follow-up data in the analysis of predictors of improvements in outcomes. As only a small number of variables were captured to reduce the data burden on the app's users, it is likely that several important covariates that affected participants' mental

well-being were not captured, including social characteristics (such as ethnicity) and mental health indicators.

Sixth, 3 of the 6 well-being questions asked were based on recent past (how happy and anxious you were yesterday and how easy it was to get up this morning) and might not reflect users' overall state.

Seventh, there was a lower proportion of users who were less engaged with the app (inactive or who had become inactive user groups) in the qualitative study compared with those who were more engaged (ie, active and irregular user groups). Although we used a diverse range of recruitment methods (eg, sent emails and push notifications and used incentives) to include an equal number of participants from each group, we found it very challenging to get inactive users to engage with the qualitative study. Ultimately, we interviewed everyone who expressed interest by the end of the study, thus potentially introducing self-selection bias [71]. We appreciate that this limits the conclusions that can be drawn from this study as we did not reach data saturation and interviewed those who were more motivated to share their experience. Interviewing more inactive people might have provided us some additional insights that potentially may have diverged from our sample.

Eighth, the occurrence of the COVID-19 lockdown may have had an impact on the study outcomes and user engagement with the app.

Conclusions

Digital mental well-being solutions are often aimed at people from higher socioeconomic groups, and the majority struggle with high drop-off rates. This study shows that an app could not only be potentially engaging across socioeconomic groups if its content is grounded in theory and evidence but also be engaging and entertaining. There is also an indication that this type of app can have a positive impact on mental well-being among more engaged users.

However, this study was a pragmatic trial, which was based on a limited sample without a control group, and these results apply to the particular group of people in the study. Thus, it is not possible to generalize the results to a wider population.

As we saw that the uptake of the app was significantly lower in lower socioeconomic groups, further work that involves cocreation with the target group is to be undertaken.

Authors' Contributions

ST, IJ, and DC were involved in the study design. ST and MÖ carried out the study, analyzed the data, and drafted the manuscript. All authors read and contributed to the finalization of the manuscript. All authors approved the final manuscript.

Abstract

Background: Telemedicine visit use vastly expanded during the COVID-19 pandemic, and this has had an uncertain impact on cardiovascular care quality.

Objective: We sought to examine the association between telemedicine visits and the failure to meet the *Controlling High Blood Pressure* (BP) quality measure from the Centers for Medicare & Medicaid Services.

Methods: This was a retrospective cohort study of 32,727 adult patients with hypertension who were seen in primary care and cardiology clinics at an urban, academic medical center from February to December 2020. The primary outcome was a failure to meet the *Controlling High Blood Pressure* quality measure, which was defined as having no BP recorded or having a last recorded BP of ≥140/90 mm Hg (ie, poor BP control). Multivariable logistic regression was used to assess the association between telemedicine visit use during the study period (none, 1 telemedicine visit, or ≥2 telemedicine visits) and poor BP control; we adjusted for demographic and clinical characteristics.

Results: During the study period, no BP was recorded for 2.3% (486/20,745) of patients with in-person visits only, 27.1% (1863/6878) of patients with 1 telemedicine visit, and 25% (1277/5104) of patients with ≥2 telemedicine visits. After adjustment, telemedicine use was associated with poor BP control (1 telemedicine visit: odds ratio [OR] 2.06, 95% CI 1.94-2.18; *P*<.001; ≥2 telemedicine visits: OR 2.49, 95% CI 2.31-2.68; *P*<.001; reference: in-person visits only). This effect disappeared when the analysis was restricted to patients with at least 1 recorded BP (1 telemedicine visit: OR 0.89, 95% CI 0.83-0.95; *P*=.001; ≥2 telemedicine visits: OR 0.91, 95% CI 0.83-0.99; *P*=.03).

Conclusions: Increased telemedicine visit use is associated with poorer performance on the *Controlling High Blood Pressure* quality measure. However, telemedicine visit use may not negatively impact BP control when BP is recorded.

Introduction

The COVID-19 pandemic resulted in the rapid expansion of telemedicine as an integral part of outpatient care [1-7]. A telemedicine visit is defined as using video and telephone technology to connect patients to their clinicians as a substitute for in-person office visits. Telemedicine visits have helped maintain the continuity of care and preserve patients' access to care and are expected to remain a significant part of the health care delivery landscape even after the COVID-19 pandemic ends [8,9]. However, despite its increased utilization, concern has arisen that the content of care delivered via telemedicine visits may differ from that delivered during in-person visits. In particular, studies have shown that telemedicine visits are less likely to address standard components of care, such as blood pressure (BP) assessment, laboratory testing, and medication prescriptions and test orderings [10,11].

BP measurement is a fundamental component of hypertension management [12,13], and there has been increasing concern that the increased use of telemedicine visits in primary care and cardiology outpatient settings may impact the accurate assessment of BP and, in turn, how well BP is controlled for patients with hypertension [14]. To address this potentially unintended consequence of telemedicine expansion, we performed an electronic health record (EHR)–based retrospective analysis of a diverse population of patients with hypertension receiving care at a large, urban, academic medical center across an 11-month period during the COVID-19 pandemic. Using the specification of the *Controlling High Blood Pressure* quality measure from the Centers for Medicare & Medicaid Services (CMS) that defines poor BP control as having no recorded BP measurements or having a last recorded BP of ≥140/90 mm Hg [15,16], we sought to determine the association between telemedicine visit use and the failure to meet this widely used measure for benchmarking population-level quality of care, hypothesizing that the increased use of telemedicine visits can lead to poorer performance on this quality measure.

Methods

Ethics Approval

The study was approved by the Columbia University Irving Medical Center Institutional Review Board (AAAT0375), in accordance with the ethical standards of the responsible committee on human experimentation (institutional and national) and with the Helsinki Declaration of 1975, as revised in 2000. Informed consent was waived due to the study being of minimal risk.

Study Design

After approval by our institutional review board, we queried our EHR (Epic EHR; Epic Systems) to identify all completed outpatient visits to primary care and cardiology clinics at Columbia University Irving Medical Center from February 1, 2020, to December 31, 2020. The Medical Center transitioned to Epic EHR on February 1, 2020, that is, 1 month prior to the start of the COVID-19 pandemic in New York City. For each visit, we extracted information, including patients' date of birth, sex, race, and ethnicity; the primary payer; and the International Classification of Diseases, 10th Revision (ICD-10) codes associated with the visits. BP data associated with the visits were extracted from Epic flow sheets, and BP measurements were recorded in accordance with standard clinical protocols (ie, staff or clinicians recorded BP measurements in the office during in-person visits, and self-reported BP values that were measured at home during telemedicine visits at clinicians' discretion).

For our analysis, we defined the study population by using specifications published by the CMS for the 2020 version of the quality measure *HTN-2: Controlling High Blood Pressure* [16]. Specifically, we included all patients aged between 18 and 85 years with a diagnosis of hypertension, which was defined as having the ICD-10 code "E10" associated with any visit during the study period. Patients with end-stage renal disease, those with a history of kidney transplant, or those who were pregnant during the study period were excluded based on the ICD-10 codes for these conditions published by the CMS. For the primary outcome, following the above CMS specification, we defined a patient as one who failed to meet the *Controlling High Blood Pressure* quality measure if (1) BP was not recorded during any visit included in the study period or (2) the last BP recorded during the study period was ≥140/90 mm Hg.

For the primary exposure variable—telemedicine visit use—we defined telemedicine visits based on appointment type (ie, visits that were scheduled and conducted by using video or telephone technology) [2]. Because the distribution of telemedicine visits is right-skewed, we classified patients into the following three categories: those with in-person visits only, those with 1 telemedicine visit, and those with ≥2 telemedicine visits. To adjust for the total number of visits (including in-person and telemedicine visits), we similarly defined the following patient categories: patients with a total number of 1, 2, or ≥3 outpatient visits during the study period.

We used patients' self-reported race and ethnicity to classify patients into the following race and ethnicity categories: non-Hispanic White; non-Hispanic Black; Hispanic; Asian, Hawaiian, and Pacific Islander; and other, declined to answer, or unknown. Patient insurance was categorized as "commercial," "Medicare," or "Medicaid" by using the primary payer field associated with the last visit during the study period. Using a similar approach as the one described above for hypertension, we identified patients with a diagnosis of atherosclerotic cardiovascular disease (ASCVD) and diabetes mellitus through visit-associated ICD-10 codes.

Statistical Analysis

Descriptive statistics were calculated for the proportion of visits in which BP was recorded (ie, for each type of visit [in-person, video, or telephone visits]). Descriptive statistics were also calculated for demographic and clinical characteristics according to the categories of telemedicine use. A chi-square test, a 1-way ANOVA, and the Kruskal-Wallis test were used for categorical variables, normally distributed continuous variables, and nonnormally distributed continuous variables, respectively. A multivariable logistic regression model was used to determine if telemedicine use was associated with higher odds of poor BP

XSL·FO

RenderX

control; we adjusted for age, race and ethnicity, payer, and the presence of comorbidities. Because telemedicine visits frequently do not have recorded BP data, we applied the same model for the subgroup of patients with at least 1 recorded BP. As disparities in telemedicine visit use have been previously described for older patients and by race, ethnicity, and insurance status [2,4,5], we conducted additional subgroup analyses for patients aged ≥65 years, non-Hispanic Black patients, Hispanic patients, and patients with Medicaid. All analyses were carried out by using Stata statistical software (version 16; StataCorp LLC).

Results

For the study population, we identified 32,727 patients aged between 18 and 85 years who had at least 1 completed outpatient visit to primary care or cardiology clinics at Columbia University Irving Medical Center between February 1, 2020, to December 31, 2020, and who had a diagnosis of hypertension (but not end-stage renal disease, history of kidney transplant, or pregnancy). Of these patients, 20,745 (63.3%) had an in-person visit only, 6878 (21%) had 1 telemedicine visit, and 5104 (15.6%) had ≥2 telemedicine visits. Detailed baseline characteristics are described in Table 1. Specifically, patients with more telemedicine visit use were more likely to be female, be Hispanic or non-Hispanic Black, and have Medicaid insurance. They were also less likely to have ASCVD but more likely to have diabetes mellitus, and they had a higher total number of visits.

Of the total 87,309 visits across the study period, 59,409 were conducted in person, 14,982 were video visits, and 12,918 were telephone visits. BP was recorded for 93% (55,370/59,409) of in-person visits, 20% (3011/14,982) of video visits, and 9% (1187/12,918) of telephone visits (Figure 1).

Table 1. Demographic and clinical characteristics of patients with hypertension by telemedicine use.

Characteristic	All in-person visits (n=20,745)	1 telemedicine visit (n=6878)	≥2 telemedicine visits (n=5104)	P value
Age (years), mean (SD)	66.7 (11.8)	65.7 (11.9)	65.4 (12.1)	.08
Sex, n (%)				<.001
Male	10,489 (50.6)	3325 (48.3)	1868 (36.6)	
Female	10,256 (49.4)	3553 (51.7)	3236 (63.4)	
Race and ethnicity, n (%)				<.001
Non-Hispanic White	7492 (36.1)	1946 (28.3)	883 (17.3)	
Hispanic	3127 (15.1)	1810 (26.3)	2484 (48.7)	
Non-Hispanic Black	1518 (7.3)	600 (8.7)	537 (10.5)	
Asian, Hawaiian, and Pacific Islander	485 (2.3)	140 (2)	90 (1.8)	
Other, declined to answer, or unknown	8123 (39.2)	2382 (28.3)	1110 (21.8)	
Primary insurance, n (%)				<.001
Commercial	7169 (34.6)	2150 (31.3)	927 (18.2)	
Medicare	11,865 (57.2)	3826 (55.6)	2982 (58.4)

[a]N/A: not applicable.

When restricting the analysis to the 29,101 patients (patients with in-person visits only: n=20,259, 69.6%; patients with 1 telemedicine visit: n=5015, 17.2%; patients with ≥2 telemedicine visits: n=3825, 13.1%) with a least 1 recorded BP, telemedicine use was associated with lower odds of not meeting the *Controlling High Blood Pressure* quality measure (1 telemedicine visit: OR 0.89, 95% CI 0.83-0.95; *P*<.001; ≥2 telemedicine visits: OR 0.91, 95% CI 0.83-0.99; *P*=.03; reference, in-person visit only). In this model, female sex, Hispanic patients of color, Black patients, Medicaid insurance, and diabetes mellitus were associated with higher odds of not meeting the measure, while ASCVD and 2 or ≥3 total visits during the study period continued to be associated with lower odds of not meeting the measure (Table 2).

Subgroups analyses for patients who were aged ≥65 years, Hispanic patients, non-Hispanic Black patients, and those with Medicaid insurance are shown in Multimedia Appendix 1. The impact of telemedicine use on BP control in these subgroups was similar to that in the analysis that was restricted to the subgroup of patients with at least 1 recorded BP, both in the model that included all patients with hypertension and when only patients with at least 1 recorded BP were included.

Discussion

In our analysis of patients with hypertension who were seen in primary care and cardiology clinics at an urban, academic medical center during the COVID-19 pandemic in 2020, we found that increased telemedicine visit use was associated with poorer performance on the *Controlling High Blood Pressure* quality measure. These findings are largely driven by BP being recorded in less than 20% (4198/27,900) of telemedicine visits, as BP was recorded in 93% (55,370/59,409) of in-person visits.

When the analysis was restricted to patients with at least 1 recorded BP, patients with higher telemedicine visit use had a better or similar likelihood of poor performance on the *Controlling High Blood Pressure* quality measure. These findings were also robust for the subgroups of patients who were previously described to have more difficulty with using telemedicine services, including patients aged ≥65 years, Black or Hispanic patients, and those with Medicaid insurance [2,4,5,17,18].

Our finding that primary care and cardiology telemedicine visits are less likely to have recorded B*P* values when compared to in-person visits is consistent with prior literature. A recent report from a large US database containing 125.8 million primary care visits from 2018 to 2020 demonstrated that BP is recorded in less than 10% of telemedicine visits, whereas BP is recorded in approximately 70% of in-person visits [10]. In our analysis, we additionally found that the disparate rate of BP being recorded at telemedicine visits versus in-person visits resulted in patients who used telemedicine visits being more likely to not meet the *Controlling High Blood Pressure* quality measure. These findings highlight potential unintended consequence of the rapid adoption of telemedicine visits and have direct implications for various quality payment programs, such as those of Medicare accountable care organizations, that use BP control as a key quality benchmark [16]. More broadly, our findings highlight the importance of the continued assessment of the content and quality of care delivered via telemedicine services [10,11], especially as telemedicine visits are expected to remain an integral part of the health care delivery landscape after the COVID-19 pandemic ends.

Nonetheless, it is reassuring that telemedicine visit use did not negatively impact the *Controlling High Blood Pressure* quality measure when the analysis was restricted to patients with at least 1 recorded BP. This suggests that while BP is less likely to be recorded during telemedicine visits, in general the quality of BP management in primary care and cardiology settings may be similar regardless of telemedicine visit use. It is also reassuring that we observed similar results even in populations that are known to have decreased telemedicine use and poorer BP control, such as older patients, Black or Hispanic patients, or patients with Medicaid [2,4,5,19]. However, we cannot fully exclude residual confounding, such as from patients who use more telemedicine services also being more likely to maintain the continuity of care and other health behaviors during the COVID-19 pandemic [6,7,20]. Future studies would need to more rigorously evaluate how telemedicine use can impact BP management as well as determine the best approaches to incorporating BP management strategies, including BP telemonitoring, into routine clinical practice during the telemedicine era [21,22]. Examples of such strategies might include conducting randomized clinical trials of interventions to improve the accuracy of home BP assessments performed by patients in advance of telemedicine and office visits [23] as well as using approaches to integrating telemedicine visits as part of novel BP telemonitoring and medication titration programs [24,25].

There are several additional limitations to our study. As a retrospective cohort study that uses EHR data, our study is necessarily hypothesis-generating research, and additional confounding factors, including those outside of EHR data capture, cannot be excluded. Because we did not assess the quality of BP medications and potential clinical inertia, we have limited insight on how telemedicine use can affect clinical management practices for hypertension. Furthermore, the BP recordings used for this analysis reflect actual clinical practice, and we could not assess the quality of BP measurements that were taken at patents' homes and then recorded during telemedicine visits, although home BP measurements have been shown to be potentially more reliable than BPs measured during office visits [23,26]. The *Controlling High Blood Pressure* quality measure may also not accurately reflect a patient's true BP control status at a given point in time. Finally, because there were dramatic care disruptions during the COVID-19 pandemic, our findings may not be generalizable to in-person visits and telemedicine visits when the COVID-19 pandemic ends, and longitudinal research is needed to assess the continued impact of telemedicine visits on cardiovascular care delivery.

Despite these limitations, our study is among the first to describe the real-world impact of telemedicine visits on BP control for a diverse population of patients who access ambulatory care. We found that while the higher use of telemedicine visits was associated with poorer performance on the *Controlling High Blood Pressure* quality measure, this was mainly driven by BP being much less likely to be recorded during telemedicine visits. When BP was recorded, telemedicine use was found to be associated with similar or slightly improved BP control. These results provide timely insights into the impact of telemedicine on cardiovascular care quality with important implications for research, implementation, and policy making in the telemedicine era.

Conflicts of Interest

None declared.

Abstract

Background: Information systems based on artificial intelligence (AI) have increasingly spurred controversies among medical professionals as they start to outperform medical experts in tasks that previously required complex human reasoning. Prior research in other contexts has shown that such a technological disruption can result in professional identity threats and provoke negative attitudes and resistance to using technology. However, little is known about how AI systems evoke professional identity threats in medical professionals and under which conditions they actually provoke negative attitudes and resistance.

Objective: The aim of this study is to investigate how medical professionals' resistance to AI can be understood because of professional identity threats and temporal perceptions of AI systems. It examines the following two dimensions of medical professional identity threat: threats to physicians' expert status (professional recognition) and threats to physicians' role as an autonomous care provider (professional capabilities). This paper assesses whether these professional identity threats predict resistance to AI systems and change in importance under the conditions of varying professional experience and varying perceived temporal relevance of AI systems.

Methods: We conducted 2 web-based surveys with 164 medical students and 42 experienced physicians across different specialties. The participants were provided with a vignette of a general medical AI system. We measured the experienced identity threats, resistance attitudes, and perceived temporal distance of AI. In a subsample, we collected additional data on the perceived identity enhancement to gain a better understanding of how the participants perceived the upcoming technological change as beyond a mere threat. Qualitative data were coded in a content analysis. Quantitative data were analyzed in regression analyses.

Results: Both threats to professional recognition and threats to professional capabilities contributed to perceived self-threat and resistance to AI. Self-threat was negatively associated with resistance. Threats to professional capabilities directly affected resistance to AI, whereas the effect of threats to professional recognition was fully mediated through self-threat. Medical students experienced stronger identity threats and resistance to AI than medical professionals. The temporal distance of AI changed the importance of professional identity threats. If AI systems were perceived as relevant only in the distant future, the effect of threats to professional capabilities was weaker, whereas the effect of threats to professional recognition was stronger. The effect of threats remained robust after including perceived identity enhancement. The results show that the distinct dimensions of medical professional identity are affected by the upcoming technological change through AI.

Conclusions: Our findings demonstrate that AI systems can be perceived as a threat to medical professional identity. Both threats to professional recognition and threats to professional capabilities contribute to resistance attitudes toward AI and need to be considered in the implementation of AI systems in clinical practice.

Introduction

Objective

Advances in machine learning and image recognition have driven the implementation of systems based on artificial intelligence (AI) in clinical practice. These systems are able to perform tasks commonly associated with intelligent beings, such as reasoning or learning from experience [1]. AI systems based on machine learning gain insight directly from large sets of data [2]. Such AI systems can, therefore, make more complex decisions and complete more complex tasks than can rule-based systems. Moreover, machine learning has the potential to improve AI system capabilities with growing amounts of training data. In medical disciplines such as radiology, AI systems already diagnose specific diseases in a manner comparable with that of experienced physicians [3]. Current AI systems provide diagnosis and treatment recommendations, facilitate access to information, and perform time-consuming routine tasks of physicians, such as the segmentation of radiological images [4]. In the light of an accelerated technological development, AI systems in health care are expected to pave the way for truly personalized medicine by augmenting medical decisions and helping physicians cope with increasing amounts of relevant data and growing numbers of medical guidelines [5]. In fact, future AI systems are expected to autonomously execute medical actions (eg, communicating results and making diagnosis decisions) as efficiently and accurately as expert physicians [3]. Thus, medical professionals will be able to delegate more complex medical tasks to those systems than to any traditional rule-based clinical decision support system [6].

Despite their benefits and the great expectations toward their future use, AI systems do not cause only positive reactions in medical professionals. Although nearly all current applications of AI are still limited to narrow use cases, the future potential of this technology has resulted in a discourse driven by a duality of hyped expectations and great fears [7]. Many physicians seem to be concerned about the changes that AI systems impose on their profession [8]. Such negative attitudes toward new technology can manifest as *resistance* attitudes, resulting in hesitation toward adopting a technology [9] and even in active resentment against using a technology in clinical practice [10]. Although multiple studies have investigated attitudes toward AI [11-13], they did not consider how resistance attitudes toward AI are formed. Specifically, they did not examine whether negative attitudes toward AI stem from the perception that AI is threatening the medical professional identity. Therefore, we aim to address the following research questions:

1. How is the medical professional identity threatened by AI systems?
2. Under which conditions do medical professional identity threats contribute to resistance to AI?

Theoretical Background

Professional identity refers to *how professionals define themselves in terms of their work roles and provides an answer to the question* "Who am I as a professional?" [14]. In general, professionals strive to maintain a coherent and positive picture of themselves [15], resulting in a tendency to interpret experiences in identity-coherent ways. This helps individuals to adapt to social changes, such as technological innovations, and to create benefits from the positive identification with a social group. Professional identity can be considered as a combination of social identity [16] (ie, membership in a group of professionals) and personal identity (ie, the individual identification and enactment of professional roles) [15]. Medical professionals are known for their strong commitment to their professional identity, which is already developed in the early phases of their socialization and later refined through practical experience [17]. The medical profession's group boundaries are very rigid and shaped by strong core values and ideals [18]. Medical professionals can, therefore, be seen as a *prototypical profession* [17], and their professional identity is particularly resilient to change [19].

Identity threats are "experiences appraised as indicating potential harm to the value, meanings, or enactment of an identity" [20]. Such experiences are potentially decreasing an identity's value, eliminating a part of the identity, or disturbing the connection between an identity and the meaning the individual associates with the threatened identity [20]. In the following, we distinguish between two parts of individuals' identity that can be threatened: personal identity and professional identity.

First, *self-threat* describes a context-independent threat to *personal identity* by challenging fundamental self-motives of distinctiveness, continuity, generalized self-efficacy, and self-esteem [21]. Self-threat can bias information processing, result in avoidance of threatening information [22-24], and adverse emotional reactions [25]. Recently, self-threat has been identified as an antecedent of resistance to technology [26].

Second, medical professionals can be threatened along different dimensions of their *professional identity*. Drawing on a synthesis of prior work (Multimedia Appendix 1 [9,10,14,27-34]), we differentiate between 2 dimensions of medical professional identity threats. First, *threats to professional recognition* refer to challenges to the expertise and status position of medical professionals [10,27]. Second, *threats to professional capabilities* refer to the enactment of roles related to the medical work itself. The latter include threats to the care provider role [28], autonomy [14,29-31], and professional control [9,32]. Multiple studies show that professional identity threats can stipulate resistance to new technologies and organizational change [10,28,35]; however, it is unclear how these threats manifest in the context of AI systems.

Multiple conditions do influence how medical professionals experience identity threat from AI systems. In this paper, we focus on the following two conditions: professional experience and the perceived temporal distance of AI. First, perceived

experience influences how likely medical professionals perceive that AI systems can replace parts of their work. In particular, more experienced physicians believe that they have unique skills that AI systems cannot substitute, whereas novices have yet to develop those skills. Second, medical professionals might have different perceptions of how fast AI systems are implemented in clinical practice. Perceiving AI systems as temporally close and relevant in the immediate future suggests that AI systems will be seen as more influential on concrete medical work practices, thus threatening one's professional capabilities. Conversely, if AI systems are perceived to be relevant only in the distant future, the perceived threat might be less specific to medical work practices but more relevant for the long-term reputation of medical professionals, thus threatening their professional recognition. Hence, the perceived temporal distance of AI systems could affect how relevant each dimension of the professional identity becomes [36].

Methods

Survey Design

We collected data in 2 waves of a web-based survey. The first wave survey mainly addressed medical students, whereas the second survey focused on experienced physicians from different specialties. All participants were provided with a vignette of an AI system named *Sherlock* (Textbox 1) that was based on the description of IBM Watson and was pretested with researchers and medical students. We selected this vignette because it depicts a general AI system in which the participants were familiar with because of the marketing efforts of the vendor. It does not limit the abilities of the AI to a specific medical specialty. The vignette was purposefully focused on the benefits of the system and evoked expectations of high accuracy to establish the picture of a powerful AI system that goes beyond extant narrow use cases and, thus, has the potential to be threatening. Then, control questions were included to ensure that participants associated AI with the vignette and that it was perceived as realistic. The vignette was pretested with medical students and professionals. We then asked an open question about the participants' perceptions of the changes to their professional role caused by AI systems to gain qualitative insights into the perceived upcoming change of their identity. Afterward, we asked participants to complete the provided survey of experience, identity threat, resistance attitudes, and perceived temporal distance of AI systems.

Textbox 1. Vignette Sherlock—a general artificial intelligence system.

What is an intelligent clinical decision support software?

- Physicians often need to quickly analyze all the information provided to make diagnoses and decisions about treatments. These decisions have far-reaching consequences for patients and yet often have to be made under time pressure and with incomplete information. This is where the Sherlock decision support software comes in.

- Sherlock can be used in different specialties but will be presented here as with the following example of an oncological system.

- Every physician has an iPad or a laptop through which he or she can access his or her electronic medical records. The "Ask Sherlock" button is integrated into each medical record. When the physician asks Sherlock, he or she receives a 1-page treatment recommendation with up to 40 pages of explanations as backup.

- With the help of artificial intelligence, Sherlock can integrate and compare millions of patient data to identify similarities and connections. In addition, Sherlock has been trained by renowned experts. On the basis of the evidence base and the expert training, Sherlock then generates treatment options. Sherlock then presents those treatment options ranked by appropriateness (recommended, for consideration, or not recommended) alongside key information from the medical record and relevant supporting articles from current research. As a result, the practicing physician can easily follow Sherlock's recommendations and directly access relevant articles or clinical data.

- Sherlock is already in use in some clinics and tests have shown that Sherlock's recommendations are 90% in line with the decisions of renowned tumor boards.

Measures

We used a 4-item measure of self-threat [21] on a 6-point Likert scale and a 3-item measure of resistance [9]. Furthermore, we asked participants whether they perceived the change from AI systems as temporally close or distant by assessing the agreement to the following statements: "Such systems will only become relevant in the distant future," "Such systems are unlikely to be implemented technically," and "Such systems are too abstract and intangible for me." We extended existing measures for threats toward professional recognition and professional capabilities following the procedure of MacKenzie et al [37], as outlined in Multimedia Appendix 2 [9,28,29,37-46]. For medical students, we also assessed positive expectations toward AI, which mirrored the negatively framed items that we used for identity threat (*identity enhancement*). We also included an open question about their expectations of how the medical role would change with the introduction of AI systems. As a control variable, we asked for participants' familiarity with clinical decision support systems. Except items related to self-threat, all items were measured on a 5-point Likert scale from totally disagree to totally agree. Table 1 lists the survey items. The items for *identity enhancement* can be found in Multimedia Appendix 3 [47-50].

XSL•FO

RenderX

Table 1. Final list of items used for the hypothesis testing.[a]

Construct	Item

Threats to professional recognition (self-developed from literature review)

Threat to expertise

E2: I fear that when using the system, physicians may lose their expert status.

E3: I fear that when using the system, certain physician specializations can be replaced.

Perceived threat to status position

S1: I fear that when using the system, physicians' position in the hospital hierarchy may be undermined.

S2: I fear that when using the system, physicians may have a lower professional status.

S4: I fear that the status of physicians, who use the system, may deteriorate within the physician community.

Threats to professional capabilities

Perceived threat to autonomy (adapted from Walter and Lopez [29])

A1: I fear that when using the system physicians' job autonomy may be reduced.

A3: I fear that physicians' diagnostic and therapeutic decisions will be more monitored by nonphysicians.

Perceived threat to professional influence

I1: I fear that when using the system physicians may have less control over patient medical decisions.

I2: I fear that when using the system physicians may have less control over ordering patient tests.

I3: I fear that when using the system physicians may have less control over the distribution of scarce resources.

Perceived threat to being a care provider (self-developed from literature review)

C1: I fear that when using the system physicians have less influence on patient care.

C3: I fear that when using the system physicians are less able to treat their patients well.

Self-threat from AI[b] (adapted from Murtagh et al [21])

ST1: Using Sherlock undermines my sense of self-worth.

ST2: Using Sherlock makes me feel less competent.

ST3: Using Sherlock would have to change who I am.

ST4: Using Sherlock makes me feel less unique as a person.

Resistance to AI (adapted from Bhattacherjee and Hikmet [9])

RC1: I do not want Sherlock to change the way I order patient tests.

RC2: I do not want Sherlock to change the way I make clinical decisions.

RC3: I do not want Sherlock to change the way I interact with other people on my job.

RC4: Overall, I do not want Sherlock to change the way I currently work.

Temporal distance of AI (self-developed)

A1: Such systems will only become relevant in the distant future.

A2: Such systems are unlikely be implemented technically.

A3: Such systems are too abstract and intangible for me.

Familiarity

F1: I have never heard of such systems to I have heard a lot of such systems

F2: I have never used such systems to I have used such systems quite often

F3: I have never dealt with such systems to I have dealt with such systems in great detail.

F4: I am not at all familiar with such systems to I am very familiar with such systems.

[a]Items with the identifiers E1, S3, A2, and C2 were removed because of measurement properties (see Multimedia Appendix 2).

[b]AI: artificial intelligence.

Scale Validation

We validated the scales of professional identity threats in the sample of novices and experienced physicians and the corresponding identity enhancement values, as outlined in Multimedia Appendix 2. A confirmatory factor analysis with all measurement scales resulted in a good model fit. All scales displayed good psychometric properties, including reliability, convergent validity, and discriminant validity (Multimedia Appendix 2). The correlation between threats to professional recognition and professional capabilities was 0.64, which was smaller than the lowest square root of the average variance extracted of 0.77, indicating acceptable multicollinearity. Similarly, multicollinearity between self-threat and threats to professional recognition was acceptable with a correlation of 0.66 being lower than the lowest square root of the average variance extracted of self-threat. We accounted for potential common method bias in the survey design and through testing for a common method factor. The results indicated that common method bias is unlikely to have a strong impact on our results (see Multimedia Appendix 2 for details). The items of identity enhancement were combined into 1 factor because of the result of the exploratory factor analysis. All analyses were performed using SPSS (version 26; IBM Corporation) and Stata (version 16; StataCorp).

Sample and Participants

A total sample of 227 novice and experienced physicians participated between fall 2017 and spring 2019. Participants were recruited from medical social media groups and by personal reference. After excluding participants because of failed comprehension checks or poor data quality (ie, very fast completion time or answers to the open question that were completely unrelated to the question), a total data sample of 206 participants was used for data analysis. Of these 206 participants, 164 (79.6%) were medical students and 42 (20.4%) participants were medical professionals across different specialties (see Table 2 for details on sample). We included both medical students and trained physicians in our sample for two reasons: First, especially inexperienced physicians are susceptible to the influence of technology [51]. They may thus provide valuable insight into the effects of AI systems. Second, particularly medical students face strong, long-term career consequences if AI systems alter the meaning of specific medical disciplines such as radiology. They are thus likely to cognitively engage with potential identity threats to make reasonable career decisions, for example, with regard to the specialty they pursue. Conversely, experienced medical professionals may have a more pronounced professional identity and may experience threats from AI systems differently.

Table 2. Sample properties of novice and experienced physicians.[a]

	Novice physicians	Experienced physicians
Total sample size, N	182	45
Sample used for data analysis, n (%)	164 (90.1)	42 (93.3)
Age (years), mean (SD)	24.65 (3.23)	39.57 (13.14)
Gender (female), n (%)	131 (72)	18 (40)
Experience (average)	Eighth semester	12.6 years of job experience

[a]The specialties of experienced physicians are presented at a later stage.

Statistical Analysis

Our main outcome variable measures participants' resistance toward using the *Sherlock* application. Because of differences in sample size between novice physicians (n=164) and experienced physicians (n=42), we conducted a nonparametric Mann–Whitney *U* test to test the differences between the 2 samples regarding resistance attitude and self-threat. We conducted seemingly unrelated regression analyses with self-threat and resistance as the dependent variables because we expected their error terms to be correlated. The predictors were included in a stepwise approach to assess how much additional variance they explain. To test the effect of perceived temporal distance of AI, we incorporated 2 interaction terms between temporal distance and the 2 dimensions of professional identity threats into the regression analysis. We conducted a mediation analysis following Hayes [52] with 10,000 bootstrap samples to test the mediating role of self-threat on resistance attitudes.

Ethics Approval

Ethics approval was not sought or obtained from the Ethics Committee at the University of Mannheim, as an approval was not required under the institution's current ethics statute.

Results

Descriptives and Group Differences

We find that both experienced and novice physicians perceived identity threats from the upcoming change from AI systems (Table 3). Novice physicians showed relatively high resistance to AI and self-threat, whereas experienced physicians showed slightly lower resistance and self-threat from AI. The group differences were significant for resistance (P=.005) and self-threat (P<.001). Novices perceived equally strong threats to their professional recognition (mean 3.05, SD 1.23) and professional capabilities (mean 3.25, SD 0.97), whereas experienced physicians perceived a stronger threat to their professional capabilities (mean 2.72, SD 1.18) than to their professional recognition (mean 2.38, SD 1.03). Group differences were statistically significant; novices experienced more threats to professional recognition (P<.001) and

professional capabilities (*P*=.80) than experienced physicians. Similarly, novices reported AI systems as slightly more temporally distant than did experienced physicians (*P*=.08). Moreover, in the sample of experienced physicians, the experienced threats and resistance attitudes differed based on the medical specialty (Table 4). The descriptive statistics show, for example, that physicians in the psychiatry specialty reported stronger threats to professional recognition than to professional capabilities, whereas surgeons reported stronger threats to professional capabilities than to professional recognition. However, as the sample size was relatively small, more research is needed to fully understand the effects of different specialties on experienced identity threats.

Table 3. Mann–Whitney *U* test between novice and experienced physicians.[a]

	Novice physicians (n=164), mean (SD)	Experienced physicians (n=42), mean (SD)	Group differences	
			Z value	*P* value
Resistance to AI[b]	3.58 (0.97)	3.13 (0.97)	2.83	.005
Self-threat from AI	2.78 (1.36)	1.92 (0.91)	3.85	<.001
Threats to professional recognition	3.05 (1.23)	2.38 (1.03)	3.36	.001
Threats to professional capabilities	3.25 (0.97)	2.72 (1.18)	2.62	.01
Perceived temporal distance of AI	2.23 (0.84)	2.03 (0.94)	1.75	.08
Familiarity with AI	1.75 (0.89)	2.32 (0.77)	−4.28	<.001

[a]All items except self-threat were measured on a 5-point Likert scale and self-threat was measured on a 6-point scale ranging from strongly disagree to strongly agree.

[b]AI: artificial intelligence.

Table 4. Means (SDs) by specialty of experienced physicians (n=42).

Specialty	Values, mean (SD)				
	Self-threat from AI[a]	Resistance to AI	Temporal distance of AI	Threats to professional recognition from AI	Threats to professional capabilities from AI
Not specified (n=7)	2.32 (0.89)	3.71 (1.25)	1.71 (0.65)	2.48 (0.87)	3.18 (1.33)
Internal medicine (n=10)	2.05 (0.98)	3.15 (0.88)	1.83 (0.65)	2.28 (1.33)	2.62 (1.27)
General medicine (n=3)	1.92 (1.01)	2.92 (0.88)	2.78 (1.68)	3.06 (0.59)	3.57 (0.95)
Psychiatry (n=5)	1.55 (0.82)	2.70 (0.97)	1.53 (0.61)	2.50 (0.90)	1.94 (0.73)
Pediatrics (n=5)	2.05 (1.25)	2.80 (1.14)	2.13 (1.17)	2.97 (0.84)	3.00 (1.06)
Surgery (n=5)	1.45 (0.45)	3.10 (1.10)	2.07 (0.64)	1.53 (0.63)	2.11 (1.44)
Anesthesiology (n=3)	1.75 (0.90)	3.58 (0.63)	1.78 (0.38)	2.94 (1.08)	2.96 (0.83)
Others such as neurology and pathology (n=4)	1.94 (1.13)	2.81 (0.59)	3.08 (1.52)	2.40 (0.83)	2.96 (1.04)

[a]AI: artificial intelligence.

Regression Analyses

Testing the relationships between different types of identity threat and resistance attitudes in the total sample (Tables 5 and 6; Multimedia Appendix 3), we found that perceived professional identity threats directly affected resistance attitudes and personal identity threat (self-threat). Both threats to professional recognition (*P*<.001) and threats to professional capabilities (*P*<.001) were significant predictors of self-threat (model 4a, Table 6). Moreover, we found that both professional identity threats contributed independently to resistance to change. However, threats to professional recognition predicted resistance only in isolation (Multimedia Appendix 2; *P*<.001) but not in combination with threats to professional capabilities (Multimedia Appendix 3, model 3b; *P*=.50). Hence, threats to professional capabilities overruled the impact of threats to professional recognition on resistance attitudes and significantly increased resistance (Multimedia Appendix 3, model 3b; *P*<.001). The findings suggest that threats to professional recognition are more strongly related to personal identity, whereas threats to professional capabilities are more strongly and directly related to resistance to change.

Table 5. Descriptive statistics of the measurement model (N=206).[a]

Variables	Mean (SD)	Square root of the AVE[b]	Resistance	Self-threat	Age	Gender	Gender	Temporal distance	ProCap[c]	ProRec[d]

Temporal distance x ProCap	–0.165 (0.082; –0.325 to –0.005)	–2.020	.04
Intercept	0.237 (0.261; –0.274 to 0.748)	0.910	.36

[a]ProRec: threats to professional recognition.

[b]ProCap: threats to professional capabilities.
[c]AI: artificial intelligence.

We also analyzed how perceiving AI systems as temporally close or distant interacted with perceived professional identity threat. The perception of AI systems as temporally distant interacted positively with threats to professional recognition (P<.001) and interacted negatively with threats to professional capabilities (P=.02) in predicting self-threat (Table 6, model 4a). In predicting resistance, the perception of AI systems as temporally distant interacted negatively with threats to professional capabilities (Table 6, model 4b; P=.04), whereas the interaction with threats to professional recognition was not significant (P=.24). Figures 1-4 show the moderating effects of temporal distance on both dimensions of identity threat. The findings suggest that experienced identity threats are closely related to how temporally distant or close the technological change from AI systems is perceived. Threats to professional capabilities refer to more concrete and context-specific elements of professional identity. Thus, these threats are more salient if physicians believe that AI systems are temporally close and relevant to clinical practice in the near future. Conversely, threats to professional recognition require physicians to consider their profession in a holistic way. Thus, these threats are more salient if physicians perceive AI systems to be relevant only in the distant future.

Figure 4. Moderating effect of temporal distance on the association of threats to professional capabilities with resistance. AI: artificial intelligence.
For the sample of novice physicians, we also collected data about perceived identity enhancements through AI. We used these data for robustness analysis to exclude the possibility that our results regarding the effects of identity threat are biased by hidden positive attitudes. The identity enhancement items mirrored the wording of the identity threat items to capture any positive expectations toward the change induced by AI systems (Multimedia Appendix 3). The analysis shows that identity enhancement reduced resistance to AI (P=.02) and was not related to self-threat (P=.52). After including identity enhancement as a control variable, the above-described effects of perceived identity threat remained qualitatively unchanged. This indicates that perceived professional identity threats have a significant effect on resistance to AI over and beyond any effects of perceived identity enhancement through AI.

Finally, we conducted a content analysis of the qualitative statements from novice physicians to validate that our measured dimensions capture the experienced changes through AI systems. The data set consisted of a total of 414 distinct statements by 176 participants. The content of all statements was classified as positive or negative statements about AI systems by 2 independent coders (EJ and one student assistant; Table 7).

Table 7. Content analysis of the qualitative statements.

Dimensions of identity threat and categories identified in the data	Example statements from participants (survey ID)
Threats to professional recognition	
AI[a] replaces important knowledge tasks leading to a loss in professional status	• "Physicians appear to be less competent as patients believe that a small machine can also find solutions and solve their problem." (#98) • "Physicians will be replaced by computers and will only fulfill an assistant job." (#894)
Decreasing importance of professional knowledge and expertise	• "Physicians are tempted to study less as they know that the system will have all data accessible." (#492)
Threats to professional capabilities	
Loss of professional autonomy in decision-making	• "Physicians might stop to think for themselves and do not reflect on the results presented by the system which is a severe source of mistakes" (#98) • "Less legal protection for the physician if he/she acts against the AI's recommendation due to experience" (#954)
Pressuring the role of care provider	• "A physician will be more someone who operates a machine than being a doctor taking care of his/her patient's individual needs." (#2426) • "less patient oriented care when using technology" (#850)
Loss of influence	• "The management will then require even faster decisions which results in increased time pressure." (#719)
Perceived enhancements	
AI supports decision-making by increasing decision certainty	• "AI is a relief for the physician and helps to gain security in diagnosing by providing a second opinion which either encourages the physician to reflect his diagnosis a second time or strengthens the certainty of having found the right diagnosis." (#47) • "work more independently and provides them more security in their work." (#3159)
AI supports decision-making by helping to stay up-to-date	• "it is no longer necessary to know the smallest detail of every single disease." (#743) • "AI stays abreast of the fast changes and developments in medical science." (#250)
AI increases workflow efficiency	• "AI saves time which can then be invested in the treatment of more patients or more personalized care." (#94)
AI leads to better patient care	• "AI increases security in diagnosing and might lead to better results. This again can increase the patient's trust towards the physician." (#2277)

[a]AI: artificial intelligence.

One-third of the negative statements (34/105; 32.4%) described threats to professional recognition. The implementation of AI systems was perceived as leading to a loss of status and prestige for the occupational group of physicians and made participants fear that physicians might become redundant and reduced to a mere voice of the AI system. Moreover, participants feared that expert knowledge would become less important as AI systems incorporated more up-to-date knowledge than ever possible for a human being. The statements also contained multiple threats to professional capabilities. As such, participants feared that physicians might lose their autonomy in decision-making as they might trust the AI system more than appropriate, whereas the system would perform tasks autonomously. In addition, participants perceived that it would become more difficult to be a care provider with AI systems in place, as these systems would increase the distance between physicians and patients. The participants also feared that liability issues would arise if they disagreed with AI decisions. Conversely, 3 categories of positive statements emerged from the content analysis. AI systems were perceived as supporting decision-making through reduced uncertainty and complexity in diagnostics. Moreover, they were seen as facilitators of access to knowledge, supporting especially novice physicians, by providing access to the newest guidelines and empirical findings.

Discussion

Principal Findings

Our work contributes to the knowledge on the impact of AI and the future of work in health care [53-55]. It shows that professional identity threats from AI systems are indeed a serious concern for novice and experienced physicians and contribute to resistance to AI. AI systems threaten both professional recognition and professional capabilities of medical professionals. Threats to professional capabilities directly contribute to resistance to AI, whereas the effect of threats to professional recognition is mediated through self-threat. Professional experience and perceived temporal distance of AI systems influence the relationship between perceived identity threats and resistance attitudes. Medical novices experience

stronger identity threats than medical professionals. In addition, if AI systems are perceived as more relevant in the near future, threats to professional capabilities are more profound. If, however, AI systems are perceived as relevant in the distant future, threats to personal recognition gain in importance.

Our findings have implications for the understanding of how the medical professional identity changes with increasingly powerful AI systems and how AI systems are integrated into medical decisions. First, experienced identity threats influence how physicians adapt their professional identity to the upcoming change. For instance, study participants who indicated that "the role of the physician will be more passive, since decisions will be automated" might be less likely to choose specialties such as radiology. This can lead to fewer physicians who actively work with AI systems and develop the technological capabilities to evaluate those systems. Furthermore, several participants declared that they planned to focus on soft skills instead of analytical decision-making skills, which would rather be performed by an AI. Thus, instead of using AI systems as a second opinion and engaging in elaborate decision-making, physicians might end up delegating important tasks to AI systems without considering them in detail.

Second, threats to the professional identity cause identity protection responses [20] that directly impact technology use. In health care, physicians are pivotal for developing the ground truth for learning algorithms and for identifying relevant explanations and predictive values. Furthermore, physicians can make better diagnosis decisions with the support of trained algorithms and use them as a second opinion [56]. However, if they feel threatened in their identity, physicians are less likely to engage in the active development and adaptation of AI systems and resist their implementation. Moreover, identity protection responses can lead to incorrect medical decisions with AI systems if physicians reject AI advice as soon as it contradicts their opinion and is perceived as threatening [51]. In particular, threats to professional capabilities play a focal role in developing negative attitudes toward AI systems and should, thus, be addressed through specific medical training in interacting with AI systems.

Limitations and Future Research

This study has several limitations that can serve as a springboard for future research. First, by using the survey method, we were not able to capture how the identity develops through a longer period of time and whether medical students who perceived stronger threats to their future from AI would switch to a *nonthreatened* profession that requires more subjective interpersonal skills. In addition, it would be interesting to see how the professional identity is affected in clinical practice through a more intensive interaction with AI systems. Furthermore, our study provides first insights into potential differences in experienced identity threats across medical specialties. Specialties such as radiology or pathology were scarce in our sample, although those specialties often use AI in medical practice. Consequently, a follow-up study that looks at differences across specialties in more detail might provide interesting insights. In addition, our sample consisted of respondents who reported a relatively low degree of familiarity with AI systems. This reflects the current situation in medical education, in which medical novices are not trained in the use of AI systems. However, whether a sample with more familiarity would experience lower degrees of threat from AI systems needs to be further researched. Second, as noted in the literature [28,33,57] and underlined by the qualitative survey responses, there are also positive appraisals of AI systems that can enhance, rather than threaten, individuals' identity. Given that there are both strong positive and negative perceptions of the impact of AI systems on the professional identity, future research should consider the impact of ambivalence [58] on professional identity formation and restructuring. Third, we presented an AI system with a 90% accuracy rate. However, in clinical practice, the accuracy rate is highly dependent on the context, that is, the complexity of patient cases, and can be heavily disputed by medical professionals. Furthermore, with lower perceived or actual accuracy, physicians might develop more negative attitudes toward the AI system. Finally, as our study examined only 2 dependent variables, it is important to investigate how professional identity threat from AI systems impacts other variables, such as anxiety and long-term behaviors.

Abstract

Background: There remains a need to engage at-risk primary care populations in cancer prevention behaviors, yet primary care physicians often lack the time or resources to discuss these behaviors with their patients.

Objective: The objective of this study is to evaluate the content, usability, and acceptability of a mobile app that leverages insights from goal-setting and social network literature to facilitate cancer prevention goal setting, tracking, and sharing between non-Hispanic Black primary care patients and their social ties.

Methods: We recruited eligible non-Hispanic Black primary care patients (aged ≥18 years) from 2 practice sites in West Philadelphia, using nonprobabilistic purposive sampling. We conducted semistructured interviews with 5 to 7 participants over 3 weeks to solicit feedback on paper mock-ups of the app, iteratively adapting these mock-ups after each set of interviews. Thereafter, and informed by initial feedback, we created an electronic beta version of the app and sought acceptability and usability feedback from a different set of participants. Then, we conducted content analysis of all user responses to search for unifying themes on acceptability and usability of both the initial mock-ups and beta version of the app. We further assessed app usability using questions derived from the System Usability Scale.

Results: A total of 33 non-Hispanic Black primary care patients participated in this study. The mean age was 49 (SD 13) years, and 26 (79%) out of 33 participants identified as female. Semistructured interviews revealed three primary generalizable insights from our target population: the framing of each goal and its relevance to cancer impacted the likelihood that the goal would be chosen, participants thought that sharing health goals with others facilitates health behaviors, and most participants found it motivating to see other users' goal progress, while still collaborating with these users on their health goals. An overarching insight that permeated across each theme was the participants' desire to customize and personalize the app. Usability testing revealed that 100% (33/33) of participants found the app easy to use, and 76% (25/33) of participants reported that they would like to use this app frequently.

XSL•FO
RenderX

Conclusions: Cancer prevention in the modern era must include options that are accessible to all, but this does not mean that all options must be universal. This study's iterative process led to the development of a cancer prevention mobile app that non-Hispanic Black primary care patients deemed usable and acceptable and yielded noteworthy insights about what intended end users value in setting and accomplishing health goals.

Introduction

Background

Increasing the adoption of health behaviors at a population level is essential if we are to significantly decrease the burden of preventable cancer and improve public health. In the United States, more than 600,000 people die of cancer each year [1]. Approximately 30% of these deaths are linked to poor diet, physical inactivity, and carrying too much weight, with another 30% due to tobacco use, comprising nearly two-thirds of US cancer deaths [2-5]. Furthermore, cancer disproportionately impacts non-Hispanic Black populations largely due to inequities stemming from structural racism [6-9]. Evidence suggests that current primary care services do not effectively engage all patients in cancer prevention [10-16]. Therefore, there remains a need for other potential interventions to address this gap, especially among those most at risk.

One strategy to increase cancer prevention health behaviors is goal setting [17,18]. Collaborative goal setting, a process whereby the provider and patient agree upon a health-related specific SMART (specific, measurable, achievable, realistic, and time-bound) goal and action plan [19], has been shown to modify behaviors by directing intention and building self-efficacy [20-22]. However, in primary care, we lack an approach to implement a strategy for collaborative goal setting. A second approach to increase cancer prevention health behaviors is to disseminate health behaviors and knowledge through social networks, which are known to influence behaviors related to cancer risk, such as obesity and smoking [23-26]. Experimental studies suggest that reinforcement from multiple social ties (ie, through a network) increases health behavior adoption more than social reinforcements from single ties [27]. Prior work also suggests that cancer prevention strategies involving some form of social support are more effective in changing behaviors in BIPOC (Black, Indigenous, and People of Color) populations as compared with non-Hispanic White people [28,29]. There is evidence that BIPOC populations have denser social networks, with more reliable and frequent activation of informal social support [12,14].

The objective of this study is to develop and evaluate the content, usability, and acceptability of an electronic decision support tool—ie, a mobile app—that leverages these insights to facilitate cancer prevention goal setting, tracking, and sharing between primary care patients and their social ties. We conducted a series of semistructured interviews to determine the optimal content and app features before piloting the prototype with our priority population: non-Hispanic Black primary care patients. Although non-Hispanic Black populations use health technology at greater rates than their White counterparts [30-32], they remain underrepresented in studies about health technology and health behaviors [33,34]. There is evidence that end user experiences may vary by background and culture with the need for culturally sensitive and effective design [35-37]. In addition, there is a call for evaluating public health interventions with messaging grounded in the understanding of the populations served and without White bias [38,39].

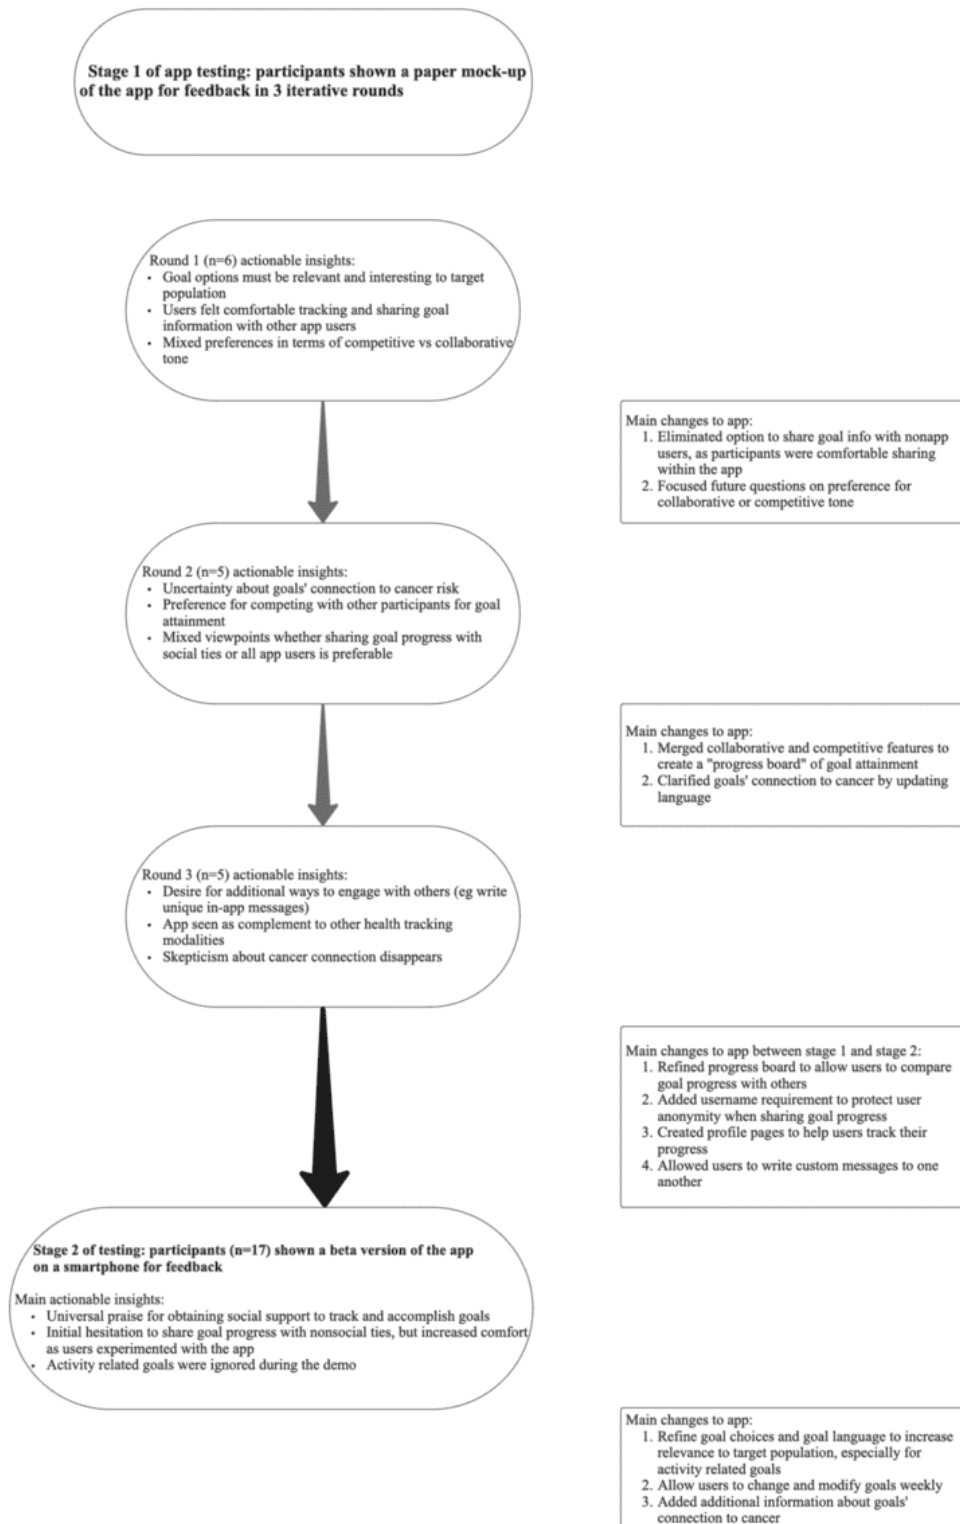
Objective

Given that this app will center on facilitating cancer prevention behaviors in populations most at risk, we aimed to ensure the app is culturally attuned to and meets the needs of its targeted end user. We also aimed to test features, such as leveraging social ties, given the evidence that such features may work better among non-Hispanic Black populations [28,29]. Therefore, this study aims to evaluate the content, usability, and acceptability of a cancer prevention app designed with direct input from and specifically for a non-Hispanic Black primary care patient population.

Methods

Study Overview

We conducted a multistage, mixed methods study to develop and evaluate the content, usability, and acceptability of a mobile app that facilitates cancer prevention goal setting, goal tracking, and goal sharing. Consistent with mHealth app development best practices [40], this study comprised 2 stages. First, we obtained feedback from potential end users regarding the paper prototypes of the app. Then, we solicited feedback on a beta version of the app, informed by initial feedback, from a new set of participants. Participants completed questionnaires containing both open- and closed-ended questions, which were subsequently analyzed to refine the prototype. The study team guided the design, features, and content of both the paper prototype and the electronic beta version of the mobile app in collaboration with Transmogrify (Conshohocken, PA), a firm that helps create, build, and grow digital products. Figure 1 shows a visual representation of the study design and stages.

Figure 1. Visual representation of the app design process and the iterative changes made during app development.


Setting and Participants

Participants and Eligibility Criteria

Participants had to (1) self-identify as non-Hispanic Black, (2) be aged ≥18 years, (3) speak English, (4) be seen at one of our study sites once in the past 3 years (if the patient has a designated primary care provider [PCP]) or twice in the past 2 years (if no assigned PCP), (5) be able to provide informed

consent, and (6) not have participated in another stage of testing for the intervention.

Setting and Recruitment Process

We recruited participants for both stages at 2 internal medicine primary care clinics in West Philadelphia, which serve a racially/ethnically diverse patient population, using a nonprobabilistic purposive sampling technique. We first generated a list of patients that met the first 4 eligibility criteria

above with upcoming appointments. Then, between April and May 2019 (stage 1) and May and June 2019 (stage 2), study team members invited potential participants from the clinics' waiting rooms that were on the pregenerated list to screen for the study. Interested participants reported to a private room after their appointments, where the study team confirmed the participants' eligibility, including their self-reported race/ethnicity, informed participants of the study's aims, and obtained formal consent for participation.

In stage 1, we aimed to recruit 5 to 7 participants per week over 3 weeks to rapidly modify the prototype based on participant feedback. Early usability testing research demonstrates that optimal feedback is derived from multiple rounds of testing with potential end users that inform refinements in between rounds [41-43], rather than one larger study that examines only one version of an app. In stage 2, we targeted a sample size of 15 to 20 participants to achieve thematic saturation of feedback and generate quantitative usability data of the beta version of the app [42,44]. Participants were incentivized at US $30 to complete the interviews.

Ethics Approval

The University of Pennsylvania Institutional Review Board approved the protocol for this study (828151).

Mobile App Prototype

The main objectives of the mobile app prototype were to (1) communicate the value of collaborative goal setting for cancer prevention, (2) provide a selection of concrete SMART goals [45] related to cancer prevention behaviors informed by evidence-based guidelines and recommendations from the American Cancer Society (ACS) [46], and (3) serve as a patient-held prompt to facilitate cancer prevention collaborative goal-setting discussions with PCPs and encourage easy sharing of information with social ties. The earliest version of the prototype was based on guidelines for the adoption of cancer prevention behaviors [29]. We ensured it tested at a Flesch Reading Ease score of 86.2% (ie, is understood by 11- to 13-year-olds) and a Flesch-Kincaid grade level score of 4.3 (ie, is at a fourth-grade reading level) [47]. Through quantitative and qualitative assessments, we aimed to solicit end user perspectives and preferences on the apps' (1) content and format, (2) delivery and use during primary care visits, and (3) use to share information with social ties (please refer to Multimedia Appendices 1 and 2 for iterative versions of our prototype at different stages of our study).

Data Collection, Measurements, and Analysis

Qualitative and Quantitative Data Collection

Stage 1

Over a 3-week period, the study team conducted semistructured interviews with 5 to 7 participants each week to solicit feedback on paper mock-ups of the app. Semistructured interviews averaged 30 minutes and included both closed and open-ended questions about the app's content, features, delivery methods, and potential future use. The study team synthesized and discussed the interview feedback weekly, iteratively refining the prototype before the subsequent set of participant interviews

until the study team felt as though it could proceed to the next stage of testing. Please refer to Multimedia Appendix 1 for examples of our prototype and the corresponding interview guides.

Stage 2

Before stage 2, the development team transformed the latest paper prototype into an electronic beta version of the app. In stage 2, the study team walked individual participants (n=17) through the beta version of the app on a smartphone. During this 30-minute walk-through, team members asked each participant approximately 33 close-ended and approximately 20 open-ended questions about the usability and acceptability of the app and its features. Multimedia Appendix 2 illustrates an example of our prototype and interview guide.

For both stages, we recorded all open-and close-ended responses verbatim into REDCap (Research Electronic Data Capture; REDCap Consortium) [48].

Participant Characteristics

In stage 1, we assessed participants (n=16), age, sex, technology use, and health habits. Survey questions evaluated participants' typical use of their mobile devices, comfortability with sharing health information with social ties on the internet and offline, and current goal setting and health tracking behaviors. In stage 2 (n=17), we collected the participants' age and sex.

Qualitative Measures

We asked certain open-ended questions in both study stages to inquire about the participants' overall impressions of the acceptability and usability of the app and its main features. We modified the interview guide iteratively each week in stage 1 to incorporate questions focused on specific changes made to the app based on the prior week's feedback. Examples of our early prototypes and corresponding interview scripts are provided in Multimedia Appendix 1. The stage 1 prototype went through 10 refinements to inform stage 2. For stage 2, we developed this prototype within InVision [49], a digital product design platform that allows end users to interact with the prototype as if it is an app. Examples of this prototype and sample interview guides are provided in Multimedia Appendix 2.

Quantitative Measures

In addition to the open-ended questions, we asked participants in stage 2 (n=17) close-ended survey questions about the usability of certain app features and the app overall. These questions were adapted from the System Usability Scale [50], an instrument commonly used to evaluate the usability of different technology products.

Analysis

We first assessed the participants' characteristics by tabulating the distributions or frequencies of the questions detailed above. We also calculated the distribution of Likert scale responses, ranging from strongly disagree to strongly agree, for the modified *System Usability Scale* questions asked in stage 2 of app testing.

Iterative Qualitative Analysis

Study team members (JMS, AB, LJ, and JA) met after each round of interviews to analyze feedback for key themes to inform refinements to the app content and features. This form of analysis allowed for the rapid implementation of the participants' feedback and strengthened the development of the app [42].

Qualitative Content Analysis

Two team members (DR and MDK) conducted a qualitative content analysis [51] of all responses to search for unifying themes across stages of testing, by reading through the responses and creating the initial codebook. We randomly selected one interview from each round of testing (4 total) to refine the codebook and achieve consensus on code definition, inclusion criteria, and exclusion criteria. JMS then coded the remaining interviews using a constant-comparison technique. Throughout the coding process, a total of 8 out of 33 interviews (24% of the total sample) were jointly coded by DR, MDK, and JMS to assess interrater reliability. Facilitated by NVivo software (version 12; QSR International), we calculated the percent agreement [52], a measure of coding consensus, and determined that there was satisfactory interrater reliability (median 75% agreement; mean 69.4%, SD 23.5%). The study team then reviewed all coded responses and extracted key themes from across responses. This allowed for the simultaneous analysis of interviews collected throughout all stages of app development.

Results

Participant Characteristics

Of the 33 non-Hispanic Black primary care patients participating in the study, the mean age was 49 (SD 13) years, and 26 (79%) identified as female. Of the initial stage 1 (n=16) participants, 14 (88%) reported using a smartphone multiple times a day, 7 (44%) specifically used an app or digital fitness tracker to track their health, 13 (81%) reported tracking their health either digitally or manually, 15 (94%) reported sharing "some" or "a lot" of health information with close friends and family, and 13 (81%) said they have relied on friends to accomplish health goals. Only 25% (4/16) of the participants reported that they were comfortable discussing health matters on the internet.

Qualitative Analysis

Table 1 summarizes the 3 dominant themes and associated subthemes that emerged from the qualitative content analysis of both stages. Below, we expand on these qualitative themes and add additional insights and changes made during the iterative analysis.

Table 1. Content themes and representative quotes.

Theme and subtheme	Representative quote
Messaging matters	
SMART[a] goals resonate	"It's something that I'm already working on, so actually a lot of [the] options were pretty good, so I wanted to pick more than one of them" [stage 2]
Achieving buy-in for cancer prevention messaging	"...[the app is] to the point. It tells me exactly what we're working on and gives me some things right on hand to reduce my chances of getting cancer." [stage 1, round 2]
Specifying goals for the target population	"I was already interested in cutting down red meat, but I wasn't sure if I was ready to do it yet. So, it was cool to see that as an option." [stage 2]
To share or not to share	
Working with others facilitates goal accomplishment	"I like the idea of sharing with friends and family and seeing other people sharing their progress. Overall, I think it's pretty good. It helps you keep on track." [stage 2]
Preferences for sharing goals with loved ones only versus all app users	"...I like [the app]. I would only pick [to share with] my friends. Since I'm trying to quit smoking, I wouldn't open it to everyone." [stage 2];
	"Family sometimes are critical. You could get more compassion from someone you don't know." [stage 1, round 2]
Competition versus collaboration	
Deriving motivation from competition	"Ah yeah, some people like to do things out of competition." Prompt: Would it be motivating for you personally? "Yes. I don't like to lose." [stage 1, round 2]
Success through collaboration	"I think it's a good idea to be able to communicate with [other users] the things that they are doing and the things that I'm doing to make better choices to reduce our risk of contracting cancer." [stage 2]
The progress board: a Goldilocks solution	"I really like the progress [board]. I like that you can click on a person and send them encouragement, or even your own personal message. I think I would use this app." [stage 2]

[a]SMART: specific, measurable, achievable, realistic, and time-bound.

Theme 1: Messaging Matters

SMART Goal Framing Resonates

A key objective of this app is to encourage the setting of appropriate and motivating health goals. Therefore, we sought feedback on how to present the SMART goals in a manner that is relevant to the target population, which highlights the important connection between these goals and cancer prevention. Overall, we found that messaging mattered to the participants. Participants appreciated the goals' specificity and commented that these goals seem relevant to their efforts to become healthier. One participant stated as follows:

> [The goals are] good...they're all something that I can work on. I like the 'Make small changes for a big impact.' That makes a lot of sense. [stage 1, round 3]

### Achieving Buy-in for Cancer Prevention Messaging

A few participants noted confusion and skepticism about the relationship between lifestyle behaviors and cancer prevention. One participant said as follows:

> only the smoking makes people think of cancer. The other ones seem more like basic health as opposed to associating it with cancer.

She then asked for "more specific information about how [these goals] relate to cancer." [stage 1, round 2]. This initial feedback led to the following modifications: (1) we changed the language in the app to emphasize that small lifestyle modifications, such as those advocated by the app, can lead to a direct impact on cancer risk and (2) we added direct links to ACS webpages on lifestyle behaviors and cancer, to further emphasize the importance of these goals. Feedback on these modifications was positive in stage 2, with 15 (88%) participants out of 17 indicating that they agreed or strongly agreed that the connection to cancer in the app was both clear and useful. (See Figure 2 for additional quantitative results from stage 2).

Figure 2. Usability feedback for key app features.
Specifying Goals for the Target Population

In another example of the importance of SMART goal framing, we made significant changes to the app's "Get Active" goals when we realized that none of the participants chose those goals when using the app in stage 2. Specifically, we centered each "Get Active" goal around a type of exercise (eg, "I will do 30 minutes of dancing"), rather than a more general goal (eg, "I will do 30 minutes of moderate intensity exercise"). As noted in a separate report, these new "Get Active" goals became more popular in future rounds of testing [53].

Desire for Customization

Participants broadly supported the goal choices offered by the app. However, nearly all participants wished to further adapt the goals themselves. Given this feedback, we added a number of customization options, from allowing users to choose the frequency of an action (eg, "I will do 30 minutes of dancing 4 times a week") to permitting users to change their goals on a weekly basis. Even with these modifications, all goals remained SMART (ie, specific, measurable, achievable, realistic, and time-bound) and connected to cancer prevention.

Theme 2: To Share or Not To Share

Working With Others Facilitates Goal Accomplishment

One key feature of this app is sharing health goals with other users and working on those goals together. Across the rounds of testing, participants universally agreed that this social component of the app was a valuable feature. One end user said as follows:

> *What I really like is the whole concept of sharing with someone else and getting them actively involved. It reminded me more of a safety plan [in the context of social work.] This is how we help you get where you need to get* [stage 1, round 2]

Participants expressed numerous benefits to working on health goals with others, from increased accountability for one's own goals to the positive consequences of helping others.

Preferences for Sharing Goals With Loved Ones Only Versus All App Users

However, there is a lack of consensus about the user with whom health goals can be shared. Many users preferred only sharing their goal progress with the users they knew before joining the app. One participant did not want to reveal that he smokes outside his social circle, while another thought she would feel "pressured" by sharing her goals with all users. Nonetheless, some participants appreciated the opportunity to work on these health goals with all app users, with a couple of participants remarking that they may receive more valuable feedback from a user they did not know rather than from close friends and family. In addition, we noticed that as participants used the app in stage 2 of testing, their willingness to share the information with all app users increased. While using the app, 47% (8/17) participants selected "share with everyone." In a postuse questionnaire, however, 82% (14/17) participants said they would select "share with everyone" in the future.

Customization Supports Personal Sharing Preferences

In response to different preferences, we modified the app to facilitate all aspects of goal sharing. Between stages 1 and 2, we added a username feature to protect anonymity when users shared goal information with unknown social ties on the app. We also permitted users to customize and change their share settings, allowing participants to choose whether to share information with only social ties or with all app users.

Theme 3: Competition Versus Collaboration

Deriving Motivation From Competition

A third key feature of the app is helping users track their health goal progress, which participants universally agreed would facilitate goal accomplishment. Many participants also commented that it was motivating to view the progress of other users on the app. In fact, a number of participants suggested that the app should create a leaderboard to foster competition among users to rise to the top:

> *I definitely like the challenging [competitive version]. It's good because it's just like a game.* [stage 1, round 2]

Success Through Collaboration

Some participants strongly rejected the idea of a competitive tone on the app, with one woman stating as follows:

> *I'm not in competition with [other users] for my health...I don't see where being in competition with someone else [is helpful]; there's certain things I'm not competitive about and my health is one of them.* [stage 1, round 3]

Instead, many participants wanted the app to facilitate collaboration on health goals among users. Participants thought the app would be a valuable space to provide and receive suggestions on how to accomplish certain goals (eg, sharing recipes for healthy meals) and encouragement for goal progress.

The Progress Board: A "Goldilocks" Solution

In synthesizing this feedback on competition and collaboration, we changed the name of the "leaderboard" to "progress board," so that users could visualize other users' health goal progress without incentivizing competition. We also added a messaging feature because users expressed a strong interest in collaborating with one another. These changes resonated with participants in stage 2 of testing, with 88% (15/17) participants stating they would check their social ties' goal progress weekly and 82% (14/17) stating they would send their friends encouraging messages weekly as well.

Discussion

Principal Findings

We conducted 2 stages of semistructured interviews with non-Hispanic Black primary care patients to develop and iteratively refine a cancer prevention goal setting mobile app. Our study yielded three primary generalizable insights from our target population: (1) the framing of each goal and its relevance to cancer impacted the likelihood that the goal would be chosen, (2) participants thought that sharing health goals with others facilitates the adoption of healthy behaviors, and (3) most participants found it motivating to see other users' goal progress, while still collaborating with these users on their health goals. An overarching insight that emerged across themes was the participants' desire to customize and personalize the app.

Our first theme highlights the importance of framing goals as relevant to cancer prevention. Some participants in our study initially struggled to understand the connection between cancer and lifestyle behaviors, remarking instead that they felt as though "genes" and "God's will" had a larger role to play. Nonetheless, we maintained the overall cancer prevention framework of the app, as health behavior research has demonstrated that framing behaviors as cancer preventing increases their adoption [54-56]. Moreover, a 2019 meta-analysis found that underserved populations in the United States are comfortable receiving cancer prevention information and interventions on the internet and through mobile devices [57]. In response to the feedback received, we clarified the language on the app to better communicate how changes in behavior can make a difference in cancer risk. We re-enforced this message with links to the ACS lay resources. Following these changes,

participants in subsequent rounds did not convey similar confusion, and in fact, many appreciated the link between health behavior and cancer prevention. This change is one example of the numerous adaptations we made to optimize the app for the intended end users.

The second and third themes indicate the values of goal sharing and collaboration, respectively. Although some participants hoped that the app would foster competition among users for completing health goals, most expressed a strong desire for the app to facilitate collaboration with others to achieve their health goals. This tension between competition and collaboration is frequently studied in behavioral economics, with mixed evidence as to which approach yields a greater impact on health behavior [58]. To respect the diverging opinions among our participants, we created a progress board that displays each user's goal success count, allowing more competitive-minded users a chance to compare their progress to others. We removed any references to "leaderboards" and added new avenues for participants to communicate with each other on the app, responding to most participants who expressed a desire to collaborate with other app users. Brewer et al [59] similarly found a "sharing board" to be a popular feature in their app promoting cardiovascular health among church-going African Americans. Participants in Brewer's study were likewise motivated by the ability to send and receive encouraging messages while keeping track of other users' progress.

Finally, we found that participants uniformly valued the ability to customize the app to meet their unique needs, and in response, we provided additional options for goal sharing and goal setting. The desire for customization is common in health app development [60,61], and we aimed to satisfy participant requests while ensuring that the app remained grounded in evidence-based techniques. For example, although we allowed participants to modify the frequency of a particular health goal (eg, dance for 30 minutes three vs four times a week), we did not allow users to write their own health goals. We made this choice to ensure that all of our goals remained consistent with ACS recommendations and an evidence-based SMART [19] set-up.

Given that this study evaluated end user experience with a mobile app exclusively among a non-Hispanic Black population, it is difficult to ascertain whether our findings are unique to this population or perhaps more broadly applicable to other populations. However, we did find a preference for collaboration over competition that aligns with prior evidence of this among non-Hispanic Black populations [59]. In addition, our findings of fatalism in early iterations of app content feedback aligned with prior studies that demonstrate this among non-Hispanic Black populations [62-64]. Future studies should be designed to compare the experiences of apps and messaging between users to determine what features may be uniquely appreciated by one racial/ethnic population as compared with another.

Strengths and Limitations

These findings must be considered in the context of several limitations and strengths. First, the study used a nonprobabilistic purposive sampling technique to recruit non-Hispanic black primary care patients from 2 primary care clinics and thus may not be generalizable. Second, we recognize that stated intentions do not always align with future behavior, and we cannot predict the effectiveness of this tool based on this study. The objective of this study is to develop and optimize the features and content of the app with and for our target population. This methodology also has several strengths. In contrast to many other behavior change apps [65], we followed a user-centered design approach to optimize the app for our intended audience, which may have different content wishes than other populations [57,66,67]. We also followed app design best practices by conducting iterative rounds of testing, allowing ample opportunities for usability feedback from potential end users [40,42]. Finally, 2 team members experienced in qualitative research analyzed all participant feedback using more traditional qualitative content analysis techniques to search for generalizable insights that may inform future health intervention research beyond the development of this app.

Conclusions

Cancer prevention in the modern era must include options that are accessible to all, but this does not mean that all options must be universal. A mobile app—or any intervention, importantly—that promotes healthy, cancer-preventing behaviors in population A is not guaranteed to work as well with population B. Accordingly, given the disproportionate burden of cancer and cancer-related mortality among non-Hispanic Black populations in the United States [6-9], our iterative development approach for a cancer prevention mobile app focused uniquely and specifically on goal setting among non-Hispanic Black primary care patients. This iterative process led to the development of a cancer prevention mobile app that potential end users deemed usable and acceptable and yielded noteworthy insights about what intended end users value in health goals and how they may work on these goals with others.

Conflicts of Interest

LJ was employed by the app developer Transmogrify. Transmogrify had no input in the study design or evaluation.

Abstract

Background: Continuously growing medical knowledge and the increasing amount of data make it difficult for medical professionals to keep track of all new information and to place it in the context of existing information. A variety of digital technologies and artificial intelligence–based methods are currently available as persuasive tools to empower physicians in clinical decision-making and improve health care quality. A novel diagnostic decision support system (DDSS) prototype developed by Ada Health GmbH with a focus on traceability, transparency, and usability will be examined more closely in this study.

Objective: The aim of this study is to test the feasibility and functionality of a novel DDSS prototype, exploring its potential and performance in identifying the underlying cause of acute dyspnea in patients at the University Hospital Basel.

Methods: A prospective, observational feasibility study was conducted at the emergency department (ED) and internal medicine ward of the University Hospital Basel, Switzerland. A convenience sample of 20 adult patients admitted to the ED with dyspnea as the chief complaint and a high probability of inpatient admission was selected. A study physician followed the patients admitted to the ED throughout the hospitalization without interfering with the routine clinical work. Routinely collected health-related personal data from these patients were entered into the DDSS prototype. The DDSS prototype's resulting disease probability list was compared with the gold-standard main diagnosis provided by the treating physician.

Results: The DDSS presented information with high clarity and had a user-friendly, novel, and transparent interface. The DDSS prototype was not perfectly suited for the ED as case entry was time-consuming (1.5-2 hours per case). It provided accurate decision support in the clinical inpatient setting (average of cases in which the correct diagnosis was the first diagnosis listed: 6/20, 30%, SD 2.10%; average of cases in which the correct diagnosis was listed as one of the top 3: 11/20, 55%, SD 2.39%; average of cases in which the correct diagnosis was listed as one of the top 5: 14/20, 70%, SD 2.26%) in patients with dyspnea as the main presenting complaint.

Conclusions: The study of the feasibility and functionality of the tool was successful, with some limitations. Used in the right place, the DDSS has the potential to support physicians in their decision-making process by showing new pathways and unintentionally ignored diagnoses. The DDSS prototype had some limitations regarding the process of data input, diagnostic accuracy, and completeness of the integrated medical knowledge. The results of this study provide a basis for the tool's further development. In addition, future studies should be conducted with the aim to overcome the current limitations of the tool and study design.

Introduction

Background

Digital tools play an increasingly relevant role in the health sector. Most patients search the internet to complement their knowledge of health care topics [1]. In addition, patients increasingly use *symptom checkers* instead of standard search engines for symptom analysis [2]. In contrast to the fast uptake in the consumer sector, professional tools similar to symptom checkers designed to support physician decision-making have not found widespread adoption in the clinical and outpatient environment [3] even though this concept is not new. A variety of digital technologies and artificial intelligence–based methods are currently available and have recently emerged as impressively persuasive tools to empower physicians in clinical decision-making and improve health care quality [4]. Diagnostic decision support systems (DDSSs) have been demonstrated to facilitate the assessment of clinical data input by using an extensive medical knowledge base [5,6].

Continuously growing medical knowledge and the increasing amount of data make it difficult for medical professionals to keep track of all new information and to place it in the context of existing information [7]. DDSSs have been suggested as a solution to this problem [8]. An expert system can help by expanding the clinician's differential diagnosis list and suggesting other avenues of investigation [9].

Diagnostic errors, consisting of inaccurate, delayed, or missed diagnoses, remain major challenges in public health care [10] that need to be addressed.

The overall purpose is to invite physicians to rethink and re-examine their steps and possible alternatives in light of the presented diagnostic information [11]. DDSSs are not intended to replace physicians but rather to augment and optimize the diagnostic decision-making process. If they are to be adopted, it is important that they provide accurate information and are trusted by clinicians. The diagnostic decision-making process must be as transparent and comprehensible as possible. The trustworthiness of the data handling and the medical quality of the knowledge base and algorithms are essential to this. Poor usability is another important barrier that could limit adoption and be a deterrent to the routine use of new technology.

In this study, we pilot-tested whether the use of a DDSS prototype from Ada Health GmbH is feasible in an emergency department (ED) setting.

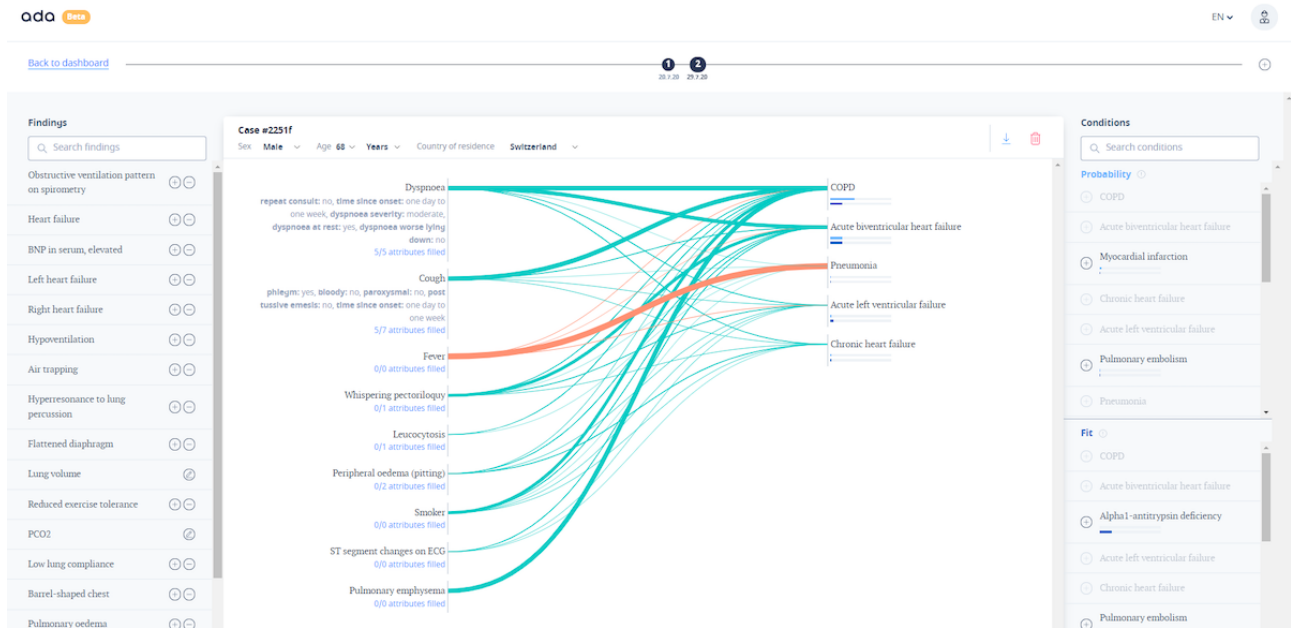
The Diagnostic Decision Support Tool

The DDSS is a web-based diagnostic decision support system for medical professionals developed as a research prototype by Ada Health GmbH that can be accessed by laptop or tablet.

In the DDSS, the physician can input a patient case over time with several visits (if relevant), and the system updates the provided decision support dynamically. The user interface consists of pages representing the steps during an individual patient visit and a case overview page. The design of this prototype provides full transparency over the artificial intelligence–based medical reasoning. The user interface allows for a continuous and transparent exchange between the machine and human.

The case starts with the input of the epidemiological data followed by a consultation page where one or several findings are entered. On the case analysis dashboard, symptoms, findings, and their related attributes can be added as *present* or *absent* for the case. The search allows the user to enter synonyms or related terms to find a specific symptom. In addition, the tool suggests a ranked list that changes in real time of symptoms and findings that have the highest potential for information gain for the current case. The DDSS supports the collection of both patient-reported complaints and findings gathered via medical examination or testing. Lifestyle or risk factors that may affect the patient's condition can also be recorded, and it is taken into consideration via the reasoning engine. The system does not use a predefined standard ontology or taxonomy to enter symptoms.

The patient information, symptoms, and findings, as well as a list of differential diagnoses ranked by *probability* and *fit*, are represented on the main page of the tool (Figure 1).

Figure 1. Screenshot of the case analysis dashboard of the diagnostic decision support system prototype.


The *probability* list is ranked by the estimated probability of a disease. It is based on the representation of medical knowledge using a probabilistic reasoning engine considering existing epidemiological data such as age, sex, or geographical location. This mirrors the approach that a health care professional takes during clinical routine. The *fit* list is ranked by the most likely conditions that could explain the finding constellation without knowledge of the probability of the conditions occurring in the general population. The reasoning engine infers disease probability estimations based on a representation of medical knowledge. The medical knowledge base is used to define a Bayesian network in which approximate inference is carried out.

Contribution lines visualize the correspondence between a symptom and a disease. The relative weighting of the symptoms to the diseases is indicated by the thickness of the lines. The color of the lines indicates the presence or absence of the finding in the constellation. This user interface was designed to ensure the transparency of the underlying reasoning engine inferences to the physician in real time. The medical knowledge base of the prototype DDSS was not based on a pre-existing database or medical knowledge ontology. Instead, it was generated and reviewed by in-house medical professionals using a process of curated integration of peer-reviewed medical literature. The medical knowledge and reasoning of the tool were designed with the primary goal of achieving high condition suggestion accuracy. More than 1300 conditions and 11,000 findings and symptoms are available in the medical knowledge base.

The DDSS prototype has been examined in a retrospective study with a focus on rare diseases, demonstrating that Ada suggested accurate diagnoses earlier than clinical diagnoses in more than half of all cases [12]. However, this tool has not been investigated prospectively in a real-life setting. The DDSS is a prototype in development, has not yet been optimized for everyday use, and is not publicly available. Nevertheless, the user interface is novel and unique in its presentation and

transparency. In this regard, we aimed to conduct feasibility testing with a focus on a very common symptom; namely, *dyspnea*. Patients presenting to the ED with dyspnea were chosen as the focus area for testing as dyspnea has a wide range of possible etiologies, including cardiac, pulmonary, and infectious diseases [13]. This approach ensured a broad range of possible outcomes to comprehensively test the system's novel user interface while being appropriate to the stage of development of the prototype.

Aim of the Study

This is the first prospective study evaluating a DDSS prototype from Ada Health GmbH, which uses a novel approach for dynamically interacting with the physician in a real-life clinical setting by entering routinely collected health-related personal data. Our primary goal is to investigate the potential of this concept. Secondary outcomes are the identification of any key reasons for inaccuracy, current technical limitations, and the potential for further development and adaptation of the DDSS prototype based on the findings and needs identified with regard to the usability of the tool.

Methods

Study Design and Case Selection

We conducted this prospective feasibility study (ClinicalTrials.gov: NCT0482734) at the ED and internal medicine ward of the University Hospital Basel, Switzerland. A convenience sample of 20 adult patients admitted to the ED with a chief complaint of dyspnea and a high likelihood of inpatient admission was selected. The participants had to be able to understand, speak, and read in German. The exclusion criteria were refusal of consent and discharge from the ED without inpatient admission. The study period was from May 2020 to August 2020. The study participation of each patient lasted as long as the patient stayed in the hospital.

This study design was observational—patients with dyspnea admitted to the ED of the University Hospital Basel were monitored, diagnosed, and treated according to the usual clinical routine. The study physician (PDS) shadowed the treating physician and the patient throughout the entire hospitalization without any interference with the routine clinical work (Figure 2).

Figure 2. Study process. CIS: clinical information system; DDSS: diagnostic decision support system; ED: emergency department.
A first evaluation of potential patients for recruitment against the inclusion and exclusion criteria was based on a patient's medical file using the triage findings from the ED. The decision whether the patient could be included was made after the first patient contact (ie, within hours of the patient's arrival at the ED). The investigator explained the objective of the study and its observational nature to the patient. For ethical and organizational reasons, consent from the patient was obtained post hoc once the patient was hospitalized (following Human Research Act Article 31 [14] and Clinical Trials Ordinance Article 15 [15]). Data from patients who refused to provide post hoc consent were no longer used for the research project.

Data Acquisition

Data Collection

All patients underwent an initial clinical assessment at the ED in which the study physician used a checklist to document symptoms, medical history, vital signs, and physical examination in a structured manner. Complementary information documented by the treating care team during hospitalization as well as all other investigation findings were extracted from the medical record.

The treating physician at no point had access to insights into the case from the DDSS prototype. The patients received usual care from their examining and treating medical staff. The study investigator (PDS) was not involved in patient care at any point.

Prototype DDSS Input

Once a patient was admitted, a new case was created in the DDSS with the patient's sex, age, and geographical location as the first information. As we focused on patients with dyspnea in this study, a new patient case was started by entering the finding *Dyspnea* and selecting the corresponding attributes and specifications. All clinical evidence collected from the patient was entered as DDSS input data to build the case (Figure 1). Findings that would have been marked as *absent* (eg, no fever) were only added if relevant to the list of diagnoses or if explicitly mentioned in the medical record.

Information from the medical record was assigned to the time of the visit in the DDSS prototype. The idea was to mirror the patient's journey in the hospital and provide the system with the same amount of information the treating physician had at a certain point in time. The first visit (visit 1) in the DDSS was created at the end of the ED stay. All evidence prospectively collected until this moment was entered into the DDSS. The second visit (visit 2) in the DDSS corresponded to when the patient was discharged from the hospital. All information from the first visit was transferred to the second visit, modified if necessary, and complemented with additional information from the patient file gained during the hospital stay. Any information of potential relevance to diagnosis that could not be entered into the DDSS as it was not found in the tool was recorded in a separate document. Missing diagnoses were also noted.

An additional visit (visit 2.1) in the Ada DDSS was performed retrospectively by a physician and former Ada employee with expert knowledge of the medical content and technical aspects of the Ada DDSS. This person screened the clinical cases and lists of missing information in the tool generated by the study research team. The goal was to show the user dependency of the DDSS and the influence of this on the accuracy of the DDSS suggestions.

All inputs were performed in German as all clinical evidence was gathered in German.

Feasibility and Usability of the DDSS

The time of data entry, search functions and functionalities, availability of findings and diagnoses, and applicability of the tool in an acute ED setting were recorded to assess the feasibility of the DDSS prototype. We also evaluated the workflow and whether the navigation, data entry, and retrieval would impede clinical task completion. Furthermore, the input procedure with the tool's robustness to irrelevant variations in input data as well as the technical aspects and potential restrictions were analyzed.

The usability was assessed by considering the structure and composition of the DDSS interface and whether it was satisfactory.

As the novelty of the tool is mainly reflected in the design of the interface, this was a key object of investigation. Therefore,

the clarity of the visual representation of clinical data and the ease of acquiring information at a glance were examined in detail.

The guidance through different levels of the tool (onboarding, consultation page, and case analysis) was another point of interest. We tested whether the logic and availability of the desired options were consistent and rigorous and if the tool provided an effective layout. A risk evaluation of the misinterpretation of information was conducted.

Metrics

Different metrics for the assessment of the accuracy of the DDSS suggestions are listed and defined in Textbox 1.

Textbox 1. Metrics for the assessment of the accuracy of the diagnostic decision support system suggestions [5].

- Correct or accurate diagnosis retrieval: proportion of cases in which the correct diagnosis was the first diagnosis listed (M1), listed as one of the top 3 (M3), or listed as one of the top 5 (M5)

- Diagnosis in knowledge base: proportion of the diagnoses that were included in the knowledge base of the tool

---

The accuracy of the tool's diagnostic suggestions was evaluated at each of the different time points of the hospital stay. The list of the 5 most probable conditions provided by the tool was recorded for visit 1, visit 2, and visit 2.1. For the same time points, a maximum of 5 diagnoses were provided in the medical record. If <5 diagnoses were provided in the hospital, the total number of condition suggestions for the case from the DDSS was reduced accordingly. The first listed diagnosis in the ED and the final discharge diagnosis from the hospital were defined as the gold-standard diagnosis for visits 1, 2, and 2.1. The top 1 diagnosis, the top 3 diagnoses, and the top 5 diagnoses provided by the DDSS disease *probability* list were compared with this gold-standard main diagnosis for the 3 different visits. Furthermore, the proportion of diagnoses included in the knowledge base of the tool was assessed. In addition, the missing potentially important information of the findings and symptoms for each case was analyzed and categorized.

Matching of Diagnoses

The first 5 diagnoses from the DDSS and the first 5 diagnoses from the medical record for each visit were shown to 3 different physicians separately and independently following the completed data collection. They decided whether the diagnosis from the DDSS matched the diagnosis from the treating physician at the different time stamps. This process was necessary as the naming and, therefore, the interpretation of the matching of the diagnoses were not standardized. The 3 physicians did not see the entire case, only the diagnosis lists. They had different levels of clinical expertise and knowledge of the DDSS and the patient case. None of the physicians were involved in anamnesis, clinical examination, or treatment of the patient. The three physicians comprised (1) the study physician, who was involved in the data collection and entry into the DDSS prototype and was therefore familiar with the patient case and who saw the patient in the ED to obtain informed consent and evaluate the appropriateness of the patient for study inclusion; (2) a second independent physician who was an experienced senior physician and fellow of internal medicine and cardiology; and (3) a third physician with several years of work experience in the Medical Knowledge Team of Ada Health GmbH in Berlin and detailed knowledge of the available medical content and the reasoning engine of the DDSS and who also saw the DDSS case in detail to analyze potential user dependencies.

Precise matching criteria were not specified; instead, the physicians were directed to use their experience to decide on the appropriateness of the DDSS condition suggestions. The reasons for inaccurate suggestions of diagnoses were analyzed and categorized. Several causes per case could be assigned, and the related proportions were calculated.

Statistical Analysis

The top-1, top-3, and top-5 performance of the Ada DDSS prototype condition suggestion for each of the visits, with comparison against the ratings by the 3 physicians, were compared using descriptive statistics and tests appropriate for categorical data. Chi-square tests were used to test whether the proportion of correct answers was drawn from the same distribution, with the application of this test across all visits, once for each of the metrics for comparison (top 1, top 3, and top 5 matching condition suggestions) for each of the 3 physicians' ratings, to be followed in case of a significant difference by post hoc 2-sided pairwise Fisher exact tests [16]. *P* values were corrected for multiple comparisons using the Benjamini–Hochberg procedure [17], guided by the interpretation of Armstrong [18], and considered significant if <.05.

Data Processing and Ethical Approval

The conducted study complied with the ethical principles of the World Medical Association Declaration of Helsinki [19]. Ethical approval was obtained from the Ethics Commission Nord-West-Schweiz (reference 2020-00095, date of approval January 24, 2020). All data were stored and transferred in a pseudonymized form. Data processing and transfer were performed in accordance with national and local guidelines. An order data processing agreement was made between the University Hospital Basel and Ada Health GmbH.

Results

Patient Characteristics

A total of 33 patients with dyspnea were considered for inclusion, of which 61% (20/33) cases were included and 33% (11/33) were excluded because of direct discharge from the ED without referral to the ward. The refusal rate was low (2/33, 6%). The resulting study population consisted of 40% (8/20) women and 60% (12/20) men aged 54 to 93 years (mean 74 years, SD 10.44 years).

Feasibility Measures

To create a case in the DDSS prototype, it is required to enter basically all recorded patient data, which is time-consuming, especially in a setting as time-limited as the ED. The data entry took 1.5-2 hours per patient. The checklist used in the ED by the study physician resulted from a pilot round that preceded this study and was a key component of the initial feasibility findings. It was accepted at the outset of the study that the novel user interface of the DDSS prototype was not yet fully developed for use in parallel to every patient's examination or consultation. The checklist, observational recording, and non–real-time use of the system allowed for the identification of how such a prototype DDSS would need to be involved in capturing the high speed and complexity of clinical data delivery.

Usability

Overview

The Ada DDSS could be usable in the research setting; however, the research team considered that it required optimization before it could be adopted in everyday use in the ED.

Usability insights from our study were principally related to the DDSS *main page* (ie, the *Case analysis* page). This interface consists of three sections: findings and symptoms on the left, case dashboard in the middle, and diagnosis suggestions on the right side (Figure 1).

Usability of the Findings Section

The findings were easily located in the search function via several synonyms and terms by the study physician. However, the search engine contained some subcategories and finding synonyms that were sometimes misleading. For more specific findings such as *orthopnea*, the superordinate category *dyspnea* must first be selected and provided with corresponding attributes (in this case, *occurs while lying flat*). This led to a time-consuming search for the right designations by the study physician.

During case input in this study, the finding suggestions were rarely used as the ranking by probability often did not match the physician's natural clinical workflow.

Dashboard Usability

If a finding was added via search function or the list of relevant suggestions (left panel in Figure 1), it must be declared as *present* or *absent* before it was transferred to the case dashboard. Once added to the case, it was not immediately recognizable to the physician how the finding had been marked, which confused the study physician during his work. The color of the contribution line indicates the presence or absence of the finding, but the finding itself is not marked in either way.

The clarity of the presentation of the symptom constellation in relation to the diagnosis list by the contribution lines creates transparency for the user on how the reasoning engine is working. This is one of the main advantages of this DDSS prototype in comparison with others according to the study team.

Usability of the Diagnostic Suggestions

As soon as the first finding was entered, the 5 most probable suggested diagnoses were automatically transferred to the case dashboard when switching from the consultation page to the main page.

Once they were listed on the case dashboard, the diagnoses did not update themselves automatically when adding or deleting information. The *probability* and *fit* lists of potential diagnoses on the right side, in contrast, changed in real time, which was confusing for the study personnel.

Accuracy of Suggested Diagnoses

Overview

The results for the accuracy of the DDSS suggested diagnoses are shown in Table 1.

Table 1. Accuracy of suggested diagnoses compared with the gold-standard diagnosis (N=20).

	M1[a]			M2[b]			M3[c]		
	(%)	(n/N)	(SD)	(%)	(n/N)	(SD)	(%)	(n/N)	(SD)
Visit 1	18	3.67/20	0.58	42	8.33/20	1.53	57	11.33/20	0.58
Visit 2	35	7/20	1.00	62	12.33/20	1.53	75	15/20	1.00
Visit 2.1	40	8/20	1.00	62	12.33/20	1.53	80	16/20	1.00

[a]First diagnosis listed.

[b]One of the top 3 diagnoses listed.

[c]One of the top 5 diagnoses listed.

The table shows the average top-1, top-3, and top-5 accuracy of the DDSS's suggestions compared with the gold-standard diagnosis at the different visits, with assessment of the matching of the diagnosis suggestions by physicians with different levels of clinical and tool experience.

Different reasons for incorrect suggestion at the time of diagnosis could be identified and are listed in the following sections.

Multimorbidity or Multiple Confirmed Diagnoses or Symptom as Diagnosis

Inpatients in the department of internal medicine often have >1 diagnosed disease, either as known pre-existing diseases or as

unknown diseases diagnosed during the inpatient stay. The DDSS prototype seems to focus its reasoning on the evaluation of 1 main diagnosis and, thus, multimorbidity seems to be one of the biggest challenges in correcting condition suggestions. In a few cases, this was the main reason for an incorrect diagnostic suggestion in the DDSS.

In half of the cases (10/20, 50%), the treating physician did not provide a working or final diagnosis compliant with the International Classification of Diseases, 10th revision, as the first listed diagnosis but instead provided a list of several potential working diagnoses or a presenting complaint, which

made assessment of the accuracy of the DDSS suggestion impossible. This was especially true for visit 1, when the patient was transferred to the ward for further investigation.

Missing Entities in DDSS Knowledge Base

Another aspect that led to incorrect condition suggestions was the lack of relevant entities in the knowledge base of the tool, which limited its ability to suggest a diagnosis. In all these cases, there were one or more relevant diagnostic findings missing (Table 2). In addition, in 20% (4/20) of the cases, the final diagnosis did not exist in the DDSS knowledge base.

Table 2. Coverage of symptoms and findings in the medical knowledge base of the diagnostic decision support system (N=20).

Coverage category	Cases with missing relevant information, n (%)
Diagnostic findings (including laboratory, imaging, and histology)	20 (100)
Medical history (pre-existing condition, social, family, and medication)	20 (100)
History or examination findings	9 (45)
Attributes (investigation findings and factors)	6 (30)
Final diagnosis (first diagnosis)	4 (20)
Physiological finding≠negative pathological finding	4 (20)

User Input Dependencies

In a number of cases, the level of user experience with the tool was a decisive criterion for the subsequent accuracy of the diagnostic suggestions. In 10% (2/20) of the cases, it was essential for the physician inputting information into the DDSS to know the precise finding name in the DDSS to enable the system to provide accurate diagnosis suggestions.

Coverage of Diagnoses in the DDSS

For the analysis of the coverage of the clinical diagnoses in the knowledge base of the DDSS prototype (Table 3), a maximum of 5 confirmed diagnoses was considered. There was a total of 186 diagnoses for all cases. Each exact match was considered. In addition, each disease in the differential diagnosis list provided by the hospital was calculated as 0.5 if the diagnosis existed in the DDSS but not in the exact specification, grade, or localization described by the treating physician.

Table 3. Coverage of diagnoses in the knowledge base of the diagnostic decision support system.

Item	Visit 1	Visit 2
Sum of diagnoses	93	93
Sum of matches	56.5	65.5
Proportion (%; matches/diagnoses)	61	70

In all the cases, there were one or several entities (out of a large number of relevant entities for each case) that could not be found via the search function in the DDSS (Table 1). Those that could not be entered were mainly diagnostic findings, such as radiologic, laboratory, and histologic findings. In addition, the DDSS did not provide the possibility to report the medical history of pre-existing conditions, medications, or social and familial anamnesis.

Discussion

Principal Findings

Regarding the functionality and usability of the tool, it can be summarized that the dynamically interactive DDSS has high potential, with limitations. It showed convincing performance in its clarity of presentation (including transparency of the working of the medical engine) and provided a user-friendly interface. However, the tool as currently developed is not

perfectly suited to acute medical settings such as the ED as manual case entry is very time-consuming.

The findings on the DDSS disease suggestion accuracy indicate that it could provide accurate results in the clinical inpatient setting for the many patients who had dyspnea as the main presenting complaint. The symptom analysis algorithm of the DDSS seems to weigh the order of the symptoms present in a case, the likelihood of a finding for a diagnosis, and the epidemiology. Unlikely symptoms, absent common symptoms, and misleading findings as well as an atypical age of the patient for a disease or an uncommon primary anatomical site of involvement might lead to misdiagnosis in the system. These results should be interpreted with caution at this stage as the study setting was observational, and real-world interventional studies are suggested for confirmation.

Another finding of this study is that, although the medical professional knowledge base already covers many different

findings, it is nonetheless incomplete in some areas. Many findings from investigative procedures in the hospital are not yet provided by the tool and, in some cases, this decreased the accuracy of the suggested diagnoses.

The diagnosis suggestions also depend to a large degree on appropriate user input. The treating physician's medical knowledge and skills as well as the expertise of the study team with the use of the tool could potentially have influenced the outcome of this study. A higher experience in all of these fields might improve the accuracy outcome and should be investigated separately. It is acknowledged that the use of a DDSS of this type in a real-world setting requires training of personnel on the use of the system and how to obtain the best results from the tool.

The results from this study suggest that the Ada DDSS could have the potential to support the clinician in their daily work, but an enlargement of its professional medical knowledge base and a larger-scale evaluation study would be necessary beforehand.

Possible Improvements to the Ada DDSS

This feasibility study found some areas where the DDSS could be improved. The search and selection of symptoms and findings is one of the areas with the greatest potential for improvement. A structure that follows the logic of how physicians think (eg, a step-by-step selection starting with the examination or the investigation method, ending with the proofing pathological finding, and dividing the findings into categories) could improve the intuitive usability for physicians. The manner of displaying the highest–information-gain symptoms and finding suggestions on the case dashboard could thereby also be improved. In its current stage, this list shows a collection of unsorted and uncategorized symptoms and findings generated by the reasoning engine.

As it is up to the using physician to select the relevant diagnoses from the diagnosis lists and add them to the case dashboard, this should be made clear to the user, or the list of added diagnoses should automatically update itself. It would be helpful to signal to the user at a glance whether the finding was marked as absent either by using a different font color or by placing a cross in front of the finding. This would be a simple change with a large impact on usability.

The routine adoption of the tool in a highly dynamic setting such as the ED could only be achieved after a reduction in active effort to enter information. Automatic integration of basic patient and anamnestic information as well as further extraction of information from the electronic medical record could save a large amount of time for the treating physician and decrease potential bias because of user dependencies. The acceleration of rare disease diagnosis [12] and the higher accuracy in the inpatient setting also indicate that, in its current form, the DDSS is more suited to those disciplines. Used in the correct medical setting, it has the potential to support the physician in their decision-making process by showing new pathways of diagnostic reasoning and suggesting unintentionally ignored diagnoses. The pooling of the immense medical knowledge available has the potential to extend the medical disease spectrum of a physician in their routine work. If this functionality is extended through a wider professional medical knowledge base, it has the potential to assist in rational test choice and avoid important diagnostic investigations being overlooked.

Many patients in the internal medicine ward have >1 diagnosis. Multiple diagnoses at the time of discharge from the ED to the ward or from the ward to an outpatient setting led to a lower accuracy in the tool. This seems to be one of the biggest challenges and should be a focus area for the improvement of the DDSS.

Currently, medication and information about the therapy of a patient cannot be entered into the DDSS. This results in the underconsideration of possible therapeutic symptom improvements, therapy failure, or medicinal side effects in the probability estimation of the diagnosis suggestions.

Social or family history has a rudimentary representation in the DDSS and, consequently, follow-up or secondary diseases, exacerbation of an existing disease, social measures, or familial predisposition are underreflected.

An optimized and extended Ada DDSS based on the system evaluated here could save time and improve investigative and diagnostic efficiency and quality, thereby improving health economic outcomes [20,21]. These effects need to be assessed in future studies.

Strengths and Limitations

This study has several strengths and limitations. The study design, with a real-world setting, prospective data collection, and the shadowing of the treating physician by a study physician without any interference with usual care, as well as the measurement of accuracy analysis through the use of a panel of 3 physicians with different clinical backgrounds, was important for the study strengths.

The small number of cases is a limitation of the study, as is the focus on only 1 main presenting symptom for the selection of participants. Both factors offer potential for selection bias; however, they are appropriate for this stage of feasibility evaluation.

Our study showed that the DDSS condition suggestions are user-dependent—the level of knowledge, expertise, and familiarity had a large impact on accuracy. In some cases, an additional finding, which was difficult to find via the tool's search function because of specific wording, led to a completely altered differential diagnosis list and accuracy. As the case set was small and a large range of physician users was not explored, the range of user dependency of the DDSS was not precisely quantified. The focus of this study was to assess the feasibility and usability of the novel interface of the DDSS. It was not intended as a validation of the accuracy of its diagnosis suggestions. A future large-scale study with blinded, maybe automated data entry after consistent training of the clinical users of the system should be performed to evaluate and validate the accuracy of a ready-for-market DDSS.

XSL·FO

RenderX

Conclusions

This study provides insights into the applicability and performance of the DDSS prototype and the potential of the highly dynamic case input interface for medical professionals, especially in an inpatient setting. The clear and user-friendly presentation of a clinical patient case, with a transparent visual explanation of the algorithmic decisions, is the outstanding novelty of the tool used in this study.

At its current stage of development, the DDSS prototype has some limitations regarding the automation of data input, the accuracy of the diagnostic suggestions, and the completeness of the integrated medical knowledge. Data entry and analysis are still highly user-dependent; however, this could be minimized through training and experience.

The results of this study provide a basis for the further development of this and related tools. Further development of dynamic and highly transparent DDSS case interfaces is warranted and, once systems are optimized further, setting-appropriate studies are required to evaluate clinical outcomes.

Authors' Contributions

JT, BB, MO, JE, MCH, SG, and ET contributed to planning (study conception and protocol development). JE supervised the study and is sponsor of the project. JT and PDS conducted the study. PDS was the study physician. JT, BB, and SG contributed to the data analysis and interpretation. JT and BB wrote the manuscript. PDS, JE, MO, SG, and MCH revised the manuscript.

Abstract

Background: Mobile health (mHealth) interventions, a more cost-effective approach compared with traditional methods of delivering lifestyle coaching in person, have been shown to improve physical parameters and lifestyle behavior among overweight populations. In Japan, the Specific Health Checkups and Specific Health Guidance (SHG) started in 2008 to treat obesity and abdominal obesity. However, the effectiveness of SHG is limited owing to its in-person counseling. The effect of mHealth on SHG has yet to be demonstrated.

Objective: This study aims to determine whether a mobile self-management app (DialBeticsLite) could make the SHG more beneficial among patients with abdominal obesity to achieve a reduction in visceral fat area (VFA).

Methods: This study was an open-label, 2-arm, parallel-design randomized controlled trial. We recruited 122 people in September 2017 and randomly assigned them into either the intervention or control group. All participants attended an educational group session that delivered information regarding diet and exercise. In addition, participants in the intervention group were asked to use DialBeticsLite for 3 months. DialBeticsLite facilitated the daily recording of several physical parameters and lifestyle behavior and provided feedback to encourage an improvement in behavior. The primary outcome was the change in VFA from baseline to the 3-month follow-up. Secondary outcomes included changes in both physical and metabolic parameters from baseline to the 3-month follow-up. The Welch 2-tailed *t* test was conducted to analyze the effects of DialBeticsLite on both the primary and secondary outcomes.

Results: Of the 122 participants recruited, 75 (61.5%) were analyzed because 47 (38.5%) were excluded: 37 (30.3%) because of ineligibility and 10 (8.2%) because of withdrawal of consent. The mean age was 49.3 (SD 6.1) years in the intervention group (41/75, 55%) and 48.5 (SD 5.3) years in the control group (34/75, 45%), and all participants were men, although unintentionally. The baseline characteristics did not differ significantly between the intervention and control groups, except for VFA. The average change of VFA was −23.5 (SD 20.6) cm^2 in the intervention group and +1.9 (SD 16.2) cm^2 in the control group (*P*<.001).

Statistically significant differences were also found for the change of body weight, BMI, and waist circumference. These findings did not change after adjusting for VFA at the baseline. The intervention had no significant effect on any of the metabolic parameters. An exploratory analysis showed significant associations between the change in VFA and steps per day and between the change in VFA and calorie intake per day within the intervention group.

Conclusions: Our findings indicate that an mHealth intervention facilitating the daily monitoring of several physical parameters and lifestyle behavior can be highly effective in inducing visceral fat loss and weight loss among adults eligible for SHG.

Introduction

Background

Obesity is an increasingly concerning epidemic that is in need of urgent management [1], as its prevalence and the comorbidities and mortality associated with it have been, and continue to, rise rapidly worldwide [2-6]. It has also tremendously increased the global health burden and health care cost [1,5,7,8]. Abdominal obesity (AO), which is defined by the amount of visceral fat, is especially known as a risk factor for cardiovascular disease, diabetes, and fatty liver disease [9-12]. Lifestyle and behavioral interventions are considered effective for improving AO [13,14]. In recent years, nationwide lifestyle interventions have been implemented in several countries [15,16]. In Japan, the Specific Health Checkups and Specific Health Guidance started in 2008. All health insurers in Japan were required to offer health screening programs to all enrollees and their dependents aged between 40 and 74 years and to provide lifestyle counseling to participants who were not taking medication but who had AO or obesity and were at risk for metabolic syndrome. These programs have been shown to successfully lead to weight loss and improvements in several other physical parameters [16]. However, behavior changes are usually difficult to achieve in wide-scale clinical practice because of limited resources and professional support [17,18]. The Specific Health Guidance suffers from suboptimal participation, with only 23.2% of those asked to enroll in the guidance completing the course in 2019 [19]. There is the problem that there is great disparity of implementation rates between different insurers, as well as a likely variation of intervention intensity due to the relatively loose requirements for the content of support sessions.

These issues necessitate an effective self-management tool that can automate and standardize much of the counseling process [20]. In this regard, strategies using information and communication technology (ICT) could have great potential for the development of an effective and scalable lifestyle intervention. ICT-based interventions offer patients various benefits depending on the intervention design, including easier self-monitoring, access to health-related information, and personalized feedback, all contributing to optimizing the impact and convenience of the intervention [21,22]. They are also expected to minimize health care providers' workload and costs [21,23-25]. Previous ICT-based interventions have been shown to successfully reduce physical parameters such as body weight (BW), BMI, and waist circumference (WC) among overweight adults [21,22,26].

Objectives

In Japan, several companies and local governments started approaches to using ICT for the Specific Health Guidance [27,28]. However, to our knowledge, the effectiveness of ICT for the participants of the Specific Health Guidance has not been adequately evaluated in randomized controlled trials. Our primary aim is to investigate whether an app-based intervention was effective for people who are eligible for the Specific Health Guidance, the prevention program for lifestyle diseases in Japan. The authors of this study have developed an ICT-based self-management system, *DialBeticsLite*. This is a mobile app that allows the input of data on blood glucose, blood pressure (BP), BW, pedometer counts, diet, and physical exercise. It also provides users with fully automated evaluative feedback on diet modification and amount of physical exercise following the input of data each day. We provided some devices for people who use DialBeticsLite to measure their daily data. DialBetics, its former version, has been shown to successfully improve hemoglobin A_{1c} (HbA_{1c}) and fasting blood glucose levels in previous trials for patients with type 2 diabetes [29,30].

Methods

Study Design

This study was designed to be an open-label, 2-arm, parallel-design randomized controlled trial and was conducted at the University of Tokyo Hospital, Japan. The main objective is to evaluate the efficacy of treating AO using DialBeticsLite in a population who were eligible for the Specific Health Guidance.

Ethics Approval

The protocol and forms of informed consent were submitted to and approved by the Research Ethics Committee of The University of Tokyo Graduate School of Medicine and affiliated institutions (11696-[3]), and this study was carried out in compliance with the Declaration of Helsinki. This study was conducted among volunteer participants in a nonclinical setting, that is, a company, and was retrospectively registered at the University Hospital Medical Information Network Clinical Trials Registry (UMIN000042045).

XSL·FO

RenderX

Participants

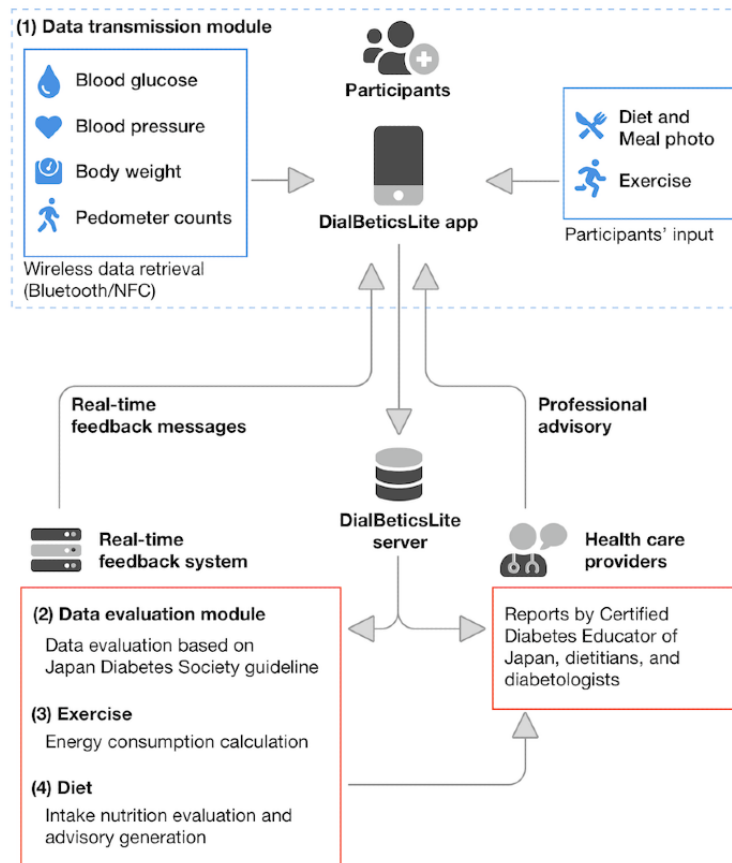
The selection and recruitment of participants were conducted among the employees of a securities company located in Tokyo by advertising via email and the company intranet. This company is one of the top-ranked securities companies in Japan, and the average annual salary of employees is approximately JPY ¥10,000,000 (US $85,000). We recruited participants of the Specific Health Guidance who were also smartphone users and were willing to use the ICT system. Participants of the Specific Health Guidance were aged 40 to 75 years, who also satisfied both the following conditions: (1) WC ≥85 cm (men) or WC ≥90 cm (women) or BMI ≥25 kg/m^2 and (2) at least one of the three metabolic abnormalities from (1) hyperglycemia (fasting glucose level ≥100 mg/100 mL or HbA$_{1c}$ ≥5.6%), (2) hypertriglyceridemia (triglycerides ≥150 mg/dL) or low high-density lipoprotein (HDL)-cholesterol (HDL <40 mg/dL), and (3) high BP (systolic BP ≥130 mm Hg or diastolicBP ≥85 mm Hg). Patients who received any medication for the treatment of hypertension, dyslipidemia, or diabetes were excluded.

All participants who met the eligibility criteria had AO (WC ≥85 cm for men or ≥90 cm for women). The WC values used had been measured for screening AO at an annual routine health checkup.

All participants provided written informed consent before the trial commenced; they were informed of their right to withdraw from the study at any time and how the data collected from the study would be used. This included an explanation of how data would be accessible to the research team to be used for analysis and dissemination, following the conclusion of the trial. Any results obtained from analyzing these data were to be presented at major domestic and international scientific conferences and submitted for peer-reviewed journals of international repute and visibility.

Design of DialBeticsLite

The details of the DialBeticsLite system are shown in Figure 1. The app facilitated the daily recording of several physical parameters, in addition to tracking lifestyle behavior, that is, diet and exercise. Participants were asked to measure their blood glucose and BP levels twice a day at home, once after waking up in the morning and once before going to bed at night. They were also required to measure their BW in the morning. We also asked them to wear a pedometer for the entire day to measure the number of daily steps and approximate the energy expended by walking. These data were then transferred to the participant's smartphone by near-field communication or Bluetooth and sent instantly to the server, where the data were automatically evaluated. The evaluation of pedometer counts was carried out following the Japanese official physical activity guidelines for health promotion, which sets the target count >8000 steps per day [31]. Other data including blood glucose and BP levels were evaluated based on the Japan Diabetes Society guideline's target values [32]; desired values were set at (1) blood glucose concentrations <110 mg/dL before breakfast and <140 mg/dL at bedtime, and (2) BP with systolic BP <125 mm Hg and diastolic BP <75 mm Hg. Once DialBeticsLite determined whether each reading was satisfactory according to the guidelines, the evaluation outcomes were received by each participant's smartphone immediately. When DialBeticsLite detected critical values including (1) blood glucose concentrations >400 mg/dL or <70 mg/dL and (2) BP with systolic BP >220 mm Hg or diastolic BP >110 mm Hg, they were automatically reported to the research team, and if deemed necessary, attending physicians were informed to contact a participant with abnormal data as appropriate.

In addition, the participants could also input dietary information (type and quantity of food, accompanied by a photograph of the meal) and details of the type and duration of physical exercise, which had been completed each day separately from pedometer counts. The app evaluated these data on lifestyle similarly to blood glucose concentrations and BP, with specific advice on diet modification sent to the participant immediately after the input of data. The app provided feedback on whether the participants' macronutrient balance was appropriate, along with visualizations that indicated the nutritional balance of each meal. Specific guidance regarding dietary fiber and salt was also provided, in an effort to maintain intake within the recommendation set out by the Japan Diabetes Society guidelines.


Intervention and Control

Blocked randomization within strata [33] was used to allocate participants equally to the intervention and control groups. We separated the participants into 2 BMI groups (BMI <25 kg/m^2 and BMI ≥25 kg/m^2), 2 visceral fat area (VFA) groups (VFA <100 cm^2 and VFA ≥100 cm^2), and 2 WC groups (WC <85 cm and WC ≥85 cm). This gave us 2×2×2=8 strata, and the block size in each stratum was 4. In other words, 4 participants in the same strata at a time were randomized to ensure that 2 patients were assigned to the treatment group and 2 patients were assigned to the control group.

All participants attended an educational group session at baseline, which was a 40-minute lecture at the University of Tokyo Hospital. This lecture was conducted by nurses, diabetologists, and dietitians who were all part of the research team and included information regarding diet and exercise.

The participants in the intervention group were asked to use DialBeticsLite for the next 3 months and trained on how to use the app by the research team after the lecture to ensure correct and informed use of the app (ie, how to take measurements and record them as intended, as well as how to interpret the readings). The intervention group was also provided with various other devices, including a Bluetooth-enabled BP monitor (HEM-7271T; Omron) and scale (HBF-255T; Omron), a near-filed communication–enabled glucometer (MS-FR201B; Terumo), and a pedometer (MT-KT02DZ; Terumo). These devices were all paired with a single smartphone (Galaxy Note3

SC-01F; Samsung) also provided as part of the intervention, which transmitted the readings to the DialbeticsLite server via a wireless network. For the full duration of the study, the research team provided technical assistance to the participants in the intervention group in addition to monitoring the content and frequency of daily records. The system automatically triggered an alert if participants failed to record data for >3 days, and these alerts were checked by the research team via the administrator screen. The nurse encouraged participants to restart measurements, either by email (after 1 week of inactivity) or by giving a call on the phone (after an additional week of inactivity). In cases where a participant failed to record any data (ie, not recording any of the physical parameters, food, or exercise) for 3 weeks, we deemed the participant as a dropout. As the system was solely designed for self-management and direct feedback using the input data, participants were asked to consult the physicians of their company if they had any health concerns unrelated to the intervention.

In contrast, the participants in the control group were not provided with the app or electronic devices, and they only participated in the assessment and lecture at baseline, in addition to the follow-up assessments at the end of 3 months.

Study Outcomes and Data Collection

The primary outcome of this study was the change in VFA from baseline to the 3-month follow-up. VFA was measured by differentiating visceral fat and abdominal subcutaneous fat using the current flow from 2 routes (DUALSCAN, HDS-2000; Fukuda Colin). HDS-2000 underestimates VFA compared with

computed tomography scan, but the correlation was very high (r=0.89) [34]. HDS-2000 can be a good alternative for evaluating VFA because of its simplicity and noninvasiveness. To prevent variation across raters in the measurement procedures, the VFA of all participants was measured by the same individual with sufficient experience. The person was unblinded for the group of intervention. Secondary outcomes were changes in both physical and metabolic parameters from baseline to the 3-month follow-up. Physical parameters included BW, WC, BMI, and BP. Metabolic parameters included cholesterol, triglyceride, fasting plasma glucose, and HbA$_{1c}$ levels, which were measured using blood tests. The physical parameters and metabolic parameters of all participants were measured at baseline and at the 3-month follow-up at the University of Tokyo Hospital. BP was measured after the participants took two deep breaths in the sitting position, whereas WC was measured at the umbilical level in the standing position. BMI was determined by calculating the ratio of BW (kg) to height squared (m^2). Blood tests were used to measure the concentration of fasting plasma glucose, HbA$_{1c}$, triglyceride, total cholesterol, low-density lipoprotein (LDL) cholesterol, and HDL cholesterol.

For the intervention group, the following variables were also assessed: total energy intake (kcal), steps taken per day, the use rate of the app, and the use rates of individual functions within the app, including blood glucose, BP, BW, diet, and physical exercise.

Statistical Analysis

The demographic characteristics and other parameters of the intervention and the control groups at baseline were presented as mean (SD) and compared using the Welch 2-tailed t test. To evaluate the effect of the DialbeticsLite, we used the Welch t test to compare the change in VFA (primary outcome) and changes in other parameters (secondary outcomes) between the 2 groups. We also conducted a linear regression analysis for both the primary and secondary outcomes, adjusted for VFA at baseline, as a post hoc test.

We also conducted several exploratory analyses to examine whether the improvement in AO was associated with lifestyle factors (pedometer counts and calorie intake) or the different use patterns of DialBeticsLite observed within the intervention group. We presented the numbers of days for which each parameter was recorded (ie, the number of days each function was used for) as the median (IQR). We calculated the Pearson correlation index and conducted tests for noncorrelation for each function to examine the relationship between the change in VFA and the use rate of each function. We plotted the trend of the average pedometer counts and calorie intake per day over the study period. We performed linear regression analysis to assess the effect of average pedometer counts and calorie intake per day on the change in VFA, adjusted for age and VFA at baseline. The retention rates of the pedometer count and diet functions were also plotted to help visualize engagement and retention over time.

A P value of <.05 was considered statistically significant, and all statistical analyses were performed using available-case analysis and using SAS (version 9.4; SAS Institute Inc).

Results

Participants

The study was approved in September 2017, and participants were recruited. The final 3-month follow-up was completed in February 2018. As shown in Figure 2, a total of 122 participants who provided written informed consent were randomly assigned to either the intervention or control group at randomization. This initially resulted in 50% (61/122) of participants for each group. Upon reassessment of eligibility, of the 61 participants, 20 (33%) were excluded from the intervention group: 18 (30%) owing to ineligibility and 2 (3%) owing to withdrawal of consent. Similarly, for the control group, of the 61 participants, 27 (44%) were excluded: 19 (31%) owing to ineligibility and 8 (13%) owing to withdrawal of consent. Furthermore, 2 participants dropped out over the course of the trial and were excluded from the intervention group.

There was a significant difference in VFA between the intervention and control groups at baseline but no difference in the other variables (Table 1). Although there was no intention of studying well-educated men exclusively, all the participants who participated in this trial were men university graduates.

[a]Comparisons of sex were not conducted because all participants were males.

[b]BP: blood pressure.

[c]LDL: low-density lipoprotein.

[d]HDL: high-density lipoprotein.

[e]HbA_{1c}: hemoglobin A_{1c}.

Changes in VFA and Physical and Metabolic Parameters

At the 3-month follow-up, although the control group observed an increase in VFA (mean +1.9, SD 16.2 cm^2), participants in the intervention group lost considerable amounts of VFA (mean −23.5, SD 20.6 cm^2). Consequently, those who underwent the intervention had statistically significant reductions in the primary outcome compared with those in the control group ($P<.001$). This finding did not change after adjusting for VFA at baseline between the 2 groups as a post hoc test (Table 2).

In addition, the intervention group displayed a statistically significant improvement in BW (mean −3.0, SD 2.8 kg vs mean+1.1, SD 1.6 kg; $P<.001$), BMI (mean −1.0, SD 1.0 kg/m^2 vs mean+0.4, SD 1.6 kg/m^2; $P<.001$), and WC (mean −4.8, SD 3.8 cm vs mean −1.6, SD 7.7 cm; $P=.04$) compared with those in the control group. For all of the remaining physical and metabolic parameters that were assessed, including BP, cholesterol, triglycerides, fasting plasma glucose, and HbA$_{1c}$, no differences between the 2 groups were observed (Table 2).

Further analysis revealed that the reduction in VFA in the intervention group was significantly associated with both the number of steps per day ($P<.001$) and calorie intake per day ($P<.001$), after results were adjusted to take age and the VFA at baseline into consideration (Table 3).

Table 2. Change in parameters.

Variable	Intervention group (n=39), mean (SD)	Control group (n=34), mean (SD)	P value	Adjusted P value[a]
Physical parameters

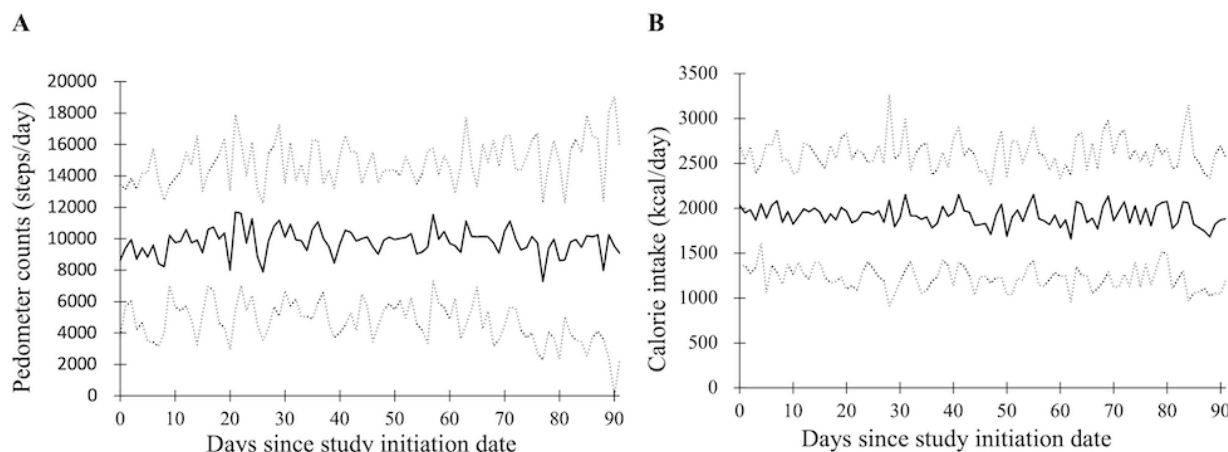
Changes of Number of Steps and Calorie Intake During the Study Period

In the intervention group, participants walked an average of nearly 8000 (SD 5139) steps (Figure 3). Similarly, the average calorie intake was nearly 2000 (SD 703) kcal/day (Figure 3). Both parameters remained almost constant during the study period.

Figure 3. Variables of lifestyle behavior recorded during the study period. (A) Number of steps. Solid line: daily mean pedometer counts; dotted lines: mean (SD). (B) Calorie intake. Solid line: daily mean calorie intake; dotted lines: mean (SD).


Use of DialBeticsLite in the Intervention Group

By analyzing the data recorded by DialBeticsLite, we found the median use rate of the app to be 100% (IQR 98%-100%) within the intervention group (Table 4). When examining individual functions, differences in use rates were observed. The use rates of the self-monitoring functions for BW (median 93%, IQR 73%-98%), pedometer counts (median 85%, IQR 74%-93%), BP before breakfast (median 88%, IQR 61%-95%), breakfast (median 98%, IQR 78%-100%), lunch (median 97%, IQR 62%-99%), and dinner (median 95%, IQR 75%-99%) were high, whereas those regarding exercise input (median 1%, IQR 0%-14%), BP at bedtime (median 61%, IQR 29%-86%), blood glucose (median 0%, IQR 0%-0%), and snacks (median 20%, IQR 10%-36%) were low. We examined the use of functions that recorded lifestyle and behavior, specifically the pedometer count function and the diet function (including breakfast, lunch,

dinner, and snacks). We found that both the retention rate of the pedometer counts function and diet function decreased over time during the study, with the former declining from 90% to 50% and the latter declining from 90% to 70% (Figure 4). We analyzed the recorded data by producing a Pearson correlation matrix to determine whether any of the individual function's use rates showed a correlation with the reduction of VFA (Multimedia Appendix 1). We found that the BW ($r=-0.27$, $P=.10$), pedometer counts ($r=-0.25$, $P=.13$), BP before breakfast ($r=-0.27$, $P=.10$), and snacks ($r=-0.27$, $P=.10$) functions showed a positive correlation with the reduction of VFA, although this was not statistically significant. In contrast, a significant correlation was observed between the use rates of the functions. Correlation coefficients of over 0.9 were obtained between the BW and BP before breakfast functions, as well as between the individual diet functions, including breakfast and lunch, breakfast and dinner, and lunch and dinner.

Table 4. Number of days with recordings and use rate for each parameter in the intervention group.

Variable	Days with recordings (n=92), median (IQR)	Use rate (%), median (IQR)
Total[a]	92 (90-92)	100 (98-100)
Body weight	86 (67-90)	93 (73-98)
Pedometer counts	78 (68-86)	85 (74-93)
Exercise input	1 (0-13)	1 (0-14)
Blood pressure		
Before breakfast	81 (56-87)	88 (61-95)

Discussion

Principal Findings

In this randomized clinical trial, we examined the effect of using DialBeticsLite for approximately 3 months in addition to traditional counseling for the participants of the Specific Health Guidance with AO. Statistically significant reductions were observed in VFA, which was the primary end point, and some other parameters (BW, BMI, and WC). These results suggest that the addition of mHealth interventions could make the Specific Health Guidance more beneficial. According to an exploratory analysis within the intervention group, the mean number of steps and calorie intake per day during the study period were associated with a decrease in VFA.

We observed a significant reduction for VFA, BW, BMI, and WC after the intervention, which is consistent with other studies that have shown that mHealth interventions can reduce BW, BMI, and WC [21,22,26]. DialBeticsLite encourages self-monitoring through daily records and provides personalized advice. Frequent self-weighing and recording of daily weight patterns by patients with obesity has been reported to be effective in weight loss programs [35]. Our findings also reinforce the effectiveness of self-monitoring for individuals with AO. Owing to the nature of the intervention, its impact relies on engagement [36]. Previous studies have indicated so, reporting a significant association between weight loss and the use rate of self-monitoring functions or the use rate of an app in general [36,37]. The same was observed for behavior, with

participants with higher app use exhibiting increased physical activity and decreased caloric intake [37]. In this study, although strong correlations were not observed between the loss of VFA and the use of self-monitoring functions, they do not necessarily contradict previous studies. Engagement in the intervention group was higher than that in other studies involving behavioral self-monitoring with mHealth, as the median number of days of full app use was 92 out of 92 days [22,38]. Similarly, a median of over 80 days for both BW and diet self-monitoring functions (excluding snacks) was observed, which was also higher than that in past trials [29]. The higher engagements may have resulted in difference of reduction of VFA between the intervention and control groups.

Another important finding, but perhaps least surprising, was that VFA reduction was associated with the number of steps taken and calorie intake in the intervention group. Increasing the number of steps and decreasing the number of calories are natural ways to improve AO. In the intervention group, participants walked an average of nearly 8000 steps (Figure 3), which seems to be sufficient, but an increase in the number of steps may still be effective. Similarly, further reduction of calorie intake from 2000 kcal/day (Figure 3) may further improve AO. Although some randomized controlled trials have shown that mHealth interventions are effective [21,22,26], few studies have revealed the cause of the improvement. Our findings may support the idea that we should focus not only on increasing engagement but also on causing behavior change.

In contrast to the significant reduction for VFA, BW, BMI, and WC after the intervention, all remaining physical and metabolic parameters, including BP, cholesterol, triglycerides, fasting plasma glucose, and HbA_{1c}, showed no differences between the 2 groups. However, because these parameters were well controlled and almost within the normal range at baseline, improvement may have been difficult regardless of the intervention.

Although mHealth allows for easier initiation and recruitment, it is also more prone to disengagement [39]. Over the course of this study, the retention rates declined within the intervention group (Figure 4). This is also seen in other studies, and there is a need to explore potential methods to increase engagement and retention to maximize the benefits and efficacy of mHealth as a replacement for in-person support [36]. A study examining the reasons for dropout identified that daily recording could become overly repetitive and burdensome, with too much data to track [38], whereas another study targeting patients who had been prescribed medication discovered that the time and effort required were the predominant barriers to using personal health record systems [40]. In contrast, the frequent use of self-monitoring functions has been shown to increase retention [41], and low engagement has been identified as a predictor for participants abandoning the app [42]. Therefore, retention and adherence could potentially be improved by identifying specific functions of the app with higher use rates and associations with positive outcomes while eliminating other features to simplify the app. For instance, in our study, the recording function for blood glucose was rarely used and may have been useless. In addition, although not statistically significant, the BW,

pedometer counts, BP before breakfast, and snacks functions showed a positive correlation with the reduction of VFA. The high measurement rates of this study population might have resulted in an insignificant correlation; placing further emphasis on and developing these functions might further improve the effect of the intervention on AO. Furthermore, the use rates of some functions were strongly associated with those of other functions. For example, those who used the BW function were more likely to have been using the BP before breakfast function, and the same was seen between the individual diet functions, including breakfast and lunch, breakfast and dinner, and lunch and dinner. To optimize the app design, further detailed investigations into the effect of each feature are required.

Limitations

Although the results of this study are promising, they should be interpreted with some caution, as there are several limitations to this study. First, past studies have revealed that for studies examining the effect of lifestyle interventions, those with sample sizes of >90 and intervention durations of >8 weeks tend to have more successful outcomes [36]. Although, at randomization, our study included 122 individuals, only 73 (59.8%) were included in the final analysis of results, and this relatively small sample included only Japanese men aged 40 to 75 years. Many patients were found to not meet the eligibility criteria after allocation because of our lack of confirmation; assessment was determined only by the information obtained before allocation. Thus, the transportability of the results to other populations, including those with women and different ethnic groups, is limited. As there has been evidence from a recent study to support a difference in retention and willingness to use mHealth interventions between men and women, with the latter being more reluctant to use apps intended to treat diabetes [43], there is a need to assess whether DialBeticsLite also has an uneven adherence between the 2 sexes.

Second, the participants were observed for a relatively short period of 3 months, and although this is longer than 8 weeks, the long-term impact of the intervention remains to be tested. This is especially important considering that many participants in lifestyle interventions struggle to maintain the significant physical and behavior changes achieved at the end of the intervention [44,45]. There has been evidence of the effect of mHealth being relatively short-lived, with participants regaining any weight they had lost during the intervention period [46].

Third, despite using stratified randomization, VFA differed between the 2 groups at baseline. As we categorized the VFA and allocated participants by stratified randomization, this phenomenon has some probability of occurrence. However, a sensitivity analysis to examine the influence of this difference was conducted during the analysis of primary and secondary outcomes, and as the results were relatively unchanged, we concluded that the difference in VFA at baseline had little influence on the primary and secondary outcomes.

Fourth, the provision of some medical devices to the intervention group may have influenced the results obtained by improving the participants' motivation. Therefore, it may be more appropriate to interpret the results of this study as indicative of

the combined effect of the app and the distribution of medical devices, rather than the effect of the app alone.

Finally, as daily steps and caloric intake were not recorded in the control group, we cannot be certain of the extent to which these 2 factors were affected by the intervention. Although physical parameters improved significantly, we were unable to observe a significant reduction in total energy intake or an increase in physical activity during the intervention. At first glance, this may suggest that the intervention did not contribute to improving lifestyle and behavior; however, considering a previous study that showed that mHealth intervention prevented the reduction of daily steps, this may not be the case [47]. Although this previous study did not produce statistically significant results, likely owing to its small sample size, it suggests that an increase in daily steps is not necessary for an mHealth intervention to be meaningful. Allowing participants to maintain a high level of physical exercise in itself is an achievement and may explain why our study saw a significant decrease in BW, BMI, and VFA despite seeing no significant change for daily steps and total caloric intake.

Conclusions

Our study suggested that DialBeticsLite, a mobile app designed to assist self-management, was feasible among Japanese adults who were eligible for the Specific Health Guidance. The mHealth intervention resulted in a statistically significant reduction in VFA, BW, BMI, and WC over the course of 3 months. Compared with traditional methods, ICT systems offer greater scalability and convenience and could be more cost-effective. Thus, these findings are promising and show that mHealth interventions have great potential for treating patients with AO.

Conflicts of Interest

KW was a member of the Department of Ubiquitous Health Informatics when the study was conducted and developed the information and communication technology–based self-management system, DialBeticsLite.

Abstract

Background: A number of evidence-based knowledge translation (KT) tools for parents of children with acute health conditions have been developed. These tools were created and tested with parental input and disseminated to groups proficient in English. Therefore, it is unclear whether they are useful for populations that are more diverse. To enhance the reach of our current and future KT tools, language translation and cultural adaptations may promote relevance for previously underserved knowledge users.

Objective: This study aims to explore and understand considerations for the cultural and linguistic adaptation of a KT tool in French and Filipino communities.

Methods: A KT tool (whiteboard animation video) describing the signs and symptoms of croup was originally developed in English to provide parents with evidence-based information couched within a narrative reflecting parents' experiences with the condition. This KT tool was adapted (linguistics and imagery) for French- and Tagalog-speaking parents and caregivers through feedback from key stakeholders. The videos were presented to the respective language speakers for usability testing and discussion. Participants were asked to view the KT tool, complete a usability survey, and participate in semistructured interviews. Audio recordings from the interviews were transcribed verbatim, translated into English, and analyzed for relevant themes by using thematic analysis.

Results: French- (n=13) and Tagalog-speaking (n=13) parents completed the usability survey and were interviewed. Although analyzed separately, both data sets produced similar findings, with key themes relating to understanding, relatability, and accessibility. Both the French and Tagalog groups reported that the video and other KT tools were useful in their adapted forms. Participants in both groups cautioned against using verbatim vocabulary and suggested that cultural competency and understanding of health languages were essential for high-quality translations. Parents also discussed their preference for videos with diverse visual representations of families, home environments, and health care workers, as such videos represent their communities more broadly.

Conclusions: French and Filipino parents appreciated having KT tools in their first language; however, they were also supportive of the use of English KT products. Their suggestions for improving the relatability and communication of health messages are important considerations for the development and adaptation of future KT products. Understanding the needs of the intended end users is a crucial first step in producing relevant tools for health evidence dissemination.

Introduction

Background

In the context of pediatric health care, connecting parents and caregivers to research evidence has the power to improve health decision-making and access to support services [1-3]. Knowledge translation (KT) facilitates the actioning of evidence to improve such outcomes. Furthermore, by integrating patient experiences, KT tools (eg, videos, e-books, and infographics) may be more relevant and impactful [4].

Parents and caregivers have become increasingly reliant on web-based sources for health information [5,6]. Subsequently, we developed >25 digital KT tools to improve dissemination and reach of health information for parents seeking help for acute childhood conditions (eg, bronchiolitis, croup, acute otitis media, and fever) [7-11]. The theoretical foundation underpinning our work was the Knowledge to Action framework [12], and the process development for our tools is situated within the tailoring *knowledge* portion of the knowledge to action cycle. Our research teams worked with clinicians and families to co-develop and disseminate the KT tools for Albertans and Canadians in general [13]. Throughout the process, our team engaged with and integrated end user (parent) feedback to ensure that our KT tools were devised and tested with the health consumer in mind [13]. However, our end users have often represented majority cultures in our community, and our KT tools were piloted with and disseminated primarily to English-speaking residents.

Although integrating feedback from end users or stakeholders has become a standard practice for many involved in KT tool development, those providing feedback commonly represent majority voices in the health care community [14,15]. Few studies have explored the usability of KT tools with minority cultural groups [16], and even fewer have tested culturally adapted tools with their target populations [17].

Objective

Our goal was to broaden the reach of our work to different linguistic and cultural contexts to enhance knowledge and awareness among diverse user groups. The objective of this study is to explore how to adapt these tools to 2 non–English-speaking groups. Alberta is a diverse province and continues to grow in represented cultures. Other than English, French and Tagalog are the most common languages spoken in Alberta homes [18]. The relatively high proportion of those who speak French and Tagalog prompted our decision to include these communities in our efforts to understand cultural adaptations for consideration in KT tool development.

To address the different cultural communities in Alberta, we adapted a pre-existing KT tool for French- and Tagalog-speaking parents. By engaging community members, we aim to explore the key cultural aspects of French and Filipino parent experiences as well as to understand considerations for cultural adaptation processes in general.

Methods

The KT Tool

A pre-existing English digital whiteboard animation video depicting the signs and symptoms of croup was chosen for adaptation [18]. This topic was chosen for adaptation as croup is one of the most common causes of upper airway obstruction in children and accounts for significant rates of emergency department visits in Canada [19]. This video was originally produced through consultation with predominantly White, English-speaking parents [20]. Recent usability testing showed that parents rated the tool highly and gave favorable scores to all usability questions. Parents also reported that the video was informative, easy to understand, short and to the point, and visually appealing [21]. Audio and visuals of the original video were representative of mainstream Canadian health care providers' and parents' experiences.

Adaptation Process

Overview

Although the adaptation process for the 2 different cultural groups varied slightly, in the absence of a cultural adaptation theory, model, or framework for KT tools (or KT interventions), we used elements of the Ecological Validity Framework by Bernal et al [22]. Adaptations were considered to be related to language (translation and differences in regional or subcultural groups), persons (patient–health care provider relationship, family roles), metaphors (symbols and sayings), and content (values, customs, and traditions).

French Adaptation Process

The adaptation process for French-speaking parents was purely linguistic. French-speaking members of the research team translated the original English video script into French by using a forward-back translation process [23]. French-speaking researchers and clinicians were consulted during the script translation process to ensure appropriate communication of the medical terminology. A video production company then incorporated the linguistic changes by creating a new French narration and editing visual text to French terminology (Multimedia Appendix 1). Once edits from the digital media company were approved by key stakeholders, the tool was ready for evaluation by the end user group (ie, French-speaking parents).

Tagalog Adaptation Process

The adaptation process for Tagalog-speaking parents involved linguistic and visual adaptation. The linguistic adaptation component of this process was similar to the French adaptation, with narration and video text translation by Tagalog-speaking members of the research team, integration by the digital media company, and review by key stakeholders. We also adapted character appearances to more similarly represent Filipino community members. Through continual consultation with Filipino parent stakeholders and graphic designers from the

digital media company, character visuals were adapted to represent the Filipino community more accurately (Multimedia Appendix 1). Linguistic and visual edits from the digital media company were approved by key stakeholders before evaluation.

Participants and Ethics Approval

Participants were purposively sampled based on self-reported preference for speaking French or Tagalog at home, having English as a second language, and having a parent or guardian role of a child aged <18 years. Ethics approval was granted by the University of Alberta Health Research Ethics Board (Pro00087285 and Pro00085766). All the study documents were translated into French and Tagalog (recruitment materials, study information letters, consent forms, usability surveys, and interview guides). All participants provided informed consent before data collection. Recruitment materials were posted on social media platforms and bulletin boards throughout the respective communities.

Usability Survey

In both studies, parents were asked to complete a usability survey in French or Tagalog after viewing the adapted KT tool. The survey (Multimedia Appendix 2) collected demographic information and evaluated the video's quality of information, format, appropriateness of visuals, and communication of health information. The survey content was informed by a knowledge synthesis of over 180 usability evaluations [24]. Participants were instructed to state their agreement with 9 statements (eg, "it is simple to use" and "its length is appropriate") on a 5-point Likert scale ranging from *strongly disagree* to *strongly agree*. Following survey completion, parents were invited to participate in one-on-one semistructured interviews to elaborate on their survey responses and speak about the usability of the translated tool within their communities.

Interviews

French- and Tagalog-speaking research team members conducted interviews with French and Filipino parents who completed the usability survey. These interviews occurred in French or Tagalog with research team members who were trained in qualitative data collection, following an interview guide and asking relevant probing questions. The interview questions were chosen to explore the participants' perspectives on general cultural considerations, as well as specific feedback for the adapted croup video (Multimedia Appendix 3). The interviews were recorded, transcribed verbatim by a native French- or Tagalog-speaking translator, and then translated into English for analysis. Conducting the interviews in French and Tagalog allowed participants to communicate their perspectives in their preferred language [25]. The decision to translate interview transcripts was appropriate for communicating findings within the predominantly English research team and readership audience. This choice was methodologically consistent for thematic analysis, unlike more deeply phenomenological methodologies in which the participant language could articulate nuances in experience [26]. Nevertheless, any cross-language qualitative study can introduce concerns regarding data trustworthiness [27]. To mitigate potential translation errors, the bilingual research team members validated the translated transcripts and communicated with the broader research team. The English field notes taken by the interviewers also aided in the cross-language study process, where participants' nonverbal responses were noted.

Analysis

Descriptive statistics were used to describe the study sample and the usability survey results. Interview data collection and analysis occurred concurrently until no new responses transpired. The translated transcripts were analyzed using inductive thematic analysis [28]. Data management and analysis were facilitated using NVivo 12 software (version 12; QSR International). The analysis process was iterative, where each transcript was read in its entirety, verbatim codes were assigned to topics in the transcript, and codes were grouped into preliminary categories. The preliminary categories from all the coded transcripts were compared and organized into themes. Common themes were reviewed and verified by all authors. Interviewers wrote field notes during the interviews to promote confirmability, reflexive practice, and rigorous research processes [29]. The trustworthiness of the data was guided by three criteria: fairness, ontological and educative authenticity, and catalytic and tactical authenticities [29]. Fairness was addressed through detailed field notes, interview recordings, and transcripts. Ontological and educative authenticity were addressed through an inductive interview process in which participant perspectives were considered true. Catalytic and tactical authenticities were addressed through continual consultation with key stakeholders, positioning the participants as experts of their own experiences. Analytic rigor was promoted through communication within the research team and the verification of themes. Bilingual research team members validated translated interview transcripts to mitigate interpretation errors that can occur in cross-language qualitative research [27].

Results

Overview

A total of 13 French- and 13 Tagalog-speaking parents residing in Alberta completed the study. The participant demographics are shown in Table 1. Briefly, most French-speaking participants were mothers (12/13, 92%) and were born in Canada (8/13, 62%), whereas Tagalog-speaking participants were mothers (9/13, 69%) and fathers (4/13, 31%) born outside Canada (12/13, 92%).

Table 1. Demographic characteristics of French and Filipino parents who participated in usability testing and interviews (N=26).

Variable	Participants, n (%)

Usability Survey Findings

Overall, parents in both groups found the video helpful, simple to use, and informative. Most French (12/13, 92%) and Filipino (10/13, 77%) parents strongly agreed that the adapted form of the tool was useful. Most parents (10/13, 77% for both French and Filipino parents) also strongly agreed that the tool would help them in making decisions about their child's health (eg, when to use health services and management of the condition). Table 2 displays the detailed responses to the usability survey of the parents in each group.

Table 2. Frequency of responses from French and Filipino parents on usability survey items (N=26).

Items	Strongly agree, n (%)		Agree, n (%)		Not sure, n (%)		Disagree,[a] n (%)	
	French (n=13)	Filipino (n=13)	French (n=13)	Filipino (n=13)	French (n=13)	Filipino (n=13)	French (n=13)	Filipino (n=13)
It is useful	12 (92)	10 (77)	1 (7)	3 (23)	0 (0)	0 (0)	0 (0)	0 (0)

[a]Options were listed on a 5-point Likert scale ranging from *strongly agree* to *strongly disagree*. The *strongly disagree* option was not chosen by any participant in any category.

Qualitative Interview Findings

Overview

All interviews were one-on-one, with the exception of a Filipino parent dyad who were interviewed together. The analysis of the translated interview transcripts identified the following three major themes: enhancing understanding, relatability, and accessibility. Table 3 displays detailed examples of themes, subthemes, and related participant quotes. It should be noted that the analysis occurred for each community group separately; between-group differences are explained in more detail throughout this section.

Table 3. Themes, subthemes, and quotes developed from interviews with French and Filipino parents.

Themes and sub-themes	Quotes
Enhancing understanding	
Knowing what to do	• "It is rather easy to confuse it with a cold, but you notice a dry and hoarse cough, a noisy breathing." [Interview_004_French] • "I'm even excited to show it and share it to my friends." [Interview_001_Tagalog]
Video format	• "It's excellent, yes very well done, simple, clear, the visual helps a lot, I just like the white and the black, you know it's very well done." [Interview_012_French] • "It seems that the drawing is helpful to get a better understanding of the video." [Interview_013_Tagalog]
Relatability	
Inclusion in Canadian health care	• "I'm more bilingual now than I was before, but when I arrived in 2003, my command of English wasn't as good, and I would have certainly appreciated having this kind of video." [Interview_013_French] • "I feel valued. Just having this, I feel valued already." [Interview_003_Tagalog]
Other child health concerns	• "[my daughter] was diagnosed with pneumonia the last time we went she was diagnosed but they didn't diagnose her with Asthma, they say treating her for Asthma." [Interview_007_French] • "Most of the children have ear infection." [Interview_009_Tagalog]
Video images	• "If you'd like to add something cultural, I'll say you can do it and I'll add something, a little bit of colors or something that symbols but other than that I think it's fine." [Interview_010_French] • "It seems that the drawing is helpful to get a better understanding of the video." [Interview_013_Tagalog]
Accessibility of information	
N/A[a]	• "I don't know where but it will be accessible, but if it's accessible through social networks, through Youtube there are so many videos, who does anything." [Interview_006_French] • "Usually, the method of delivery is when you go to the hospital or your physician doctor, you get a pamphlet, like that. So this is something that [is] a little bit different, and easily accessible anywhere and you don't have to really dig for it." [Interview_012_Tagalog]

[a]N/A: not applicable.

Theme 1: Enhancing Understanding

Subtheme 1: Knowing What to Do

The main goal of the KT tool presented in this study was to help parents understand how to respond when their child has symptoms consistent with croup. The applicability of the tool to French and Tagalog parents could be assessed through the parents' gained understanding of the health condition. Participants from both communities commented that they felt more equipped to respond to future occasions on which their children could have croup. It should be mentioned that although none of the parents had experience with their child having croup, several parents did have experience with their child having laryngitis or asthma. One French-speaking parent described noticing their child had "the barking coughs, with the difficulty to breathe"[Interview_002_French], so they felt prepared to handle a similar symptom in the future. Parents also voiced their appreciation for the health information that they could pass along to friends and family. A Tagalog-speaking participant said the following:

> *I'm even excited to show it and share it to my friends.*
> [Interview_001_Tagalog]

In both the French and Tagalog translated videos, participants were confused by some of the terminology used. The names of drugs and symptom descriptions were the most commonly confused terms in the video, which were terms without verbatim translations. Parents suggested using sounds and visuals to describe symptoms more clearly. Parents also suggested displaying English words for drug names and health conditions to assist the viewer in future conversations with English-speaking health care providers.

Subtheme 2: Video Format

Although parents were presented with a whiteboard animation video for discussion, they were also asked to comment on their preferences regarding the format of KT tools in general. Throughout the interviews, French- and Tagalog-speaking parents described their preferred format as succinct informational videos in simple language. A Tagalog-speaking participant described their positive opinion of the whiteboard animation style in saying the following:

> *It seems that the drawing is helpful to get a better understanding of the video.* [Interview_013_Tagalog]

Theme 2: Relatability

Subtheme 1: Inclusion in Canadian Health Care

Overall, the interviewed French- and Tagalog-speaking parents were pleased with the opportunity to comment on the cultural relevance of the video. Parents liked seeing their languages represented despite most having a high English language

proficiency. A Tagalog-speaking parent voiced this appreciation by saying the following:

> I feel valued. Just having this, I feel valued already. [Interview_003_Tagalog]

Subtheme 2: Other Child Health Concerns

Along with commenting on the present video, French- and Tagalog-speaking parents were asked which child health topics they would like to see represented in future KT efforts. French-speaking parents only mentioned the inclusion of information on asthma and other respiratory conditions. Approximately 15% (2/13) of Tagalog-speaking parents wanted more information tools for eczema, whereas others suggested that juvenile diabetes and treatment of burns would improve their knowledge base.

Subtheme 3: Video Images

Several Tagalog-speaking parents believed that the video images were already representative of their experiences, as their culture was assimilated into a Western Canadian lifestyle. A participant said the following:

> we are more westernized than any other Asians that's why to translate the video in Tagalog to give out information with regard to health care and with the Canadian setting it's really awesome. [Interview_005_Tagalog]

Others viewing the Tagalog adaptation suggested the inclusion of images of religious items in the household to represent the importance of Catholicism for many Filipino community members. Both French- and Tagalog-speaking parents commented on showing more diverse family representations. French-speaking parents suggested that showing a father in addition to a mother would be helpful, whereas several Tagalog-speaking parents thought the inclusion of grandparents would more accurately depict their experiences. A French-speaking parent mentioned the practical considerations for diverse representation in saying the following:

> ...French Canadian, another one from West Africa and then another one from North Africa, and then in fact, heterosexuals or homosexuals, there's lots of possible combinations, I don't think in 3 minutes you can put it all together. [Interview_013_French]

Of note, several parents from both groups situated their experiences as not wholly representative of everyone in their community.

Theme 3: Accessibility of Information

Parents were interested in discussing how to improve the accessibility of information to others in their communities and in Canada in general. Their discussions revolved around the format and dissemination avenues. As previously mentioned, parents strongly preferred using videos as a medium for KT tools. Parents described their previous experiences with finding information as challenging and preferred having easy to access web-based resources. A Tagalog-speaking parent described the importance of web-based tools by saying the following:

> Usually, the method of delivery is when you go to the hospital or your physician doctor, you get a pamphlet, like that. So this is something that [is] a little bit different, and easily accessible anywhere and you don't have to really dig for it. [Interview_012_Tagalog]

Parents also offered suggestions for where to find this information in the future. Many recommended social media sites where parents are already active. A French-speaking parent suggested that the tools should be "accessible through social networks, through Youtube" [Interview_006_French]. Regardless of their recommendations for further adaptation, their preferences for web-based tools and videos similar to the shown croup video were noticeable.

Discussion

Principal Findings

One of the overall goals of our research program is to understand how best to develop and adapt KT tools that are relevant for culturally and linguistically diverse populations. As a first step to support the understanding of best practices when adapting KT products, we adapted a whiteboard animation video for French and Tagalog speakers and sought the perspectives of parents from the respective groups.

Increasingly diverse populations in Alberta and Canada [18] offer new lived experiences and perspectives through which health information can be understood. Efforts to culturally adapt health promotion campaigns [30,31], health care screening inventories [32], and health interventions [33,34] have previously been reported. However, to date, no substantive guiding protocols exist for culturally adapting KT products. As researchers become more interested and able to adapt their KT products to diverse audiences, general considerations will provide guidance in their adaptation endeavors.

By involving stakeholders and engaging end users, we were able to learn some key considerations when adapting tools, which could prove helpful in future KT development or adaptation work. Participants emphasized the importance of enhancing understanding through relatable and accessible KT tool adaptations. French and Filipino community members suggested that future tools should have translations available; primarily use video format; use visuals representative of the community they serve; and be disseminated through commonly used platforms to improve the understanding, relatability, and accessibility of KT tools. On the basis of the recommendations from parents in this study, researchers interested in reaching diverse communities with their KT efforts should consider how best to enhance understanding, relatability, and accessibility within the community of interest. Although these studies involved French and Filipino parents in Alberta, many of the findings could be extended to best practices when engaging with other communities in the KT process. Addressing these areas will undoubtedly look quite different for each specific community of interest; therefore, further patient-centered research should include diverse perspectives.

It is important to acknowledge that culture is not a fixed set of characteristics limited to race and ethnicity; rather, it is a constantly evolving and dynamic concept that encompasses collective views, beliefs, norms, expectations, traditions, customs, and interactions that distinguish population groups [2,3,35]. Therefore, navigating cultural adaptation work can be an involved and complicated process. As mentioned by both Filipino and French parents in this study, understanding the Canadian health care system and Canadian culture more broadly improves with time. Francophone parents were primarily born in Canada; however, Filipino parents who were born elsewhere had an added barrier to accessing Canadian health care services. However, both the French and Filipino parents described that their communities were quite integrated into mainstream Canadian culture; thus, they felt represented by images developed for most cultures. When adapting or developing knowledge products, it is important to assess how the target community has integrated into mainstream Canadian culture. It is likely that newcomers to Canada would experience unique and difficult cultural barriers to accessing health services. Further research into newcomer perspectives in seeking care and how cultural assimilation may affect health information–sharing efforts would add value to the field of KT.

Previous efforts to culturally adapt interventions and health promotion materials suggest that engaging with stakeholders in specific communities will produce more impactful tools for knowledge users [31,32,36]. Although very little data are available on how this is implemented in evidence-based KT tools, public health messaging campaigns have explored the cultural nuances that influence knowledge uptake and interpretation [16,30]. There are a few examples of cultural and linguistic adaptations of health promotion materials for specific cultural communities available [31,36]. Telenta et al [31] found that community member engagement allowed for the successful adaptation of a public health campaign for African migrants in Australia. In addition, Bronheim et al [36] further stressed the importance of involving key community partners to assure cultural and linguistic appropriateness in health campaign development and adaptation. Through these examples, researchers emphasize the importance of engaging with specific cultural groups during the creation of health promotion materials [17,31,36] and acknowledging information preferences to ensure effective KT efforts. Despite the recommendation for co-designed KT products, there is little clarity on the protocols for cultural adaptation co-design research.

When adapting or developing KT products for a particular community, there will undoubtedly be unique considerations specific to that cultural group; however, common threads for researcher practice may exist to guide future efforts. Exploring the effective processes that researchers have used during their cultural adaptation work may provide guidance to streamline the adaptation process for others. In addition, crucial for KT tool development is researchers' willingness to understand the needs of the target community to produce effective tools for health evidence dissemination.

Adapting and translating KT products is a time-consuming and costly endeavor for researchers and may not be achievable for all groups. Certain components of the adaptation process may be prioritized by evaluating the feasibility and impact for the target community. By sharing cultural and linguistic translation processes, we hope to provide guidance for future research efforts in this area.

Limitations and Future Directions

We acknowledge that this study involved participants from only 2 cultural communities in Alberta, Canada; thus, the findings may not be generalizable to the experiences of those from other cultural groups or in other settings and countries. However, as mentioned by the participants in this study, French and Filipino people's experiences differ, particularly in terms of access to support. This suggests that cross-cultural adaptation needs may transcend language and culture and be related to how different community groups assimilate, including their awareness of health care support and how to access them. Therefore, understanding the needs of a community and the intricacies of culture may not be fully available to those outside the community.

The process of adapting KT tools for culturally and linguistically diverse communities can be time consuming and involved. Therefore, studies exploring what elements are cross-cutting versus unique to different communities, as well as what elements are related to culture specifically versus familiarity with the local language and system, are warranted.

In addition, future research understanding the needs of other cultural communities using the engagement of families and community leaders and in collaboration with health care providers would add to this nuanced field of KT.

Conclusions

French- and Tagalog-speaking parents were supportive of the use of English KT products with westernized images but suggested considering cultural components when adapting or developing KT tools. Producing tools with high-quality language translations, video formats, and appropriate and diverse visuals and disseminating on the web would improve understanding, relatability, and accessibility for French- and Tagalog-speaking parents.

As researchers increase their KT efforts, there is a need for more patient-centered cultural adaptation research to inform the development of relevant tools for diverse communities. Important factors such as the community's integration into mainstream culture, literacy, and newcomer status may influence the adaptation process.

Abstract

Background: Many people who experience harm and problems from gambling do not seek treatment from gambling treatment services because of personal and resource barriers. Mobile health (mHealth) interventions are widely used across diverse health care areas and populations. However, there are few in the gambling harm field, despite their potential as an additional modality for delivering treatment and support.

Objective: This study aims to understand the needs, preferences, and priorities of people experiencing gambling harms and who are potential end users of a cognitive behavioral therapy mHealth intervention to inform design, features, and functions.

Methods: Drawing on a mixed methods approach, we used creators and domain experts to review the GAMBLINGLESS web-based program and convert it into an mHealth prototype. Each module was reviewed against the original evidence base to maintain its intended fidelity and conceptual integrity. Early wireframes, design ideas (look, feel, and function), and content examples were developed to initiate discussions with end users. Using a cocreation process with a young adult, a Māori, and a Pasifika peoples group, all with experiences of problem or harmful gambling, we undertook 6 focus groups: 2 cycles per group. In each focus group, participants identified preferences, features, and functions for inclusion in the final design and content of the mHealth intervention.

Results: Over 3 months, the GAMBLINGLESS web-based intervention was reviewed and remapped from 4 modules to 6. This revised program is based on the principles underpinning the transtheoretical model, in which it is recognized that some end users will be more ready to change than others. Change is a process that unfolds over time, and a nonlinear progression is common. Different intervention pathways were identified to reflect the end users' stage of change. In all, 2 cycles of focus groups were then conducted, with 30 unique participants (13 Māori, 9 Pasifika, and 8 young adults) in the first session and 18 participants (7 Māori, 6 Pasifika, and 5 young adults) in the second session. Prototype examples demonstrably reflected the focus group discussions and ideas, and the features, functions, and designs of the Manaaki app were finalized. Attributes such as personalization, cultural relevance, and positive framing were identified as the key. Congruence of the final app attributes with the conceptual frameworks of the original program was also confirmed.

XSL•FO
RenderX

Conclusions: Those who experience gambling harms may not seek help. Developing and demonstrating the effectiveness of new modalities to provide treatment and support are required. mHealth has the potential to deliver interventions directly to the end user. Weaving the underpinning theory and existing evidence of effective treatment with end-user input into the design and development of mHealth interventions does not guarantee success. However, it provides a foundation for framing the intervention's mechanism, context, and content, and arguably provides a greater chance of demonstrating effectiveness.

Introduction

Background

Gambling problems are viewed across a continuum of risk in New Zealand, ranging from no risk to problem gambling, where high-risk gambling behavior results in considerable health and social problems. Consistent with this framework, the term problem gambling is described as any kind of harm, distress, or adverse impact caused or exacerbated by a person's gambling [1-3]. Gambling-related harm is a significant public health problem in New Zealand [4,5] and internationally [6-8]. In New Zealand, the latest prevalence estimates suggest that 0.1% of the population experiences problem gambling, with a further 1.5% and 3.3% experiencing moderate- and low-risk gambling, respectively [9].

Different treatment service modalities, such as face-to-face counseling, phone support, self-management workbooks, and web-based tools, such as those provided on the Safer Gambling Aotearoa website [10], are readily available, although none are mobile health (mHealth) apps. A recent survey reported that only 3.2% of people with problem gambling had accessed at least one type of support service [9]. Therefore, a significant proportion of the population does not receive optimal therapeutic support [11]. In New Zealand, the Māori (indigenous people of New Zealand) and Pasifika peoples are disproportionately impacted by problem gambling [12,13]. Although some theories of addiction help explain gambling addiction attributes [14], the influence of historical and cultural intergenerational experiences is equally important in understanding the gambling context for Māori [15,16]. Thus, it is vital that interventions accommodate and reflect the cultural appropriateness and presentation of content relevant to their needs and understanding.

The ubiquity of smartphone ownership and the exponential growth of new mobile technology functionality provide an opportunity to add new modalities for delivering evidence-based health interventions [17]. mHealth apps, defined as the use of mobile and wireless technologies for health promotion [18], have extended support for health behavior changes beyond standard treatment contexts. These interventions continue to be in demand, with a reported 3.7 billion mHealth downloads in 2017 [19] and an expected 29% growth rate over 2020-2027, equating to a forecast of 311.9 billion by 2027 [20]. Nonetheless, the retention and use of mobile apps is less than ideal, with reports suggesting that most are uninstalled within 5 days, with mHealth apps deleted slightly later, at 8.8 days [21]. However, app reinstalls are also not unusual, with mHealth apps reporting a reinstall rate of 14% [21].

Some mHealth research reviews explain that the lack of underpinning theory to support the app's intent (ie, the set of determinants that influence cognitive and behavior change assertions) contributes to the lack of app retention and hence the paucity of demonstrable evidence of effectiveness [22-27]. Other mHealth research highlights that the lack of involvement of intended end users or consumers in the design and development is an essential yet missing ingredient in creating effective mHealth interventions [28,29].

Therefore, informing mHealth interventions with research evidence, insights from domain experts, and a theoretical framework for high-fidelity interventions are critical [30], as is the involvement of consumers and intended end users [31-34]. Blending these strategies into concrete elements for digital interventions is not straightforward [35]. Although adopting this approach does not guarantee success [36,37], it can optimize the creation of an effective mHealth program. To that end, there has been a call to publish research that outlines the development processes underpinning mHealth interventions [38,39]. Publishing and sharing such research, which involves both mapping theoretical constructs and cocreation with end users, is a positive step in building a robust and replicable evidence base.

Objectives

In this study, we describe the formative research that was an integral part of developing a mobile app for gambling harm for use in New Zealand: Manaaki. Specifically, we aim to (1) adapt and refine an evidence- and web-based program, GamblingLess [40-42], into a mobile app intervention and (2) engage domain experts and intended end users to help inform the content conversion and the design, features, and functions of the app and maximize the effectiveness of the program. This study is part of a larger project to evaluate the effectiveness of this designed cognitive behavioral therapy (CBT) mHealth intervention—Manaaki—for people with self-reported gambling problems [43].

Methods

Ethics Approval

Ethical approval was obtained from the New Zealand Health and Disability Ethics Committee (19/STH/100). As part of the ethics consenting process, participants gave consent for a summary of the focus group contributions, including quotes where relevant, to be included in publications as part of the participant consenting process.

Development Process

The development process encompassed 2 key phases.

Phase 1 consisted of the research team reviewing the current GamblingLess program and adapting and refining it into a first draft prototype of content, features, and functions suitable for a mobile phone–delivered intervention.

Phase 2 involved a qualitative approach using repeated focus groups and prototype testing to engage end users as collaborative design partners. This approach was used to inform and refine the app's features, style and functions, and content presentation.

Phase 1: Intervention Content Development

Overview

The multidisciplinary research team included clinical gambling research domain experts, including GamblingLess [40] program creators (Associate Prof Dowling, Dr Merkouris, and Dr Rodda, Deakin University, Australia); mHealth and digital health experts; public health physicians; Māori, Pacific, and Asian health addiction research experts; a statistician; and 2 researchers from Hāpai te Hauora (an Iwi-led [groupings of the indigenous population based on kinship] community health organization). Collectively, these team members provided expert advice to unpack the program's core elements to ensure that the content remained evidence based. The Aotearoa New Zealand context also informed practical and clinical considerations during the design and development phases.

Unpacking GamblingLess

GamblingLess [42] is a comprehensive and intensive web-based CBT program designed to help people with gambling problems. It was designed to emulate the intensity and depth of the face-to-face programs. The original program content included 4 modules that were delivered over 8 weeks. The modules included motivational enhancement, behavioral strategies, cognitive strategies, and relapse prevention, and each module included 13-15 discrete activities. Although it was recommended that participants complete all modules and activities in numerical order, they were allowed to complete as many activities as they liked, in any order they chose.

Associate Prof Dowling, with the support of Dr Merkouris and Dr Rodda, initially reviewed the 4 modules of GamblingLess, reflecting on the findings from their original research [41]. This revised program intentionally maintained the original GamblingLess principles underpinned by the transtheoretical model [44]. The key was to acknowledge that some end users (help seekers) would be more ready to change than others. As change is a process that unfolds over time, a nonlinear progression is needed, enabling the end users to select the interventions they need according to their stage in the change process.

Accordingly, the goal of this redeveloped program is to support the end user in selecting and using the most appropriate module or modules based on their needs. It is designed to be nonlinear, and hence presents the end user with a range of options (modules) with which one or more resonates with what they hope to achieve; that is, managing urges or relapse prevention.

Therefore, it was anticipated that not all end users would need or want all modules or all activities within the program.

To create Manaaki, the acceptability data from the original GamblingLess program were also reviewed, with the most helpful treatment content identified and assessed for inclusion in this program [41]. The outcome of this revision was that the original 4 treatment modules were expanded to 6 modules. The research team reviewed the 6 new modules and provided initial suggestions on how each module and associated actions or activities might be adapted to fit a smartphone mobile app interface. Iterative cycles of face-to-face meetings, web-based meetings, and email conversations were used to create and refine the core structure, content, and activities of the 6 new modules.

The researchers adopted the consumer engagement strategies common in marketing [45,46], and with a user experience designer and research partners from Hāpai te Hauora, ideas and examples for the draft elements for each module and the control app were drafted. These ideas were translated into the following mixed medium modalities for use during the cocreation phases with end users:

- A draft wireframe to illustrate flow and give depth and perspective using Adobe XD (Adobe Inc)
- Large A0-sized posters of each module's wireframes, including color palette ideas
- A set of A4-sized paper mobile phone screens to show draft content
- A set of various images for app screens

Phase 2: Cocreation With End Users

Overview

We used a qualitative cocreation methodology [47] to determine the look, feel, function, and features of the Manaaki intervention app. As gambling impacts more marginalized and economically deprived populations, the research team created three groups: a Māori group, a Pasifika group, and a specific young adult group that was limited to participants aged 18-25 years. These groups were selected to maximize the app's acceptability for those most likely to benefit the most. In all, 3 cocreation cycles were planned for each group. This approach encourages increased involvement and ownership of the process by participants, as they can see how their contributions help shape each design iteration of the app [48].

Researchers from Hāpai te Hauora led participant recruitment. Through their networks, contact was made with various community groups and organizations to help identify potential participants for the different groups. The eligibility criteria were as follows: (1) having experienced problems or harms from their gambling or supporting someone who is or has experienced problems with gambling, (2) able to understand and converse in English, (3) able to participate in at least two of the three cocreation cycles, and (4) aged ≥18 years for the Māori and Pacifika groups or 18-25 years for the young adult group.

The focus groups were conducted between July and November 2019. The focus groups for the Māori and Pasifika groups were held in Auckland, whereas for the young adult group, it was held in Wellington. Each workshop lasted between 60 and 90

minutes and was audio recorded with notes taken. The workshops were facilitated by the Hāpai te Hauora researchers and were attended by the design experts.

A mixture of methods was used to elicit feedback and comments from participants. These included open-ended questions, iteratively adding to or removing elements on the Adobe XD wireframes, Post-it notes, writing on A0-sized posters, and ad hoc prompts for a more detailed discussion when new ideas emerged.

After each focus group, various engagement modalities (posters and Adobe XD wireframes) were adapted to reflect emerging ideas and discussions. These were incorporated into the next prototype version, ready for participants to reassess, discuss, and modify the subsequent focus group sessions.

As an appreciation of their time, each participant received an NZD $30 (US $20.30) voucher to attend the first focus group and an NZD $20 (US $ 13.50) voucher for each additional focus group attended.

Data Analysis

The data for the focus groups were analyzed using a general inductive approach [49]. The purpose of using an inductive approach was to (1) condense raw textual data into a brief summary format (using images, words, wireframes, and prototypes), (2) establish clear links between the research objectives and the summary findings derived from the raw data, and (3) develop a framework of the underlying structure of experiences or processes that are evident in the raw data. All focus group data were grouped under the relevant themes, unless it was pertinent to describe a particular group's findings separately. All direct quotes are in *italics* and illustrate specific conversation points.

Results

Phase 1: Converting the Internet-Based GamblingLess Program to a Draft mHealth Program

On the basis of the GamblingLess research findings, the original 4 core modules were altered into 6 new modules, each with 5-7 learning topics. Each learning topic had a set of activities or interactions to support the learning intent of the module's theme (Figure 1).

Each new module was carefully reviewed and remapped to the underpinning conceptual frameworks and intent to ensure fidelity and conceptual integrity (Table 1).

The outcome of this process enabled early wireframes, design ideas (look, feel, and function), and content examples to be drafted, which helped initiate discussions and ideas with end users during phase 2 and cocreation with end users.

Figure 1. Mapping web-based GAMBLINGLESS program content to the Manaaki mobile app content. mHealth: mobile health.
**Table 1.** Remapping modules to concepts and the intervention intent.

Module names	Conceptual framework	Underpinning intent
Knowing Myself (and my gambling)	Developing self-awareness and insight [50-52]	Designed to provide personalized feedback, goal setting, and understanding of gambling motivations, triggers, and consequences.
Getting Ready (to make changes)	Targeting thoughts and feelings and activating behaviors [53]	Designed to enhance readiness and confidence to gamble less, helping to shape thoughts and values to help make a change. Incorporates ideas of prediction of outcomes from their behaviors.
Taking Control (right now)	Targeting practical behaviors and identification of situational and contextual triggers	Designed to identify strategies to be used to contain and control the problematic gambling behavior in the short term. Directs the end user to other useful tools, such as venue exclusions, managing money, services and other resources.
Taking Actions (that last)	Activating personal strengths and resources and enhancing belief for successful change [54,55]	Designed to identify strategies and skills to be used to ensure longer-term success in gambling less.
Managing Urges (to cope with real situations)	Reframing thoughts and reflecting on your future self [54,55] and relapse prevention [56] (see also Marlatt and Gordon, 1985)	Designed to help the end user to cope with urges and cravings.
Change for Good (and building a new future)	Relapse prevention [56]	Designed to prevent gambling relapses in the future and to support cognitive capability to understand their lived experience of gambling harms and problems as a mechanism for maintaining their new behavior.

Phase 2: Cocreating and Designing With End Users

Overview

In all, 2 rounds of focus groups were conducted, with 30 unique participants (13 Māori, 9 Pasifika, and 8 young adults) in the first session and 18 participants (7 Māori, 6 Pasifika, and 5 young adults) in the second session (Figure 2). The time between the 2 focus group sessions varied from 4 to 7 weeks among the groups, as arranging an agreeable time for all participants was difficult.

Figure 2. Focus groups and participant numbers. FG: focus group.

Focus Group Cycle 1

Gathering Experiences

Participants were encouraged to think aloud and share difficulties when they or a loved one experienced gambling problems. The concept of *whakama* or shame was the dominant theme across all groups. Some participants remarked that they did not want to acknowledge that they had a problem with their gambling and had a strong desire to keep their gambling problems a secret. Consequently, few reported seeking professional help, but most remarked that they had completed a web-based quiz that assessed their gambling. Even when the quiz results suggested that they may have had a significant gambling problem, taking action was self-reported as trying the strategies that the websites had recommended. Although most remarked that these strategies were helpful, many found that they had returned to their previous harmful gambling behavior. A participant remarked that they felt that without support or reminders, it was easy to forget the learnings. The idea of a mobile phone intervention (*app*) that could provide help wherever and whenever needed was positively established across all 3 groups.

Initially, all groups discussed and conceptualized the app as a one-off tool to be used and then discarded it. However, as the participants continued to share their experiences and discuss what they would find helpful, the concept of a one-off tool was abandoned. The app was increasingly described as something that would be used to *help now and later*. Terms such as
faigamalaga (Pacific group) or *haerenga* (Māori group) were used to convey the idea of recovery and about being on a journey or voyage. The Māori focus group also discussed the concept of *kotahitanga* (togetherness and sharing) as an important concept and that recovery with whānau (family or extended family) is crucial, as it is "through our whānau āwhina" (extended family support) "that we can be and stay well."

The Look and Feel of the Intervention App

In all, 12 draft design images were presented to the participants, and it was clear that the participants expressed excitement in seeing their ideas of a journey already coming to life. As each focus group began selecting images that they liked, conversations within the groups became energetic. Although all 3 groups navigated these discussions differently, their outcomes were similar. Each group concluded that keeping a range of different images of New Zealand was better than keeping a single image or theme.

The 6 images that were the most popular across all 3 focus groups are presented in Figure 3.

In addition to selecting these images, engagement with the images was such that participants thought of ideas to enhance their look and feel, such as to "add more birds; have the bush image a bit more open" (Figure 3; image 2). The footprints were designed to illustrate movement; yet a Pasifika participant wanted to "remove the footprints," whereas others in the group liked them. The footprints were not mentioned by the young adult or Māori group participants. The fisherperson and tent in Figure 3 (images 3 and 4, respectively) were disliked across all 3 groups, commenting that they "did not fit with the other images." A few participants in the Māori focus group remarked that the perspective in these 2 images was different from the others, and "it didn't work." The young adult group remarked that Figure 3 (image 6) "needs people and needs some life in it. It's too sad looking, aye." Similarly, the Pasifika group said Figure 3 (image 6) "looks a bit too lonely. Where is everyone?" The Māori group participants also commented that Figure 3 (image 6) needed "people and activity in that scene so that you felt part of the world, you know, just being normal with your whānau. Yeah, more life."

Figure 3. The 6 most popular initial concept imagery selected.

Shaping the Features, Functions, and Content Desired

The conversations naturally segued from the look and appeal of the images to the important attributes (features and functions) needed to make the app useful and easy to use. The participants in all 3 focus groups began noting down the key features, functions, and some content elements they wanted in the app, using Post-it notes or writing directly on the posters, Textbox 1 summarizes these initial attributes.

Textbox 1. Early attributes to have in the app from the all first focus group sessions.

Features

- Make it personal
- Able to share with others
- Progress and achievement
- Receive feedback
- Measuring where I am
- Self-checks
- Help guide me to where to go next
- Reminders and prompts
- Links to services if needed
- Tracking on how I am going
- Goals
- A place for reflection and celebration
- Quick access to other help if needed

Functionality

- Easy to use
- Navigation around makes sense
- No need to do everything
- Be interactive
- Short things to do
- Not too many clicks to find things
- Needs to be fun and have animation
- Quick, no lagging when loading

Content

- Simple language
- Use images
- Video
- Not too much text
- Positively framed
- Can listen not just read
- Self-help resources
- What other help is available
- Culturally appropriate
- Shows helpful skills
- Activities

Cross-cutting elements

- Secure, private, and confidential
- Easy to download, not complicated
- No own data use
- Not too intruding
- No cost
- Works offline

Creating Ownership of the App Name and Logo

In consultation with our Māori research team members, the name *Manaaki* was suggested as a possible name for the mHealth intervention app. The name Manaaki has a special meaning in Māori, which blends the words mana and āki. Mana means to bring strength or give strength and to cherish. Almost every activity is linked to the maintenance and enhancement of mana. The word āki encompasses the concept of encouragement or urge for support, as well as to hold fast and be strong. To ensure that this term was acceptable and appropriate, the team sought guidance from the governance group at Hāpai te Hauora (our Māori research partner organization). They supported the use of the word Manaaki as the name for the new app.

The focus group participants had positive remarks about the name Manaaki. "I love the name Manaaki; it is perfect," said a Māori group participant. "It gives a positive vibe," was reported by a young adult group participant, and a Pasifika participant remarked, "I like it. Manaaki is all about being encouraging, so perfect for this app."

In all, 10 concept designs (images, colors, and text types) were created, and participants were encouraged to comment on the options provided and select the text, logo, and colors they liked or offered other ideas.

Figure 4 shows the text, images, and colors that were frequently selected, with those circled in red confirmed as the final designs.

Figure 4. Concept designs for name and logo.

Encouraging Recruitment Into the Study

The final discussion element for the first focus group was gathering insights into the study design—a randomized waitlist control study—and its impact on recruiting participants. It was evident that participants in all the groups understood that tools and treatments offered to people experiencing harm from gambling needed to be effective and that research is needed to prove effectiveness. Despite understanding the need to research the app for effectiveness, both the young adult group and the Pasifika group remarked, "that having to wait to get the full app is a put-off." Similar remarks were made in the Māori group:

> If you have to wait, you need to let us know that we can still go look for help. You know, that being in this study thing, doesn't stop that. Gotta be real clear too, about the information saying that, all the stuff in the app will be able to be used, after the wait. [Māori focus group, P3]

Although the idea of waiting was viewed as negative, having some functions was suggested as a way to help retention. The following comment clearly reflects this:

> If I had made the decision to do something about my gambling, and then was told, oh wait for a bit. [Laugh] Well, I would think, that's useless, and delete it and try something else. It may even put me off. But you know, seeing that there is still something for me, well maybe, [Laugh], that's better than nothing. So

> I might stick with it a bit, who knows. [Young adult participant, P2]

Functions and attributes commonly mentioned across the groups had a countdown icon showing how long to when the full Manaaki app would be available. The young adult group also suggested that the countdown icon be a clickable button that could *flip* and show the same outcome using different metrics, such as months, weeks, or days. Common to all groups was that the waitlist app needed to offer support within the app. Support such as links to services or websites was frequently noted, with the Pasifika group also mentioning that links to money management would also be good to have.

Focus Group Cycle 2

The purpose of the second focus group was to present the changes made to the designs and show the features and functions that were added or modified based on the group contributions from the focus group 1.

Look and Feel

The new image designs (Figure 5) and an animated version using Adobe XD were presented to each focus group, and they all received positive comments such as, "These are great. I love the colours, and the animation is sweet," from a young adult participant.

All groups remarked that the various interactive content and features that support users engaging with and using the app

were clear and intuitive. The use of different styles (images and themes) for different modules was received positively (Figure 6).

An animated Tui (a native New Zealand bird [Figure 7]) was designed to appear at the beginning of each module to explain the learning intention and topics for the module. This information was presented in an auto-scrolling speech bubble next to Tui. The participants could also listen to the message using the audio option. This audio feature was highly liked and recommended by all the focus group participants, although a

few comments from the Māori focus group remarked that the "computer voice is a bit annoying." In contrast, some participants in the Pasifika focus group were excited by this option and thought this audio option could enable the text to be spoken in different languages.

Participants were noticeably excited when they saw how the text, images, and colors that were selected during their first focus group session formed the framework for the final branding of Manaaki.

Figure 5. Modified screen imagery based on participant feedback.
Figure 6. Example of ideas for presenting text and activity interactions.

Example of text presentation by using tabs

Example activity with choices scrolling in from side and fading if selected

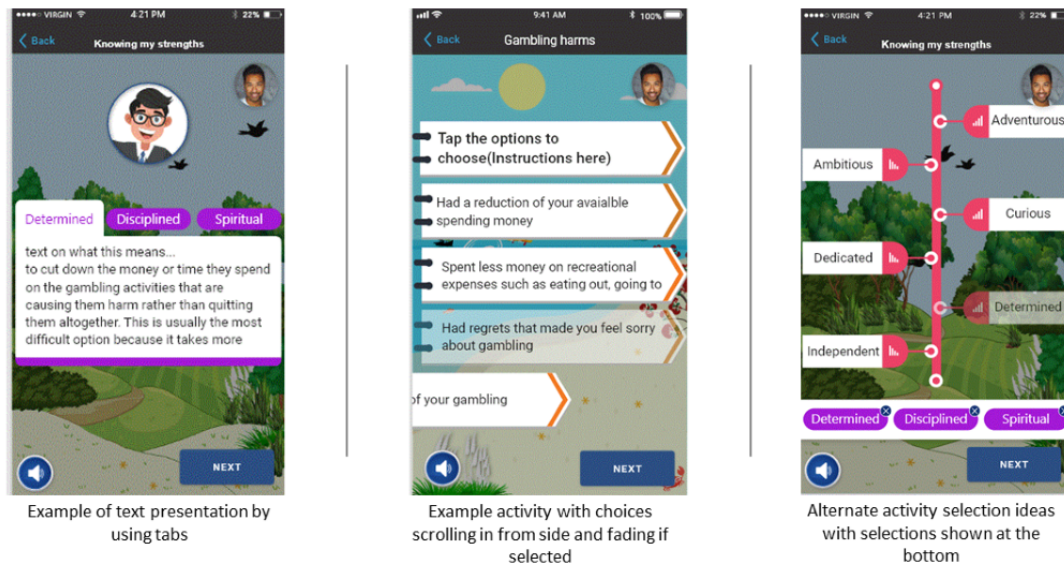
Alternate activity selection ideas with selections shown at the bottom


Figure 7. Tui guide.
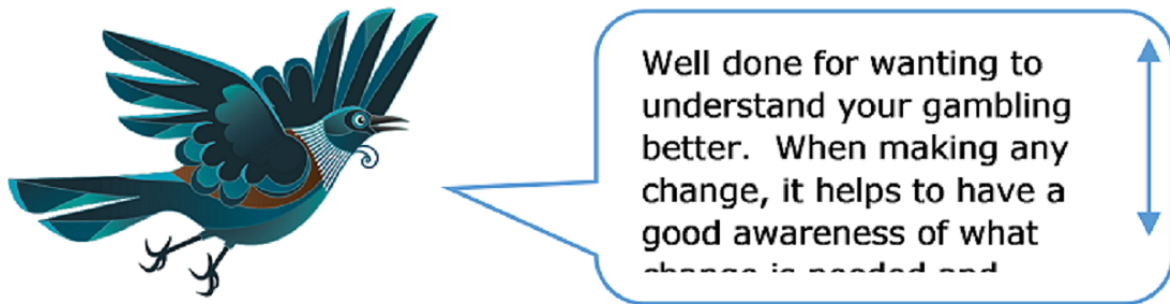

Personalization

In focus group cycle 1, all participants expressed a strong desire for the app to be personalized. The examples that showed how a user's first name would be integrated through the app were highly commended. Similarly, the use of language-specific greetings and phrases throughout the text was seen as acknowledging the population Manaaki intended to support. For many, these "little things [that will] help keep people engaged." Similar comments were made when the function of uploading an image or selecting a personalized avatar to represent a user visually was presented as an idea for how the app could be personalized to the user.

Participants also acknowledged that people could be at different stages of their journey to reduce the behaviors contributing to their gambling-related harm. They all remarked that the designs reflected their ideas from the first focus group sessions, especially the way the app was designed to enable the user to navigate their journey and yet receive prompts and suggestions to help guide them. Other functions, such as the journal, the link to the helpline chat, and the services being visible using the maps, were remarked on as meeting different users' needs and stages, making Manaaki useful to a diverse range of potential people.

Positivity

Positive framing and strength-based content were considered important, and the use of positive and simple language was repeatedly remarked on as being successfully shown across all focus groups:

> *I like how it is about knowing strengths.* [Pasifika focus group, P6]

Although some changes still such as the following needed to be made:

> *Some words are more researchy, like - Fallacy - wouldn't be understood by most. Use a simple way to say this.* [Māori focus group, P1]

> *Maybe instead of looking at what are you spending, it could be, umm, learning to save?* [Young adult focus group, P2]

The range of notification message examples was presented as suggested in the first focus groups as an additional way to provide support and insights to a user as they progressed through activities in the app. These were positively remarked upon, and the young adult groups suggested that a mix of notifications and pop-ups would be more appealing than a single modality. The motivating and encouraging message examples "hit the spot," said a young adult participant. All groups liked the notifications that prompted people to use the app, and many felt that this functionality would help with engagement and retention.

Ability to Share Insights and Progress With Others

The participants suggested that the app could share progress or success with others. This type of networking system was suggested as a positive method for users to encourage each other, share tips and strategies, and provide a sense of *not being alone*. This feature is technically complex, and as such, the solution presented to the groups was that sharing would be limited to those within the study. Feedback from all 3 groups indicated that they would have liked to connect with others beyond the study, as these broader social connections were important.

Tracking My Progress

Being able to track progress appealed to participants in focus group cycle 1. In total, 2 examples were presented as a way to represent progress. These were progress bars under the modules and the emergence of footprints on each module's home screen. The progress bars were identified as the best across all groups, primarily because they were used in other apps and as such, were familiar and easy to understand.

In several instances, participants in the Pasifika group indicated that the app should be able to track the amount of money spent on gambling, money saved from not gambling, and how much time they had or had not spent gambling. Various ideas have been suggested for presenting this in the app. The design that resonated across all groups was one in which the time and money recorded as spent gambling was converted into other activities; for example, the number of dinners with family or friends or movies went to with friends.

Use Images and Multimedia

The app interface needed to be engaging and attractive to all the participants. The young adult group remarked that if the app looked unattractive at the start, they were unlikely to engage. Updated high-fidelity images were shown to the groups, and the following remark summarizes the generally positive comments made across all the groups:

> *Good background now that there is Pacific/Māori punch to it – waka, marae, native birds. Thanks.* [Māori focus group, P11]

Regarding the inclusion of multimedia, feedback was mixed, with participants in the Māori and Pasifika groups liking that short videos from real gamblers were part of the app. The young adults group participants were less enthusiastic, but they liked the cartoon animation videos than those with real people. Having different video styles was seen as a good option.

Overwhelmingly, all participants were concerned that having these videos in the app might affect the ability to download the app, that is, too large or that it would take up too much of their phone's storage, slowing down their phone or stopping other functionality. Hearing that the videos would not be embedded within the app but would be stored externally and linked to YouTube generated positive remarks.

Connect With Treatment Services

The participants in all groups agreed that connecting to a professional or treatment provider through the app would be

advantageous. Participants were shown the services feature and interactive function that presented services by geography (map). List-based search options (Figure 8) were good options as illustrated by the following comments:

> *This feature is perfect, it allows users to look for help without needing to know the name or address of the place.* [Pasifika focus group, P7]

> *The app helps to find a service of your choice if you want to, it's neat.* [Young adult group, P1]

The link to the gambling helpline chat function was highlighted. A participant in the Pasifika focus group commented that "this is like a rescue button. There if you need it." Overall, the ability to access other help (not just the app) was reinforced as a core feature of Manaaki.

Figure 8. Image of the map search feature.

Work Offline

The ability of the app to be accessible offline and not require a Wi-Fi connection at all times was expressed by several participants across all groups:

> *Use will be restricted cause most people do not have data on their phones nor will they spend money [on data] just to use the app. So it is good that you can do stuff that don't need to connect. It's a critical thing, for us.* [Young adult focus group]

Confirming the Final Functions and Features for Manaaki

At the conclusion of the second focus group session, participants confirmed that the core desired features and functions were clearly identified and reflected their insights and experiences. The constant across all groups was that Manaaki would appeal to and be helpful to people seeking help for gambling-related problems. This is illustrated by the following conversation in the Māori focus group:

> *Wow, this is really going to be great for people.* [M1]

> *Yeah, we are awesome aye!* [M2]

> *Yeah, I can't wait to see it all done.* [M1]

> *I am gonna tell people about it, man.* [M3]

> *Ka pai, whānau [well done].* [M4]

Confirming the Final Design Features and Functions Against the Conceptual Framework

The final action undertaken by the research team was to appraise the functions, features, and attributes within the underpinning conceptual framework. Table 2 presents the process outcomes.

Table 2. Confirming the final attributes to be included in Manaaki with associated conceptual frameworks.

Attributes and conceptual framework	Use case examples	Final features and functions for Manaaki
Personalization—developing self-awareness and insight [50-52]	- To be able to add my comments on things that are working well - Put reminders in - To encourage retention, create a longitudinal experience or history as it makes it difficult to stop interacting with the app and difficult to delete - Show where I have come from so it is useful to me - Can add other information that is important to me	- Personal journal that auto-adds from modules plus can add information independently - Shared forum feature that links others in the study (opt-in) - Each module has a progress bar - Videos of people like me within modules and in resources - Use of other languages to help convey complex terms or concepts. Te Reo Māori and Pasifika languages used where relevant - Use of avatars or ability to add own photo
Internal support progress—activating personal strengths and resources and enhancing belief for successful change [54,55]	- To add or interact within the app and receive unanticipated rewards or appreciation that help reinforce behavior - Having information in smaller sections and showing easy actions to promote a sense of capability and then skill development - Messages that pop up that are positive and keep me motivated - Real-time notification messages to reinforce activities and help to interpret or reinforce the activity	- Informative and timely messages and notifications created - Action prompts to complete a topic or module - Instant feedback is given when an activity completed; that is, summary of what the outcomes of an activity are - Assessments can be repeated with scores showing past and current outcomes and an interpretation to help understanding - Able to post specific activities into a journal
External support—relapse prevention [56]	- Can quickly find other help - Resources provided	- Webchat link to national gambling helpline - Additional services section includes links to treatment services - Links to external resources and tools (such as budgeting tools)
Literacy tools—activating personal strengths and resources and enhancing belief for successful change [54,55]	- To have new or novel information presented through videos or notifications or links if needed to read more - Attracting the attention of the user is about relevance and supports the usefulness of the app - Supports how to make changes and maintain these	- Resources and additional help and tools section - Audio options to help when literacy is a challenge (only in English) - Links to other resources such as budgeting and web-based gambling blocker tools - Links to trusted resources - Use of animations - Use of the information icons to provide definitions or interpretation for some words
Navigation—literacy	- Being able to see information in a way that is relevant to me and minimizes unhelpful and inappropriate comparisons - Creates achievements and motivations to keep me engaged - Can add other information that is important to me	- Suggestions of where to next depending on outcomes - A range of distraction activities that are relevant to intended users
Engaging—targeting thoughts and feelings and activating behaviors [53]	- Has a good look and feel - Looks engaging - Tells a story that I can identify with	- Use of New Zealand imagery - Tui guide that provides an explanation of the purpose of each module - Animations
Secure and simple	- It needs to be secure and private - Easy to download - I do not want to be online all the time to use it	- Registration and log-in simple with clear direction - App size low and cater to the lowest operating system as possible - The main elements within the app can be used offline

Discussion

Principal Findings

This paper describes in detail the development of Manaaki, a CBT mobile app intervention designed to support reduction in gambling-related harm. The blending of theory, domain expert input with end-user insights, and lived experience in a collaborative approach is effective for designing mHealth applications [31,36,57]. Creating a visual identity for the new Manaaki app, which resonates with end users, was an important step in establishing and reflecting a sense of trust, connection, and value with the overall intent and purpose of the intervention. To the best of our knowledge, this study is the first to adapt an evidence- and CBT-based program for people experiencing gambling problems into an app-delivered program using a cocreation process with end users.

The demand for mHealth tools that provide interventions (behavior change and cognitive therapy) and generalized support directly to individuals is growing [58-60]. The opportunity to provide interventions for population groups who are unable or unwilling to access more traditional forms is substantial [61,62].

The value of presenting best-practice approaches and evidence in understandable ways (posters, images, and Adobe XD) and cocreating with end users on how they can help translate it into the app's look and feel was an important process for creating a sense of ownership and investment across all aspects of the content, features, function, and format of the final Manaaki app. The use of draft designs and real-time modifiable design flows enabled end-user participants to discuss and identify attributes to be included in the app that would resonate with them. Among the focus group sessions, the research team was able to explore the findings through a theoretical lens, convert the concepts into app designs, and then represent them in ways that were easily understood. Concepts such as personalization were presented using the app user's name and included the creation of a personal avatar. The concept of engagement was reflected in background designs depicting a journey, animation of tools, use of the Tui, and audio features. Empowerment was demonstrated with progress bars, shared forums, self-assessment, and notifications.

Similarly, the content presented back to the participants was adapted and personalized to reflect within-app responses. To support health literacy, words such as fallacy and recovery continued to be used but with the information icon next to them to help participants understand and interpret these terms. In some cases, words and concepts were converted to Reo Māori (the Māori language).

The importance of positively framed and strength-based content was vital. The inclusion of audio files and information icons again elicited positive participant remarks about the app being relevant and appropriate to them. Similar findings are reported elsewhere [63]. The unanticipated prompts (notifications) that support actionable recommendations or app navigation suggestions are tools used in other domains and jurisdictions, such as marketing for supporting retention and motivation [64].

Research on addiction recovery has reported the importance of conveying a sense of social connectedness [65]. The end-user participants in this study also mentioned this, and the inclusion of features such as the webchat, forum, and visibility of services were seen as adding a layer of connection and support within the digital modality.

Adopting learning from the marketing discipline [66] and creating the naming and visual identity for Manaaki (ie, brand) that resonated with participants was essential in establishing and reflecting on them a sense of ownership, trust, connection, and value.

Finally, the attributes of information security, data use, accessibility (ie, available to older mobile phone operating systems), and offline capability were noted as part of the overall app usability discussions; however, they did not overshadow the key aim of the process.

Limitations

Owing to the nature of the research methodology of focus groups, this study also comprises some biased and motivated responses as described in other research using focus groups [67,68]. Nonetheless, our participants were a subset of the target group that focused on the intervention app. The lived experiences of the participants flavored all discussions and decisions and were woven within the final application. Although it may not be possible to suggest that the process and outcome may not adequately represent the wider population of people who experience harm from gambling, it is more likely to resonate than an intervention that does not include any end users [69,70]. Adding a final step in which a small cohort of end users actively used the final app prototype before initiating the clinical trial was not possible in this study because of the overall project timeframe. This step can offer insights that initial design processes cannot anticipate and as such, provide an opportunity to refine the final product by applying active use insights before release, further enhancing the potential for effectiveness.

Conclusions

The importance of domain expert input and evidence-based content combined with end-user insights and involvement should not be undervalued. Weaving these strands and following an iterative process, the research team, with the participants, produced an app that was intentionally tailored to the functional needs of individuals seeking to reduce gambling harm. This process gave the second phase of this study, a randomized waitlist control study to test the effectiveness of Manaaki—a CBT mHealth intervention—the best chance of demonstrating effectiveness. Although adopting this approach does not guarantee success, it is more likely to provide evidence of fidelity to the outcomes of the intervention. Manaaki is currently being trialed using a pragmatic randomized controlled trial with a waitlist control design [43]. This trial was completed in August 2021 and analyses are underway.

Authors' Contributions

GH and CB conceived and wrote the full study grant, which included the cocreation phase and a randomized control trial. JTC, ND, SM, SR, DN, EH, and VN provided expert input for both studies. ND, SM, and SR provided the original GamblingLess content. ND and SM modified the content into 6 modules based on the findings of the GamblingLess study. GH adapted the content to the Manaaki app.

GH designed the cocreation study methodology with inputs from CB, JTC, SEP, and RRC. GH wrote the first draft of this manuscript, and JTC provided the first revisions. All authors reviewed and edited the manuscript. All authors approved the final manuscript.

Abstract

Background: Medications for the treatment of opioid use disorder, such as buprenorphine, are effective and essential for addressing the opioid epidemic. However, high dropout rates from medication remain a challenge. Behavioral treatment with contingency management and cognitive behavioral counseling has shown promise for improving the outcomes of buprenorphine treatment but is complicated to deliver. The delivery of behavioral treatment through technology-based platforms has the potential to make it more feasible for widespread dissemination.

Objective: reSET-O is a prescription digital therapeutic and a commercial adaptation of the Therapeutic Education System, an internet-based program with a Community Reinforcement Approach to cognitive behavioral therapy. It delivers cognitive behavioral therapy modules and contingency management rewards upon completion of modules and negative urine drug screens. This pilot study aims to assess the feasibility and acceptability of reSET-O in a community-based opioid treatment program with a Hub and Spoke model of care as part of a larger strategy to maintain individuals in treatment. Objective and qualitative results, as well as acceptability and likeability of reSET-O, were obtained from 15 individuals.

Methods: English-speaking individuals aged ≥18 years with a diagnosis of current opioid use disorder were recruited after being on buprenorphine for at least 1 week of treatment. Two 12-week prescriptions for reSET-O were written for the 24-week study. Patient reports of drug use and likeability scales of reSET-O were conducted at weeks 4, 8, 12, and 24 of the study. Qualitative interviews were also conducted. A total of 4 providers were recruited and provided feedback on the acceptability and feasibility of reSET-O.

Results: Of the 15 participants who participated in this pilot study, 7 (47%) completed 24 weeks, and 8 (53%) were unable to complete because of dropout after enrollment, attrition in treatment, or incarceration. An average of US $96 in contingency management rewards were earned by participants for the completion of modules for the duration of the pilot study. Participants' subjective feedback revealed that reSET-O was easy to use, enjoyable, and helped provide a safe space to admit recurring substance use.

Conclusions: reSET-O was well accepted based on patient and provider feedback in this pilot study; however, adherence and retention in treatment remain areas for improvement. Randomized control trials are needed to assess whether retention of community-based buprenorphine treatment is enhanced through the use of technology-based behavioral interventions such as reSET-O.

Introduction

The opioid epidemic has spread rapidly over the past decade, reaching virtually every region of the United States. Approximately 2.4 million Americans are currently addicted to opioids, and the prognosis is poor; if left untreated, the risk of death from opioid overdose is high [1]. Although different types of medications for opioid use disorder (MOUDs), such as buprenorphine–naloxone, buprenorphine, methadone, and extended-release naltrexone, may be remarkably effective if patients adhere to treatment, adherence to treatment remains challenging [2]. Retention rates in treatment range from 10% to 60%, depending on the medication type [3-14]. In addition to the challenges in adherence, challenges in accessing MOUD present an obstacle not easily surmounted. Methadone can only be dispensed under special regulations that are burdensome to patients (eg, daily attendance at a clinic is initially required). Buprenorphine, available by prescription from any licensed physician who, up until recently, has completed an 8-hour waiver training, has struggled to penetrate primary medical care settings. The supply of physicians, nurse practitioners, and physician assistants prescribing buprenorphine remains limited, and the use of a buprenorphine waiver to the maximum extent of allowed patients is underused [15]. A combination of universally available MOUD along with strategies to combat MOUD treatment attrition and adherence is critical to combat the opioid epidemic.

A key systemic barrier that has been identified is the lack of access to behavioral intervention and counseling to accompany MOUD prescribing [16-18]. Behavioral interventions have the potential to address poor adherence to medication. The provision of counseling is a regulatory requirement for methadone, buprenorphine, and buprenorphine–naloxone treatment. Furthermore, evidence suggests that counseling and behavioral treatments improve the adherence to and effectiveness of MOUD [19], particularly with contingency management (CM) approaches [20-22]. Primary care practices and other clinical settings that are new to addiction treatment typically lack staff with expertise in relevant behavioral treatments, and this gap in care contributes to a reluctance to treat patients with opioid use disorder (OUD) in this setting [16]. Even specialty addiction treatment programs may struggle to deliver more than rudimentary counseling because of time constraints and a lack of expertise in the latest evidence-based interventions. Different models of care have been implemented to address this with success. Vermont established a Hub and Spoke system [23] meant to provide support for practices that may have had barriers to successful outcomes. In this system, the *hub* acts as the specialty treatment center, initiating or escalating OUD medication treatment quickly with the ability to provide the most intense care, including MOUD and therapy, whereas *spoke* sites are primary care practices that may continue patient MOUD after stabilization. Penn State Health partnered with an opioid treatment program (OTP) at the Pennsylvania Psychiatric Institute to use State-Targeted Response funds to establish a Hub and Spoke program [24]. This has allowed for the coordinated care and expansion of MOUDs based in Harrisburg, Pennsylvania, and surrounding counties, including rural regions in south-central Pennsylvania.

Despite the implementation of Hub and Spoke systems, challenges related to behavioral interventions persist, including limited counselor capacities at *hub* sites and potentially no counseling services at *spoke* sites. Mobile apps that deliver behavioral interventions may be beneficial to OUD treatment, helping to fill the gap in the provision of behavioral interventions [25,26]. reSET-O, generated by Pear Therapeutics, Inc, is a comprehensive cognitive behavioral treatment delivered through a mobile phone–based app, with an evidence base suggesting that it can improve the adherence and outcome of MOUD treatment for OUD compared with standard counseling alone [27]. reSET-O is derived from the Therapeutic Education System (TES), developed by academic investigators as a web-based tool delivered by interacting with a computer, delivering a combination of CM—modest monetary or nonmonetary rewards for completion of therapy modules and producing negative drug urine—with cognitive behavioral counseling based on the Community Reinforcement Approach (CRA). reSET-O is a commercial version of TES, adapted for marketing and widespread use, and is delivered as a mobile-based app. reSET-O is available through prescription, and the cost is intended to be covered by insurance. Importantly, the cost of contingent rewards is built into the third-party reimbursement.

CM has been well-established as effective for the treatment of substance use disorders (SUDs) [20,28]; however, funding for incentive rewards has been almost exclusively provided by research grants. The problem of how to fund contingent rewards has stymied the application of CMs in real-world treatment. Thus, the fact that reSET-O can fund incentives by bundling costs into third-party payments is an important advancement. Cognitive behavioral counseling delivered by reSET-O is modeled after the CRA, focusing on cognitive behavioral strategies to achieve abstinence from drugs and build a healthy lifestyle. As approved by the Penn State Health College of Medicine institutional review board, this study piloted the feasibility and acceptability of reSET-O in conjunction with buprenorphine management to (1) assess how individuals in treatment in this Hub and Spoke clinic would interact with this novel intervention and (2) inform future, larger controlled trials using reSET-O.

Methods

Overview

An uncontrolled, 24-week pilot feasibility and acceptability study that added reSET-O to standard care for patients with OUD initiating buprenorphine in an OTP and serving as the hub in a Hub and Spoke system was conducted. The *hub* provides both methadone and buprenorphine treatment in an outpatient clinic specializing in medication treatment for OUDs.

reSET-O was prescribed for a 12-week period and was then renewed for a second 12 weeks for each participant to reach a total prescription duration of 24 weeks. English-speaking individuals aged ≥18 years who were on buprenorphine treatment for at least 1 week were eligible to participate and enroll in the pilot study.

reSET-O is a commercially available prescription digital therapeutic that delivers interactive, self-paced psychoeducational therapeutic modules regarding substance use and is based on the TES. TES is a web-based program that provides written, auditory, and video modules that instill cognitive behavioral skills based on a CRA. The CRA is a therapeutic system that teaches coping skills for staying off drugs and builds skills and activities that are consistent with a healthy lifestyle. The topics of these modules range from managing triggers of substance use and building healthier coping and social skills to HIV prevention and reducing high-risk sexual behavior (see Figure 1 for examples of topics as displayed on the clinician dashboard). Modest monetary rewards (such as gift cards) or nonmonetary rewards are earned for module completion and when negative urine drug screens (USDs) are achieved (see Figure 2 for an example of the reward programming viewed by the participant). With the commercial release of reSET-O, new additions included contingent rewards that may be delivered in the form of gift cards to retail outlets, with the cost covered by third-party insurances. Furthermore, reSET-O prompts daily check-ins, beginning with in-app reports of substance use and cravings, as indicated by the participant (see Figure 3 for an example of endorsed cravings as displayed on the clinician dashboard). Finally, the Patient Services Center, currently referred to as PearConnect, created by Pear Therapeutics, the makers of reSET-O, is a call center that connects patients to a dedicated advocate for support throughout their treatment and prescribers and health care providers to clinician dashboard resources. If a lower activity of reSET-O is detected, Patient Services Center representatives can communicate with patients on a weekly basis to troubleshoot any technical difficulties. reSET-O includes a web-based provider dashboard that permits treatment providers to examine participation and patient engagement remotely (see Figure 4 for an example of a participant snapshot as displayed on the clinician dashboard), as well as facilitate future patient-provider clinic discussions on lessons learned from the modules completed.

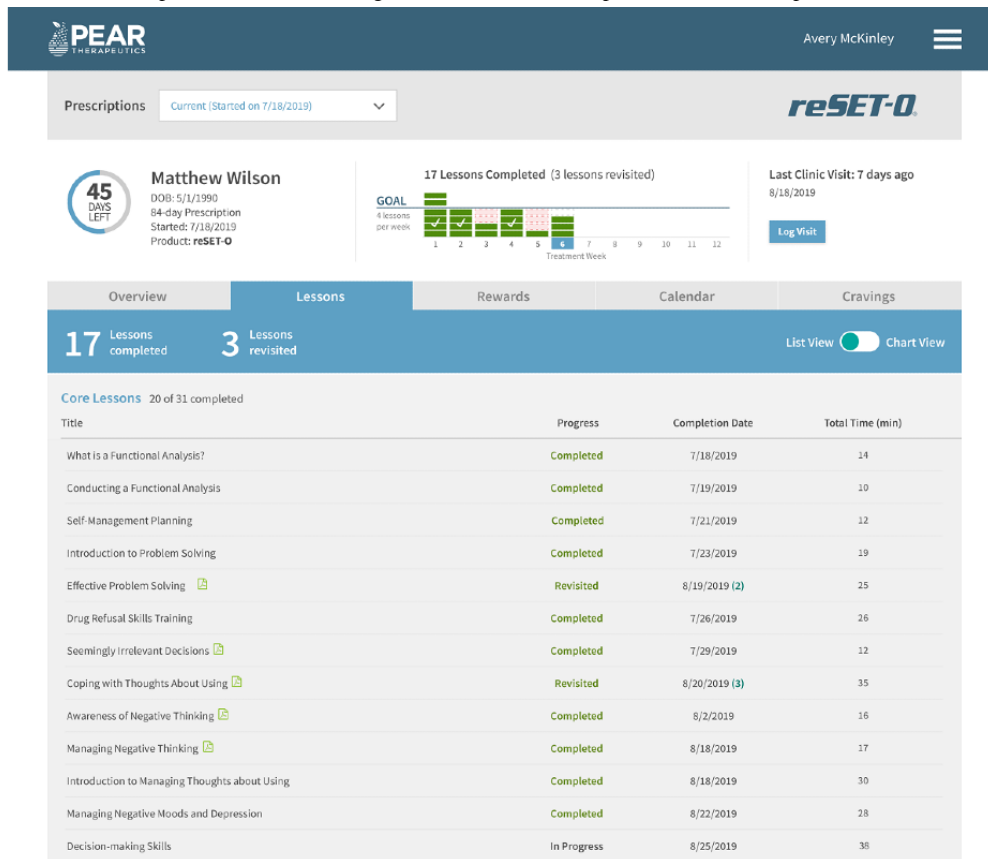
Figure 1. reSET-O clinician dashboard and participant lesson progress. This screenshot is an example of the clinician dashboard while viewing an enrolled participant's progress with reSET-O modules. Note that only some of the reSET-O modules are shown in this screen shot. Provided is the title of the module; whether the module was completed, revisited (eg, completed more than once), in progress, or not completed (not pictured); date of completion; and the total amount of time spent on the module. For modules not completed, the Completion Date and Total Time (min) columns would be blank. Copyright 2022 Pear Therapeutics (US), Inc. All rights reserved. Used with permission. Not real patient data.


Figure 2. reSET-O participant quiz question and reward screens. This is an example of the type of quiz question that a participant could see (right) while using reSET-O, as well as when the participant was eligible and prompted to spin the wheel (left) to earn a reward of either a monetary amount applied to a specified gift card vendor or written reinforcement. Ethics Approval

Institutional review board approval was obtained for this pilot study from Penn State College of Medicine, under study number 9931 on November 27, 2018, and procedures were followed in accordance with the ethical standards of the institutional committee on human experimentation and with the Helsinki Declaration of 1975, as revised in 2000.

Patient Participants

Eligible individuals were aged ≥18 years; able to read, write, and comprehend English; had a diagnosis of OUD, as determined through routine clinical evaluation; initiated treatment at a community-based OTP serving as the *hub* in a Hub and Spoke system of care; and were prescribed buprenorphine for OUD. We excluded any individuals engaging

in outpatient detoxification or needing a higher level of care, such as inpatient or residential treatment, as well as those not desiring MOUD. Individuals were invited to join the pilot study during their medical appointments and consented in the clinic if interested. All participants provided written informed consent.

Procedures

After obtaining participant consent, reSET-O was prescribed to participants for 12 weeks at a time, with a total of 2 prescriptions (24 weeks of consecutive treatment). reSET-O asks participants to log onto the app and complete 4 learning modules per week, each focusing on a particular skill. The modules are presented in a fixed order, beginning with modules on skills to avoid drugs, followed by modules on building a healthy lifestyle and HIV risk reduction. Each completed module yields a chance to earn rewards in the form of gift cards to retail outlets. Participants were evaluated via the self-report of drug use with the Timeline Follow-Back (TLFB) method, USDs, and three mood assessments: the Kessler-10 [29,30], the Posttraumatic Stress Disorder (PTSD) Checklist–Civilian [31-33], and the Patient Health Questionnaire-9 [34]. These evaluations occurred at baseline and at 4, 8, 12, and 24 weeks after study entry. Self-reported drug use was collected using TLFB [35,36] and verified using USDs. Participants were scored as not abstinent at a visit if either a self-report or a USD was positive for opioids. Within the reSET-O, craving assessments were performed throughout the duration of the prescription.

Participant feedback data regarding reSET-O was collected on the Intervention Acceptability Feedback Form (IAFF), evaluating seven characteristics—interest, usefulness, new information learned, ease of understanding, relevancy, satisfaction, and likeability—on a Likert scale of 0 to 9 (0=lowest and 9=highest). The IAFF was completed at each visit after baseline (weeks 4, 8, 12, and 24).

Qualitative interviews with participants were conducted by research assistants between weeks 8 and 12 to capture information from participants about their experience using the app, acceptability of the app, and suggestions for improvement. Approximately 60% (9/15) of the participants completed the interviews. Each participant was asked 9 standard questions (Textbox 1); then, the staff member could ask follow-up and probing questions as needed to elicit additional information. The interviews lasted between 30 and 45 minutes, were digitally audio recorded, and transcribed verbatim for analysis purposes.

A total of 3 research staff members reviewed all 9 interviews, extracting transcribed text relevant and responsive to the domains of satisfaction or dissatisfaction and the likeability of the intervention. Responses to the following research question: "How did participants like using reSET-O?" were categorized into unique themes, which were reviewed and discussed by a larger research team to reach a consensus.

Textbox 1. Qualitative interview questions and examples of follow-up questions.

Tell me how you use technology in your life.

- What other apps do you use regularly?
- How often do you use other apps?
- Where do you get information about health and/or medical questions?

Think about the times you used the reSET-O app.

- At what times during the day did you use the app? How often?
- When did you access the reSET-O app the most?
- Where did you access the reSET-O app?
- How often did you check in with the app between modules?

What interested you about this study?

- Why did you decide to participate in the study?
- How did it fit in with your counseling at the clinic?
- Did you talk about the reSET-O app with other people (friends, family, or other clinic patients)?

How did you like using the reSET-O app?

- Can you give me an example of what you liked about it?
- What did you not like?
- Would you recommend this app to someone? Why or why not?

How useful/relevant to your life was the reSET-O app?

- Which modules were most useful and/or relevant?
- Which were the least useful and/or relevant? Why did those not work for you?
- Did you repeat any of the modules? Which ones? Why?
- Which features of the app were most useful and/or relevant?
- Which features were the least useful and/or relevant? Why did those not work for you?

Is there anything about the reSET-O app that you would change?

- Content?
- Language?
- Videos?
- Examples?
- What type of changes would you make?

What else would you like the reSET-O app to do?

- Give examples of additional features or module topics not currently available.

Were you able to complete all the study tasks up to this point?

- Was there anyone or anything that helped you complete all of the research study tasks up to this point?
- If not, why were you not able to complete all of the study tasks up to this point?
- Was there anyone or anything that helped you complete some of the research study tasks up to this point?
- Was there anything about the research study that kept you from completing all the study tasks?
- Was there anything about using the reSET-O app that made you not want to continue in the study?
- What was the main reason for you to continue in the study?
- Was there anything else about the research study that made you not want to continue?

Were you able to complete all or some of the reSET-O learning modules up to this point?

- Was there anyone or anything that helped you complete all of the learning modules up to this point?

- If not, why were you able to complete all of the learning modules up to this point?

- Was there anyone or anything that helped you complete some of the learning modules up to this point?

- Was there anything about the reSET-O app that kept you from completing all of the learning modules?

- Was there anything about using the reSET-O app that made you not want to continue the learning modules?

- What was the main reason for you to continue using the app (if applicable)?

- Was there anything else about the research study or the app that kept you from completing the reSET-O modules?

Provider Participants

Provider data regarding the acceptability and feasibility of reSET-O were also collected. Clinicians working in the treatment programs were asked to create their own reSET-O accounts and review the learning modules. After 3 weeks of reSET-O use, data from 4 clinical providers were collected through the Weiner Intervention Acceptability, Appropriateness, and Feasibility form (WIAAF; Multimedia Appendix 1), evaluating the acceptability, appropriateness, and feasibility of the app intervention. Each category was assessed through 4 prompts, each using a 5-point Likert scale (1=lowest and 5=highest). The highest score for any given category could be 20. The WIAAF, currently in development, has no cutoff scores for interpretation; however, higher scores indicate greater acceptability, appropriateness, or feasibility.

Results

Overview

Of the 15 participants, 3 (20%) female patient participants and 12 (80%) male patient participants with OUD were enrolled in the study, with an average age of 36.2 (SD 9.3) years (Table 1). Approximately 73% (11/15) of the participants identified as White, whereas 7% (1/15), 13% (2/15), and 7% (1/15) identified as Black or African American, biracial, or other, respectively, and 13% (2/15) identified as Hispanic (Table 1). Of these 15 participants, 2 (13%) withdrew consent after baseline; 3 (20%) participants dropped out of clinical care before week 8 and were unable to be reached, and another 3 (20%) became incarcerated between weeks 12 and 24 during the study. Thus, of the 15 participants, 8 (53%) withdrew and/or were unable to complete the study, and 7 (47%) were able to complete all 24 weeks of the study.

Table 1. Study demographics (N=15).

Characteristics	Baseline (n=15)	Week 4 (n=11)	Week 8[a] (n=10)	Week 24 (n=7)
Age (years), mean (SD)	36.2 (9.3)	37.4 (9.4)	37 (9.1)	41.4 (8.1)
Gender, n (%)				
Male	12 (80)	11 (100)	10 (100)	7 (100)
Female	3 (20)	0 (0)	0 (0)	0 (0)
Race, n (%)				
White	11 (73)	8 (73)	7 (70)	5 (71)
Black or African American	1 (7)	1 (9)	1 (10)	1 (14)
Biracial	2 (13)	2 (18)	2 (20)	1 (14)
Other[b]	1 (7)	0 (0)	0 (0)	0 (0)
Ethnicity, n (%)				
Hispanic	2 (13)	1 (9)	1 (10)	14

[a]At weeks 8 and 12, the same 10 participants remained in the study.

[b]Participants identified as Hispanic only.

Patient Participant Feedback and Outcomes

Clinical Outcomes

Although all 15 participants had current opioid use at the time of entry into the clinic, at the point of entry into the study, 8 (53%) had already achieved abstinence from opioids through outside treatment, whereas 7 (47%) participants reported and tested positive for opioid use. Of the 7 participants who reported and/or tested positive for opioid use at baseline, 1 (14%) endorsed opiate use at weeks 4, 8, and 24, and 3 (43%) endorsed opioid use at week 12 (Table 2). Of the 8 participants who did not report or test positive for opioid use at baseline, none endorsed opioid use at weeks 4, 8, and 24, whereas 1 (13%) endorsed opioid use at week 12 (Table 2). Of the 15 participants, 7 (47%) participants completed the TLFB at all time points; however, 1 (7%) participant had trouble urinating at some

appointments because of other medical conditions. In this case, only TLFB was used to assess abstinence.

Current symptoms of emotional distress were measured using the self-report screening instruments for depression (Patient Health Questionnaire-9), general emotional distress (Kessler-10), and PTSD symptoms (PTSD Checklist–Civilian were collected at all 5 time points. Means and SDs were calculated and are reported in Table 3. Compared with the baseline, the mean scores decreased over time across all measures, although the scores reflected, at most, mild levels of severity from baseline through the follow-ups.

In application, patient-reported and -endorsed cravings and craving triggers were collected throughout the duration of the reSET-O prescriptions and reported as frequency counts (Table 4). Approximately 53% (8/15) of patients reported cravings within reSET-O. Overall, by the end of the trial, there were fewer reports of endorsed cravings and craving triggers when compared with the beginning of the trial; however, 13% (2/15) of participants continued to report cravings and subsequent triggers throughout both of the reSET-O prescriptions.

Table 2. Opioid positive and negative results based on Timeline Follow-Back and urine drug screens (N=15)[a].

Opioid status at baseline	Baseline (n=15)	Week 4 (n=11)	Week 8 (n=10)	Week 12 (n=10)	Week 24 (n=7)
Participants testing *positive* at baseline (positive for opioids), n/N (%)	7/7 (100)	1/4 (25)	1/4 (25)	3/4 (75)	1/1 (100)
Participants testing *negative* at baseline (positive for opioids), n/N (%)	0/8 (0)	0/7 (0)	0/6 (0)	1/6 (17)	0/6 (0)

[a]Patients were scored as negative if both self-report for the past 30 days by Timeline Follow-Back was negative for opioids and urine toxicology was negative for opioids and scored as positive otherwise.

Table 3. Negative mood scores.

Time point	Participants, n (%)	PHQ-9[a,b], mean (SD)	Kessler-10[c], mean (SD)	PCL-C[d,e], mean (SD)
Baseline	15 (100)	10.33 (6.93)	21.66 (10.76)	17 (14.73)
Week 4	11 (73)	6.46 (6.19)	15.86 (11.03)	14.73 (13.23)
Week 8	10 (67)	5.06 (5.49)	14.66 (11.27)	11.86 (10.84)
Week 12	10 (67)	5.93 (5.79)	14 (11.55)	12.6 (11.87)
Week 24	7 (47)	4.53 (5.57)	10.86 (12.22)	11.6 (14.20)

[a]PHQ-9: The Patient Health Questionnaire-9.

[b]Scores range from 0 (minimal) to –27 (severe) depression asking, "over the last 2 weeks, how often have you been bothered by any of the following problems?" Scores in the 5 to 9 range are considered mild severity.

[c]The Kessler-10 Psychological Distress Scale asks participants how they have been feeling over the past 1 month. Scores range from 10 (minimal) to 50 (severe distress).

[d]PCL-C: Posttraumatic Stress Disorder Checklist–Civilian.

[e]The PCL-C asks, "how much have you been bothered by each of the following 20 statements in the past 1 month?" Scores range from 0 to 80, with scores >30 being likely to have a diagnosis of posttraumatic stress disorder.

Table 4. In-app patient-reported triggers to endorsed cravings (n=8 respondents)[a].

Category	Pain	Anger	Other	Tired	Hungry	Lonely	Social pressure
Patients reporting triggers (first 12 weeks), n (%)	3 (38)	3 (38)	5 (63)	5 (63)	2 (25)	6 (75)	0 (0)
Patients reporting triggers (second 12 weeks), n (%)	1 (13)	0 (0)	1 (13)	2 (25)	0 (0)	1 (13)	0 (0)

[a]Each reSET-O check-in featured craving assessment and triggers that induced cravings to use drugs: pain, anger, fatigue, hunger, isolation, and social pressure.

reSET-O Patient Feedback

After the first 12 weeks, 73% (11/15) of participants had accessed reSET-O, with an average lesson completion of 15.7 lessons, ranging from 0 to 36 completed lessons. The rewards earned during this time averaged US $50, ranging from US $5 to US $120. Approximately 33% (5/15) of participants engaged with reSET-O throughout the 24 weeks of the trial. Among these participants, there was an average lesson completion of

15.2 lessons, ranging from 0 to 37 completed lessons, and an average of US $49 rewards earned, ranging from US $0 to US $85.

It should be noted that individuals who completed all 24 weeks of the study completed, on average, 6.2 lessons per week and repeated modules. Those who dropped out before 12 weeks completed an average of 2.5 lessons per week.

XSL•FO

RenderX

Likeability scores, as assessed by the IAFF, are shown in Figure 5. The IAFF comprises 7 categories, including likeability, which was assessed using a Likert scale ranging from 0 to 9. Anchors were generated based on the prompt. For example, for the likeability category, a score of 0 indicated *I do not like it at all*, and a score of 9 indicated *I like it a lot*. With regard to likeability, after 4 weeks of reSET-O use, the average scores ranged between 6 and 8 out of a maximum possible score of 9 across all categories. The overall trend of scores appeared to drop slightly by the end of the 24 weeks, with an average range of 4.9 to 7.1 across all categories (Figure 5).

Qualitative feedback indicated overall reSET-O feasibility and acceptability by participants, as well as suggestions for improvement. The first identified theme was motivation and attitude regarding treatment delivery (eg, delivery similar to a provider appointment). Participant 3 illuminated this theme stating the following:

> *I also like that the app [reSET-O®] is more personal, I feel like I can be open and honest because it's a person but not a person. I feel like I can say things or endorse things in the app [reSET-O®] that I normally wouldn't say or want to talk about in a group setting* [participant 3, male, 45 years]

The second identified theme was relevancy (eg, content relevant to personal use or life). Participant 9 expressed the following:

> *time management and anxiety. I think there was one on depression and anxiety stuff like that, relates to me* [participant 9, male, 30 years]

The third theme was app features (eg, ease of use). Participant 11 stated the following:

> *the general app [reSET-O®], you know, the bones of it are good, you know. It takes you where you need to be, and it's very easy to use.* [participant 11, male, 40 years]

The last theme was the impact on knowledge, skills, and behavior (eg, module content). Participant 8 expressed the following:

> *People that actually want to stay clean, it [reSET-O®] actually gives you different information that you never knew.* [participant 8, male, 30 years]

Many participants reported liking the rewards earned, the novelty of the treatment, and its similarity to provider treatments. Some participants found the content relevant to their own situations, and most felt that reSET-O was very easy to use. Additional analyses demonstrated that, overall, reSET-O felt personal to participants with relevant content and ease of use.

Areas of improvement were also suggested by participants during the qualitative interviews. Reported problematic areas with reSET-O included varying individual relatability to any module, as noted by a participant that the modules sometimes "felt like a drag," and a burdensomely persistent notification system if a participant did not use the app by an expected time point.

Figure 5. Average participant Intervention Acceptability Feedback Form scores. Participants were asked to rate the reSET-O in each of the 7 categories listed on the x-axis. Overall, the scores fluctuated in the range of 5 to 9 out of a maximum possible score of 9, suggesting moderately good acceptability on all dimensions. Scores appeared to diminish over time, especially during week 24.
reSET-O Provider Feedback

Provider feedback was collected on the WIAAF after 3 weeks of reSET-O use to gauge provider insights on the acceptability, appropriateness, and feasibility of reSET-O; the average score for the acceptability of reSET-O was 13.8 (SD 2.1), whereas appropriateness and feasibility were 12.5 (SD 2.5) and 15.8 (SD 0.5), respectively. Each category was assessed by 4 prompts, which were measured using a Likert scale ranging from 1 (completely disagree) to 5 (completely agree), and these scores were summed for a maximum score of 20. Although the WIAAF does not have established or validated cutoff scores for interpretation, the higher the score, the greater the acceptability, appropriateness, and feasibility. These scores suggest acceptability and feasibility in the good range but are short of the maximum.

Qualitative feedback from providers suggested that providers liked reSET-O and saw its potential as being implemented in a clinical setting. However, areas for improvement were also noted. Some providers indicated that the content and examples felt as though they were written by someone who had not experienced substance use and recovery. For example, providers expressed that some of the language used was not at an appropriate reading level and that the language used was stigmatizing. For instance, the phrase *beating drug addiction* was reported as pejorative, as if substance use was simply something to overcome and move on with one's life as opposed to a chronic illness, for which "life changes and long-term commitment [were] needed to sustain recovery," as quoted by an individual. Providers also indicated that it would be useful to have an alert option within reSET-O to alert a provider or recovery support person when a patient is in an emergency situation, in distress, or in need of support. It was also suggested that when starting a new module, a review of the last completed module should occur before beginning the new module content.

Discussion

Principal Findings

In this preliminary feasibility pilot study among patients undergoing buprenorphine treatment for OUD, reSET-O appeared generally acceptable and feasible, warranting further study. However, there was still a high rate of dropout, and the extent to which patients used the app varied. Some patients used the learning modules and appreciated the cognitive behavioral skills covered, whereas others did not engage. Opioid use was low among patients who remained in the study, although many of these patients had already achieved abstinence at the study baseline. Depression and anxiety symptoms were within the mild range of severity, with trends toward improvement. In addition, across all 24 weeks, the participant IAFF satisfaction ratings were between 5 and 9, out of a total of 9, for the seven assessed areas (interest, usefulness, new information learned, ease of understanding, satisfaction, relevance, and likeability), suggesting a good level of satisfaction. These scores decreased slightly over time for all assessed categories, which may be a reflection of the decay in enthusiasm over time. There was a high rate of dropout from the study, with 91% (10/11) of the patients who initiated reSET-O completing 12 weeks of

reSET-O and 64% (7/11) completing 24 weeks. This is perhaps not surprising, given the general problem of attrition from apps, as well as the high rates of dropout from the treatment characteristics of patients with SUDs. However, this suggests that strategies are needed to improve engagement and retention in treatment with reSET-O.

One such strategy could be more integration between counseling sessions with clinical providers and the therapy modules delivered by the app. reSET-O is largely psychoeducational and didactic in nature. Future studies should invite counselors and medical providers to discuss reSET-O and the topics therein with patients to make the content more relevant and engaging. Clinicians prescribing medication routinely discuss medication adherence, side effects, and whether and how it may be helpful. Similarly, clinicians prescribing reSET-O could ask about what modules the patient has completed, troubleshoot adherence problems, and discuss how the patient is applying the therapy modules delivered by the app in their daily lives. In this way, in-person and mobile treatments can enhance one another to perhaps increase treatment retention. Some patients suggested additional praise or encouragement for reaching certain milestones, such as maintaining a certain number of favorable urines or reaching a specified length of time of sobriety, which could be further facilitated by counselors. A team approach among providers, patients, and reSET-O may better address any problems with adherence, perceived burden, and the relevance of the topics. The integration of remote therapy with in-person treatment might enhance the salience of reSET-O and reduce enthusiasm decay over time.

Second, provider feedback, although encouraging, provided some helpful suggestions on language. On the basis of the WIAAF scores, the feasibility of implementing reSET-O had the highest average score when compared with the other categories. The category with the lowest average score was appropriateness because of the content language. As noted above, some providers felt that the language appeared stigmatizing in some areas or was difficult to understand (eg, reading level). TES was created >15 years ago, and much has changed in the culture and lexicon surrounding SUDs. This presents a challenge in terms of how a digital therapeutic could be adjusted based on the patient population and setting, perhaps based on real-time feedback from local patients and providers, to provide a product that is maximally inviting and relevant. Regarding the scope of services, providers felt that emergency information might be beneficial to the patient. Mobile technology in this arena has been developed through the Addiction–Comprehensive Health Enhancement Support System [28], and perhaps, interapplication communication can broaden the scope to help more patients.

The monetary remuneration for participants was relatively low compared with traditional evidence-based CM programs [20,37]. reSET-O rewards negative USDs and module completions, with the idea that incentives will help patients participate in the therapy modules; thus, internalizing techniques of cognitive behavioral therapy can prevent ongoing drug use and address problems with cravings, mood, and relationships. Traditionally, CM has shown efficacy in rewarding individuals for appointment adherence and negative USDs alone. Moreover,

larger rewards were available in prior grant-funded studies [38,39]. That reSET-O funds incentives through third-party reimbursement is an innovation that overcomes the problem of how to fund incentives and makes CM feasible in community-based practice. However, only modest reward values are possible using this approach. reSET-O, and its forerunner TES, use the *prize bowl* model for low-cost CM developed by Petry [37]. This turns CM into a game where rewards are determined by chance; some are just verbal (eg, *good job*), and most rewards have low monetary value, approximately US $5, with an occasional larger reward value, which keeps the overall costs of contingencies low across treatment episodes.

Limitations

Limitations include that this study was an uncontrolled trial with a small sample size and a high attrition rate. This study is most useful for generating ideas for improving feasibility and acceptability; however, without a control group, it is not possible to evaluate effectiveness. Patients retained in the study were mostly abstinent over the course of the study, and mood ratings were in the mild range of severity, which is encouraging. However, it is not possible to evaluate treatment retention or patients' individual trends in substance use and mood without a larger sample and control condition. The fact that many patients who were abstinent during the study were already abstinent at baseline suggests the importance of covarying for

baseline in future trials. The sample comprised predominantly White men, reflective of the local patient population, affiliated with the one particular clinic in which the study was conducted. The providers did not systematically discuss reSET-O with the enrolled patients during clinical visits. Participants might achieve more therapeutic benefits from reSET-O if it is integrated more into in-person counseling.

Conclusions

Prescription digital therapeutics, such as reSET-O, have the potential to bridge a gap in MOUD, which often prevents potential providers from prescribing these life-saving medications, namely by addressing the need to deliver medication in conjunction with behavioral counseling. For providers who practice without live behavioral counseling on site and within financially stressed clinical programs, a mobile app has the potential to expand a clinic's ability to meet the needs of populations with SUDs. Larger controlled trials are warranted to evaluate whether this intervention improves the adherence to and outcome of MOUD in community-based treatment settings such as the Hub and Spoke model of care in which this pilot study took place. Future work should examine ways that clinicians can integrate the patients' participation in an app such as reSET-O into the counseling of their patients in an effort to improve adherence to the use of the app and maximize its impact as a clinician extender.

Abstract

Background: Black people are disproportionally impacted by hypertension. New approaches for encouraging healthy lifestyles are needed to reduce hypertension and promote health equity in Black communities.

Objective: In this report, we describe the early-stage, virtual design of a just-in-time adaptive intervention (JITAI) to increase physical activity in partnership with members of a low-income, predominantly Black community.

Methods: The hallmark of JITAIs is highly contextualized mobile app push notifications. Thus, understanding participants' context and determinants of physical activity are critical. During the height of the COVID-19 pandemic, we conducted virtual discovery interviews and analysis guided by the Behavior Change Wheel (which focuses on participants' capacity, opportunity, and motivation to engage in physical activity), as well as empathy mapping. We then formed a community-academic participatory design team that partnered in the design sprint, storyboarding, and paper prototyping.

Results: For this study, 5 community members participated in the discovery interviews, 12 stakeholders participated in the empathy mapping, 3 community members represented the community on the design team, and 10 community members provided storyboard or paper prototyping feedback. Only one community member had used videoconferencing prior to partnering with the academic team, and none had design experience. A set of 5 community-academic partner design principles were created: (1) keep users front and center, (2) tailor to the individual, (3) draw on existing motivation, (4) make physical activity feel approachable, and (5) make data collection transparent yet unobtrusive. To address community-specific barriers, the community-academic design team decided that mobile app push notifications will be tailored to participants' baseline mobility level and community resources (eg, local parks and events). Push notifications will also be tailored based on the day (weekday versus weekend), time of day, and weather. Motivation will be enhanced via adaptive goal setting with supportive feedback and social support via community-generated notifications.

Conclusions: We completed early-stage virtual design of a JITAI in partnership with community participants and a community design team with limited design and videoconferencing experience. We found that designing JITAIs with the community enables these interventions to address community-specific needs, which may lead to a more meaningful impact on users' health.

Introduction

Hypertension is the most important modifiable risk factor for cardiovascular disease, the leading cause of mortality in the United States [1,2]. Black Americans have the highest prevalence of hypertension of any racial/ethnic group in the United States, contributing to their disproportionately high burden of cardiovascular disease [3]. Lifestyle modifications, such as increasing physical activity, play an essential role in hypertension management [4,5]. However, about half of Americans do not meet the American Heart Association recommendation of 150 minutes/week of moderate-intensity physical activity [6], and Black Americans engage in less physical activity than White Americans [6-9]. To improve health equity, new approaches to promote healthy lifestyles are needed.

One approach may be just-in-time adaptive interventions (JITAIs, pronounced as "jedis") [10-12]. This novel approach incorporates real-time data streams from wearable devices (eg, Apple Watch, Fitbit) to generate tailored notifications delivered at moments when there is a higher likelihood of their successful adoption. Not surprisingly, JITAIs introduce several design considerations, including the timing, frequency, modality, and presentation of intervention support, along with an understanding of the impact of behavior change strategies such as "provide feedback on performance" and "prompt specific goal setting" [13]. In the myBPmyLife project, as part of the Wearables In Reducing risk and Enhancing Daily Lifestyle (WIRED-L) center, we are designing and adapting a JITAI to increase physical activity and reduce blood pressure that will then be tested in a randomized controlled trial [11].

The myBPmyLife JITAI is based on a JITAI designed and tested among a predominantly White population [11]. To ensure that JITAI design is inclusive of a low-income, predominantly Black community, we undertook a community-based participatory design approach [14,15]. This paper describes our virtual, early-stage, community participatory approach, as necessitated by the COVID-19 pandemic, grounded in health behavior theory, to adapt a physical activity JITAI to be community-inclusive.

Methods

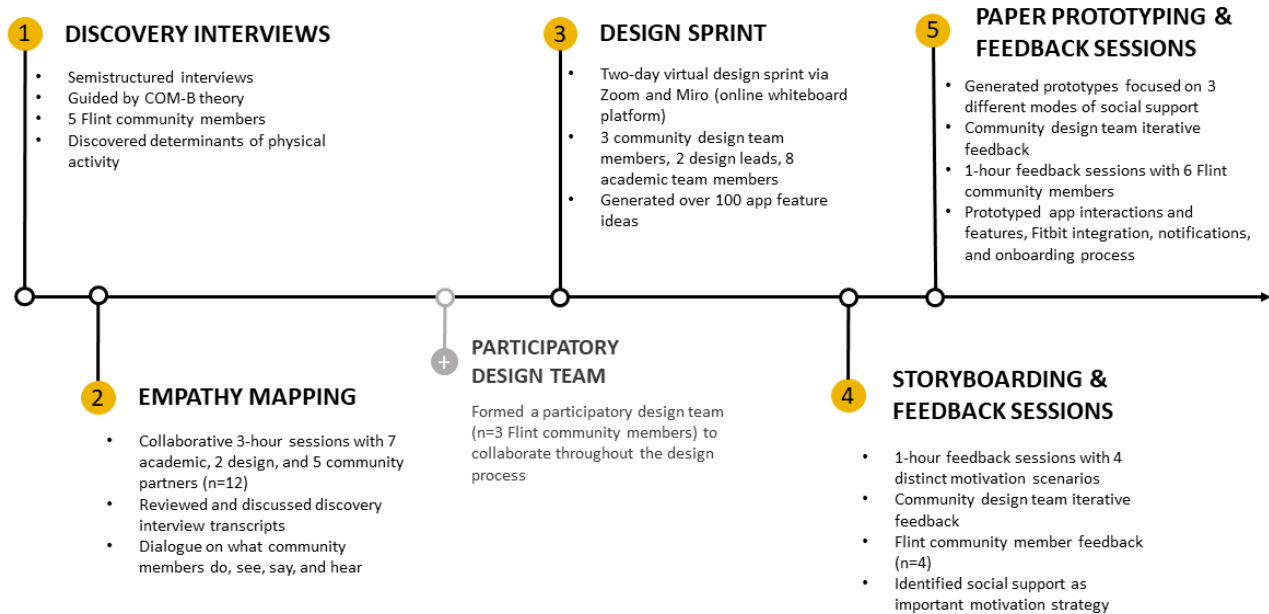
Community-Based Participatory Design Approach

Flint, Michigan, has a population of 95,358 people: 54% are Black people, and 12% of adults have a bachelor's degree or higher [16]. About 40% of Flint residents self-report hypertension [17]. Furthermore, Flint is recovering from a lead crisis, which may be associated with the development of hypertension [18,19].

Our work in Flint is based on an established community-academic partnership focused on addressing racial disparities in cardiovascular disease, which has been in place for over a decade [20]. The principal community-partner organization is Bridges into the Future, a grassroots community organization dedicated to the health and well-being of the Flint community. The principal academic partner organization is the University of Michigan-Ann Arbor, with support from the University of Michigan-Flint. Before starting the design phase, the myBPmyLife project underwent review and received approval from the Flint Community Ethics Review Board (HUM00181363) [21]. Bridges into the Future led recruitment for discovery interviews and empathy mapping. This involved identifying possible participants with a smartphone or computer access, a willingness to use videoconferencing, and initial interest. Contact information was then provided to the academic team, who obtained consent and delivered videoconferencing training. The community design team was composed of the director of Bridges into the Future (SB) as well as 2 other community members recruited by Bridges into the Future to provide a wider view of the community. The director of Bridges into the Future (SB) and one of the academic partners (LES) led the community advisory board, which consists of representatives from the Flint medical community, including Hamilton Health Center, the largest Federally Qualified Health Center in Flint, and the community-based organization partners. The community partners and community advisory board will continue to partner in designing the app and trial and will lead community dissemination of the results.

Design Process Overview and Formation of Community Design Team

Our early-stage design consisted of five components: (1) discovery interviews, (2) empathy mapping, (3) design sprint, (4) storyboarding, and (5) paper prototyping (Figure 1). Only one of the community participants had used videoconferencing prior to the discovery interviews or empathy mapping. After completion of empathy mapping, the academic and community partners determined that technology was a barrier to creativity and innovation. Thus, we formed a community participatory design team, whose members underwent more intensive training on the use of Zoom, a videoconferencing platform, and intensive training with Miro, a virtual collaborative whiteboard platform. Miro and Zoom were selected based on their ease of use and compatibility with phones. We then moved to design sprints, storyboarding, and paper prototyping. The community design team consisted of three Black women aged 32-72 years who provided near real-time, longitudinal feedback.

Figure 1. Discovery and design. COM-B: Capability, Opportunity, and Motivation.


Discovery Interviews

We conducted virtual semistructured interviews with Flint adults with hypertension from July to August 2020. The community partners identified individuals interested in the study. The academic team then consented eligible participants and conducted an individualized training session on using the Health Insurance Portability and Accountability Act–approved videoconferencing service Zoom. Our interview guide was based on the Capability, Opportunity, and Motivation (COM-B) model. The Behavior Change Wheel (BCW), which synthesizes 19 established frameworks of behavior change, posits that for individuals' behaviors to change, they must have the capability, opportunity, and motivation to enact the behavior. The findings from the COM-B–guided interviews were then mapped to the BCW framework to identify candidate behavior change strategies. We also queried participants about smartphone and wearable device usage. All interviews were conducted via Zoom by a primary interviewer and were recorded and transcribed. For analysis, we used a direct content analysis with coding into the COM-B framework [22].

Empathy Mapping

A collaborative 3-hour empathy mapping session was held with academic partners, designers, and community members who participated in the discovery interviews to contextualize the discovery interviews and gain a collective understanding of end user needs. Empathy mapping allows researchers and designers to hear and understand the end user's struggles and frustrations firsthand and in their own words [23]. Before the session, participants were assigned two transcripts to review, each from the discovery interviews. During the videoconferencing session, participants were asked a series of questions and were instructed to reflect on their perceptions and understanding of the reviewed transcripts. The questions included the following:

1. What does the interview participant think and feel?
2. What does the interview participant see?
3. What does the interview participant hear?
4. What does the interview participant do?
5. What does the interview participant say?

These data were added to the qualitative coding results to enable a deeper understanding of the data.

Design Sprint

Design sprints are typically conducted in person to move from empathy generation to the intervention design phase [24]. The design sprint aimed to generate as many diverse and creative ideas as possible for a physical activity intervention in the Flint community. Unlike traditional in-person design sprints, we used videoconferencing with Zoom and Miro. Before the first session, a 60- to 90-minute individual training session was conducted with community participants, often with in-home support from a family member or friend on using Zoom and Miro. Facilitators provided additional real-time tech support during the design sessions. Despite these efforts, real-time workarounds, including email and text, were still needed during the design sprint.

The first day of the design sprint was dedicated to the following: (1) identifying the primary challenges to physical activity and (2) developing problem-solving statements. After a short icebreaker, talks were delivered by a digital technology expert (on mobile technology), a physical activity behavior change expert, a research assistant (on the process of data collection), and a leader from the Flint community. Participants were then asked to create "How Might We" statements to launch brainstorming sessions.

The second day was focused on brainstorming and discussing mobile app features that would address the identified challenges. It began with a Lightning Demos activity [24]. Lightning Demos are a preliminary design exercise by which individuals identify and present 2-3 product and service inspirations prior to concept sketching. For the concept sketching portion of the design sprint, we elected to use three exercises: (1) Notes, (2) Ideas, and (3) Crazy Eights. For exercise 1 (Notes), the primary goal was to

XSL•FO
RenderX

note concepts and problems we previously discussed and established. During exercise 2 (Ideas), participants were given 15 minutes to elaborate on the ideas. Participants were encouraged to creatively doodle, write sample text headlines, and sketch diagrams, cartoons, and stick figures. The messaging provided was "the crazier the idea, the better!" For the final portion of the brainstorming activity, we used the Crazy Eights exercise, asking participants to create 8 distinct ideas in 8 minutes [24]. Participants then synthesized their ideas into one final concept, which they shared with the group. We discussed the concepts as a group and then voted on the ones we thought would form the core intervention. Following the design sprint, the design team categorized all sketches and notes using Evernote, a digital note organizing tool.

Storyboarding and Paper Prototyping

The design team used the information generated during the sprint to create storyboards. These storyboards were presented iteratively to our community design team and then during 4 videoconferencing feedback sessions with Flint community members. Community participant identification, recruitment, and videoconferencing training mirrored that of the discovery interviews. During each session, community design team members were shown the 4 storyboards sequentially. Participants were asked for their reactions—specifically, which parts of the storyboard resonated for them and which elements warranted change or were missing. Design team members were present for all sessions, which were conducted virtually and recorded. After each storyboard was discussed, participants were asked to rank them based on the likelihood of use. The highest-rated storyboards guided the design and development

of the paper prototypes. A critical insight from storyboard feedback was the importance of social interaction, which we then represented in different forms through paper prototypes of the JITAI. Feedback on the paper prototypes was gathered over videoconferencing iteratively from the community design team and then from 6 community participants.

Results

Our findings are categorized into two main domains: (1) user needs discovery and (2) design.

User Needs Discovery

We conducted 5 discovery interviews and 14 stakeholders (7 academic partners, 5 community members, 2 design team members) participated in an empathy mapping session to further contextualize these findings. Guided by the direct content coding using the COM-B framework and enhanced by empathy mapping, we identified unique community physical activity determinants. Physical capability, often due to more chronic physical impairments, was a barrier to physical activity, as was physical opportunity (eg, access to places for older adults to exercise, gym membership costs, and personal safety). Participants reported a desire to exercise more (reflective motivation). On the other hand, automatic motivation (ie, impulses) was a challenge, with community members lamenting how challenging it can be to adhere to a physical activity plan and feeling discouraged by their failure to adhere. These findings were then linked to the BCW to identify behavior change strategies to address the identified barriers and enhance facilitators (Table 1).

Table 1. Results from discovery interviews and empathy mapping mapped to behavior change techniques through the Behavior Change Wheel.

Theme	Exemplar quotes	Selected intervention functions	Behavior change technique
Physical capability	• *It limits me, very much so, because sometimes I have to walk with a cane with these issues. There's been time when I've fallen, and because I haven't had any physical therapy, I've not been able to get out and do things, my body sort of feels tightened and locked up* [Participant 6] • *I can't run. I can still walk. My knees are not good like they used to be* [Participant 1]	Training • Enablement	• Instruction on how to perform a behavior (level of physical activity); graded tasks • Action planning; social support
Psychological capability	• *I think you should at least spend 40 minutes to an hour every day, doing something. Every day. Even if you have small things around the house, or like a 10-minute exercise, just something, some type of physical activity every day, I think, is a must.* [Participant 4]	• Enablement	• Social support
Social opportunity	• *Not a lot of physical activity unless we're cleaning the house or something like that because everyone will work in the yard in our household but not a lot.* [Participant 2] • *My daughter wanted to take me [to the track] but she doesn't go too much herself* [Participant 3]	• Enablement	• Social support
Physical opportunity	• *The neighborhood has parks but I don't see anything for seniors. The only things would be the old forest park where you could walk around the park. Other than the rest of the park is surrounded by kids or teenagers. They got basketball courts and play structures for the toddlers but they don't have tracks for the seniors so it's not senior friendly in the neighborhood I live in.* [Participant 1] • *I would love to be able to have a gym membership. But there's only a certain amount of income—I'm on a fixed income. If I was able to afford it, I certainly would love to be able to…But everything is so expensive, it's difficult.* [Participant 6]	• Environmental restructuring • Enablement	• Prompts/cues; restructure physical environment (or make aware of options) • Goal setting
Reflective motivation	• *I believe that it is very important. For one, as you get older, things kind of lock up. You want to keep those things loose* [Participant 4]	• Persuasion	• Credible source
Automatic motivation	• *It was easy for me then because I was slim but then I got my stroke and my balance and I couldn't do things and I was sitting home all the time and gained 100 pounds ever since and have struggled ever since* [Participant 3] • *I had a good regimen going and I was doing really good. Then I had to go to the nursing home and hospice more. Then my son went to the rehab center. I wore myself down to the point where it was easier to come home, sit in the couch, and watch NBC and just be snacking.* [Participant 2]	• Persuasion • Incentivization • Environmental restructuring • Enablement	• Credible source • Audit and feedback • Prompts/cues • Goal setting, self-talk

Participants primarily used their smartphones for email and text messages, followed by scheduling, receiving news and weather information, taking and storing photos, and using social media (eg, Facebook). None of the participants reported using wearable technology.

Design

The design sprint was facilitated by two members of the design team and attended by 8 academic team members, 2 design team members, and the 3 community design team members. The design exercises yielded approximately 100 app features. Each feature was analyzed as an artifact and tagged into a categorical theme by the design team. Overall, 204 total tags were categorized into 55 themes. The most common tags were motivation (n=22), options (n=13), personalization (n=13), social connection (n=13), and social motivation (n=13). Five design principles emerged from the design sprint and these guided the remainder of the design process (Textbox 1).

XSL•FO
RenderX

Textbox 1. Design principles generated by the community-academic partnership.

1. Keep the user front and center (users first, then researchers, then technologists).

2. Tailor to the individual (customize features to individual users depending on physical and environmental barriers, as well as personal preferences).

3. Draw on existing motivation (connect activities with the user's existing motivation, such as social connections or personal goals).

4. Make physical activity feel approachable (broaden the definition of "exercise" or "physical activity" to simply "moving one's body" in daily life).

5. Make data collection transparent yet unobtrusive for the user (make it clear to the user what data are being collected, and ensure the data are gathered in a minimally intrusive manner).

Based on our user needs discovery and design sprint results, we focused on motivation. Motivational strategies including gamification, social interaction, education, and emotional support were incorporated into storyboards. Overall, the idea of social interaction as part of their physical activity journey most resonated with the community design team and community participants. The concept of social interaction was then broken down into 3 main concepts for paper prototypes. The first prototype was a 1:1 interaction with an accountability buddy. The second prototype focused on developing teams of people who would challenge each other. The final prototype was community-focused and included participant-facing community statistics and community-gathered suggestions. There were mixed opinions on the "accountability buddy" feature, with one participant asking "what if you don't have anybody?" Two participants noted it might be challenging to create a group of people who have similar availabilities. Lastly, participants viewed the community-focused feature positively, although there was concern about the interpretation of statistics. All were in favor of community-gathered suggestions.

Design Implications

Tailored notifications are the foundation of JITAIs. Our first major design decision was to tailor push notifications to participants' respective communities (Table 2). Second, we identified wide variation in physical capability, necessitating tailoring to a participant's functional capacity. For example,

participants with joint pain will be encouraged to engage in shorter, more frequent bursts of physical activity. One behavior change technique to increase automatic motivation is prompts/cues. However, the prompts/cues must be contextualized and, as such, we will tailor push notifications based on day (weekday versus weekend), time of day, and weather. We will enhance reflective and automatic motivation as well as social opportunity and psychological capability by creating a bank of community-generated push notifications to promote social support and app engagement. Community-generated notifications will infuse community voices into the intervention, leading to enhanced authenticity and relatability. Finally, we will acknowledge and support participants when they do not meet their goals through support and adaptive goal setting of steps [25]. Participants will be assigned a weekly task to review their progress over the previous 7 days and select a daily step goal for the upcoming week. The system will automatically suggest a step goal and allow the user to modify the proposed goal within a specified range before accepting it. The notifications will be celebrative when participants reach their goals and support them when they do not reach their goals [26]. During the trial, all participants will be given a wearable. To assess engagement with the push notifications, we will assess the change in step count in the 60 minutes following the push notification. In the intervention, participants will receive daily messages across 4 time periods.

Table 2. Results of community-based participatory design approach to just-in-time adaptive interventions.

Overall findings from community design	Just-in-time adaptive intervention design implications
Physical opportunity is a barrier	Tailor push notifications based on enrollment community
Expanding definition of physical activity (eg, household chores, walking up/down stairs)	Include expanded definition in materials and notifications
Limited physical capability/mobility (eg, pain or multiple comorbidities)	Tailor push notifications to participants' functional capacity
Social support (ie, strong familial and community ties) is a facilitator of physical activity	Community-generated supportive push notifications
High reflective motivation (want to exercise more, but it is hard)	Community-generated supportive push notifications
Automatic motivation is a barrier to physical activity	Contextual tailoring of push notifications based on time, weather, and step count; weekly adaptive step goals; audit and feedback of steps (daily, weekly, monthly)

Discussion

Partnering with community members who had limited experience with videoconferencing, we completed virtual ideation, design sprint, and early prototyping. Virtual

community-based participatory design was facilitated by the creation of a community design team. Our findings highlight that communities have unique needs. Designs that focus on addressing these community-specific barriers and facilitators may increase the efficacy of the JITAIs and ultimately reduce cardiovascular disease disparities.

We initially planned to include the voices of many community stakeholders to understand the breadth of the community experience and capture community innovation. However, the COVID-19 pandemic posed recruitment challenges, as many of our prepandemic recruitment strategies were predicated on in-person interactions with community partners, and there were technological challenges given the lack of videoconferencing experience among nearly all of our participants. After conducting ideation activities over Zoom, we realized that technology was a barrier to creativity. Thus, we created a 2-stage approach to the early design. We initially obtained iterative, near real-time feedback from the community design team, made adaptations, and then shared later prototypes with community users. We found that this 2-stage approach engendered feelings of responsibility among the community design team, increased trust between the community and design team, and optimized the time spent with community participants.

Our community-based participatory design process had several limitations. Our community design team did not include any men, and men were underrepresented among our community participants more generally. Although a community-based participatory research approach to recruitment was successful, other best practices for recruitment, such as face-to-face interaction, were unable to be initiated due to the COVID-19 pandemic [27-29]. Future studies should use strategies that promote the recruitment of men, such as prioritization of men by the study team, including men as part of the recruitment team, and expanding community partners. Of note, a health emergency prohibited our lead male community partner from participating, although women predominantly lead community-based organizations in Flint. Second, we conducted this early phase design during the COVID-19 pandemic. Pandemic stress may have influenced the study findings, although discovery interviews were framed to prompt participants to consider themselves prepandemic. In addition, given the dependence on videoconferencing during the pandemic, community members may be more facile at using this technology now.

We found it was feasible to conduct a virtual, early-stage, community-based participatory design process with participants with limited videoconferencing experience. Initial design prototypes are currently being developed in tandem with a community-generated push notifications bank. Feedback sessions with the community design team and community members will assess our designs in preparation for clinical trial enrollment.

Abstract

Background: Continuous heart rate monitoring via mobile health technologies based on photoplethysmography (PPG) has great potential for the early detection of sustained cardiac arrhythmias such as atrial fibrillation. However, PPG measurements are impaired by motion artifacts.

Objective: The aim of this investigation was to evaluate the analyzability of smartwatch-derived PPG data during everyday life and to determine the relationship between the analyzability of the data and the activity level of the participant.

Methods: A total of 41 (19 female and 22 male) adults in good cardiovascular health (aged 19-79 years) continuously wore a smartwatch equipped with a PPG sensor and a 3D accelerometer (Cardio Watch 287, Corsano Health BV) for a period of 24 hours that represented their individual daily routine. For each participant, smartwatch data were analyzed on a 1-minute basis by an algorithm designed for heart rhythm analysis (Preventicus Heartbeats, Preventicus GmbH). As outcomes, the percentage of analyzable data (PAD) and the mean acceleration (ACC) were calculated. To map changes of the ACC and PAD over the course of one day, the 24-hour period was divided into 8 subintervals comprising 3 hours each.

Results: Univariate analysis of variance showed a large effect ($\eta_p^2 > 0.6$; $P<.001$) of time interval (phase) on the ACC and PAD. The PAD ranged between 34% and 100%, with an average of 71.5% for the whole day, which is equivalent to a period of 17.2 hours. Between midnight and 6 AM, the mean values were the highest for the PAD (>94%) and the lowest for the ACC ($<6\times10^{-3}$ m/s^2). Regardless of the time of the day, the correlation between the PAD and ACC was strong ($r=-0.64$). A linear regression analysis for the averaged data resulted in an almost perfect coefficient of determination ($r^2=0.99$).

Conclusions: This study showed a large relationship between the activity level and the analyzability of smartwatch-derived PPG data. Given the high yield of analyzable data during the nighttime, continuous arrhythmia screening seems particularly effective during sleep phases.

Introduction

Background

Stroke is a leading cause of mortality and disability resulting in considerable economic costs of treatment and poststroke care [1]. With 5.5 million deaths in 2016, stroke was recognized as the second leading cause of death globally, after ischemic heart disease [1]. In the European Union, the number of people living with stroke is estimated to increase by 27% between 2017 and 2047, mostly due to population aging and improved survival rates [2]. Nevertheless, the constantly increasing burden of stroke also implies inadequate implementation or effectiveness of primary prevention strategies [1]. There is no doubt that besides targeting behavioral risk factors, effective screening for conditions that raise stroke risk, such as hypertension, diabetes mellitus, and atrial fibrillation (AF), is essential [1]. In that respect, particular attention must be paid to AF since it represents one of the main causes of stroke [3] and the most common sustained cardiac arrhythmia in adults, affecting between 2% and 4% of the general population [4]. Due to its paroxysmal and often asymptomatic (silent AF) clinical presentation, AF often remains undetected and is frequently only diagnosed upon a suffered stroke [5]. According to the guidelines of the European Society of Cardiology (ESC), 24- to 72-hour electrocardiography (ECG) is the standard of care to detect AF [4]. However, this is usually prescribed only when the patient is already experiencing symptoms (eg, palpitations, exertional shortness of breath, and chest pain), which is a strong indicator that the disease has already progressed to an increased severity (persistent, long-standing persistent, or permanent AF). In addition, the diagnostic yield of standard ECG monitoring is limited in the case of paroxysmal AF since prolonged (>7 days) observation periods are required [5]. Additionally, long-term monitoring using an insertable cardiac monitor is superior to traditional follow-up methods in detecting AF [6]. Thus, in patients over 65 years of age, routine self-monitoring of one's pulse is a class I recommendation in the ESC guidelines for raising the suspicion of AF [4].

Previous Work

Mobile health (mHealth) technologies enabling patient-initiated short-term or continuous long-term pulse recordings are thought to have extraordinary potential to improve the care and management of AF and may yield a practical option to determine AF burden [4,7,8]. In principle, the currently available mHealth devices for AF screening can be divided into the following types: smartphones, smart bands or smartwatches, earlobe sensors, and handheld ECG devices [7]. Aside from handheld ECG devices, all of these devices are based on photoplethysmography (PPG), which is an optical measurement technique for the detection of blood volume changes in the microvasculature [9]. PPG sensors are applied on the surface of the skin, where a light source illuminates the tissue that in turn scatters and partially absorbs the emitted light [10]. A photosensitive diode is used to measure variations in scattered light intensity attributed to cardiac synchronous changes in the blood volume with each heartbeat, resulting in the typical pulsatile component of the PPG waveform [9,10].

The evaluation of the diagnostic performance of various mHealth devices for AF detection revealed the highest sensitivity (95% to 98%) and specificity (95% to 99.6%) for smartphones and their associated applications [7]. Accordingly, both the Preventicus Heartbeats algorithm (PHA, Preventicus GmbH), which is a certified medical device (class IIa, CE marked), as well as the competing product FibriCheck (Qompium NV), showed excellent performance for smartphone recordings [11-14]. However, the diagnostic accuracy of smart bands and smartwatches was highly variable between studies and strongly dependent on the test conditions [7]. This is because PPG measurements are vulnerable to artifacts caused by contact pressure, skin tone, user movement, or bright ambient light [7,9,15]. In addition, the signal can also be affected by physiologic variations such as vasoconstriction, coughing, a deep gasp, or a yawn [10]. Hence, the best data quality is to be expected when subjects are sleeping or sitting still [7]. For 1-minute measurements using wrist-worn devices in a controlled laboratory setting (relaxed sitting position with both arms resting on a firm surface), both algorithms (PHA and FibriCheck) demonstrated sensitivity and specificity comparable to smartphone analyses [16,17].

This Study

Against this background, the question arises whether PPG-based smartwatch measurements provide a sufficient data basis for noninvasive continuous AF screening. The PHA performs an automatic signal quality check before rhythm analysis and outputs the percentage of exploitable minutes [11]. Based on this, the present study aimed to evaluate the analyzability of smartwatch-derived PPG data generated by the PHA during everyday life and to determine the relationship between analyzability and activity level in adults who are in good cardiovascular health. Furthermore, this study aims to determine when it is worthwhile to screen for AF, which will help to save data and increase the life of the device battery.

Methods

Participants and Procedures

A total of 41 (19 female and 22 male) adults with an average age of 43.2 (SD 15.8; range 19-79) years volunteered to participate in this investigation. Excluded from the study were shift workers, those who were unable or unwilling to give informed consent, and patients already diagnosed with a cardiovascular disease, especially heart rhythm disorders (eg, AF or ectopic beats). Each participant was asked to continuously wear a smartwatch for a period of at least 24 hours while following their individual daily routine. Thus, the measurements comprised the whole span of everyday life situations ranging from nonphysical activities, like sleeping or office work, to physically demanding activities, such as sports.

Ethics Approval

The study was conducted according to the Declaration of Helsinki. Informed consent was obtained after verbal and written explanation of the experimental design. This investigation provided the technical preparation for our Clinical Trial "Determine AF Burden with PPG Trial," which was approved

by the Northwest and Central Switzerland Ethics Committee (Project-ID: 2020-01983)

Data Acquisition and Processing

The PPG and mean acceleration (ACC) signal during everyday life were measured at the wrist using a smartwatch (Cardio Watch 287, Corsano Health BV). In total, 3 watches of the same type were used for data collection. Besides a 3D accelerometer (sensor range ±16 g), the device was equipped with a single channel PPG sensor module. A total of 2 green light-emitting diodes (LEDs; peak wavelength of 525 nm and maximum current of 30 mA) served as light sources for the sensor (Figure 1). The smartwatch measured PPG and accelerometric data with a sampling rate of 25 Hz.

Figure 1. The smartwatch used for measuring photoplethysmographic (PPG) and accelerometric data. (A) A photograph of the front side of the wearable used in the study (Cardio Watch 287, Corsano Health BV). (B) The back side of the device indicating the exact position of the light-emitting diode (LED), the PPG sensor, and the charging contacts.

Data transfer and storage was performed via a wireless connection (Bluetooth Low Energy, version 5.0) to a paired and preconfigured smartphone (Galaxy A40, Samsung Electronics Co Ltd) with the Android 10 operating system (Google LLC) that was running a data acquisition application provided by MMT. To avoid data loss, the internal memory (8 MB) of the Corsano smartwatch enabled data buffering for a period of about 24 hours. The PPG and ACC signal were automatically saved as JSON files on the smartphone and manually transferred to a desktop PC after the participant completed the measurement period. The raw data were further processed in MATLAB R2016a (MathWorks Inc). First, all data sets were manually inspected for completeness or potential data gaps. Since the smartwatch did not have an algorithm capable of automatically detecting when the watch was not worn, these phases were eliminated afterwards using custom-written programs in MATLAB. These periods were easy to identify as they appeared as Gaussian white noise in the raw data. Data sets containing more than 10% (2.4 hours) of erroneous data were excluded from the analysis. For each participant, a period of 24 hours was analyzed on a one-minute basis using the PHA. Consequently, a maximum of 1440 minutes (data points) was analyzed for each participant. To map changes over the course of a day, the 24-hour period of a day was divided into 8 equal subintervals (P1 to P8) of 3 hours or 180 minutes. The phases should divide the 24-hour day as sensibly as possible, thus resulting in the following phases: P1 (midnight to 3 AM; sleeping phase), P2 (3 AM to 6 AM; sleeping phase), P3 (6 AM to 9 AM; wake-up phase), P4 (9 AM to noon; working phase), P5 (noon to 3 PM; working phase), P6 (3 PM to 6 PM; working phase), P7 (6 PM to 9 PM; coming to rest phase), and P8 (9 PM to midnight; going to sleep phase). We have assumed that most people tend to behave roughly according to these time windows. Furthermore, on the one hand, one needs a division that is sufficiently large to be suitable for statistical tests. On the other hand, this division should not be too fine because otherwise, one obtains error probabilities that are too small with the Bonferroni correction for multiple testing. For this purpose, a compromise had to be found.

Outcomes

The percentage of analyzable data (PAD) described the ratio between the number of measured PPG minutes and the number of exploitable minutes for the PHA. Exploitable minutes are determined by using the signal-to-noise ratio and the ACC data. For example, data sections disturbed by movement can be detected and marked. If the ratio of disturbed data sections to data sections with sufficient quality is more than 10%, then the

entire minute is nonexploitable. A minute must therefore contain no more than 6 seconds of disturbed data for it to be exploitable [11]. The activity level of the participant (represented by the ACC) was estimated using the triaxial acceleration. For each time increment, the magnitude of acceleration change was calculated using the Euclidean norm (ie, the square root of the sum of squares) (Figure 2). Finally, the standard deviation of this was calculated for each period (P1 to P8) and expressed as the ACC .

Figure 2. A visualization of the method for quantifying the activity level (represented by the ACC) of a participant. The length of the vector between 2 successive triaxial acceleration values (green arrow) was calculated using the Euclidean norm. ACC: mean acceleration.
Statistical Analysis

Statistical analyses were performed using SPSS, version 23 (IBM Corp). Results are presented as means with SD and 95% CI. Sex comparisons were verified with Student t tests for unpaired samples. Where appropriate, effect sizes were calculated as standardized mean differences (d) with values >0.2, >0.5, and >0.8, indicating small, moderate, and large effects, respectively. The effects of measurement time on activity level or percent analyzability of PPG data were verified using univariate repeated measurement analysis of variance (ANOVA). Following the findings of the sex comparisons (comparing the outcomes between males and females), the ANOVA was conducted irrespective of sex using the whole sample (N=41). Bonferroni post hoc tests were used to verify localized differences. Practical relevance was estimated using partial eta squared (η_p^2) with values ≥ 0.01, ≥ 0.06, or ≥ 0.14 indicating small, moderate, or large effects, respectively [18]. Pearson product-moment correlations were calculated to examine linear associations between activity level and the analyzability of PPG data. The following criteria were adopted for interpreting the magnitude of correlations (r) between measures: <0.2, trivial; 0.2 to 0.3, small; 0.3 to 0.5, moderate; 0.5 to 0.7, large; 0.7 to 0.9, very large; and 0.9 to 1.0, almost perfect.

Results

The comparisons of means did not reveal differences between sexes (P>.10) and for the PAD (P>.30) in any of the time intervals (P1 to P8). The only effect on a moderate level (d=0.52) was found for ACC in P5. No effects (for ACC d<0.19) were found for the PAD in P1, P2, P5, and P6, as well as for ACC in P4. All remaining sex comparisons resulted in small effect sizes (0.20<d<0.45).

In principle, the temporal changes in the PAD and ACC followed a characteristic but opposite trend throughout the day (Figure 3A and B) that roughly showed a u-shaped (PAD) or inverted u-shaped (ACC) pattern, respectively. The univariate ANOVA showed a large effect (η_p^2>0.6; P<.001) of the time interval on ACC and the PAD (Table 1). Accordingly, ACC values were significantly lower (P<.01) in P1 and P2 than in the remaining intervals (P3 to P8). This resulted in a PAD above 94% between midnight and 6 AM (P1 to P2; Table 1). In the time frame between 9 AM and 9 PM (P4 to P7), ACC values reached a plateau without significant changes (Table 1) on the highest level across the day (Figure 3A). During this period, the ACC average was approximately 37×10^{-3} m/s^2. In accordance with ACC, there was little change in the PAD between 9 AM and 9 PM (P4 to P7). During this phase, values for this percentage ranged between 55% and 60%, on average.

At the same time, these values represented the minimum over the span of a day. Moreover, the values of this parameter in P3 and P8 were clearly higher (73% to 80%), though not reaching the level of P1 and P2.

Interindividual variations in the PAD (SD<7%) and ACC (SD<5×10^{-3} m/s^2) were lowest at night (P1 to P2) and highest around midday (P3 to P4; SD [ACC] 15×10^{-3} m/s^2 to 18×10^{-3} m/s^2; SD [PAD] 10% to 15%).

The PAD and ACC showed an inverse correlation in all investigated periods (Figure 4A). Except for P2 (r=–0.37), all correlations were large (P1, P4, P5, P7) or very large (P3, P6, P8). The linear regression analysis of the averaged data resulted in an almost perfect coefficient of determination (r^2=0.99; Figure 4B).

The values of the PAD ranged between 34% and 100%, with an average of 71.5% for the whole day, which is equivalent to a period of 17.2 hours.

Figure 4. The relationship between activity level as expressed by the average standard deviation of the acceleration (ACC) and the analyzability of the photoplethysmographic data for arrhythmia screening generated by the Preventicus Heartbeats algorithm over 8 periods of a single day (P1-P8, compare to Figure 3). (A) Data from different time intervals are symbolized by diamonds, squares, and triangles, and Pearson product-moment correlations (r) are given for each period. (B) Mean values across all subjects for the ACC versus percentage of analyzable data (PAD) in each of the 8 periods. The dashed line represents the linear regression and the corresponding equation with the coefficient of determination (r^2) is given.
Discussion

Principal Findings

The present study demonstrates a strong relationship between activity level during a routine day and the analyzability of smartwatch-derived PPG data. In addition, a large effect of daytime on the ACC and PAD was found that was mainly based on differences between day and night.

The inverted u-shaped ACC pattern (Figure 3A) represents the rest-activity circadian rhythm of the persons investigated, which reflects the function of the circadian timing system [19]. Since people working in shifts were excluded from this study, it can be reasonably expected that all participants were sleeping and therefore hardly moving between midnight and 6 AM (P1, P2). In accordance with that, the average ACC values and the corresponding variations were minimal. By contrast, the ACC was the highest between 9 AM and 9 PM, which is equivalent to the main activity phase of the day for most people and typically comprises daily working as well as leisure activities. The comparatively high variability in the ACC data during this period can be explained by intraindividual differences in the load level and the temporal course of the everyday activities performed. Furthermore, in the 2 intervals (P3, P8), on an intermediate ACC level, differences in the times for waking up and going to bed are reflected. Since an almost perfect inverse linear relationship (r^2=0.99) has been found between the ACC and the PAD (Figure 4B), all aforementioned statements for ACC also apply in an inverse manner for the PAD.

In line with other studies, it can therefore be concluded that movement strongly impacts the quality of the PPG signal [9,10,15]. During ambulatory monitoring, various types of motion (eg, walking, stretching, and finger tapping) are present that can cause periodic or nonperiodic motion artifacts (MA) [20]. Besides whole-body movements, the relative movement between the PPG sensor and human skin is a potential source of MA, as well. Therefore, it is essential to tighten the wristband of the smartwatch in such a way that the device cannot shift, but keep it loose enough to avoid cutting off blood circulation. Although all participants were instructed to do so in this investigation, it cannot be ruled out that in some cases, the device was not fitted correctly. This may be a potential explanation for the occurrence of some erroneous measurements during the night as well, besides nightly physical movement like going to the bathroom.

The reduction of MA remains a major challenge in processing PPG data since they can be in the same frequency range as the heart rate signal [21]. Although various signal processing methods have been proposed, satisfactory performance in removing or reducing MA has not yet been achieved [21]. Thus, efforts have been made to improve the performance of noise reduction algorithms through adaptations in sensor design.

Nowadays, multichannel PPG measurement systems comprising multiple sensor modules with LEDs of different wavelengths or colors (ie, green, red, or infrared), constitute the standard across multiple models of current PPG-based smartwatches (eg, Polar Vantage series, Samsung Galaxy Watch3, Apple Watch Series 6, and Withings ScanWatch) [21]. Given this, the sensor module used in this study comprised of only 2 LEDs with one wavelength and one photodiode fails to comply with the current standard. Consequently, the PAD is likely significantly higher when measured with newer smartwatches. This hypothesis must be investigated in further studies.

However, the present findings identified a nocturnal time frame of 6 hours with an excellent PAD. Of the 360 minutes between midnight and 6 AM, on average, only about 20 minutes were not exploitable for the PHA, suggesting that AF screening may be particularly effective during this phase. This strategy is supported by several studies showing that AF typically occurs at night or in the early morning hours [22-25].

Limitations

Some limitations must be mentioned. Firstly, the participants were mainly recruited from occupational groups performing office work. We assume that the participants have similar activity profiles (ie, sleep during P1 and P2, wake up during P3, active during P4 to P7, go to sleep during P8). The participants did not keep a diary detailing their activities. Furthermore, no actigraphy techniques were used, either. Other occupational groups such as craftspeople or postal workers might show clearly different activity patterns during the same time of day, which might have an impact on the analyzability of PPG data. In addition, our results only apply for weekdays and not for weekends, when activity profiles most likely look different, especially among the working population. Finally, this study only involved healthy participants and excluded patients with cardiovascular diseases. Hence, the present findings cannot be generalized to the overall older adult population. The analyzability of smartwatch-derived PPG data for a population with major disorders requires further investigation.

Conclusions

This study showed a strong relationship between activity level and the analyzability of smartwatch-derived PPG data and a large effect of time of day on both parameters. That effect was mainly based on the differences between day and night. In conclusion, the present findings suggest that nocturnal AF screening may be particularly effective since the yield of analyzable data was the highest in the time interval between midnight and 6 AM. During this phase, around 94% of the PPG recordings had an appropriate signal quality for rhythm analysis, which is a crucial prerequisite for reliable screening for cardiac arrhythmias such as AF.

Conflicts of Interest

SM is employed full-time as a research developer at Preventicus GmbH, the company involved in the development of the Preventicus Heartbeats algorithm (PHA).

Abstract

Background: Antipsychotic medications have limited benefits in schizophrenia, and cognitive behavioral therapy may be beneficial as an adjunct. There may be potential for implementing mobile cognitive behavioral therapy–based treatment for schizophrenia in addition to standard antipsychotic medications.

Objective: This study aims to determine whether PEAR-004, a smartphone-based investigational digital therapeutic, improves the symptoms of an acute psychotic exacerbation of schizophrenia when it is added to standard treatments.

Methods: This was a 12-week, multicenter, randomized, sham-controlled, rater-blinded, parallel group proof-of-concept study of 112 participants with moderate acute psychotic exacerbation in schizophrenia. This study was conducted in 6 clinical trial research sites in the United States from December 2018 to September 2019. The primary outcome, change in Positive and Negative Syndrome Scale (PANSS) from baseline to week 12 or the last available visit, was analyzed using the mixed-effects regression model for repeated measures, applied to an intent-to-treat sample.

Results: The total PANSS scores slightly decreased from baseline over the study period in both groups; the treatment difference at day 85 between PEAR-004 and sham was 2.7 points, in favor of the sham (2-sided P=.09). The secondary scales found no benefit, except for transient improvement in depressive symptoms with PEAR-004. Application engagement was good, and patient and clinical investigator satisfaction was high. No safety concerns were observed. There was some evidence of study site heterogeneity for the onboarding processes and directions on PEAR-004 product use at baseline and throughout the study. However, these differences did not affect the efficacy results.

Conclusions: In the largest-to-date randomized, sham-controlled study of a digital therapeutic in schizophrenia, PEAR-004 did not demonstrate an effect on the primary outcome—total PANSS scores—when compared with a nonspecific digital sham control. The secondary and exploratory results also did not demonstrate any notable benefits, except for possible temporary improvement in depressive symptoms. This study provided many useful scientific and operational insights that can be used in the further clinical development of PEAR-004 and other investigational digital therapeutics.

Introduction

Schizophrenia is a common condition [1] treated with standard antipsychotic medications, which can help acute exacerbations of delusions or hallucinations but do not improve the long-term course of the illness. Cognitive behavioral therapy (CBT) has been shown to improve the symptoms of schizophrenia both for delusions and hallucinations (*positive* symptoms) and for apathy and flat affect (*negative* symptoms) and functional status (engagement with employment or social interactions) [2]. However, access to CBT can be difficult based on the cost and availability of psychotherapists [3].

Digital therapeutics (DTx) represents a novel treatment modality in which digital technology systems are used as evidence-based therapeutic interventions to prevent, manage, or treat a medical disorder or disease [4]. DTx products based on CBT can be delivered through smartphone apps, and they can potentially provide safe, inexpensive, easy-to-use, consistent quality, personalized treatment strategies for patients with medical needs. The potential value of DTx is magnified during the current COVID-19 pandemic, when face-to-face physician visits are problematic and self-management of long-term conditions is becoming more common. There is an increasing interest in developing DTx for mental health disorders [5,6]. However, the evidence base for the clinical effectiveness of such products is still sparse [7,8]. There are natural challenges in designing clinical trials of DTx interventions, including the choice of a control group, blinding, and potentially lower-than-expected patient engagement [9].

Several digital interventions in psychosis have recently been evaluated in randomized controlled trials (RCTs) [10-12]. The experimental treatments in these studies varied in terms of mode of delivery, features or functionalities, and theoretical framework. In addition, there were different control conditions and different degrees of involvement of health professionals. For instance, Actissist (University of Manchester) [10] was developed as a stand-alone self-management mobile app targeting five domains of early psychosis, such as auditory verbal hallucinations, paranoia, perceived criticism, socialization, and cannabis use. It was tested in a small (n=36) proof-of-concept RCT against an active control condition (ClinTouch), which was a self-reporting symptom severity mobile app. Although the study [10] showed evidence of feasibility, acceptability, safety, and indications of beneficial effects after 12 weeks of treatment with Actissist, its findings are limited owing to the small sample size and the fact that engagement with both experimental and control apps was incentivized.

Another mobile app intervention, Personalized Real-Time Intervention for Motivation Enhancement (PRIME) [11], was designed to target the motivational system of young people with recent-onset schizophrenia spectrum disorders by using social reinforcement to engage and sustain goal-directed behavior. The PRIME intervention provided a supportive web-based environment for social interaction, motivational coaching, personalized goal setting in the domains of health or wellness, social relationships, creativity, productivity, and a system to track progress in achieving personal goals. After 12 weeks of PRIME treatment, there was evidence of improvement in the experimental group of several important components of motivational behavior, depression symptoms, defeatist beliefs, and self-efficacy, compared with the waitlist control condition. Despite a relatively small sample size (a total of 43 participants) and the use of a waitlist control that did not allow for assessment of a relative effect of PRIME compared with other mobile treatment approaches, the study [11] provided important evidence of feasibility, acceptability, and potential clinical benefit of a mobile intervention in this patient population. Notably, this study was implemented fully remotely, across the United States, Canada, and Australia.

The Audio Visual Assisted Therapy Aid for Refractory auditory hallucinations (AVATAR) therapy [12] is a computer-assisted intervention designed on the principles of CBT for psychosis, with the specific aim of controlling persistent, distressing auditory verbal hallucinations. The AVATAR therapy is delivered by experienced clinicians and involves the creation of a computerized representation of the entity (Avatar), which is believed to be the source of the voice heard by the patient, and subsequent therapy sessions at which the clinician facilitates a direct dialogue between the patient and the Avatar, with the goal of having the Avatar less hostile and conceding power over the course of therapy. In the RCT [12], which was formally powered (150 patients randomized equally between the AVATAR therapy and the supportive counseling control condition), the AVATAR therapy led to significantly greater reductions in auditory hallucinations, as assessed by the Psychotic Symptoms Rating Scales Auditory Hallucinations total score, compared with the control condition after 12 weeks of treatment; however, there was no between-group difference at 24 weeks follow-up. The study [12] was conducted at a single center and involved experienced therapists, which limits the generalizability of the results to other centers or to delivery by a wider mental health workforce.

FOCUS is another software-based intervention (delivered via mobile devices) designed with input from both treatment providers and patients to optimize both usability and engagement and developed to be used in conjunction with ongoing outpatient treatment [13]. The feasibility, acceptability, and initial efficacy of FOCUS for improving symptoms and treatment engagement in patients with schizophrenia or schizoaffective disorder was established in a 1-month open-label trial [14]. In another study [15], engagement with FOCUS among patients with schizophrenia was measured during a 6-month period following psychiatric hospitalization discharge. Similar to findings from the 1-month feasibility trial, patients with schizophrenia were highly engaged over the course of 6 months (active use on 82% of the weeks during which they had access to the intervention). Taken together, these preliminary findings regarding FOCUS show the promise of prescription DTx for improving symptoms and treatment outcomes in patients with schizophrenia.

Overall, theory-based digital interventions hold promise in psychosis and schizophrenia spectrum disorders. Given the increasing availability and use of smartphones, CBT-based mobile interventions may potentially augment existing standard-of-care pharmacological treatments or target specific

domains of illness by promoting cognitive and behavioral change strategies.

PEAR-004 is being developed as a prescription digital therapeutic delivered via smartphone for schizophrenia patients who are under the care of a qualified health care professional and are on antipsychotic pharmacotherapy. It is intended to deliver multimodal evidence-based neurobehavioral mechanisms of action, which include cognitive restructuring, illness self-management training, and social skills training. If efficacious, it would demonstrate that 24×7 access to evidence-based coping skills, which when added to medications, may improve symptom management and functional outcomes.

This paper reports the results of a randomized, sham-controlled study of PEAR-004 in patients with schizophrenia.

Methods

Study Design

The study was a multicenter, randomized, sham-controlled, rater-blinded, parallel group proof-of-concept trial of participants with schizophrenia (trial registration: ClinicalTrials.gov NCT03751280). Eligible participants were equally randomized on day 1 to receive either PEAR-004 (investigational digital therapeutic) or sham (control) for a period of 12 weeks. Participants in both groups continued to receive clinician-directed standard-of-care for schizophrenia, including pharmacotherapy. The participants returned to the clinic for outpatient visits at week 4 (day 29), week 8 (day 57), and week 12 (day 85). At each visit, standard assessments, including efficacy and safety, were performed according to the assessment schedule. A final follow-up visit was performed at week 16 (day 115).

Study Objectives

The primary objective was to compare the effect of PEAR-004 versus sham, as assessed by the change from baseline to day 85 in the total Positive and Negative Syndrome Scale (PANSS) score. It was hypothesized that the PEAR-004 group would exhibit a greater reduction in the total PANSS score than the sham group. In addition, retention to assigned study treatment (dropout rate), patient engagement data, secondary efficacy outcomes, clinician outcome assessments, and safety and tolerability data were analyzed.

Study Sites

Potentially eligible participants were enrolled in 6 investigational study sites in the United States. The site details are as follows:

- 1001: Collaborative Neuroscience Network, Garden Grove, California. Principal investigator (PI): Dr David Walling.
- 1002: Collaborative Neuroscience Network, Torrance, California. PI: Dr Lara Shirikjian.
- 1003: Pacific Research Partners, Oakland, California. PI: Dr Corinna Gamez.
- 1005: Meridien Research, Maitland, Florida. PI: Dr Andrea Marraffino.
- 1006: Cherry Health, Grand Rapids, Michigan. PI: Dr Eric Achtyes.
- 1008: Albuquerque Neuroscience, Albuquerque, New Mexico. PI: Dr Glenn Dempsey.

Study Participants

The investigators ensured that all participants being considered for the study met the eligibility criteria at screening. The inclusion and exclusion criteria are described in Textbox 1.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Signed informed consent obtained before participation in the study
- Healthy men and women aged 18 to 65 years, inclusive, and in good health as determined by medical history, physical examination, and vital signs at screening
- Structured Clinical Interview for DSM-5–based Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-5) diagnosis of schizophrenia and a total Positive and Negative Syndrome Scale score ≥60.
- Proficient in English at the 5th grade reading level or higher, in the judgment of the investigator
- Capable of using a mobile device (compatible with PEAR-004) and using common apps, in the judgment of the investigator

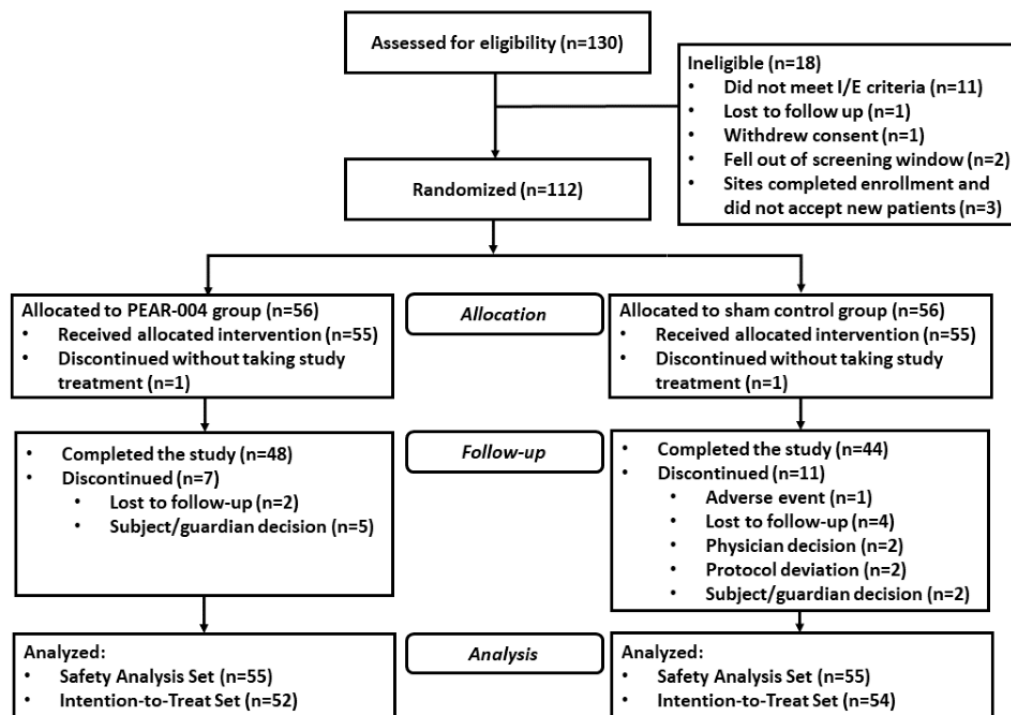
Exclusion criteria

- Major change in primary antipsychotic medication in the prior 4 weeks before screening
- Planning to move out of the geographic area within 3 months
- Unable to use English to participate in the consent process, the interventions, or assessments
- Inability to comply with study procedures owing to severe medical conditions or otherwise
- Meet the DSM-5 diagnosis for a current episode of major depression, mania, or hypomania in the past month
- Meet the DSM-5 diagnosis for a current moderate or severe alcohol or cannabis use disorder in the past 2 months
- Meet the DSM-5 diagnosis for a current substance use disorder (other than alcohol or cannabis) in the past 2 months
- Considered high risk for suicidal behavior based on InterSePT Scale for Suicidal Thinking–Plus score at screening, or in the judgment of the investigator
- Previously participated in a clinical study involving PEAR-004

Randomization

Randomization was implemented by means of interactive response technology (IRT) using permuted blocks of size 4, with a targeted allocation ratio of 1:1. An investigator or delegate at a given study site logged on to the IRT system after confirming that the participant fulfilled all the inclusion or exclusion criteria. The IRT assigned the participant to a treatment arm, which was used by the site staff to request a *prescription access code* in a separate study portal. Trained site staff assisted the participants with all treatment onboarding

activities. The participants were required to use their own personal mobile phones for the study. If a participant did not have their own phone, one was provided to them for use during the study. Additional information on the prescription access code and distribution of study treatment is provided in the site operational manuals provided to the sites. If a participant failed to be treated for any reason, the IRT was updated so that the participant was not treated. Treatment arm assignments were recorded in the case report form. Figure 1 shows the CONSORT (Consolidated Standards of Reporting Trials) participant flow through the trial.

Figure 1. Study participant flowchart—CONSORT (Consolidated Standards of Reporting Trials) diagram. Safety analysis set: all subjects who received the study treatment. Intention-to-treat set: all subjects to whom study treatment has been assigned by randomization and who have a baseline observation and at least 1 postrandomization observation for the analysis end point. I/E: inclusion and exclusion.


Interventions

On day 1, eligible participants gained access to either PEAR-004 or sham according to their randomization assignment. A single app containing both PEAR-004 and sham was downloaded from the iOS or Android app store to the participant's mobile device, and then the assigned app was unlocked using a prescription access code provided by Pear Therapeutics. The study site staff received training on how to download PEAR-004 or sham to the assigned participant's phone as part of site initiation activities. A single version of PEAR-004 or sham was used for the duration of the clinical study for all randomized participants.

The PEAR-004 smartphone app (iOS and Android-based) was designed as an illness self-management tool. Participant use of PEAR-004 during the treatment period could be either prompted or on demand. Prompted use refers to engagement initiated via 1 of the 3 daily notifications delivered at the following fixed times: 11 AM, 4 PM, and 9 PM. A participant responding to the notification would be brought to a unique survey asking whether the app can be helpful right now. Participants were free to choose from a list of modules or indicate that they were doing

well and did not need help. If they chose a module, they would be brought directly to that module. If they indicated that they were doing well, they would be brought to the PEAR-004 home screen. In addition, PEAR-004 was available on demand. For a particular skill, there would be an option of watching, reading, or listening to content about what the skill is and how they can give it a try. Patients would then view tips for successful practice, and after they practiced a skill, they would be asked to provide feedback on whether the skill was helpful. Helpful skills were stored in the toolbox to promote repeated practice and skill mastery. The final PEAR-004 digital app used in this study was developed from prior versions to have 10 categories of skills: exercise, medication, mindfulness, mood, productivity, sleep, social activity, stress, thoughts, and voices. These categories were informed directly by user research (surveys and interviews) with people with schizophrenia.

In the sham control group, the sham app was downloaded to the participant's phone but did not deliver the active therapeutic content of PEAR-004. Similar to PEAR-004, the sham app delivered 3 daily notifications prompting the participant to open the sham app, and then displayed a prescription timer (*digital*

clock) for the remaining duration of app availability. The sham control arm was chosen to account for the nonspecific effects of engagement with a smartphone. The sham app did not deliver any active coping skills (ingredients of a psychosocial intervention). It appeared similar to the PEAR-004 app in its initial screen and randomization to sham or PEAR-004 was conducted at the time of app download unbeknownst to participants to maintain blinding.

Overall, the similarity and difference between the PEAR-004 app and the sham control app can be summarized as follows:

- Both PEAR-004 and sham sent 3 notifications per day at fixed times—11 AM, 4 PM, and 9 PM—prompting the user to open the app. Once the app was opened, the experience and content differed between the PEAR-004 and sham groups.
- PEAR-004 provided therapeutic content (cognitive and behavioral exercises), whereas the sham app did not.
- Sham had a display of a *digital clock*, whereas the PEAR-004 app did not.
- Neither PEAR-004 nor sham maintained a record of the user's prescription medications or when they were to be taken.

Assessments

Demographics and Baseline Characteristics

Participant demographic and baseline characteristic data were collected from all the study participants. Relevant medical history and current medical conditions present before signing informed consent were recorded.

Engagement With App

Data on patient engagement with the assigned app were collected throughout the study. The cross-platform engagement metrics (for individuals in both PEAR-004 and sham groups) included time using the app, number of days when the app was active, total number of sessions, and number of sessions per day. For participants in the PEAR-004 group, additional metrics were derived, such as the number of skills practiced, number of skills repeated (practiced at least two times), number of skills mastered (practiced at least three times), and number of skills practiced in each of the 10 categories of the PEAR-004 app (exercise, medication, mindfulness, mood, productive, sleep, social, stress, thoughts, and voices).

Efficacy

The following assessments were performed at each study visit:

- PANSS [16]: a 30-item clinician-administered, semistructured interview of schizophrenia symptoms. The PANSS assesses positive (hallucinations, delusions, and thought disorder) and negative (blunted affect, abstract thinking, and general symptomatology). The positive and negative subscale each consist of 7 items rated from 1 (absent) to 7 (extreme) with a minimum score of 7 and maximum score of 49. The general subscale consists of 16 items with a minimum score of 16 and a maximum score of 112. The total PANSS score (positive+negative+general

scores) has a minimum of 30 and a maximum of 210. Higher scores represent greater symptom severity.
- Motivation and Pleasure-Self Report (MAP-SR) [17]: a 15-item self-report that provides a total score index of current motivation or pleasure negative symptoms. MAP-SR includes questions about social pleasure, recreational or work pleasure, close relationships, and motivation and effort to engage in activities of 15 questions with a score of 0-4, summed for a total range of 0-60. Higher values represent better outcomes.
- The Beck Depression Inventory, Second Edition (BDI-II) [18]: a 21-item self-report that provides a total score index of current depression symptom severity. Each item of the BDI-II is scored from 0 to 3, for a total of 0-63. Higher values represent worse outcomes.
- The World Health Organization Quality of Life scale [19]: a 26-item clinician-administered structured interview that assesses psychological functioning and quality of life in four primary domains: social relationships, psychological, physical, and environment. Each of the 26 questions is scored from 1 to 5, and for each of the 4 domains, a total raw score and 2 transformed scores (with ranges of 4-20 and 0-100) are derived. Higher values represent better outcomes.
- Brief Medication Questionnaire [20]: a self-report of medication use, including what medications the participant was currently taking, how they took each medication in the past week, drug effects and bothersome features, and difficulties remembering to take their medication.

Safety

Safety assessments consisted of collecting all adverse events (AEs), serious AEs (SAEs), vital signs, and the InterSePT Scale for Suicidal Thinking–Plus [21,22]. The InterSePT Scale for Suicidal Thinking–Plus is a semistructured interview that assesses the severity of suicidal ideation and behavior, consisting of three parts. Part 1 collects information on 7 days before the visit; there are 13 items that scored 0 (minimum) to 2 (maximum) for suicidality, with a higher score representing a worse outcome. Part 2 collects information on suicidal behavior from the last visit, with nominal categories yes, no, or unknown. Part 3 provides a global rating of status at the time of interview; it is scored 0 (minimum) to 5 (maximum) for suicidality, with a higher score representing a worse outcome. In our study, we focused primarily on the part 3 score (severity of suicidal risk), which was summarized by treatment group and time visit.

Other Assessments

Clinician-reported outcomes included the Clinical Global Impression (CGI) scale [23] and the Clinician Satisfaction Survey assessing the clinician's experience with PEAR-004 and the associated web portal. The CGI consists of the CGI-Severity scale, scored 1 to 7, with larger values indicating greater severity of illness, and the CGI-Improvement scale, scored 1 to 7, with smaller values representing a greater degree of improvement (1=very much improved) and larger values representing a greater degree of worsening (7=very much worse).

Patient-reported outcomes included the Insomnia Severity Index (ISI) [24] and a Subject Satisfaction Survey assessing the participant's experience with PEAR-004 or sham. The ISI includes 7 questions, each scored from 0 to 4, for a total of 0 to 28, where higher values represent more severe insomnia.

Statistical Methods

Sample Size and Power

The required sample size was calculated to address the primary objective of treatment comparison at week 12 with respect to the change in the total PANSS score. Data from 102 participants randomized in a 1:1 ratio to PEAR-004 or sham control would provide 80% power to detect a statistically significant difference between the 2 groups at a 1-sided significance level of 5% assuming the true standardized effect size of 0.5, which is considered a moderate effect size. To account for potential dropouts, 112 participants were enrolled and randomized into the study.

Statistical Analyses

Summary statistics were tabulated for demographics, baseline characteristics, relevant medical histories, and current medical conditions at baseline. The measures of patient engagement derived from the app were explored graphically and using descriptive statistics.

The primary efficacy end point, change in the total PANSS score from baseline to day 85 or last visit, was analyzed using the mixed effects model for repeated measures (MMRM) [25], applied on the intention-to-treat (ITT) set, which included all participants to whom study treatment was assigned by randomization and who had a baseline observation and at least one postrandomization observation for the analysis end point. The MMRM included fixed, categorical effects of treatment, visit, and treatment-by-visit interaction, as well as the continuous, fixed covariates of baseline score, baseline score–by–visit interaction, and disease duration at baseline. An unstructured covariance structure was used to model the within-patient errors. The Kenward-Roger method was used to adjust the estimated covariance of the mean difference and df. The primary comparison was the treatment contrast on day 85.

The secondary efficacy end points, including positive PANSS score, general psychopathology PANSS score, negative PANSS score, total MAP-SR score, total BDI-II score, and World Health Organization Quality of Life total scores for the four domains (social relationships, psychological, physical, and environment), were analyzed similarly to the primary end point (MMRM on change from baseline values, using the ITT set).

The retention to study treatment was assessed using Kaplan-Meier plots of time to drop out from any cause, on the *all randomized* set. Safety data and additional clinical outcome assessments were analyzed using descriptive statistics.

Ethics and Informed Consent

The study protocol was approved by the Copernicus Group Independent Review Board (study number 1251398). The study was conducted according to the International Conference on Harmonization E6 Guideline for Good Clinical Practice, which has its origin in the Declaration of Helsinki. Informed consent was obtained from each participant in writing at screening before any study-specific procedures were performed. The study was explained to the participant by the investigator or designee, who answered any questions, and written information was also provided.

Results

Study Sample

From December 10, 2018, to September 26, 2019, a total of 112 participants with schizophrenia were enrolled and randomized into the study (Figure 1). Of the 112 randomized participants, 92 (82.1%) completed the study (48/112, 85.7% from PEAR-004 and 44/112, 78.6% from the sham group). The most common reasons for discontinuation were lost to follow-up and participant or guardian decisions. One participant in the sham group discontinued because of an SAE of suicidal ideation. From the Kaplan-Meier plots (Figure 2), the observed time to discontinuation was somewhat longer in the PEAR-004 group than in the sham group; however, the difference was not statistically significant (log-rank test; P=.36).

Figure 2. Kaplan-Meier plot of time to dropout (all randomized participants).
Demographics and Baseline Characteristics

Table 1 describes the demographics and baseline characteristics of study participants. Most participants were men (72/110, 65.5%) and Black or African American (53/110, 48.2%). The mean age of the participants was 45 (SD 11; range 22-65) years. Overall, the treatment groups were similar with respect to background disease characteristics. The most commonly rated participant's global severity was *moderately ill* (rating 4) in each treatment group (as rated on the CGI-Severity scale at baseline). The mean and median PANSS scores were comparable between the 2 randomized groups. The overall mean duration of disease before study entry was 17.2 (SD 11.5) years, which was balanced across the treatment groups.

Table 1. Participant demographics and baseline characteristics (safety analysis set).

Characteristic	PEAR-004 (n=55)	Sham (n=55)	Total (N=110)
Age (years)			
Value, mean (SD)	43.7 (10.99)	45.7 (11.60)	44.7 (11.29)

[a]PANSS: Positive and Negative Syndrome Scale.

[b]CGI: Clinical Global Impression.

Most participants were taking prior antipsychotic medication at the start of the study. Benzatropine, aripiprazole, quetiapine, and psychiatric medications were the most common medications used for the treatment of schizophrenia in both groups.

Engagement With App

Table 2 presents a summary of key engagement metrics by the treatment group. Participants in the PEAR-004 group spent significantly more time using the app over the course of the trial than participants in the sham group. However, the sham provided a good control for attention, as there were no significant differences between the groups in the number of days using the app, the total number of sessions, or the number of sessions per day.

Table 2. Engagement metrics for the PEAR-004 and sham groups.

| Variable	PEAR-004 (n=55)	Sham (n=55)	P value

A more in-depth analysis of engagement data is provided in Tables S1 and S2 in Multimedia Appendix 1. Pear Therapeutics performed poststudy interviews with coordinators at all 6 study sites and found that there were differences among the sites' onboarding processes and directions on the product use at baseline and throughout the study. These differences in execution may have contributed to the statistically significant site differences in engagement measures observed in the PEAR-004 arm but not in the sham arm. Furthermore, we performed a visual exploration of the primary efficacy outcome (change in total PANSS score at day 85) for PEAR-004 and sham groups across 6 study sites (Figure S3 in Multimedia Appendix 1). There was no evidence that any given site had a between-group difference that would be inconsistent with the primary efficacy analysis of the pooled data across the sites (described in the *Efficacy* section). Therefore, site operational heterogeneity was associated with the measures of engagement with PEAR-004; however, this heterogeneity did not correlate with the observed difference in efficacy between the 2 groups.

Efficacy

In the primary efficacy end point of change in total PANSS score from baseline to day 85 or the last visit (Figure 3; Table 3), no benefit was seen with PEAR-004 versus sham. The estimated mean change in the PEAR-004 group was −1.6, −2.5, and −2.6 at days 29, 57, and 85, respectively. In the sham group, the estimated mean change was −2.2, −3.3, and −5.3 at days 29, 57, and 85, respectively. Thus, there was a small nondifferential improvement over time in both groups. At day 85, the treatment mean difference between PEAR-004 and the sham group was 2.7 points in favor of the sham (2-sided P=.09; 90% CI 0.1-5.4).

[a]Baseline is the last measurement before treatment administration. Model: change from baseline of efficacy end point data was modeled using a mixed effects model with treatment, visit as fixed effects, baseline and disease duration at baseline as continuous covariates, treatment × visit, and baseline × visit interaction effects. The reported P value is 2-sided.

[b]N/A: not applicable.

Table 4 presents the results of secondary efficacy outcomes. No notable benefits were seen except for a small benefit for PEAR-004 in the BDI-II total score at day 57 (least squares mean difference of 3.3 points, PEAR-004 vs sham); however, this difference did not persist at day 85.

Safety

AEs were reported in 20% (22/110) of the participants (Multimedia Appendix 2). The incidence of AEs was similar across both treatment groups: 22% (12/55) for PEAR-004 and 18% (10/55) for the sham group. All reported AEs were categorized as mild (20/110, 18.2%) or moderate (2/110, 1.8%) in severity. No severe AEs were reported. Most AEs were not suspected to be related to the treatment and resolved or were recovering at the end of the study. One SAE (suicidal ideation) was reported in the sham group, and the participant was discontinued from the study. This event was considered resolved on day 43, and was not suspected to be related to the treatment. No clinically significant abnormalities related to any of the vital signs were reported during the study.

Other Assessments

Table S4 in Multimedia Appendix 1 provides an assessment of the quality of blinding in the study using the sham control app. As shown, the sham app provided only a partial blinding effect, with the direction of bias of unblinding in favor of the PEAR-004 app. As the overall results showed a lack of benefit in the PEAR-004, any bias from partial unblinding would only make any interpretation of hidden potential benefit even more unlikely.

Multimedia Appendix 3 presents a summary of CGI scores at day 85 or the last visit. The proportions of participants with a score of 3 (mildly ill) or 4 (moderately ill) were similar at day 85 in the PEAR-004 group (42/48, 88%) and in the sham group (44/49, 90%). At day 85, 6 participants in the PEAR-004 group and 3 participants in the sham group were markedly ill (score=5). The percentage of participants with a global improvement rating of 4 (ie, no change) was somewhat higher in the PEAR-004 group (29/48, 60%) than in the sham group (23/49, 47%).

There was no change in mean sleep difficulties (ISI score) from baseline to the last visit in the PEAR-004 group (9.5, SD 7.34 vs 9.5, SD 6.82, respectively). A small numerical decrease (ie, improvement) in mean ISI scores was observed in the sham group (baseline: 11.2, SD 7.04; last visit: 9.8, SD 7.37, respectively).

Multimedia Appendix 4 presents a summary of the clinician and patient satisfaction surveys. The Clinician Satisfaction Survey included 4 questions on the clinician's experience with PEAR-004 (rated 1-7, with 1 indicating a highly negative response and 7 indicating a highly positive response), and the fifth question on how frequently they accessed the web dashboard during the study. Most of the clinicians' responses had scores 4, showing that the clinicians were satisfied with the PEAR-004 app. The dashboard was accessed at least once per month (21/49, 42% responses), and at least once per week (11/49, 22% responses).

The patient satisfaction survey included 8 questions on the participant's experience with PEAR-004, each rated from 1 to 7. Most responses to each question received a score of 6 or 7, suggesting that the majority found the app acceptable and usable. Most app use was during mid–late morning, 9 AM to noon (34/49, 69% respondents) and during late afternoon, 3 PM to 6 PM (25/49, 51% respondents). Most frequently, the app was used at home (46/49, 93% respondents) and at a public place (15/49, 30% respondents).

Discussion

Principal Findings

The primary objective of this study was to determine whether PEAR-004, a software-based intervention delivered via smartphone, can further reduce symptoms of schizophrenia as measured by the PANSS in participants, almost all of whom are currently on antipsychotic pharmacotherapy. No benefit was seen. Secondary outcomes suggested brief transient improvement in depressive symptoms only. No safety concerns were observed.

The lack of efficacy in this study was not because of a lack of engagement, which was demonstrated to be adequate, or lack of satisfaction. Despite the lack of definable clinical benefit, patients reported that the PEAR-004 app was engaging, interactive, and helped them feel better.

To our knowledge, this study is the largest RCT to date with a sham control group for schizophrenia. Lack of benefit when compared with sham may reflect the nonspecific aspects of benefit seen with digital interventions. It is notable that all participants improved, and if a waitlist control had been used rather than sham, we might have interpreted the results as suggesting mild benefit with the intervention. Natural history of recovery from an acute psychotic exacerbation is also relevant for improvement seen with 12 weeks of follow-up. The inclusion criteria of a moderate psychotic state (PANSS total score ≥60) might have allowed for lower levels of symptomatology, often associated with sham or placebo responses.

This study provides valuable insights that may be useful in future development programs for DTx. The development and selection of a sham control is an important design consideration. In our study, the sham app only included notifications 3 times per day, and when it was opened, it displayed a prescription timer for the remaining duration of app availability. However, this simple control intervention demonstrated a somewhat higher efficacy than PEAR-004. On the basis of feedback from poststudy interviews, the sham app was helpful in focusing attention away from internal stimuli (eg, hearing voices) to the present moment, similar to a mindfulness exercise. The notifications could have been an important ingredient too, as several participants in the poststudy interviews described the

receipt of notifications as being meaningful, given their reported lack of social connections. The sham may also present a lower barrier to engagement, which may have been helpful for participants experiencing a greater acuity of clinical symptoms.

Strengths and Limitations

This study had several strengths. This was a multicenter, randomized, sham-controlled, rater-blinded study design, in which study participants continued on their prescribed clinician-directed pharmacotherapy. Participants randomized to the PEAR-004 arm had access to the full clinical content and the logic of PEAR-004 app and of its therapeutic components. The sham control arm was chosen to account for the nonspecific effects of engagement with a smartphone. The sham app did not deliver any active coping skills (ingredients of a psychosocial intervention). The analysis of the primary and key secondary efficacy end points was performed on the ITT sample using the MMRM approach, considering all available data from the study participants. The amount of missing data was small, and the results were consistent across the different end points.

There was some heterogeneity in the study implementation aspects by different study sites. From poststudy interviews with coordinators at all 6 sites, we found that there were differences among the sites' onboarding processes and directions on product use at baseline and throughout the study. A post hoc analysis revealed some evidence of heterogeneity of engagement measures across study sites, which may be linked to a lack of consistency in how study interventions were delivered to participants (Multimedia Appendix 1). However, site operational heterogeneity did not correlate with the difference in efficacy between the 2 groups; in other words, there was no evidence that any site exhibited between-group differences that would be inconsistent with the primary efficacy analysis of the pooled data across the sites. A conclusion from this experience is that it is important to provide detailed instructions to study sites on operational aspects and ensure systematic and similar adherence to those processes.

Furthermore, although PEAR-004 offered clinical content derived from evidence-based treatments such as CBT, in-application support for practicing skills, and applying knowledge to daily life was very limited. This, when combined with the broad therapeutic focus on all patients with schizophrenia (instead of targeting a specific symptom or symptoms), may have inadvertently created an intervention that provided some help to many participants while not adequately supporting the specific needs of any particular participant.

There are several potential approaches for improving the content of PEAR-004 to provide a more personalized treatment delivery. First, to ensure adequate engagement with the CBT mechanism of action, the app could be designed with a utility of personalized goal setting and skill recommendations to help users make progress toward their goals. In addition, creating a web-based environment in which patients can receive just-in-time coaching and medical support may be beneficial. Second, foundational research to better understand users' needs and how they engage with the digital intervention is essential. The app development should be designed iteratively, evaluating both engagement data and clinical outcomes to see whether the

skills that are thought to be important for mechanism of action are adequately practiced; if not, the design should be improved and the assumptions should be re-evaluated in view of accrued experimental data. Finally, the primary goal of this study was to assess the effect of a CBT delivered as adjunct therapy through a mobile app. Additional digital ingredients to optimize patient outcomes, such as medication reminders, tracking of adherence to prescribed medication, and symptom tracking, could be implemented. A challenge would be to assess the added value of each ingredient (and possibly their combinations) when interpreting the trial results. Quantifying engagement with different components of the intervention and properly accounting for it in the analysis (eg, through regression modeling) may be worthwhile. A framework for developing and evaluating complex interventions [26] can be useful in guiding the clinical development of theory-based DTx interventions.

Comparison With Prior Work

Our results contrast with the three currently available RCTs of digital interventions in schizophrenia, of which all report benefits for delusions, hallucinations, or apathy or withdrawal. However, most of those studies (n=150) were computer-based, not smartphone-based [12]. The other two studies were small, with fewer than 45 participants in each study [10,11]. Further, 2 of the 3 studies had no sham control group and used only waitlist control [11,12]. Another important difference is that unlike previous digital interventions in schizophrenia, PEAR-004 was not integrated into clinical care and no personalized coaching was used to direct and support engagement with treatment. Directing and supporting engagement, whether by a clinician or a trained coach, can help tailor the therapeutic experience for a specific patient. As a prescription digital therapeutic, PEAR-004 was designed to be prescribed by a clinician to their patient and integrated into ongoing care. Not providing this support in this study meant that the burden of knowing what will help was placed on the patient, which may have affected how they engaged with the treatment.

It is instructive to compare the therapeutic content of PEAR-004 with that of some previous mobile-based digital health interventions for people with schizophrenia. Similar to FOCUS [13] and Actissist [10] apps, PEAR-004 content was organized into several domains of cognitive or behavioral strategies, and users received 3 daily notifications prompting them to engage with the app. However, the content of PEAR-004 also included some unique features, such as elements of gamification, to explicitly encourage and incentivize skill mastery through repeated skill practice for generalization of practice to daily life and promote lasting change. Such features may be worth exploring in future studies. In addition, the content of PEAR-004 and future DTx could potentially benefit from the inclusion of short-term and long-term goal settings tailored to specific needs of an individual and mechanisms to help the user achieve their goals. For instance, the PRIME intervention [11] had a self-identified goal setting in the cognitive and behavioral domains, and a supportive web-based community of both age-matched peers with schizophrenia spectrum disorders and motivational coaches.

In this study, the duration of treatment with PEAR-004 or sham was 12 weeks, which is consistent with the results of antipsychotic drug trials in schizophrenia to assess short-term benefits. Proof-of-concept studies of other investigational DTx in psychosis (eg, Actissist [10]; PRIME [11]) have also been conducted for 12 weeks in treatment duration. Furthermore, some other DTx products (eg, Food and Drug Administration–cleared reSET for substance use disorder [27] and reSET-O for opioid use disorder [28]) demonstrated evidence of efficacy following a 12-week treatment period. Although the *optimal* duration for a DTx intervention may vary across different indications, the 12-week treatment duration seems reasonable from the standpoint of balancing engagement and benefits of disease self-management. In this study, there was also a final follow-up visit at week 16. These data were examined descriptively, and the results are available upon reasonable request. Overall, no apparent between-group differences were observed with respect to primary or secondary efficacy outcome measures at week 16. As shown in Figure S5 in Multimedia Appendix 1, the changes in the total PANSS score at week 16 were very similar between the 2 groups.

Conclusions

In the largest-to-date randomized, sham-controlled study of a digital therapeutic in schizophrenia, PEAR-004 did not demonstrate an effect on the primary outcome of total PANSS scores compared with sham. The secondary and exploratory results also did not demonstrate any notable benefits, except for possible temporary improvement in depressive symptoms. Both clinical investigators and study patients provided high satisfaction ratings for the PEAR-004 app. The study provided many useful scientific and operational insights that can be used in further clinical development of PEAR-004 and other investigational DTx.

Abstract

Background: Experience sampling methods (ESMs) are increasingly being used to study ecological emotion dynamics in daily functioning through repeated assessments taken over several days. However, most of these ESM approaches are only based on self-report assessments, and therefore, studies on the ecological trajectories of their underlying mechanisms are scarce (ie, cognitive biases) and require evaluation through experimental tasks. We developed a novel ESM tool that integrates self-report measures of emotion and emotion regulation with a previously validated app-based cognitive task that allows for the assessment of underlying mechanisms during daily functioning.

Objective: The objective of the study is to test this new tool and study its usability and the possible factors related to compliance with it in terms of latency and missing responses. Among the compliance predictors, we considered psychological and time-related variables, as well as usability, measurement reactivity, and participants' satisfaction with the tool.

Methods: We conducted 2 extensive ESM studies—study 1 (N=84; a total of 3 assessments per day for 5 days) and study 2 (N=135; a total of 3 assessments per day for 10 days).

Results: In both studies, participants found the tool highly usable (average usability score >81). By using mixed regression models, we found both common and specific results for the compliance predictors. In both study 1 and study 2, latency was significantly predicted by the day ($P<.001$ and $P=.003$, respectively). Participants showed slower responses to the notification as the days of the study progressed. In study 2 but not in study 1, latency was further predicted by individual differences in overload with the use of the app, and missing responses were accounted for by individual differences in stress reactivity to notifications ($P=.04$). Thus, by using a more extensive design, participants who experienced higher overload during the study were characterized by slower responses to notifications ($P=.01$), whereas those who experienced higher stress reactivity to the notification system were characterized by higher missing responses.

Conclusions: The new tool had high levels of usability. Furthermore, the study of compliance is of enormous importance when implementing novel ESM methods, including app-based cognitive tasks. The main predictors of latency and missing responses found across studies, specifically when using extensive ESM protocols (study 2), are methodology-related variables. Future research that integrates cognitive tasks in ESM designs should take these results into consideration by performing accurate estimations of participants' response rates to facilitate the optimal quality of novel eHealth approaches, as in this study.

Introduction

Mood and anxiety disorders are configured by a series of dysfunctional cognitive, emotional, and behavioral factors that occur over specific periods and are inherently dynamic: (1) they are influenced (predicted) by other thoughts, emotions, and behaviors preceding them, and (2) they also have consequences in the subsequent cognitions, moods, and behaviors of the individual. Although this dynamic interplay among psychological processes is supported by empirical research [1], and it was originally formulated by conceptual models guiding current treatments [2], this view has typically been ignored by standard diagnostic approaches. Diagnostic criteria (eg, Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition [3]) are mainly focused on determining the existence of a given dysfunctional process for a given predefined period (eg, depressed mood during the past 2 weeks and generalized worry during the past 6 months), without considering their potential interplays with ongoing cognitive-affective processes that might be causing or maintaining the problems across time. The obvious consequence of ignoring time-varying data in this issue is a lack of knowledge on the proximal cognitive-affective mechanisms potentially driving the onset, maintenance, and recovery of affective dysfunctions [4].

In this line, to better understand the underlying mechanisms implicated in affective psychopathology, it is necessary to consider the ecological daily life dynamics of these cognitive-affective processes. Experience sampling methods (ESMs) and ecological momentary assessments [5] have emerged as crucial techniques to advance our knowledge on the dynamic psychological systems accounting for mental health and affective dysfunctions. They comprise repeated measures designs, where psychological assessments are performed several times a day for several days. The use of these methods has many advantages in addition to the rich and detailed information they provide. ESMs support in situ evaluations (state measures), which reduce the memory bias for self-reported retrospective assessments [6]. Furthermore, the clear improvement in the ecological validity of ESMs, in contrast to trait-based questionnaires, permits greater generalizability. It allows for the investigation of different individuals in their own contexts across time and situations, enriching theoretical and practical knowledge about the cognitive-affective processes of mental health and well-being [7]. To date, ESM research has clearly advanced the understanding of psychological processes involved in mental health, such as affective emotional reactivity [8], emotion regulation dynamics [9], the ecological use of simultaneous emotion regulation strategies [10], and the specific effectiveness of these strategies to regulate different momentary affective states [11]. However, these ESM measurements are still solely based on self-reports and do not allow for the evaluation of the underlying processes of these affective dynamics, namely cognitive-affective mechanisms. Individual preferences in the way that emotional information is attended to or interpreted (ie, cognitive biases) are typically assessed using experimental technologies such as eye tracking [12] in controlled laboratory conditions. These experimental methods allow for the capture of subtle mechanisms related to affective

disorders [13] and the differential use of emotion regulation strategies [14-16] or even individual differences in psychological well-being [17]. However, to date, no research has fully integrated this type of cognitive bias assessment into ESM protocols, thus lacking a proper understanding of how their ecological momentary manifestations affect emotional experiences and their regulation in daily life.

Therefore, we developed a highly novel app system integrating a novel app-based cognitive task that allows for the measurement of attention and interpretation biases into a new ESM tool. This new method combines self-reported assessments of mood, stress appraisals, and emotion regulation use with momentary assessments of attention and interpretation biases during real-life functioning. Such assessments are based on the computerized version of the Scrambled Sentence Task (SST) [17], where participants are asked to freely unscramble a series of 6 scrambled word sentences displayed on the screen (eg, *born loser am I winner a*) using only 5 out of 6 words. The only 2 possible solutions to resolve the sentence are into a positive or a negative meaning (eg, *I am a born winner* or *I am a born loser*, respectively), and attentional processing of positive (eg, *winner*) and negative (eg, *loser*) are further assessed through advanced eye-tracking–based techniques [18]. In a series of experimental studies using this task, it was found that participants showing higher biases toward negative over positive information have poorer abilities to use emotion regulation strategies supporting negative affect downregulation (lower use of reappraisal and higher use of rumination) [19]. Furthermore, previous studies using the presented novel web-based app have demonstrated that ecological assessments of these negative cognitive biases assessed with this app-based cognitive task through mobile phones are predictive of poorer abilities to use emotion regulation strategies in their daily life functioning, ultimately leading to increased depressive and anxiety symptoms and reduced well-being in the face of major stressors [20]. Thus, given the large potential of these novel technical approaches to inform advanced health-related research and technology innovations, a thorough analysis of their usability and the conditions that facilitate their compliance is required. Ultimately, the aim of this study is to test the usability and feasibility of our method to be implemented for advanced research on the ecological mechanisms of mental health. Specifically, we first aim to study users' perceived usability and satisfaction with the novel system, which integrates cognitive tasks within extensive ESM procedures. Second, we aim to establish the degree of measurement reactivity to the new method. Finally, we aim to establish factors that must be considered to maximize compliance with the use of the method, both in terms of latency and missing responses. For the latter, we exhaustively examine what factors are involved in effective compliance with this type of new ESM system, considering usability, satisfaction, reactivity, and emotional symptoms, as well as time-related variables as predictors.

Potential factors accounting for differences in compliance with the new ESM system were pre-established based on previously identified factors involved in the compliant use of ESM procedures in general [5,21,22]. Compliance with ESM protocols can be defined in two ways: (1) effectively answering

the scheduled signals at the arranged times and (2) preventing the missing of assessment notifications. Therefore, it comprises time latencies and missing responses. Time latency is referred to as the time lag participants require to respond to a prompt or signal to start completing a momentary assessment, which ranges across studies from 90 seconds [23] to 3 hours [24]. Studying the latency of responses has several implications for the methodological quality of ESM studies and the quantity of available data, and it is closely related to missing rates.

Dealing with low compliance and abandonment rates has become a significant challenge when applying ESM designs in general. Owing to this, there is growing evidence exploring the possible systematic predictors of larger response latencies and missing data.

First, in terms of time-related variables, several studies have consistently found that missing rates tend to increase as ESM studies extend over time [25-30], although with some exceptions [31] (see available meta-analyses [29,32,33]). Furthermore, the effects of time of day (whether responding to ESM prompt signals during the morning, afternoon, or evening) are consistently related to missing responses [30,34,35]. For instance, some studies have found higher compliance rates in the afternoon (between 12 PM and 1:30 PM) and lower compliance rates in the morning (between 7:30 AM and 9 AM) [28]. Hence, in line with the revised literature, it is hypothesized that lower compliance with the new ESM system (increases in latency and missing responses) would emerge as the days of the study progress, as well as for earlier notifications during the day.

Second, there are relevant individual-related variables that should be considered when applying ESM procedures in general and specifically in ESM systems assessing mechanisms of mental health, such as the one proposed in this research. This refers to the consideration of how participants' psychopathological conditions affect their compliance with ESM. This issue has been considered in previous research and has shown different results. Some studies have not found differences in ESM compliance among clinical conditions (schizophrenia, substance dependence, and anxiety disorders vs no diagnosis) [31]. However, other studies have found that higher missing rates are predicted by various clinical conditions, including anxiety and depression levels [29,30,32-35]. Therefore, the second aim of this study is to test whether individual differences in emotional symptoms (depression and anxiety levels) affect compliance with ESM. Considering that in this study, we evaluate 2 samples with subclinical symptom levels, it is hypothesized that no associations would be found between individual levels of depression and anxiety and compliance rates, supporting the feasibility of the ESM system for its use in this type of population.

Third, we considered it crucial to explore the implications that ESM approaches such as the one proposed have on individuals' momentary experiences. Responding to ESM assessments at various times during the day entails paying regular attention to internal states and behaviors. Different results have been found regarding how the frequency of daily ESM assessments affects the dynamic trajectory of the psychological phenomenon being measured, thus generating different forms of measurement reactivity [36-38]. To date, few studies have evaluated the relationship between ESM compliance rates and experienced negative (burden) or positive (usefulness) measurement reactivity ESM. A recent study found an association between perceived burden and higher missing rates in longer ESM protocols [23]. According to this, to test the new ESM system developed for this study, we collected information regarding several measurement reactivity indicators that could be associated with different levels of compliance: experienced overload and stress generated by evaluation requirements, perceived usefulness of the assessment, and general satisfaction with the procedure. However, given the novelty of the topic under study, only the hypothesis regarding the relationship between burden and compliance is described. It is hypothesized that experiencing stress and overload would be related to lower compliance with the ESM protocol [23]. We further explore the relationship between positive reactivity variables, such as satisfaction and usefulness, and compliance rates during ESM because of the lack of previous literature on this topic.

Finally, when testing a new technological tool such as the one developed in this study, it is necessary to establish its degree of usability in terms of the system's ease of use and learnability. Several studies have reported that patients with psychological disorders often find difficulties in engaging with technology that is challenging to use or that is perceived as irrelevant to their needs [39,40]. Therefore, given the purpose of this new ESM tool (ie, ultimately implementing it for use with clinical samples), we aim to initially test it in subclinical samples, considering the usability of the tool, analyzing its relationship with individual differences in depression and anxiety levels, and testing whether different individual levels of perceived usability have an influence on compliance with the novel ESM protocol. There is no previous evidence on this topic, despite its clear importance. Owing to this fact, no specific hypotheses were made about the relationship between usability and participants' compliance with the new ESM approach.

To test these research issues, we conducted two studies testing the new app-based tool with different ESM regimes: The first study comprised a controlled experiment of 1 week (ie, study 1: a total of 5 days), and the second study extended the used ESM system to a larger period, comparable with regimes used in other types of ESM studies (ie, study 2: a total of 10 days), as described in the following sections.

Study 1

Methods

Participants

A sample of 84 undergraduate students (age: mean 20.05, SD 2.19 years) was recruited from the Faculties of Psychology of Complutense University of Madrid and the Autonomous University of Madrid. The participants received extra credit for participating in the study.

Procedure

Participants attended an introduction session in groups of 15 to 20, during which they received information about the study protocol and completed the informed consent forms, as well as baseline questionnaires assessing demographic variables and depressive and anxiety symptom levels. During the introductory session, participants downloaded the ESM tool, comprising a mobile app, and performed practice trials to become familiar with its use. A day after the introduction session, participants were instructed to complete the ESM assessment each time they received a new signal notification. A systematic sampling approach was used to determine random signaling schedules. Experience sampling assessments were programmed to be sent to participants 3 times a day for 5 days. These assessments were prompted randomly between 9 AM and 9 PM at three time intervals (9 AM to 1 PM, 1 PM to 5 PM, and 5 PM to 9 PM). Participants had 1 hour since they received the notification to complete the assessment. In each ESM assessment, they completed measures of stress, current affect, and use of emotion regulation strategies and performed a cognitive bias task. Furthermore, using the software, we generated a database where we gathered compliance-related information, such as the latency of response, missing assessments, and abandonment rates. At the end of the study, participants completed a brief questionnaire that accounted for variables related to measurement reactivity (app stress, app overload, and app usefulness) and user experience (usability and satisfaction). Questionnaires at baseline and the end of the study were gathered using Qualtrics (Qualtrics International Inc) software.

Instruments

Baseline Measures

In the initial introduction session, participants rated their levels of depression and anxiety, which were measured with the Center for Epidemiologic Studies–Depression (CES-D 8 [41]) scale and the Generalized Anxiety Disorder-7 (GAD-7 [42]) scale, respectively.

The CES-D 8 [41] is a screening scale used to evaluate depressive symptom levels in the past week. It contains 8 items that evaluate the severity of symptoms, which show good reliability in both general and clinically depressed samples [43,44]. The internal consistency in this study was α=.86.

GAD-7 [42] is a 7-item screening questionnaire that evaluates the severity of anxiety symptom levels comprising emotional and cognitive symptoms of anxiety. This measure has good reliability and validity in both general and clinically anxious samples [45,46]. The internal consistency in this study was α=.89.

ESM Assessments

The app comprised momentary self-reported assessments of several psychological states, including self-reports of perceived ongoing stress, use of emotion regulation strategies in response to ongoing stress, motivational factors, and current mood states.

Participants also completed a novel app-based cognitive task assessing momentary attention and interpretation biases in each survey. We created a computerized SST [17] that allows for app-based assessments of these cognitive biases. This task has been previously validated for the evaluation of attention and interpretation bias in various formats, such as computers [18], and it has already been used in mobile phones for implementation in ESM procedures [20]. Participants were required to complete 20 sentences at each ESM assessment a total of 3 times a day for 5 days. The full details of the ESM assessments in the new tool are provided in Multimedia Appendix 1.

Assessments at the End of the Study

Once participants completed the ESM part of the study, they received a final questionnaire to measure variables related to the use of the app: usability, satisfaction, app stress, app overload, and app usefulness. They completed these questionnaires using Qualtrics. To date, there are no validated evaluation protocols to assess these characteristics for eHealth mobile apps. Therefore, for some of the variables of interest, we opted to select single items from the Mobile Application Rating Scale [47] that best resembled the following measurement reactivity variables of interest: app satisfaction, app stress, app overload, and app usefulness.

App stress was measured to control for the reactivity of participants while performing ESM with this app with the item "I felt more nervous than usual, while being vigilant to receive the App's notifications."

App overload was used to control for whether the length of the ESM assessments (ie, self-reported surveys and trials of the app-based cognitive task) was generating overload in participants: "The number of exercises to perform in each signal was excessive."

We also included an item to measure whether participants found the app useful in terms of facilitated introspection to understand their feelings, cognitions, and behaviors (app usefulness) with the item "Using the App has helped me to be more conscious about my emotional and cognitive responses through the day and across days."

Global satisfaction with the app was assessed using a Likert scale ranging from 0 to 10, with 10 being highly satisfied: "Indicate, from 0 to 10, your overall satisfaction with the app."

Finally, we used the System Usability Scale (SUS) [48] to measure the usability of the new ESM tool. Usability was assessed at the end of the study to estimate whether the new software had been experienced as usable. This scale has been previously validated [49], and it measures aspects such as complexity, technical support, integration, consistency, and general satisfaction. We computed the overall score following the indications of the author, which ranged from 0 to 100, with scores >68 being considered above average.

App Compliance

Compliance was defined in terms of two different dependent variables: latency and missing responses. Latency was indexed by the time participants took to respond to each signal (ie, the time lag between the prompt and the actual response, which had a maximum of 60 minutes). Missing responses were indexed

using scheduled ESM prompts that were not completed by the participant.

Analytic Plan

We first conducted descriptive analyses of the data and used correlation analyses to study the relationships between participants' symptoms (depression and anxiety levels), usability scores, and variables related to measurement reactivity (app stress, app overload, app usefulness, and satisfaction).

Then, to test factors accounting for individual differences in compliance, we ran multilevel analyses taking into account the nested structure of the data because of the repeated measures design (ie, observations nested within days and days nested within persons). This permitted the examination of the momentary variation of compliance variables (latency and missing responses) across prompts, considering the variability in intrapersonal and interpersonal variables. We used the *lme4* R package [50] to conduct the models predicting latency responses and missing responses. We applied the function *glmer* for latency because of the reaction time characteristics [51], specifying the family as Gamma. The *glmer* function was also used in models predicting missing responses, as this variable was coded as categorical, specifying family as a binomial. In all the models, we specified crossed random effects at the individual level. All models were fit by maximum likelihood estimation.

We first modeled an empty model, with each compliance variable predicted by its intercept. After that, we added one predictor variable at a time (univariate models) and then fitted a model with all predictors included simultaneously (multivariable model) to test whether the effects of predictor variables changed once the remaining variables were included. Fixed slopes were specified for all the models.

Thus, the time of day was entered as a level 1 predictor and day as a level 2 predictor. To explore whether individual differences in depression and anxiety levels affected compliance during the ESM study, these variables were introduced as level 3 predictors.

Variables such as app stress, app overload, app usefulness, global satisfaction with the app, and usability were also introduced as level 3 predictors. We performed grand centering transformation of all the variables introduced as level 3 predictors.

Ethics Approval

The study was approved by the Faculty Ethical Committee of Complutense University of Madrid (Protocol Code Ref. 2019/20-028) and complied with the Declaration of Helsinki's ethics standards.

Results

Sample Characteristics and General App Performance

Initially, we recruited 102 university students. The level of abandonment was low; only 8.8% (9/102) of participants stopped responding to the ESMs and did not finish the study. Of those 9 participants, 5 (56%) missed the last 5 ESM prompts, and 4 (44%) responded only once. In addition, 8.8% (9/102) participants did not respond to the last questionnaire after completing the ESM protocol. Therefore, of the 102 participants, the final sample comprised 84 (82.4%) participants, with a mean age of 20.03 (SD 2.19) years, ranging from 18 to 29 years. We found a low mean number of missing responses per participant—1.43 (SD 1.97), ranging from 0 to 8 missing responses per participant. The mean levels of latency per participant found in this study were 16.38 (SD 7.37), ranging from a minimum of 3.24 minutes to a maximum of 34.37 minutes per participant. As shown in Table 1, participants presented mild levels of depression and anxiety, as measured with the CES-D and GAD-7, respectively. Mean scores for measurement reactivity showed moderately high levels of stress related to the use of the app. The mean app overload showed medium levels, pointing that the number of measures per assessment (questionnaires and cognitive bias tasks) was not burdensome. The extent to which participants found the app useful reflected moderately high scores, whereas their general satisfaction with the app showed medium levels.

Table 1. Sample characteristics and general app performance (study 1; N=84).

Characteristics	Study 1 sample
Sex (female), n (%)	75 (89)
Age (years), mean (SD)	20.03 (2.19)
Anxiety (GAD-7[a]; 0-21), mean (SD)	5.55 (3.82)
Depression (CES-D[b] 8; 0-24), mean (SD)	7.64 (4.07)
App stress (1-5), mean (SD)	3.38 (1.50)
App overload (1-5), mean (SD)	2.69 (1,24)
App usefulness (1-5), mean (SD)	3.18 (1.30)
Satisfaction with the app (1-10), mean (SD)	6.95 (1.61)
Usability (SUS[c]; 0-100), mean (SD)	81.01 (12.08)

[a]GAD-7: Generalized Anxiety Disorder-7.

[b]CES-D: Center for Epidemiologic Studies–Depression.

[c]SUS: System Usability Scale.

Importantly, participants reported high levels of usability measured by the SUS.

Out of 100, it reached a mean usability score of 81.01 (SD 12.08), reflecting its ease of use and learnability. According to the authors who validated the scale [49], scores >70 are considered above average and acceptable, and >80.30 is in 10% of the best-rated systems [49].

Correlation Analyses

Correlation analyses were conducted to test how the levels of emotional psychopathology (ie, depression and anxiety levels) are related to measurement reactivity and usability indices. Given the nonnormal distribution of these variables, we conducted Spearman correlation analyses, which are shown in Table S1 in Multimedia Appendix 1. First, we found a positive, significant relationship between depression and anxiety levels ($r=0.67$; $P<.001$), indicating a relatively high degree of comorbidity among both types of symptoms. Nonetheless, neither anxiety nor depression levels were related to individual differences in the variables of user experience with the app or its usability, suggesting that such ratings were not affected by individual differences in symptom levels. Furthermore, we found significant correlations between usability and most of the measurement reactivity variables. Usability was positively related to app usefulness and satisfaction ($r=0.31$, $P=.004$ and $r=0.60$, $P<.001$, respectively) and negatively related to app overload ($r=-0.46$; $P<.001$) but not to app stress ($r=-0.21$; $P=.05$). These results show the importance of focusing on user experience when developing new eHealth app-based assessment methods, as it seems to be closely related to measurement reactivity and, in turn, the methodological quality of the design. In addition, app overload was significantly positively related to app stress ($r=0.23$; $P=.02$) and negatively related to satisfaction with the app ($r=-0.30$; $P=.008$), indicating that feeling burdensome because of the length of evaluations is related to the stress generated by the notifications' requirements and to lower satisfaction with the app.

Multilevel Analyses

Latency

We conducted a series of transformations to control for the distribution of the outliers. Outliers were substituted with the upper or lower threshold of each participant based on the IQR. After that, we calculated the interclass correlation coefficient (ICC) for the empty model, showing a value of 14% for between-person variance. After that, we performed linear mixed models to test the predictors of the variability of latency when responding to experience sampling.

First, we conducted a series of univariate models, including 1 predictor at a time, and then tested them in a multivariate model to determine whether those effects remained significant after the inclusion of all predictor variables simultaneously. This information can be found in Table 2.

Analyses testing the effects of time-related variables on latency showed a significant effect of the day on responses' latency in the univariate model (estimate 1.03 [SE 0.32]; $P<.001$), which remained significant in the multivariable model (estimate 1.00 [SE 0.22]; $P<.001$), indicating that a change of 1 unit on the score scale of the day (ie, 1 day passed) produced a 1.00 point of increase in latency. This indicated that as the study progressed, response latencies were longer. Furthermore, we did not find a significant effect of time of the day, neither in the univariate model nor in the multivariate model. Analyses testing the effects of emotional symptomatology on latency showed no significant effects of depression or anxiety levels when introduced as single predictors or in the multivariate model. Thus, participants' levels of symptomatology did not influence their response latencies. Analyses testing the relationship between app-related variables and latency rates showed no significant effects of any of the variables when introduced as single predictors in the univariate models. In the multivariate model, a significant effect of app usefulness was found (estimate 1.38 [SE 0.61]; $P=.02$), indicating that participants who found the app as more useful took more time to respond to the notifications (an increase of 1 point in the score scale of app usefulness was related with an increase of 1.38 points in latency).

Table 2. Predictors of response latency (study 1).

Outcome variable: latency	Estimate (SE)	*t* value	*P* value
Empty model			
Intercept	15.91 (0.74)	21.42	<.001
Univariate models			
Day	1.03 (0.22)	4.70	<.001
Time of day	−0.60 (0.37)	−1.61	.11
Depression	0.11 (0.19)	0.59	.55
Anxiety	−0.05 (0.20)	−0.26	.80
App stress	−0.63 (0.50)	−1.26	.21
App overload	0.14 (0.61)	0.24	.81

Missing

The ICC calculation of the empty model predicting missing responses showed a value of 41% for between-person variance. Analyses testing the effect of time-related variables on missing responses showed significant effects of the day number both in the univariate model (estimate 0.23 [SE 0.08]; *P*=.004) and in the multivariable model (estimate 0.24 [SE 0.08]; *P*=.003). Time of the day did not show a significant effect on missing responses in the univariate or multivariate models. This information can be found in Table 3. Therefore, as the study progressed, the number of missing responses became higher, whereas the time of the day in which notifications were sent did not show an effect on missing responses. Analyses testing the effects of emotional symptomatology on missing responses showed no significant effects of depression or anxiety levels when introduced as single predictors or when included in the multivariate model. Finally, analyses testing the relationship between app-related variables and missing response rates showed no significant effects of app stress, app usefulness, app overload, satisfaction, or usability on missing responses. These effects were not significant in either the univariate or the multivariate models. Therefore, we can assume that technical, personal, or usability-related variables were not related to the differential missing response rates.

Table 3. Predictors of missing responses (study 1).

Discussion (Study 1)

The main aim of this study was to examine the usability and feasibility (ie, compliant use) of a new ESM tool that integrates self-reported assessments of affective experience and a cognitive task assessing attention and interpretation biases. A series of multiple time, person, and system reactivity variables were tested as potential predictors of compliance. First, participants reported high levels of usability for the new ESM system, with scores on 10% of the best-rated systems, according to the SUS criteria. Compliance was also high in terms of both low latencies and missing responses. As for compliance predictors, we found significant effects of the day number on response latency and missing responses, indicating that latencies became longer, and there were higher missing rates as the study progressed. These results are in line with previous literature, which supports that lower compliance is found as the days of the study progress [35].

Individual differences in depression and anxiety levels did not act as significant predictors of compliance for either latency or missing responses. These results suggest that adequate compliance with the ESM system is not affected by participants' subclinical depression and anxiety levels, which is a crucial aspect of the aim of this type of new ESM system. To advance future clinical implementation, further research should analyze these issues in participants presenting with higher levels of

depression and anxiety symptomatology to test the effect of clinical status on compliance with this ESM system integrating both self-reports and cognitive tasks [36].

Furthermore, system-related variables were not significantly associated with compliance rates, except app usefulness. Interestingly, participants who found the app to be more useful were those who were slower in responding to momentary notifications. This might be indicative of an attempt to find the more proper moments to adequately perform the app tests and assessments within the allowed 1-hour period after notification. Nonetheless, this effect was only evident in the multivariate model, whereas the univariate analyses did not show any direct association and should be considered cautiously until further replication.

Overall, the results showed high usability and feasibility for the use of the new ESM system, with few factors substantially accounting for its adequate compliance. Nonetheless, we should note various limitations in this study. First, we used single items to evaluate variables related to measurement reactivity, such as app stress, overload, usefulness, and satisfaction, which might at least partly obscure some of their potential associations with compliance.

Furthermore, there might be certain limitations in the generalizability of the results, given the relatively short number

of days evaluated (ie, 5 days). These current findings invite further replication using the new ESM system in protocols with more extensive durations that are comparable with other ESM research considering compliance predictors. For these reasons, we performed a second ESM study with a longer protocol (ie, 10 days of assessments), integrating the study of measurement reactivity variables not only through single items but also through different validated scales.

Thus, study 2 overcame the abovementioned issues, adding further contributions to knowledge in particular areas. First, in study 2, we expanded the sample of participants and extended the duration of the study. It is important to verify whether the results, in terms of reactivity with the app and compliance, would change when participants were evaluated twice as long. In addition, we performed a significant methodological improvement by including validated subscales to measure the variables of app-related stress, overload, usefulness, and satisfaction to derive precise knowledge of their relationship with compliance rates.

Study 2

Methods

Participants

A sample of 135 undergraduate students (age: mean 20.52, SD 2.31 years) was recruited from the Faculty of Psychology at Complutense University of Madrid between April and May 2021. The participants received extra credit for participating in the study.

Procedure

Participants individually attended an app-based introductory session in which they received information about the study. They were trained to use the app in which the ESM system was integrated and performed a practice exercise of self-report measures and cognitive tasks. On the first day, they also completed the informed consent and a baseline questionnaire assessing demographic variables, measures of depression and anxiety levels, and other scales not relevant to the aim of this study. One day after the introductory session, participants were instructed to start completing the ESM protocol through the app on their phones each time they received a survey notification. A systematic sampling approach was used to determine the random signaling schedules. Experience sampling assessments were programmed to be sent to participants 3 times a day for 10 days. These assessments were prompted randomly between 10 AM and 9 PM at three time intervals (10 AM to 11 AM, 3 PM to 4 PM, and 8 PM to 9 PM). Participants had 1 hour since the time they received the notification to complete the assessment. At each assessment, they completed assessments of stress, current affect, and emotion regulation strategies and performed the cognitive bias task exactly as in study 1. Furthermore, as in study 1, compliance-related information, such as latency of response and missing and abandonment rates, was gathered. At the end of the study, participants completed a brief questionnaire that accounted for variables related to measurement reactivity and user experience. Questionnaires were completed at baseline and at the end of the study using Qualtrics software.

Instruments

Baseline Assessments

Depression and anxiety symptom levels were measured using the CES-D-8 [41] and the GAD-7 [42], respectively, as in study 1. The internal consistencies for the CES-D 8 and GAD-7 in this study were α=.88 and α=.86, respectively.

Momentary Assessments

As in study 1, assessments referring to self-reports of perceived ongoing stress, use of emotion regulation strategies, and current mood states were evaluated through app-based self-reports. In each signal, participants also completed a cognitive task assessing momentary attention and interpretation biases, which was based on the SST [17]. They were required to complete 15 phrases at each beep for a total of 3 times a day for 10 days. Further details of all assessments are provided in Multimedia Appendix 1.

Assessments at the End of the Study

As in study 1, after completing the ESM procedure, participants received the last questionnaire survey, which measured system usability, measurement reactivity, and user experience using the same assessments. Furthermore, study 2 also included the assessment of measurement reactivity and user experience dimensions using additional subscales extracted from validated questionnaires to measure stress, overload, usefulness, and satisfaction related to the use of the app.

Usability was measured using the SUS [48], as in study 1. The internal consistency of this scale in the study was α=.75.

Stress reactivity resulting from app use (subscale) was assessed through the Pressure/Tension subscale of the Intrinsic Motivation Inventory [52]. This subscale contains 5 items that measure the negative reactivity of participants while performing ESM with the tool. The internal consistency of this scale in the study was α=.56.

Overload resulting from app use (subscale) assessed the experienced negative affect and the degree of control and effort required during the completion of the ESM protocol. This was assessed using the Perceived Usability subscale from the User Engagement Scale [53], which comprises 8 items. The internal consistency of this scale in the study was α=.84.

To measure app usefulness (subscale), we used the Value subscale of the Intrinsic Motivation Inventory [52] to assess how participants found it useful to complete the ESM protocol by being more conscious of their own emotional and cognitive states. The internal consistency of this scale in the study was α=.94.

Satisfaction with the app was assessed using the Endurability subscale from the User Engagement Scale [53], referred to as the overall success of the interaction and users' willingness to recommend the app to others or engage with it in the future. The internal consistency of this scale in the study was α=.90.

App Compliance

Participants' level of commitment was also assessed in study 2. Therefore, latency and missing responses were recorded to perform compliance analyses, exactly as in study 1.

Analytic Plan

The analytic plan in study 1 was entirely reapplied in study 2. We conducted a descriptive analysis and performed Spearman correlation analyses because of the nonnormal distribution of the variables of interest. In addition, similar mixed model regression analyses were performed, as in study 1. Furthermore, we conducted an additional multivariate model in which we included methodological variables (day and time of the day), emotional symptomatology, usability, and variables related to the use and reactivity to the ESM system, as measured through the further included validated subscales (stress, overload, usefulness, and satisfaction). Therefore, separate analyses were conducted considering the item-based indices of measurement reactivity (ie, for the replication of the study 1 results) and further scale-based indices of measurement reactivity included in this study.

Ethics Approval

The study was approved by the Faculty Ethical Committee of Complutense University of Madrid (Protocol Code Ref. 2020/21-023) and complied with the Declaration of Helsinki's ethics standards.

Results

Sample Characteristics and General App Performance

As shown in Table 4, participants presented moderate depression and low anxiety levels, as measured with the CES-D 8 and GAD-7, respectively. Initially, we recruited 139 participants, from whom we found high compliance, as the level of abandonment was very low—2 (1.46%) participants in the sample (corresponding to 2 participants who completed <6 assessments). These 2 participants were excluded from the analysis because of the noncompletion of the questionnaires on usability and measurement reactivity at the end of the ESM protocol. Therefore, of the 139 participants, the final sample included in the analyses comprised 135 (97.1%) participants with a mean age of 20.51 (SD 2.31) years. We found a low mean number of missing responses per participant—3.60 (SD 3.32), ranging from 0 to 17 missing responses per participant. The mean levels of latency per participant found in this study were 23 to 79 (SD 8.1) minutes, ranging from a minimum of 6.15 minutes to a maximum of 49.64 minutes per participant.

Table 4. Sample characteristics and general app performance (study 2; N=135).

Characteristics	Values
Sex (female), n (%)	116 (85.9)
Age (years), mean (SD)	20.51 (2.31)
Anxiety (GAD-7[a]; 0-21), mean (SD)	8.38 (4.11)
Depression (CES-D[b] 8; 0-24), mean (SD)	9.09 (4.89)
App stress (item; 1-5), mean (SD)	2.96 (1.30)
App overload (item; 1-5), mean (SD)	2.93 (1.25)
App usefulness (item; 1-5), mean (SD)	3.44 (1.14)
Satisfaction (item; 1-10), mean (SD)	6.62 (1.92)
App stress (IMI[c] subscale; 1-7), mean (SD)	3.09 (1.09)
App overload (UES[d] subscale; 1-5), mean (SD)	1.86 (0.77)
App usefulness (IMI subscale; 1-7), mean (SD)	4.16 (1.37)
Satisfaction subscale (UES subscale; 1-5), mean (SD)	3.40 (0.95)
Usability (SUS[e]; 0-100), mean (SD)	82.17 (11.74)

[a]GAD-7: Generalized Anxiety Disorder-7.

[b]CES-D: Center for Epidemiologic Studies–Depression.

[c]IMI: Intrinsic Motivation Inventory.

[d]UES: User Engagement Scale.

[e]SUS: System Usability Scale.

In general, participants showed medium levels in variables related to the negative reactivity of the app (stress and overload), both measured using single items and their corresponding subscales. Participants showed medium to high scores in perceived usefulness when using the app and global satisfaction, as reflected by both the single items and the corresponding subscales. Overall, the results showed that participants did not report feeling stressed or overloaded because of the use of the system while participating in the study. Furthermore, participants found the app useful for its purpose of facilitating awareness of internal affective and cognitive states.

In addition, importantly, the usability of the app was rated as very high (mean 82.17, SD 11.74), as measured by SUS, where scores >80.30 are considered to be in 10% of the best-rated systems.

Correlation Analyses

The set of Spearman correlations is shown in Table S2 in Multimedia Appendix 1. As in study 1, we found a significant relationship between anxiety and depression levels (r=0.71; P<.001), indicating a certain degree of comorbidity among the symptoms. Second, we found a significant positive relationship between anxiety levels and reactive stress (measured by a single item; r=0.21; P=.01), indicating that participants who scored higher on anxiety levels felt more nervous or stressed because of ESM notifications. However, these results were not replicated in relation to the app stress subscale.

As in study 1, usability was significantly related to various variables concerning the reactivity with the app. We found negative significant relationships between usability and app stress (single item r=−0.21, P=.02; subscale r=−0.39, P<.001) and between usability and app overload (single item r=−0.40, P<.001; subscale r=−0.47, P<.001). We also found positive significant relationship between usability and app usefulness (single item r=0.26, P=.002; subscale r=0.43, P<.001) and app satisfaction (single item r=0.50, P<.001; subscale r=0.43, P<.001). Therefore, participants who found the app more usable showed lower levels of app stress and overload and higher levels of app usefulness and satisfaction with its use.

Variables referring to the negative measurement reactivity (stress and overload) were significantly and positively correlated (between single items: r=0.34, P<.001; between subscales: r=0.57, P<.001), indicating that those participants who felt more stressed because of notification requirements also felt higher overload because of completing each assessment. On the other hand, we found positive and significant correlations between general satisfaction with the app and perceived usefulness (between single items: r=0.45, P<.001; between subscales: r=0.72, P<.001). Overall, these results replicate and extend the previous findings in study 1 and are in line with previous research validating app-based tools of psychological assessment [54].

Multilevel Analyses

Latency

As in study 1, we conducted a series of transformations to control for the distribution of outliers. After that, we used linear mixed models, fitted by maximum likelihood estimation, to test time-, person-, and system-related predictors of the variability of latency when responding to experience sampling (results of empty univariate and multivariate models predicting latency can be found in Table 5). We used the same models as in study 1, and an additional multivariate model was tested, with variables related to measurement reactivity measured through the corresponding subscales. We also calculated the ICC for the empty model predicting latency responses, which showed a value of 22% for between-person variance.

Analyses testing the effects of design and time-related variables on latency showed a significant effect of the day number, showing the same effect in both the univariate (estimate 0.28 [SE 0.09]; P=.001) and multivariate models (estimate 0.29 [SE 0.09], P=.01; estimate 0.28 [SE 0.09], P=.001, respectively). Time of the day also showed significant effects on latency responses in the univariate model (estimate −0.42 [SE 0.21]; P=.04) and in both multivariate models (estimate −0.44 [SE 0.21], P=.04; estimate −0.43 [SE 0.21], P=.04, respectively). The results partially replicated those from study 1, showing that response latencies became longer as the study progressed; however, only in study 2, later notifications within the day were further related to lower latency rates and, therefore, to faster responses in those moments of the day.

As in study 1, analyses testing the effects of symptomatology levels on latency showed no significant effects of depression and anxiety on the latency response rates. Therefore, the levels of emotional symptomatology of the participants did not affect their latencies to respond to notifications.

Finally, analyses testing the effects of app-related variables on latency showed a significant effect of app overload, measured through the subscale (estimate 1.52 [SE 0.71]; P=.03) in the univariate model. This effect remained significant in the multivariate model when introduced with the remaining variables (estimate 2.20 [SE 1.02]; P=.03). Thus, higher experienced overload during the ESM protocol was associated with longer response latencies to notifications.

Table 5. Predictors of response latency (study 2).

Outcome variable: latency	Estimate (SE)	*t* value	*P* value
Empty model

App usefulness subscale	0.10 (0.56)	0.18	.86
App satisfaction subscale	0.51 (0.83)	0.61	.54
Usability	0.06 (0.06)	0.99	.32

Missing

First, we calculated the empty model predicting missing responses and the ICC, which showed a value of 20% for between-person variance. Analyses testing the effects of design time–related variables on missing responses showed that time of the day was a significant predictor in both the univariate model (estimate 0.17 [SE 0.02]; *P*=.01) and the multivariate models 1 and 2 (estimate 0.16 [SE 0.06]; *P*=.01).

As for the analyses of the effects of emotional symptomatology on missing response rates, nonsignificant effects of depression and anxiety levels were found on missing responses.

Finally, analyses testing the relationship between app-related variables and missing response rates showed that item-based app stress had significant effects in the univariate model (estimate 0.21 [SE 0.07]; *P*=.004), which remained significant in multivariate model 1 (estimate 0.18 [SE 0.08]; *P*=.004). Item-based overload also showed a significant effect in the univariate model (estimate 0.16 [SE 0.08]; *P*=.04); however, this effect did not remain significant in multivariate model 1 (estimate 0.08 [SE 0.09]; *P*=.36). As for subscale-based measurements (model 2), app overload measured through the subscale also showed significant effects on missing rates when introduced as a single predictor (estimate 0.29 [SE 0.12]; *P*=.02), as well as on app satisfaction measured through a subscale (estimate –0.20 [SE 0.10]; *P*=.049). However, when all predictors were introduced in multivariate model 2, neither of these variables showed any significant effect (results of empty univariate and multivariate models predicting missing responses can be found in Table 6).

Table 6. Predictors of missing responses (study 2).

Outcome variable: missing	Estimate (SE)	z value	P value

Discussion (Study 2)

Study 2 was conducted to test the new ESM system using a longer ESM protocol than in study 1 and increase the methodological quality of app reactivity measurement from study 1, adding further assessments of these characteristics through validated subscales of app stress, overload, usefulness, and satisfaction.

Study 2 replicated the high usability scores of the new ESM system, with high levels over the 90th percentile of the SUS scale. Higher usability was related to several indicators such as lower user stress and overload and higher usefulness and

satisfaction, replicating and extending the findings from study 1 on the acceptability of the novel procedure.

Furthermore, compliance with the protocol was high, as in study 1, showing that extending the protocol regime did not affect general compliance. After performing mixed model analyses, we replicated the findings from study 1 on the time-related predictors of compliance with the procedure. We found a significant effect of day number on response latency, indicating that latencies became longer as the study progressed. These results are in line with the findings of study 1. In addition, a negative relationship between the time of the day and latency was found, indicating that in earlier notifications, latencies tended to be slower. This result was not found in study 1 and may indicate that extending the duration of the ESM protocol may permit the identification of performance patterns that may remain undetected for shorter durations (ie, a 5-day duration in study 1). Furthermore, we found that time of the day was also a significant predictor of missing responses, indicating more missing responses in later notifications of the day (interval between 8 PM and 9 PM). These results are in line with previous research showing lower compliance in terms of missing response rates in later daily notifications [28].

In addition, as in study 1, depression and anxiety levels were not found to significantly predict variability with ESM compliance, which is important for the future implementation of these measurements in clinical samples. Importantly, study 2 was completed from April to May 2021, when the COVID-19 pandemic was a persistent source of threat, and this was evidenced by participants' symptom levels, which were higher than those for participants in study 1, which was completed in 2019. Thus, although the samples were comparable in terms of sociodemographic characteristics, depression and anxiety reached higher overall subclinical levels in the sample of study 2. The fact that symptom levels in study 2 did not affect levels of compliance is clearly indicative of the feasibility of the ESM system for further implementation in clinical settings in the future.

In terms of measurement reactivity, we found significant effects of the measurement reactivity variables in predicting compliance in study 2. Higher app overload was related to more response latencies, whereas app stress significantly predicted more missing responses. These results are in line with previous research suggesting that a higher negative measurement reactivity is related to lower compliance rates [23]. Interestingly, these effects were not found in study 1, suggesting that the influence of these variables on the compliant performance of the new ESM system may only emerge when using more extensive protocols of assessment (ie, 10 days vs 5 days).

Discussion

Principal Findings

The aim of this study was to investigate the usability and feasibility of using a new ESM system, which integrates self-report questionnaires and an app-based cognitive task that allows the assessment of ecological indicators of cognitive-affective mechanisms implicated in emotion regulation and emotional symptoms, through 2 differently extensive ESM designs (studies 1 and 2). Study 1 required participants to respond to 3 assessments per day for 5 days. Study 2 integrated the ESM design into a protocol of assessments of 3 times a day for 10 days.

Across studies, we found similar results in terms of the average levels of usability of the novel ESM system, indicating its ease of use and learnability. This is particularly relevant because of the development of a new system that integrates an app-based cognitive task into the ESM procedure. Previous platforms have been developed to repeatedly assess affect through ESM, provide a visual environment [55-57], and highlight the importance of usability testing. In the case of the new ESM system used in our studies, the results on usability showed a very high level of learnability (ie, over the 90th percentile of the SUS), which reflects the ease of use and acceptability by the participants. In fact, we found that usability rates were significantly related to lower negative measurement reactivity (stress and overload) and more perceived usefulness and satisfaction with the app in both studies. Therefore, the use of this ESM system does not require an advanced technical background, and its implementation would be appropriate in the general population. The mean values of reactivity to the assessment measure were also similar across both studies, such that the levels of app overload were moderate (burdensome because of the length of assessments) and app usefulness was high (utility to increase users' conscientiousness of their internal psychological states). Furthermore, person-related variables of depression and anxiety did not affect compliance with the ESM protocol. This also informs on the feasibility of further expanding and implementing the new ESM system in clinical settings.

Moreover, we found different results between studies, such that only in study 2 (ie, with a more extensive protocol of 10 days), individual differences in app overload and stress accounted for lower compliance rates. However, it must be noted that the degree of between-person variability in compliance rates was relatively low (as indicated by the ICC derived from empty models), suggesting that such effects might turn out anecdotical.

Limitations

Despite the implications of these studies, some limitations must be considered. First, study 2 was conducted during the COVID-19 pandemic, which makes it difficult to generalize the results in terms of compliance with other regular contexts of evaluation, given the exceptional circumstances in which the participants found themselves at that time. Despite this, measures of reactivity to the mobile app and its usability remained very similar between both studies, which indicates that they may depend more on other design- or sample-related characteristics rather than on contextual conditions. This implies the feasibility of applying similar designs with the new ESM system in different contexts in a reliable manner, including the use of the novel app for the study of cognitive and emotional dynamics within individuals across multiple contexts across time. Furthermore, in terms of between-person differences, the relatively high scores in depression and anxiety levels in the sample in study 2 (subclinical levels) minimally affected compliance with the app, which is indicative of its feasibility

for further implementation with other types of at-risk and clinical populations.

Second, studies 1 and 2 differ in the way the ESM system was implemented, as it was used through a mobile app in the former one, whereas in the latter study, an integrated app system that could be completed both on phones and computers was used. Importantly, despite this difference, participants showed similar scores on usability and measurement reactivity with the system, pointing to the adequacy of using either format of the new ESM system, depending on specific user requirements.

Third, measurement reactivity variables were only measured through item-based assessments in study 1. This was solved in study 2, in which we added further validated subscales to measure the reactivity variables. Although these subscales resembled the constructs gathered by the single items, the results were not fully replicated in multivariable models 1 (item-based) and 2 (scale-based) of study 2. As these scales showed high reliability in general and added higher methodological quality, it is recommended to use them to replicate results in future studies.

Future research should also focus on incorporating other cognitive evaluation tasks into ESM systems, not just self-report assessments, combining both implicit and explicit assessments of emotional, behavioral, and cognitive processes. This promises to bring great wealth to the understanding of the psychological dynamic underlying the ecological mechanisms of people's emotional dysfunctions (ie, depression and anxiety) in daily life.

Conclusions

This study supports the validity and feasibility of the presented new ESM system. Furthermore, our findings indicate that more systematic investigations into the design characteristics influencing data quality and quantity in ESM studies are needed. The variability of compliance rates, in terms of latency and missing responses, depended on variables related to the design of the ESM procedures and measurement reactivity variables in our studies. Lower compliance was found across both studies as the days in each study progressed, and measurement reactivity variables were found to be related to lower compliance rates (higher latency and missing responses) in more extensive ESM protocols (study 2). Importantly, participants' levels of depressive and anxiety symptomatology did not affect compliance in our study, indicating the feasibility of using this type of new system in ESM designs for multiple populations. This will permit the evaluation of ecological, cognitive, and emotional dynamics in individuals' daily life and a better understanding of the underlying mechanisms ultimately influencing mental health.

Abstract

Background: The cessation of opioid use can cause withdrawal symptoms. People often continue opioid misuse to avoid these symptoms. Many people who use opioids self-treat withdrawal symptoms with a range of substances. Little is known about the substances that people use or their effects.

Objective: The aim of this study is to validate a methodology for identifying the substances used to treat symptoms of opioid withdrawal by a community of people who use opioids on the social media site Reddit.

Methods: We developed a named entity recognition model to extract substances and effects from nearly 4 million comments from the *r/opiates* and *r/OpiatesRecovery* subreddits. To identify effects that are symptoms of opioid withdrawal and substances that are potential remedies for these symptoms, we deduplicated substances and effects by using clustering and manual review, then built a network of substance and effect co-occurrence. For each of the 16 effects identified as symptoms of opioid withdrawal in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, we identified the 10 most strongly associated substances. We classified these pairs as follows: substance is a Food and Drug Administration–approved or commonly used treatment for the symptom, substance is not often used to treat the symptom but could be potentially useful given its pharmacological profile, substance is a home or natural remedy for the symptom, substance can cause the symptom, or other or unclear. We developed the Withdrawal Remedy Explorer application to facilitate the further exploration of the data.

Results: Our named entity recognition model achieved F_1 scores of 92.1 (substances) and 81.7 (effects) on hold-out data. We identified 458 unique substances and 235 unique effects. Of the 130 potential remedies strongly associated with withdrawal symptoms, 54 (41.5%) were Food and Drug Administration–approved or commonly used treatments for the symptom, 17 (13.1%) were not often used to treat the symptom but could be potentially useful given their pharmacological profile, 13 (10%) were natural or home remedies, 7 (5.4%) were causes of the symptom, and 39 (30%) were other or unclear. We identified both potentially promising remedies (eg, gabapentin for body aches) and potentially common but harmful remedies (eg, antihistamines for restless leg syndrome).

Conclusions: Many of the withdrawal remedies discussed by Reddit users are either clinically proven or potentially useful. These results suggest that this methodology is a valid way to study the self-treatment behavior of a web-based community of people who use opioids. Our Withdrawal Remedy Explorer application provides a platform for using these data for pharmacovigilance, the identification of new treatments, and the better understanding of the needs of people undergoing opioid withdrawal. Furthermore, this approach could be applied to many other disease states for which people self-manage their symptoms and discuss their experiences on the web.

Introduction

Background

Withdrawal symptoms are major contributing factors of continued opioid misuse and relapse among those who attempt to quit [1-5]. Opioid-related withdrawal can be severe and may last for a week or longer. The symptoms often include body ache, diarrhea, nausea and vomiting, profuse sweating, insomnia, and loss of appetite [6,7]. Many patients relapse to using opioids to alleviate the symptoms. The medical treatment of withdrawal is a critical target in opioid treatment—the National Institute on Drug Abuse identified finding new treatments for opioid use disorders as its highest priority [8].

Clinicians use a variety of treatments for opioid withdrawal symptoms. Currently, opioid agonists such as methadone and buprenorphine are the most common treatments for opioid use disorder, and these are often tapered, during which time withdrawal symptoms may occur. These symptoms are often managed with standard treatments such as loperamide for diarrhea, ibuprofen for body aches, and odansetron for nausea. In 2018, the US Food and Drug Administration (FDA) approved Lucemyra (lofexidine) as the first nonopioid medication focused specifically on treating withdrawal symptoms [9,10]. At the same time, some physicians prescribe medications off-label (eg, baclofen and clonidine) to treat withdrawal. Often, these medications are used for relief of specific symptoms, such as nausea, diarrhea, or body aches. For some of these off-label treatments, the evidence base is good, but it is not as strong for others [11-15].

Although only a fraction of opioid users seek professional help to mitigate withdrawal symptoms, many seek advice from other opioid users through web-based forums and blogs [16-18]. Opioid users are actively experimenting with alternative treatments to alleviate their withdrawal symptoms. These *remedies* include use of over-the-counter medications such as loperamide for diarrhea; more experimental medication trials such as supplements (eg, vitamins and herbs); and other methods such as meditation, yoga, and acupuncture. Some of these alternative treatments are controversial (eg, the use of the opioid-containing food supplement kratom). The self-treatment practices of opioid users are poorly understood.

Social media offers unique insights into millions of web-based conversations about withdrawal remedies and can be analyzed using machine learning techniques. The broad involvement of the middle-class population in the opioid epidemic combined with the popularity of social media and the availability of smartphone devices has made web-based discussion of opioid use common. Several outlets provide searchable and analyzable information suitable for research: web-based forums such as Reddit and Bluelight, smaller personal blogs, support groups, and treatment centers, as well as Twitter. The amount of information about drug use and drug recovery contained in discussion forums is unparalleled; nowhere else is it possible

to obtain such rich information about drug use and drug recovery practices. Recent studies have analyzed forum data related to opioid recovery [19], buprenorphine [20], marijuana [21], social networking [22], and emerging trends in drug use [23]. Others have shown that web-based discussion of opioids correlates with key surveillance metrics, such as synthetic opioid death rates, and could be used as a leading indicator [24]. Although studies have begun to use these sources, such information remains underused. There have been no assessments of substances used for relieving withdrawal symptoms.

Objectives

The purpose of this study is 2-fold: (1) to validate a methodology that uses social media (Reddit posts) to investigate these self-treatment practices and (2) to better understand these practices, such as what is being used and what the consequences are of such self-help. We note that a validated methodology that uses Reddit posts to understand issues such as self-medication could have utility for a number of physical and behavioral disorders.

In our study, we focus on the following two Reddit discussion forums: *r/opiates* ("discussion of all things related to the narcotics known as opiates, from harm-reduction to pharmacology") and *r/OpiatesRecovery* ("...a group of people dedicated to helping each other kick the habit") [16,18]. Both forums are dedicated to open dialogue about opioid use, often with the intent of helping current and past users recover. As a part of these discussions, users often share their experiences with formal treatments and alternative treatments to mitigate the effects of withdrawal.

Our primary objective is to validate a methodology for identifying substances used to treat withdrawal symptoms from the discussions on these forums. There are no validation standards to relate discussions to the actual prevalence, incidence, and more detailed representative epidemiology of use, in large part because the forums are anonymous. At the same time, discussion forums can provide insights on the general knowledge among people who use opioids regarding the pharmacology of drugs that they are prescribed, that they buy over the counter, or that they obtain illicitly. We implicitly assume that, because of the large volume of discussions on social media, the strongest signals of remedies associated with prominent withdrawal symptoms would be clinically useful. We further expect that *common knowledge* would be more prevalent than *urban myths*. In addition to validating the methodology, we intend to demonstrate its utility for identifying clearly harmful approaches and discovering new, potentially useful remedies for withdrawal symptoms. If successful, such an approach may be useful to investigate other related questions about substance use, temporal trends, polydrug use, and other disorders where people self-manage their symptoms and discuss their experiences on the web.

Recent advances in natural language processing (NLP) have enabled researchers to identify and extract information from

large amounts of text, including useful information about potential remedies. NLP has been applied to an array of problems across the health care and public health fields [25], including many aspects of the opioid epidemic [19]. Using named entity recognition (NER), we train a model on a subsample of annotated discussions from both subreddits and then apply the model to extract entities from the rest of the data. We train the NER model to identify *substances* and *effects,* where effects are *the result of using or not using a substance.* In this analysis, we focus on the effects that are symptoms of opioid withdrawal and substances that are potential remedies for those withdrawal symptoms. Thus, effects are categorized as (1) symptoms of opioid withdrawal in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5), (eg, body aches); (2) effects of opioid use (eg, euphoria); (3) a medical symptom not falling into categories 1 or 2; or (4) other or unclear. Finally, we conducted a validation of the strongest signals in the data. We also developed a withdrawal remedy database and an exploration-discovery tool to assist clinicians and the pharmaceutical industry to better serve the needs of people who use opioids.

This paper is structured as follows. First, we describe the data, entity definitions, and approaches for data collection. We then describe the process for iteratively training an NER model, using it to assemble an extensive database of opioid-related substances and effects and cleaning the resulting data. Next, we describe a network analysis approach to structure the database as a network of substance and effect co-occurrence and the development of a web application tool for exploring the database. Finally, we describe the validation process, where we systematically assess some of the strongest signals in the data. We conclude with a discussion of the value of our approach, database, and tool and consider the next steps in this research.

Methods

Data

Data Acquisition and Preparation

Reddit is a public social media site comprising communities called subreddits, which organize content based on interest. A submission to Reddit is called a *post*. A post can be a link to a website outside of Reddit or a piece of text for discussion. In the latter case, this is called a *selfpost*, and the text is called *selftext*. On a post, other Reddit users can provide threaded comments. Posts and comments are archived via the pushshift service [26], and a publicly available copy of the pushshift Reddit data set is also available via the Google BigQuery platform. Using BigQuery, we downloaded all available posts and comments from the *r/opiates* (when referring to the subreddits, we adopt the nomenclature of prefixing them with *r/*) and *r/OpiatesRecovery* subreddits (the corpus), which at the time of acquisition (August 2019) extended until April 2019. In October 2020, we downloaded additional data covering May-December 2019 directly from pushshift.io using the *PushshiftRedditDistiller* package [27].

A submission on Reddit contains three possible sources of text for analysis: the title of the post, the *selftext* of the post (if it is a *selfpost*), and the threaded comments for a post. As our goal was to detect mentions of our entities within longer-form text and post titles and *selftext* often contain short phrases or incomplete sentences, we focused only on the comments that appear as discussions on a post and did not use text from post titles or *selftext* for analysis.

r/opiates and r/OpiatesRecovery Subreddits

We focused on content from two communities related to opioid use*:* the *r/opiates* and *r/OpiatesRecovery* subreddits. The *r/opiates* subreddit was created on June 24, 2009, and *r/OpiatesRecovery* was created on February 16, 2012. As of June 25, 2021, the *r/opiates* subreddit had 124,696 members, and *r/OpiatesRecovery* had 31,522 members [16,18].

Some basic statistics about the comments within each subreddit are presented in Table 1. Users have the ability to delete specific comments or delete their accounts and all comments, so both the count and nondeleted count are presented.

Table 1. Summary of comments from *r/opiates* and *r/OpiatesRecovery*.

Item	Subreddit		Total
	r/opiates	*r/OpiatesRecovery*	
First comment, date; time	April 8, 2010; 4:10 AM	February 16, 2012; 5:19 AM	N/A[a]
Last comment, date; time	December 31, 2019; 11:57 PM	December 31, 2019; 11:58 PM	N/A
Count	3,650,602	341,598	3,992,200
Count nondeleted	3,446,046	326,729	3,772,775

[a]N/A: not applicable.

NER Model

We framed our NLP task as an NER problem to identify possible remedies and their effects. We aimed to identify two possible types of entities: substances and effects.

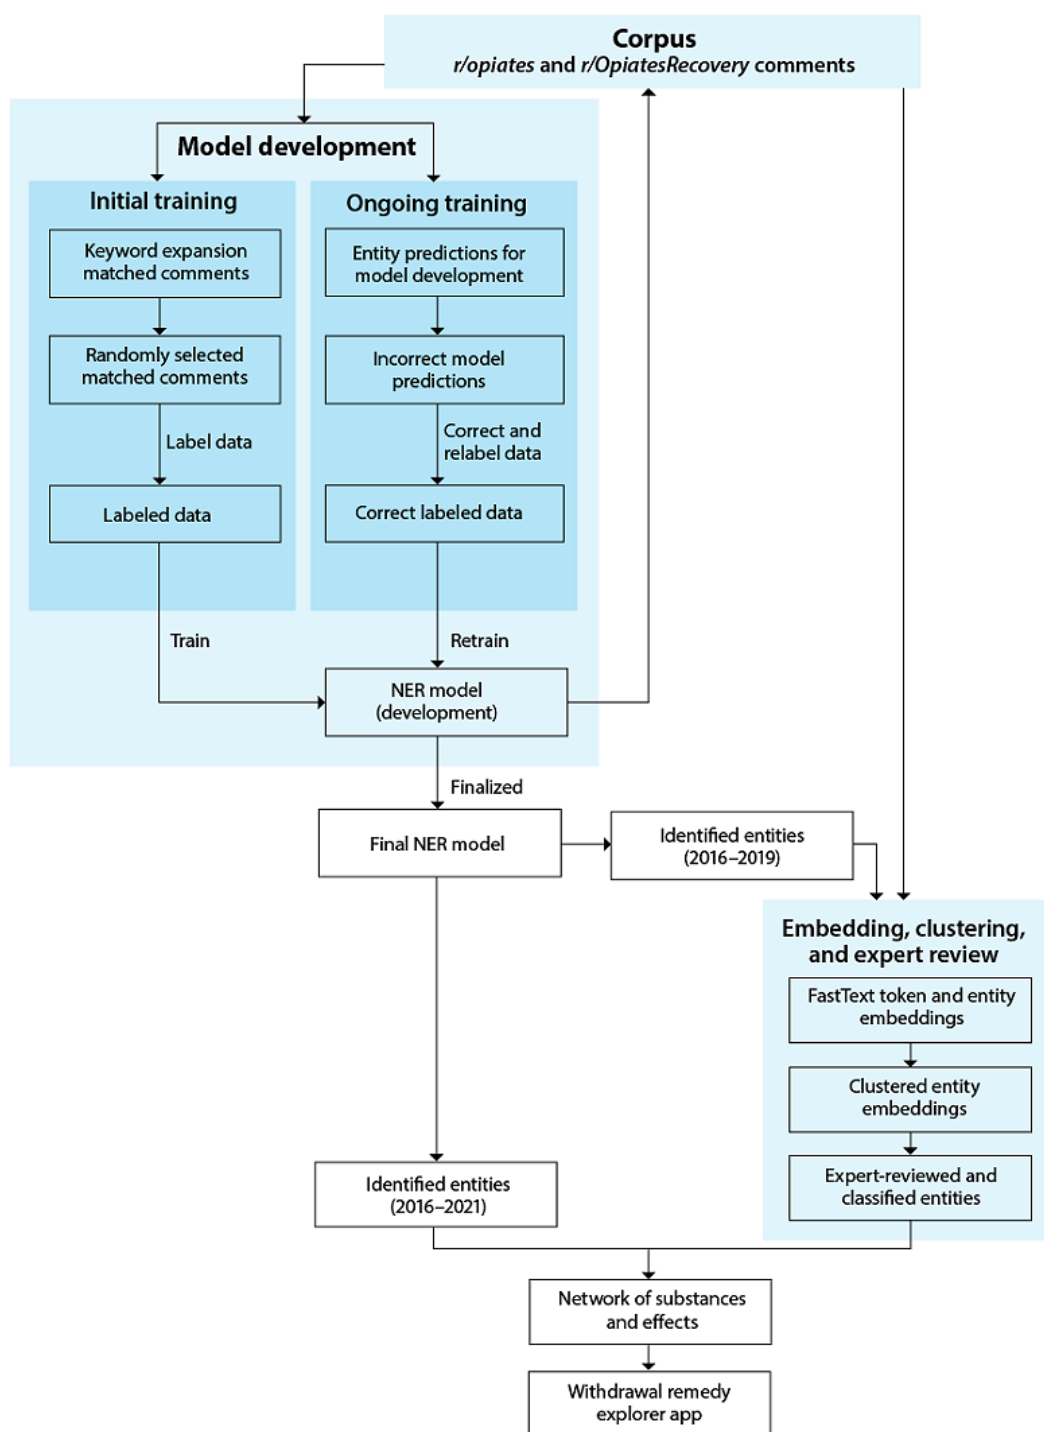
- Substance: a drug, remedy, supplement, or other consumable item used to treat an effect (eg, acetaminophen to treat body aches) or induce a desired effect (eg, heroin to induce euphoria). Although we found mentions of

meditation, yoga, and other nonmedicinal remedies, in this report we only focus on consumable substances.

- Effect: a negative or positive effect mentioned as a result of consuming a substance (eg, constipation caused by opioid use or constipation relieved by polyethylene glycol use), a result of not consuming a substance (eg, diarrhea caused by opioid withdrawal), or a rationale for consuming a substance (eg, diarrhea prompting loperamide use).

We used an iterative data-labeling and model-training process to generate 6507 labeled comments that formed our training data set. For details, see Multimedia Appendix 1 [28-36]. We trained our final NER model with the default spaCy (version 2.3.0; Explosion AI) [37] settings for NER models: 10 epochs with a dropout of 0.2 [38] and compounding batch. We trained the model on 80% of the data and evaluated its performance on a randomly selected hold-out set of 20%. Precision, recall, and F1 scores were calculated for exact matches of entities.

Our complete data-processing, modeling, and analysis pipeline is shown in Figure 1 and described in detail in Multimedia Appendix 1.

Figure 1. Withdrawal remedy analysis pipeline. NER: named entity recognition.


Deduplication of Entities

Many of the entities identified by the model were either misspellings or semantic duplicates. Misspellings were common in the data (eg, various misspellings of a drug name). Semantic duplicates resulted when the data included semantically related words, such as synonyms, hypernyms, and hyponyms. Some of the most common semantic duplicate types in our entities included the following: (1) slang terms (eg, *fent* for *fentanyl*), (2) generic and brand name drugs (eg, *loperamide* and *Imodium*), and (3) specific and general descriptions of an effect (eg, *insomnia* and *trouble sleeping*).

To deduplicate the entities, we generated fastText word embeddings for all tokens, where tokens identified as entities were combined [39]. We then clustered entities with similar embeddings. This approach is technically related (though with opposite goals) to embedding-based methods for vocabulary expansion, which have recently been applied to opioid-related discussions from Reddit [40] (see *Detailed Methods* in Multimedia Appendix 1). After clustering, all entities in a cluster were replaced with the most common entity in the cluster. For example, *cigarettes*, *ciggarettes* [*sic*], *ciggs*, and *cigs* were clustered. The most common entity in this cluster was *cigarettes*. All occurrences of the other entities in the cluster were replaced with *cigarettes*.

Expert Review and Classification of Entities

After clustering, we manually reviewed the deduplicated entities and conducted an additional round of deduplication and classification. Clustering was essential to reduce the number of entities and make manual review feasible. We generated separate lists of substances and the effects of these substances. The lists were reviewed by a psychiatrist (MJE) in 2 steps. First, we gave each entity a corrected name. This provided further deduplication of any slang terms or misspellings that remained after clustering. It also ensured that all entities were given a clinically accurate name. Often, these were controlled substances (eg, opioids, benzodiazepines, or prescription stimulants), illicit drugs (eg, hallucinogens or marijuana), or medications used to treat the symptoms of opioid withdrawals (eg, antiemetic or antidiarrheal medications). Second, we categorized the entities. Substances were categorized based on their pharmacological profile and use in clinical practice. Effects were categorized as (1) DSM-5 symptoms of opioid withdrawal (eg, body aches), (2) effects of opioid use (eg, euphoria), (3) a medical symptom not falling into categories 1 or 2 (eg, seizure), or (4) other or unclear (eg, sickness).

Network Analysis

We generated a bipartite network of substance and effect co-occurrence to assess which substances were associated with these effects. We considered entities to be nodes in the network. We drew edges between nodes when a substance and effect co-occurred in a sentence. We weighted the edges by the number of times the node pair co-occurred. However, using this edge weight alone to identify significant substance-effect pairs would favor pairs where the individual probabilities of occurrence of the substance and effect were high. Therefore, we also weighted the edges using positive pointwise mutual information (PPMI) [41]. For a pair of nodes, PPMI is high when their probability of co-occurrence is high relative to their individual probabilities of occurrence.

Application Development: Withdrawal Remedy Explorer

We built a web application called Withdrawal Remedy Explorer to provide a user-friendly way to explore the substance-effect network. Owing to its size, it was difficult to interpret the full network. Therefore, our application allows users to filter down to the ego network for a single substance or effect. Ego networks consist of a single node (ego) together with the nodes it is connected to (alters) [42] (in most cases, ego networks also include connections between the alters but, because our network is bipartite, there are no connections between entities of the same type). The application further allows users to filter according to edge count and PPMI.

Validation Review of Pairs

We generated and validated a list of top symptom and potential remedy pairs to assess the nature of the network. For each of the 16 effects identified as DSM-5 symptoms of opioid withdrawal, we identified the top 10 nonopioid substances most strongly associated (although not necessarily causally) with the symptom. We identified these substances using a weighted average of edge count and PPMI. First, we took the natural logarithm of the edge count to reduce skewness. We then used a min–max scaler to normalize the edge count and PPMI to a range of 0 to 1. Finally, we averaged the scaled edge count and PPMI. For each withdrawal symptom, we took the 10 substances with the highest value for this calculation, omitting opioids and any pairs with an edge count <5. This produced a list of 130 strongly associated symptom and potential remedy pairs. We hypothesized that the most strongly associated pairs would be most clinically applicable. We validated each of the pairs against known medical practice and evaluated each for clinical feasibility. We then classified the pairs into categories that reflected the relationship with clinical practice, common practice, or potential harm, as follows: (1) substance is an FDA-approved or commonly used treatment for the symptom, (2) substance is not often used to treat the symptom but could be potentially useful given its pharmacological profile, (3) substance is a home or natural remedy for the symptom, (4) substance can cause the symptom, or (5) other or unclear (including cases where there was no clear connection between the potential remedy and the symptom; eg, gabapentin and fever).

Results

Entity Counts

Table 2 lists the top 20 most frequent substances and effects identified within the data set. As these are simply spans of text without semantic information, we can see duplicates (*fent* and *fentanyl*), slang terms (*dope* and *h*), and abbreviations (*rls*).

Table 2. Top 20 substances and effects extracted.

Entity	Count, n (%)[a]
Substances (N=2,823,606)	
dope	192,385 (6.81)
heroin	160,595 (5.69)
opiates	160,244 (5.68)
oxy	95,960 (3.40)
subs	87,006 (3.08)
opiate	80,067 (2.84)
methadone	76,477 (2.71)
kratom	68,541 (2.43)
fent	68,475 (2.43)
suboxone	65,011 (2.30)
h	62,492 (2.21)
sub	57,959 (2.05)
weed	51,937 (1.84)
morphine	49,114 (1.74)
benzos	37,208 (1.32)
tar	35,573 (1.26)
coke	35,355 (1.25)
xanax	34,765 (1.23)
fentanyl	30,361 (1.08)
codeine	29,050 (1.03)
Effects (N=479,289)	
pain	61,783 (12.89)
anxiety	30,995 (6.47)
depression	23,579 (4.92)
sleep	22,102 (4.61)
cravings	20,319 (4.24)
depressed	11,304 (2.36)
rls	8972 (1.87)
nausea	7618 (1.59)
craving	6315 (1.32)
insomnia	5645 (1.18)
mood	5600 (1.17)
puke	5551 (1.16)
seizures	5435 (1.13)
anxious	5343 (1.11)
tired	5159 (1.08)
sweating	5099 (1.06)
puking	5029 (1.05)
sickness	4931 (1.03)
sweat	4845 (1.01)
headache	4018 (0.84)

[a]The denominator for percentages is the total number of occurrences of all substances or effects, so percentage values do not sum to 100.

The model performs slightly better in predicting substances than effects (F_1 scores of 92.059 and 81.696). Recall (92.895 for substances and 83.768 for effects) is slightly higher than precision (91.237 for substances and 79.724 for effects). Both scores are reasonable given the model architecture used and the variability and quality of the input data in comparison with common benchmark NER tasks [43].

Deduplication and Expert Review

Both clustering and expert review greatly reduced the number of entities by removing misspellings and semantic duplicates.

Clustering reduced the number of unique substances by 98.07% (from 53,730 to 1037) and reduced the number of unique effects by 95.69% (from 13,790 to 594). Relative to the number of entities remaining after clustering, expert review reduced the number of unique substances by 55.8% (from 1037 to 458) and reduced the number of unique effects by 60.4% (from 594 to 235). Our final count of unique entities was 458 substances and 235 effects.

Effects were classified into 4 categories. Their frequencies are shown in Table 3.

Table 3. Frequency of effects by category (N=235).[a]

Effect	Values, n (%)
DSM-5[b] symptom of opioid withdrawal	17 (7.2)
Effect of opioid use	17 (7.2)
Not a DSM-5 symptom of opioid withdrawal or effect of opioid use	153 (65.1)
Other or unclear	48 (20.4)

[a]Percentages may not add up to 100 because of rounding.

[b]DSM-5: Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition.

Substances were classified into 71 pharmacological categories. The four most common were opioid (71/458, 15.5%); other (60/458, 13.1%); vitamin, supplement, or herb (42/458, 9.2%); and food or drink (29/458, 6.3%). Multimedia Appendix 2 includes frequencies for all 71 categories.

Network Analysis and Application

The Withdrawal Remedy Explorer application is publicly available [44]. It allows users to explore the associated substances or effects for a chosen entity. First, users can choose to view the substances or effects. Users then select an entity from a list of categorized substances or effects. This shows the ego network for the selected entity. The PPMI and edge count filters can then refine the network down to the strongest connections. For example, one could filter the network to the connections with the highest edge counts to view the most common substances associated with a symptom. Alternatively, filtering for the edges with the highest PPMI could uncover uncommon but noteworthy connections. Finally, connections with both high PPMI and high edge count are perhaps the most salient of all. Presenting the data as ego networks encourages users to identify substances or effects of interest before using the application. We considered this the most likely use case, as discussed further below. Figures 2 and 3 show example ego networks for a substance (acetaminophen) and effect (dehydration). Both ego networks are filtered for PPMI ≥1.5 and edge count ≥10.

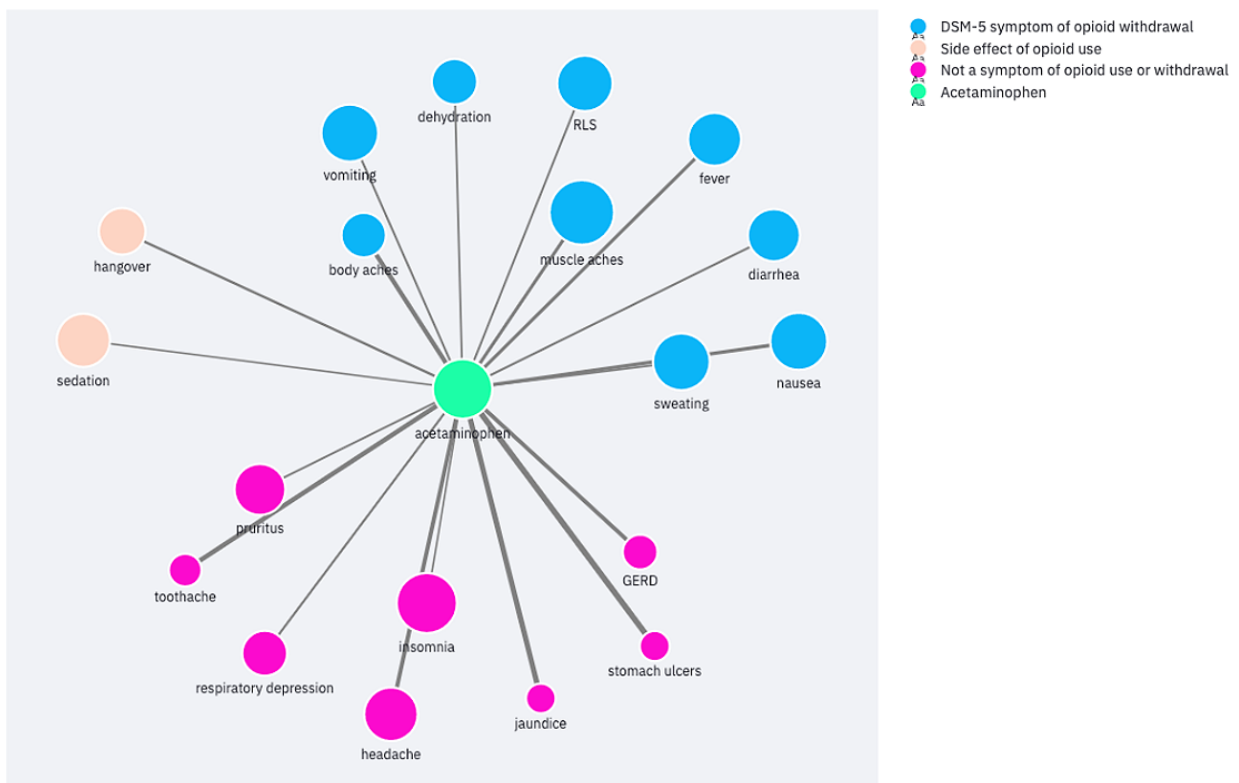
Figure 2. Acetaminophen ego network filtered for positive pointwise mutual information ≥1.5 and edge count ≥10. DSM-5: Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition; GERD: gastroesophageal reflux disease; RLS: restless leg syndrome.


Figure 3. Dehydration ego network filtered for positive pointwise mutual information ≥1.5 and edge count ≥10. DSM-5: Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition.
Validation Review of Pairs

In 64.6% (84/130) of the strongly associated symptom and potential remedy pairs, we considered the substance to be a potentially valid treatment for the symptom. This result provides evidence for the face validity of our methodology for extracting symptom–remedy pairs from Reddit. Furthermore, more strongly associated pairs were more likely to be potentially valid treatments. Of the 26 pairs in the top quintile by strength of association, 23 (88%) were potentially valid treatments for the symptom. Table 4 shows the category frequencies for the symptom and potential remedy pairs.

Table 4. Categorization of strongly associated symptom and potential remedy pairs (N=130).

Relationship	Substance-effect pairs, n (%)
Substance is an FDA[a]-approved or commonly used treatment for the symptom	54 (41.5)
Substance is not often used to treat the symptom but could be potentially useful given pharmacology	17 (13.1)
Substance is a home or natural remedy for the symptom	13 (10)
Substance can cause the symptom	7 (5.4)
Other or unclear (including pairs with no clear relationship)	39 (30)

[a]FDA: Food and Drug Administration.

Discussion

Principal Findings

In this study, we extracted information from Reddit forum posts into a database of opioid withdrawal symptoms and substances potentially used as remedies to alleviate them. Although the focus of the study was on withdrawal symptoms, we also extracted many other substances and effects associated with opioid use. We made a distinction between effects that are opioid withdrawal symptoms as defined in the DSM-5 and other effects. We validated the technical aspects of symptom and effect extraction by obtaining F_1 scores that were competitive with NER benchmarks.

We used PPMI to formalize the strength of substance-effect associations. We did not use any formal statistical tests or P values as the data themselves contain uncertainty and the population is not clearly defined. In fact, it is likely to change over time. However, the use of PPMI allowed us to compare the strength of associations with a *by chance* association and with each other.

We used PPMI to identify a list of 130 strongly associated symptom and potential remedy pairs in which the effect was a DSM-5 opioid withdrawal symptom and the substance was a potential remedy. We validated the associations between these symptoms and potential remedies based on expert review. We discovered that roughly two-thirds (84/130, 64.6%) of the potential remedies were common treatments, potentially useful treatments, or home or natural remedies. Therefore, we observed that, for DSM-5 withdrawal symptoms, the relationship between symptom and potential remedy validates well and that *common knowledge* is more prevalent than *urban myths*. We also developed a web application that allows researchers to explore these symptoms and potential remedies through visualization and to identify associations that may be strong enough to prompt further research.

Contributions

As demonstrated by the success of technical and expert review validations, our methodology has the potential to make significant contributions to ethnographic, clinical, and pharmacovigilance research. Specific areas include the following.

Understanding Potential Harm and Pharmacovigilance

Health care and public health stakeholders could benefit from knowing the types of self-medication and substitution practices that people engage in to help alleviate withdrawal symptoms, in part because those practices could lead to potential problems (eg, cardiovascular complications, medication contraindications, hospitalization, and even death). Analysis of social media discussions can rapidly inform prevention and harm-reduction activities related to new and potentially harmful beliefs and activities. This can enable stakeholders to monitor temporal trends and emerging fads. In fact, it was shown that increases in web-based posts about synthetic opioids preceded an increase in synthetic opioid death rates [45]. For example, in our study, we identified a strong association between antihistamines and restless leg syndrome (RLS). This could be a potential harm as the use of antihistamines as a remedy for RLS could in fact worsen RLS [46]. Our Withdrawal Remedy Explorer application allows one to screen for off-label use of many prescription drugs and thus assist in pharmacovigilance. Although such screening likely requires deeper follow-up with studying the actual posts, it provides a quick way to identify potential harms before they become more prevalent.

Identifying Home or Natural Remedies

Home or natural remedies have the potential to be inexpensive and effective measures against withdrawal symptoms. Such knowledge could help large numbers of struggling users, especially those who are not yet ready to receive treatment from a physician and who prefer the anonymity of 24/7 web-based communities to seek and share help [22]. For example, in our study, we identified a strong association between nausea and ginger, a common natural remedy [47]. Exploring associations between withdrawal symptoms and other herbs, vitamins, and supplements could help identify less well-known home or natural remedies.

Identifying Potentially Useful New Remedies

Successful off-label use of medications could provide leads to future clinical studies on withdrawal medications [48]. For example, in our study, we identified a strong association between gabapentin and body aches. Whether gabapentin is clinically effective for the body aches associated with opioid withdrawal is unknown; we were only able to identify 1 small study (N=32) investigating gabapentin as a treatment for opioid withdrawal [49]. Our results suggest that studies on gabapentin for opioid withdrawal may be fruitful. The identification of such remedies has not been the objective of this report, but we are partnering with clinicians and pharmacologists to identify such cases.

Understanding Patient Needs

Understanding patients' needs and issues that are of importance to them is critical for the development of better prevention and treatment programs. Web-based discussion forums and social media also provide mechanisms to inform and design better treatment and harm reduction programs. For example, future research could leverage the Withdrawal Remedy Explorer application to identify withdrawal symptoms, which, at least in these forums, are of the highest concern to people using opioids. In our study, 30% (39/130) of pairs fell into the *other or unclear* category. Although some of these pairs are likely the result of limitations to our methodology, this category provides opportunities for understanding users' beliefs and practices that go beyond *common knowledge*. Such information can lead to the discovery of new remedies or to the early identification of specific needs and potentially harmful practices.

Our approach can also be applicable to other substances of abuse, especially because currently there are no FDA-approved medications to treat cocaine, methamphetamine, and many other drug disorders. Uncovering and summarizing remedy practices for these disorders could provide at least temporary help in clinical treatment practice until treatment medications are developed and approved. Finally, by examining the symptom-related remedies, we acknowledge that some symptom–remedy pairs are quite common and are not specific to opioid withdrawal (eg, the use of melatonin for insomnia or acetaminophen for body aches). The detailed analysis of differences between remedies in opioid-specific discussions and in the general population is beyond the scope of this study.

Limitations and Future Work

Our study has several limitations. Foremost is the lack of causality in the associations between substances and effects. Without reading the posts, it is not possible to distinguish whether the effect was caused by the substance or whether the substance was used to alleviate the effect. Furthermore, we have not yet analyzed whether the remedies were helpful. An association could take many forms (eg, "gabapentin cured my body aches," "I tried gabapentin for body aches, but it didn't work," or "gabapentin gave me body aches"). However, the purpose of this study was to build and validate the foundations for such analyses. More detailed and in-depth analyses could be performed on any subset of the associations identified in the data. In future work, we plan to apply additional NLP methodologies and analysis to selected combinations of

substances and effects to identify whether the association was favorable.

We only focused on associations within the same sentence. This approach misses associations when the effect and substance are mentioned in different sentences (eg, "I get terrible body aches. Aspirin does nothing for me, but gabapentin helps"). In this study, we limited the approach to sentences for clarity and simplicity. With our success using single sentences, in future work we will focus on including associations spanning multiple sentences. This task is complicated by the necessity of defining the boundary of paragraphs and detangling multiple associations between multiple substances and effects across sentences. The ambiguity of free-flowing text in posts is a common challenge in the analysis of social media.

Since the time the data were collected and the models were developed, the field of NLP has progressed significantly because of the use of transformer models such as Bidirectional Encoder Representations from Transformers [50]. For general NER tasks, this has meant an improvement from an F_1 of 86 in 2017 to >90 in 2019. At the same time, large transformer models require significant specific computational resources [51] to train and deploy in comparison with more traditional methods and, simultaneously, focus in the field has been shifting from model-centric approaches (eg, hyperparameter tuning) to data-centric approaches (eg, higher-quality labeled data) as, in many scenarios, more benefit comes from data than architecture [52]. In summary, a limitation of our work is that we were unable to use the current state-of-the-art models, but future work will evaluate potential improvements from new model architectures and improved data quality.

In our expert review and validation processes, substances, effects, and substance-effect pairs were classified into categories according to the *face value* of the terms and without detailed assessment of the underlying post text. Different reviewers could have different opinions and interpretations, leading to variability in classifications. In future work, we plan to leverage the Withdrawal Remedy Explorer tool to seek comments and corrections from other experts.

As our study builds networks of extracted knowledge, in our future work we will consider developing a knowledge graph that would allow linking the extracted entities and their networks to external knowledge bases.

Despite these limitations, we identified and validated strong signals in the data. The discovery of valid withdrawal remedies encourages us to explore more nuanced aspects of the data. The limitations of this study point us to the next steps in our research.

Conclusions

In this study, we validated an approach to identify opioid withdrawal remedies from the web-based forum Reddit. We developed a pipeline to extract substances and effects from raw data, identified strong associations between withdrawal symptoms and potential remedies, and validated these associations. Our results demonstrate that social media and web-based forum discussions have the potential to help us understand how people treat withdrawal symptoms. This knowledge could help identify useful new treatments and

potential harms and public health concerns. We also developed the Withdrawal Remedy Explorer application to facilitate deeper analysis of these data and to seek input from other researchers, clinicians, and people with lived experience. Our approach could be generalized beyond Reddit and beyond the topic of opioid withdrawal. It could be applied to many other disease states where people self-manage their symptoms and discuss their experiences on the web.

Abstract

Background: Digital health interventions are efficient and flexible methods for enhancing the prevention and management of cardiovascular disease and type 2 diabetes. However, little is known about the characteristics associated with eHealth literacy in the Canadian South Asian population.

Objective: The aim of this study is to describe perceived eHealth literacy and explore the extent to which it is associated with sociodemographic, health status, and technology use variables in a subset of South Asian Canadians.

Methods: We analyzed data from the e-Patient Project survey, a mixed-mode cross-sectional survey that occurred in 2014. The eHealth Literacy Scale (eHEALS) was used to measure eHealth literacy in a convenience sample of 511 English- or Punjabi-speaking South Asian adults recruited from a community pharmacy, a family physician office, and community events in Edmonton, Alberta. Multivariable quantile regression was used to explore variables associated with eHealth literacy.

Results: The analysis was restricted to 301 internet users (mean age 39.9, SD 14.8 years; 166/301, 55.1% female) who provided responses to all 8 eHEALS questions and complete demographic information. The mean overall eHEALS score was 29.3 (SD 6.8) out of 40, and 71.4% (215/301) agreed to at least 5 out of the 8 eHEALS items. The eHEALS item with the lowest level of agreement was "I can tell high-quality health resources from low-quality health resources on the internet" (182/301, 60.5%). Although there were statistically significant differences in eHEALS scores according to age, educational achievement, language preference, and the presence of chronic medical conditions, multivariable regression analysis indicated that language preference was the only variable independently associated with eHealth literacy (coefficient –6.0, 95% CI –9.61 to –2.39).

Conclusions: In our sample of South Asian Canadian internet users, preference for written health information in languages other than English was associated with lower eHealth literacy. Opportunities exist to improve eHealth literacy using culturally and linguistically tailored interventions.

Introduction

Background

Digitally engaged patients are those who have taken up new digital media technologies in their own medical care and preventative health efforts [1]. These eHealth technologies typically support self-care and include internet-based resources where lay people can seek information about health, web-based communities supported by social networking sites, mobile health (mHealth)—the practice of medicine and public health with support from mobile devices, telemedicine and remote patient monitoring where patients communicate with health care providers via technology instead of face-to-face communication, and others [1-3]. Emerging evidence suggests that eHealth-and mHealth-based interventions can improve the prevention and management of chronic health conditions [4,5]. For example, systematic reviews suggest the potential for the improvement of cardiovascular lifestyle-related risk factors [6] including weight loss [7-9], physical activity [10,11], and management of diabetes [12-14].

To optimally engage with and have equitable access to a digital health care environment, health care consumers must have an understanding of their condition as well as the skills to effectively use electronic resources [15-17]. This is referred to as eHealth literacy, which is defined as the ability to seek, find, understand, and appraise health information from electronic sources and apply the knowledge gained to address or solve a health problem [18]. There are six main domains of eHealth literacy: health, computers, media, science, and information literacy, as well as traditional literacy and numeracy [18]. eHealth literacy has taken on greater importance as the COVID-19 pandemic has shifted primary care from office visits to telephone or video care in the Canadian health care system [19] and resulted in a broader *infodemic* of medical misinformation [20,21]. Assessing eHealth literacy is important because it has been associated with positive outcomes from internet searches in health knowledge and information gathering, self-management of health needs and health behaviors, and interactions with physicians [22-25]. eHealth literacy is modifiable, and several studies have shown that it can be improved in older individuals and those with chronic health conditions [15,26,27].

South Asian Canadians are a large visible minority group [28] who face a high prevalence of cardiovascular disease and diabetes, both of which are conditions for which self-management are required [29-31]. Expanded access to and use of culturally appropriate eHealth strategies may assist South Asian Canadians in addressing documented gaps in risk factors and diabetes control [30] by addressing documented barriers [32,33] such as language, sociocultural factors, misconceptions around diet and physical activity, lack of access to culturally tailored diet counseling, and compliance with pharmacotherapy.

Whether South Asian Canadians have adequate eHealth literacy to effectively use eHealth to improve their health is uncertain as are the demographic and technology use determinants of eHealth literacy in this community. Although eHealth strategies may support improving both the prevention and management

of cardiovascular disease and type 2 diabetes, a systematic review of eHealth literacy suggests that underserved populations may have lower levels of competence in the 6 core domains of eHealth literacy, decreased access to health infrastructure, and technology [34]. For example, research conducted by Statistics Canada suggests that immigrants to Canada originating from non–English- and non–French-speaking countries score below the national average in health literacy. On the basis of 2003 survey data, fewer immigrants (24%) than nonimmigrants (44%) had requisite levels of health literacy [35]. Research on Danish immigrants has suggested that descendants and immigrant women have lower levels of eHealth literacy and health literacy than women of Danish origin [36]. In contrast, data on immigrants to Israel suggest that language barriers because of immigration, negatively impact health literacy but have no impact on eHealth literacy [37]. Research on primary digital divides in internet access by race or ethnicity has been conflicting, with some suggesting no difference in digital use divides [38], whereas others suggest that they do exist [39]. Demographic and socioeconomic variables associated with eHealth literacy in the literature are inconsistent and are suggested to be population-dependent [17].

Objectives

Owing to a lack of information on digital device use and eHealth literacy in South Asian Canadians, we conducted the South Asian e-Patient Project, a survey conducted in a convenience sample of 831 South Asian Canadians in Edmonton, Alberta in 2014 [40]. We previously reported that engaging members of this community via eHealth interventions is feasible. However, we found evidence of digital divides in the use of the internet, digital devices, and apps for health purposes by language preference, education, age, gender, confidence in filling out medical forms, and the number of years lived in Canada. Further description and examination of the characteristics associated with eHealth literacy in members of the Canadian South Asian Community is important because this information could be used to identify levels of readiness for eHealth, to inform and justify the development of tailored solutions to overcome identified gaps in the required skills to effectively apply web-based health information and other mHealth interventions and to inform and assist health care providers to optimally engage individuals in remote internet-based care and with existing web-based health information resources. Therefore, the objectives of this study are to (1) describe levels of eHealth literacy among a subset of South Asian adult internet users who were invited to complete the eHealth Literacy Scale (eHEALS) as part of the community-based e-Patient Project survey and (2) explore sociodemographic, health status, and technology use variables and their association with eHealth literacy among survey respondents.

Methods

e-Patient Project Study Design

The design as well as the results on the prevalence and variables associated with internet and digital device use for health purposes from the e-Patient Project survey have been published previously [40]. Briefly, the survey was an anonymous,

mixed-mode survey conducted with a convenience sample of English- or Punjabi-speaking South Asian adults between May 18 and August 31, 2014. We used a community-based approach and worked in partnership with 13 faith-based, cultural, community, and health care organizations in Edmonton, Alberta. The survey was designed to evaluate levels of engagement with the internet, digital device ownership, use of health and fitness apps, health information–seeking practices, preferences for delivery modalities for future eHealth interventions, and eHealth literacy. (Multimedia Appendix 1) The survey was primarily a computer-assisted in-person interview conducted at faith-based gathering places, health care settings, community centers, and events using the Qualtrics (Qualtrics Corporation) web-based survey platform. Most questions were adopted from existing survey instruments, including the Pew Research Center's Internet & American Life Project 2012 Health survey [41-43] and the 2012 Statistics Canada Canadian Internet Use survey [44]. The survey was pilot-tested with 19 individuals from the target communities.

eHealth Literacy Assessment—Inclusion Criteria, Recruitment, and Data Collection

A subset of the survey participants was invited to complete the eHealth literacy assessment. Owing to the time required to complete the survey, this subset included all individuals recruited in person at the participating community pharmacy, family physician practice, a large community event, and 1 community center, as well as those who completed the survey via the web. Individuals recruited at faith-based gatherings were excluded from the eHealth literacy assessment.

Potential respondents were notified about the study via personal invitations by pharmacy or clinic staff, announcements at community events, and posters. We recruited consecutive attendees from the community pharmacy and family physician office sites. Individuals were then approached by trained, bilingual English- and Punjabi-speaking research assistants or community volunteers. They were presented with the e-Patient Project survey information letter and were asked if they would like to participate. The agreement and completion of the survey implied participants' consent.

Research staff administered the survey, including the eHealth literacy assessment, via computer-assisted personal interviews in English or Punjabi, according to respondent preferences. One-on-one interviews using paper surveys were conducted at the community event before the tablet computers became available. A web-based version was also offered to those who preferred to complete the survey on their own time. Respondents who completed the survey were offered a reusable shopping bag and the opportunity to enter a draw for a tablet computer or various gift cards as incentives.

Measurement of eHealth Literacy

eHealth literacy was measured using the 8-item eHEALS scale, which is the most commonly used validated measure of eHealth literacy [45,46]. The eHEALS measures the concept of eHealth literacy, defined as a set of skills required to effectively engage information technology for health and has shown high levels of internal consistency and test-retest reliability [46]. Each of

the 8 items is rated on a 5-point Likert scale (1=strongly disagree to 5=strongly agree). The overall score ranges from 8 to 40, with higher scores suggesting higher eHealth literacy. In addition, 2 supplemental eHEALS items, which do not contribute to the overall score, were also included before the 8 items to measure the perceived usefulness of the internet to help make health decisions and the perceived importance of being able to access health resources on the internet.

We created a Punjabi version of the survey and the eHEALS instrument according to the World Health Organization guidelines for translation and adaptation of instruments [47] (Multimedia Appendix 2). One Punjabi-speaking translator with a medical background who was also fluent in English conducted a forward translation from English to Punjabi. Emphasis was placed on conceptual rather than literal translation. A panel of 2 bilingual community member reviewers further reviewed and identified inadequate expressions and concepts in the translated versions. The back translation was conducted by a separate translator who was fluent in both English and Punjabi. The translated eHEALS was included in the pilot test, and translation discrepancies were discussed and addressed by the project team. The internal consistency for the 8 item eHEALS for the 301 respondents was Cronbach α=.950, and principal components analysis produced a single factor solution with factor loadings from 0.68 to 0.80 among the 8 items, with eigenvalue=5.95 and 74.4% of the variance explained (Multimedia Appendix 3).

Measurement of Sociodemographic and Internet Use Variables

Demographic factors included age, sex, education, marital status, duration of time lived in Canada, and South Asian community affiliation. Individuals who answered affirmatively to either *Do you go online at least occasionally* or *Do you send or receive email at least occasionally*? were characterized as internet users. Language preference was determined by asking *In what language would you prefer to receive written health information* and the categories were collapsed into includes English or does not include English. We estimated health literacy using the question *How confident are you filling out medical forms by yourself?* that was effective in detecting inadequate health literacy as measured using the Short Test of Functional Health Literacy in Adults [48]. Individuals who indicated being likely or very likely to use at least one of six different modes of eHealth interventions in the next 12 months were deemed to be interested in eHealth interventions.

Statistical Analysis

We limited the analysis to internet user respondents who provided complete responses to all 8 eHEALS questions and complete demographic information for the planned multivariate analysis. Surveys with other missing data were included in the analysis, and descriptive statistics for categorical variables were depicted as proportions of total cases, including those with missing data. SPSS (version 28; IBM Corp) was used to compute descriptive statistics for the demographic characteristics, technology use variables, and eHEALS scores. Summary eHEALS scores were calculated by summing the responses to 8 eHEALS questions. We also explored the proportion of individuals who agreed to at least five out of the eight eHEALS

items, an indicator of adequate eHealth literacy [49], and the number of participants scoring 26 or more, which has been considered an indicator of high eHealth literacy [17,50]. We explored bivariate differences in eHEALS scores across demographic, health status, and technology use outcome variables using the 2-tailed Welch t test or Welch F test as appropriate [51-57]. Statistical significance was established at $P<.05$ and Bonferroni correction was used for post hoc tests.

Multivariable quantile regression was performed using R (version 3.1.3; The R Foundation) to assess the effect of each demographic variable on the eHEALS score while controlling for the effect of others. This analysis was restricted to internet users and explored both demographic and internet use predictors. Quantile regression through the median was performed instead of mean regression [58] because regular regression residuals differed substantially from normality and violated the constant error variance assumption as well. Log and square root transformations also did not work. Quantile regression models conditional quantiles instead of conditional means. Here, we model the conditional median (the 0.5th quantile). It does not assume normality and constant error variance and is robust against outliers. The CIs and P values reported were based on bootstrap SEs with 1000 repetitions.

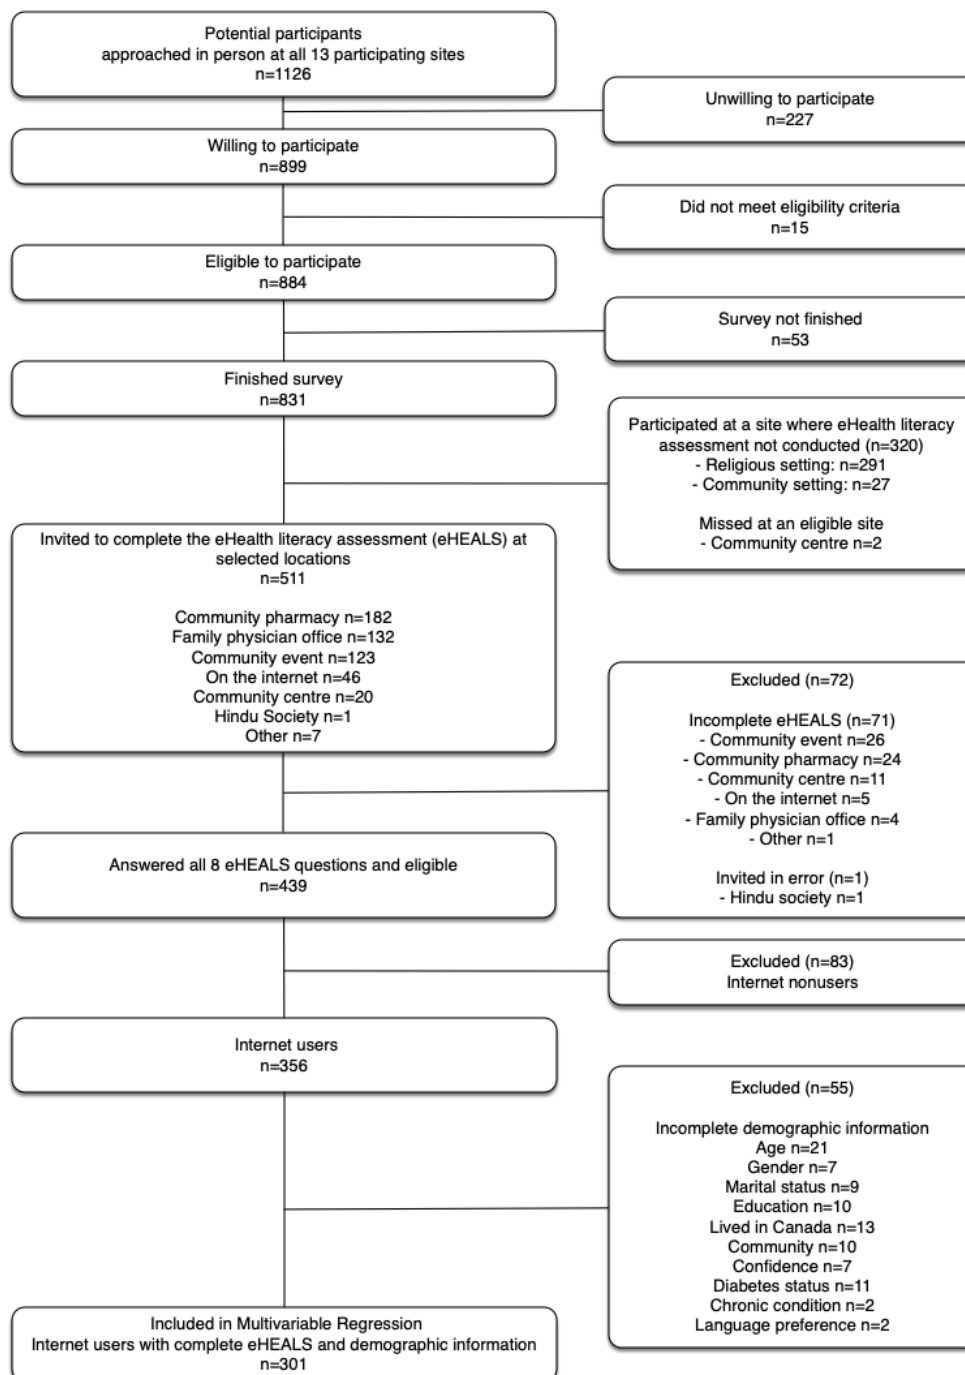
Ethics Approval

The Health Research Ethics Board at the University of Alberta (Pro00038210) approved this study.

Results

Participant Flow

A total of 511 individuals were invited to complete the eHealth Literacy Assessment. Although we originally invited both internet users and noninternet users to complete the eHEALS assessment, given that it is more meaningful to investigate eHealth literacy in internet users, in this paper, we focus on reporting the results in the n=301 internet users who provided data for all 8 HEALS items and demographic characteristics. (Figure 1). Findings from the 83 noninternet user eHEALS responders are shown in Multimedia Appendix 4.

Figure 1. Flow diagram of the eHealth Literacy Scale assessment in the e-Patient Project Survey, Edmonton, Alberta, 2014.


Participant Characteristics

Table 1 shows the demographic characteristics and the mean eHEALS scores of the study sample. The mean age was 39.9 (SD 14.8) years and just over half of the respondents were female (166/301, 55.1%). Most respondents were married (235/301, 78.1%); had college, university, or higher education (238/301, 79.1%); and self-identified as Sikh (212/301, 70.4%). A total of 29.2% (88/301) lived in Canada for <5 years. Most

respondents (260/301, 86.4%) indicated that English was their preferred language for written health information. Overall, 81.8% (246/301) indicated that their health was at least good, 53.2% (160/301) had at least 1 of the 8 chronic health conditions we inquired about, and only 1.7% (5/301) reported not being confident at all in filling out medical forms by themselves. Most respondents (194/301, 64.5%) were recruited from the participating community pharmacy and family physician office.

[b]*P* value is for the comparison of eHEALS scores.

[c]Welch *t* test.

[d]Welch *F* test on trimmed mean and Winsorized variance as data violated the constant variance assumption and were far from normal.

[e]N/A: not applicable.

[f]Pairwise comparison using the Games-Howell post hoc method; a *P* value of 0.5/number of comparisons was considered statistically significant.

[g]The bootstrap method with 1000 repetitions was used, as the data differed substantially from the normal distribution. For the bootstrap method, bias-corrected and accelerated CIs were reported.

[h]The Welch *F* test was used as the data violated the equal variance assumption of the analysis of variance.

[i]Chronic conditions included diabetes or sugar disease, high blood pressure, heart disease (eg, angina, heart attack, or stroke), lung conditions (eg, asthma or bronchitis), arthritis, cancer, high cholesterol, or other chronic conditions treated with daily medication.

Overall eHEALS Scores and Patterns of Item Responses

Total scores on the eHEALS ranged from 8 to 40 and were negatively skewed with a mean of 29.27 (SD 6.84), median of 31, and IQR of 27 to 32. A total of 2.3% (7/301) participants had the worst possible score, whereas 4.7% (14/301) of participants had the best possible score. Over three quarters of respondents (253/299, 84.6%) felt it is important to be able to access health resources on the internet and that the internet is useful in helping make decisions about their health (234/298, 78.5%). The proportion of respondents who agreed with each eHEALS item is shown in Figure 2. Almost three quarters of respondents (215/301, 71.4%) had adequate health literacy (ie, agreed to at least 5 out of the 8 eHEALS items) and 78.1% (235/301) had eHEALS scores ≥26. The 2 items with the lowest levels of agreement were for *I can tell high-quality health resources from low-quality health resources on the internet*

(182/301, 60.5%) and *I feel confident in using information from*   *the internet to make health decisions* (191/301, 63.5%).

Figure 2. Frequency of responses to 8-item eHealth Literacy Scale among South Asian study participants (n=301 internet users). Data for strongly disagree and disagree were collapsed as was agree and strongly agree.
Mean eHEALS Scores by Demographic and Health Status Characteristics

Exploratory bivariate analysis showed that mean eHEALS scores were significantly lower in those aged ≥65 years (29.68, SD 6.55 vs 24.92, SD 8.40; difference –4.76, 95% CI –8.23 to –1.29; P=.01), and age was negatively correlated with eHEALS scores (Spearman correlation coefficient=–0.188; P=.001). Further, there were statistically significant higher mean eHEALS scores in those with college or university education versus high school education (30.45, SD 5.88 vs 25.27, SD 7.91; difference 5.19, 95% CI 2.58 to 7.79; P<.001), and those who preferred to receive written health information in English versus language other than English (30.38, SD 5.86 vs 22.22, SD 8.32; difference 8.17, 95% CI 5.45-10.8; P<.001; Table 1). There were also small but significantly higher scores in those free of hypertension or other chronic medical conditions.

Mean eHEALS Scores by Web-Based Health Information Seeking, Interest in eHealth Strategies, and Use of Health and Fitness Apps

In total, 74.4% (224/301) of participants used the internet several times per day, 71.4% (215/301) of participants sought web-based health information, and 31.6% (94/297) of smartphone or tablet owners used health and fitness apps. Of the internet users, 84.4% (254/301) were interested in future eHealth interventions. As shown in Table 2, the total eHEALS scores were significantly higher in those who used the internet several times per day; those using the web for health information; those using social media, Twitter, YouTube, and health and fitness apps; and those who showed interest in future eHealth interventions.

Characteristics Associated With eHealth Literacy: Quantile Regression

The results of the multivariable quantile regression using demographic, health status, and technology use variables for internet users are shown in Table 3. Language preference was the only variable independently associated with eHealth literacy. Expressing a preference for written health information in languages other than English reduced eHEALS scores by –6.0 (95% CI –9.61 to –2.39) points.

Discussion

Principal Findings

Among our sample of primarily Sikh, highly educated internet users recruited from community pharmacies and family physician offices, the mean overall eHEALS score was 29.3 (SD 6.8) out of 40, suggesting high levels of eHealth literacy. Almost three quarters of the respondents agreed to at least 5 out of 8 eHEALS items and were categorized as having adequate eHealth literacy [49]. A large proportion of respondents (72%-78%) in this study reported knowing how to use the internet to answer health questions, how to use the health information found on the internet for support, and how to find helpful resources on the internet, whereas fewer (61%-67%) were confident in evaluating and using health information from the internet. Although there were statistically significant differences in eHEALS scores according to age, educational achievement, language preference, and the presence of hypertension or other chronic medical conditions, language preference was the only independent variable associated with eHealth literacy.

Comparison With Prior Work

Level of eHealth Literacy

Most comparable with our study, is a case study conducted by Zibrik et al [59], which used quantitative and qualitative methods to explore eHealth literacy in a convenience sample of 896 established Chinese and Punjabi immigrant seniors recruited from public health events in British Columbia, Canada. Although overall and item-specific eHEALS scores were not reported in their paper, the authors concluded that their sample had low eHealth literacy levels compounded by challenges related to language, culture, attitude, and accessibility. The discrepancy between this conclusion and our results can be attributed to the fact that we focused our analysis on internet users and excluded eHEALS scores from internet nonusers, whereas Zibrik included all participants regardless of internet use status. Another Canadian survey assessing digital health literacy in South Asian women suggested high digital health literacy via high rates of mobile phone internet use but was only reported in abstract form [60].

Our results compare favorably to existing studies that looked at measures of eHealth literacy among internet users in the general population, reporting mean overall eHEALS scores ranging between 24 and 30 out of 40 [26,49,61-63]. For example, in a 2014 survey, Milne et al [49] reported an overall eHEALS score of 24.0 (SD not reported) among 83 primary lung cancer survivors at a cancer center in Toronto, Ontario, 78% of whom had access to e-resources. Only 34% of lung cancer survivors in Milne's study agreed with 5 or more eHEALS items, whereas we found that 58% of all respondents agreed with 5 or more items [49]. More recently, James et al [63] reported a mean eHEALS score of 30.4 (SD 7.8) in a sample of 881 African American adults surveyed between April 2014 and January 2015 in North Central Florida.

In other studies focusing on eHealth literacy among internet users, as in our study, overall mean eHEALS scores ranged

from 16.1 (SD 4.25) to 30.34 (SD 5.30), depending on the population studied [16,22,50,64-68]. Our finding that the items with the lowest level of agreement among internet users are related to their ability to evaluate the quality of web-based health resources is highly consistent with the findings of several other studies [63,65,66,69].

Variables Associated With eHealth Literacy

Several studies have explored variables associated with eHealth literacy [16,17,22,34,50,62,65]. The most commonly reported are age [16,22,50,65], education [16,65], and markers of frequency or degree of internet use [17,22,34,62]. However, other associations, including the number of devices used to access web-based health information [16] and language [65], have also been reported. Conflicting results led Richtering et al [17] to conclude that variables associated with eHealth literacy are largely dependent on population. For example, in their study examining eHealth literacy in 453 participants enrolled in a randomized controlled trial of consumer-focused eHealth for cardiovascular risk management in primary care in Australia, they showed that the frequency of internet use was the sole predictor of eHealth literacy [17]. Focusing specifically on underserved populations, a systematic review of the research suggests that internet use experience, urban dwelling, higher income, overall health literacy, and higher education are associated with higher eHealth literacy [34]. Notably, Zibrik et al reported that college-level education and female gender were associated with higher eHEALS scores in 545 Punjabi seniors included in their Canadian study [59].

By contrast, we found that language preference was the only variable independently associated with eHealth literacy. This could be a proxy for acculturation, as years living in Canada were not an independent predictor in our model. Limited English proficiency is a widely cited barrier in studies examining health care and eHealth access in immigrant or minority populations [59]. However, contradictory evidence exists in this area, where language was not found to be an independent predictor of eHealth literacy in a Canadian study by Milne [49]. However, being a non-English speaker was significantly associated with lower eHealth literacy in an American study that included a significant number of Hispanic and African American parents whose children have special health care needs [65]. Further, our work is in contrast to that of Neter et al, which suggests that language difficulties should manifest as lower health literacy, rather than eHealth literacy, as health literacy as a concept is anchored in a cultural and language context, whereas eHealth literacy is anchored in the empowering and capital-enhancing qualities of the internet [37]. Our finding that educational status was not associated with eHealth literacy may be a result of the highly educated survey sample.

Implications for Practice and Research

First, although our results suggest that a large proportion of South Asian internet users have adequate eHealth literacy, there remains a sizable minority in our study group whose eHealth literacy can be strengthened. Understanding levels of eHealth literacy is even more important in 2022 than in 2014, as the COVID-19 pandemic has globally increased the remote internet-based delivery of health care [19]. Second, our results

suggest that there is an opportunity to improve internet users' ability to differentiate high- from low-quality health information. Beyond assessing web-based health information about diabetes, cardiovascular disease, physical activity, and diet or nutrition, the COVID-19 infodemic is another example that illustrates the need for individuals to be better able to identify medical misinformation on the internet [21]. Training individuals to recognize misinformation could be one way to increase their eHealth literacy. Another approach may include health care organizations and provider support for patients to navigate and access high-quality and reliable web-based health information and resources via social media [70]. Finally, given that language preference was the only predictor of eHealth literacy, and this is likely a nonmodifiable factor, we suggest that interventions to improve eHealth literacy should be targeted toward those who have low English language proficiency and delivered in the individual's preferred language. Strategies involving peers, friends, and family members may also be effective.

Our study suggests several areas for future research. First, further work with representative samples should compare levels of health and eHealth literacy using newly available tools among recent and established Canadian immigrants and nonimmigrants similar to that of Neter et al [37]. Second, work should be done to develop theory driven, cultural, and language-tailored interventions to increase the uptake of eHealth interventions and improve eHealth literacy. Finally, high-quality randomized controlled trials are necessary to evaluate theory-based eHealth literacy interventions in ethnocultural minority and immigrant populations, and their impact on health outcomes.

Strengths and Limitations

At the time the survey was conducted in 2014, our work was unique, and to our knowledge, there are only 2 other published studies exploring eHealth literacy in members of the South Asian community in Canada [59,60]. Despite this, our study has several limitations. First, our data were collected in 2014 and are not likely to reflect the current use of digital health technologies or eHealth literacy. Second, as nonprobability sampling was used and only a subset of the entire survey sample completed the eHEALS assessment, we were unable to generalize our results to the larger South Asian population, as the sample is not representative. Furthermore, our results primarily pertain to the English- and Punjabi-speaking Sikh community, as we did not translate our survey into other commonly spoken languages (eg, Hindi and Urdu). Third, we did not formally validate the Punjabi version of the eHEALS, and there may be issues with conceptual translation and some variability in administration. However, few eHealth literacy assessments have been completed in Punjabi, and we used established procedures for translating survey items. We reported high internal consistency for the 8 items in this survey, and we had 2 trained research assistants who administered over 65% of the surveys. Fourth, eHEALS measures perceived eHealth literacy rather than actual eHealth literacy or skills as measured by performance tests [67,71]. In addition, it is worth noting that the tool does not address the ability to use Web 2.0 functionalities such as social media, mobile devices, and health and fitness apps for health behavior change purposes as do new tools [72]. Fifth, as our survey was primarily administered in person, social desirability bias may overinflate reported eHEALS scores and estimates of device ownership, internet use, and willingness to use future eHealth tools, whereas self-reporting may introduce recall bias in outcome and demographic variables. Finally, we recognize that the question relating to language preference for written health information could have been improved by asking about the primary language spoken in the home and that the use of a single health literacy screening question rather than a full health literacy questionnaire is not optimal.

Conclusions

This cross-sectional study in a subset of e-Patient Project survey respondents provides insights for clinicians and researchers on the levels and variables associated with eHealth literacy in a sample of South Asian adults living in a major Canadian city. Preferring written health information in languages other than English was the only independent variable associated with reduced eHealth literacy in our sample. Our results suggest that respondents may still benefit from interventions targeting skills to evaluate web-based health resources and that linguistically and culturally appropriate interventions are required to improve eHealth literacy.

Authors' Contributions

MJM, SD, and CAJ contributed to conception and design. MJM prepared the first draft of the manuscript and contributed to acquisition of data, analysis, and interpretation. MJM, SD, and CAJ were involved in critical revision of the manuscript for intellectual content. MJM, SD, and CAJ handled the final approval of the version to be published.

Abstract

Background: Telemedicine has been adopted in the inpatient setting to facilitate clinical interactions between on-site clinicians and isolated hospitalized patients. Such remote interactions have the potential to reduce pathogen exposure and use of personal protective equipment but may also pose new safety concerns given prior evidence that isolated patients can receive suboptimal care. Formal evaluations of the use and practical acceptance of inpatient telemedicine among hospitalized patients are lacking.

Objective: We aimed to evaluate the experience of patients hospitalized for COVID-19 with inpatient telemedicine introduced as an infection control measure during the pandemic.

Methods: We conducted a qualitative evaluation in a COVID-19 designated non–intensive care hospital unit at a large academic health center (Stanford Health Care) from October 2020 through January 2021. Semistructured qualitative interviews focused on patient experience, impact on quality of care, communication, and mental health. Purposive sampling was used to recruit participants representing diversity across varying demographics until thematic saturation was reached. Interview transcripts were qualitatively analyzed using an inductive-deductive approach.

Results: Interviews with 20 hospitalized patients suggested that nonemergency clinical care and bridging to in-person care comprised the majority of inpatient telemedicine use. Nurses were reported to enter the room and call on the tablet far more frequently than physicians, who typically entered the room at least daily. Patients reported broad acceptance of the technology, citing improved convenience and reduced anxiety, but preferred in-person care where possible. Quality of care was believed to be similar to in-person care with the exception of a few patients who wanted more frequent in-person examinations. Ongoing challenges included low audio volume, shifting tablet location, and inconsistent verbal introductions from the clinical team.

Conclusions: Patient experiences with inpatient telemedicine were largely favorable. Although most patients expressed a preference for in-person care, telemedicine was acceptable given the circumstances associated with the COVID-19 pandemic. Improvements in technical and care team use may enhance acceptability. Further evaluation is needed to understand the impact of inpatient telemedicine and the optimal balance between in-person and virtual care in the hospital setting.

Introduction

The COVID-19 pandemic created an unprecedented challenge for health systems to provide high-quality care to potentially contagious patients while simultaneously keeping their workforce and uninfected patients safe [1]. In response, telemedicine was widely adopted worldwide in outpatient settings [2]. Some further adopted "inpatient telemedicine" in acute care settings to facilitate clinical interactions between on-site clinicians and isolated inpatients for the purpose of infection control and to reduce the use of personal protective equipment (PPE) [3-7]. Early evidence points to the feasibility of inpatient telemedicine as an infection control measure [3-5], but formal evaluations into their use and practical acceptance among stakeholders, particularly patients, are limited.

In the outpatient setting, robust literature suggests overall patient satisfaction with telemedicine, including in general medicine [8], urgent care [9], and specialized settings [10-12]. Factors driving increased patient satisfaction include improved outcomes, decreased travel time, and improved communication [13]. Adequate training of the staff providing telemedicine services can also improve patient satisfaction [14]. Patient acceptance of telemedicine has persisted through the pandemic [15-18], with the highest levels of adoption observed among young patients [19]. However, high rates of patient satisfaction with telemedicine in the outpatient setting do not necessarily translate to the inpatient setting, given significant differences in the clinical environment, acuity of disease, frequency of clinical interactions, and the multidisciplinary team required to care for the patient.

Prior to the COVID-19 pandemic, the use of telemedicine in inpatient settings was limited to connecting rural areas with remote expertise [20,21], particularly specialty care [14,22-24]. The COVID-19 pandemic removed traditional barriers to telemedicine adoption, including staff resistance to change, and lack of reimbursement [13]. Since the pandemic, hospitalists [3,5], intensivists [4,6], and specialists [25,26] have used inpatient telemedicine to continue their clinical duties while minimizing pathogen spread. This novel use of inpatient telemedicine is still being explored: in one academic medical setting, the technology was broadly accepted by clinicians and staff but required nurses to drastically alter their workflow practices [27]. In another setting, in-room video technology saw the greatest adoption among patients who used it to communicate with their loved ones [28]. Little else is formally known about how patients perceive inpatient telemedicine, particularly under isolation conditions that a COVID-19 diagnosis necessitates.

This is unfortunate, as the patient perspective is integral to ensuring robust patient–provider communication, the lack of which can propagate diagnostic errors and adverse patient outcomes [29-31]. Isolated patients may be more likely to receive substandard care, particularly related to patient safety [32] and staff responsiveness to time-sensitive needs [33,34]. Further, patients hospitalized under isolation precautions face unique challenges, including negative feelings associated with loneliness, stigma, and fear [31-37]. Incorporating patient insights into the design of technological solutions within the patient environment is needed to support patient autonomy, human connection, and a sense familiarity that is otherwise lost during isolation [36-38].

We therefore aim to understand patient experience as it relates to clinical use and patient acceptance of inpatient telemedicine for infection control in order to optimize technical setup and clinical workflows.

Methods

Methods Overview

We conducted a qualitative evaluation of inpatient telemedicine use on a COVID-19 designated inpatient unit at a large academic medical center. We analyzed qualitative interviews with stable patients hospitalized for COVID-19 to understand the implementation outcomes related to the practical use and acceptance of the inpatient telemedicine solution from the patients' perspective.

Setting and Population

In March 2020, a large academic health center (Stanford Health Care) designated an inpatient non–intensive care unit to care for admitted patients with confirmed or suspected COVID-19. Each patient received a tablet (iPad; Apple Inc) set up to automatically receive web conference calls (Zoom Video Communications, Inc) from one of two desktops in private workrooms on the unit, all with dual audio and video functionality. Other setting details have been previously described [3] and can be found in Multimedia Appendix 1.

The target population included stable patients who were admitted to the non–intensive care COVID-19 unit. Purposive sampling methods were used to recruit participants representing diversity across age, sex, race and ethnicity, and language until thematic saturation was reached [39].

Data Collection and Analysis

The semistructured patient interview protocol, analysis, and presentation of findings were informed through deductive themes drawn from prior qualitative work [27] and the Implementation Outcomes Framework (Multimedia Appendix 1) [40]. Interview transcripts were reviewed independently by the lead author (SV), and key themes and inductive coding that emerged were then validated using a consensus approach that included the analytic (DP, MS, JHL, and RG) and interview (SS, EA, and EEW) teams.

Ethical Considerations and Informed Consent

The Stanford Institutional Review Board determined that this project did not qualify as human subjects research (protocol

55927). All participants provided verbal consent to proceed and were informed their participation was voluntary and confidential.

Results

Participant Characteristics

A total of 20 interviews were conducted with inpatients undergoing treatment for COVID-19 without intensive care needs. Participants tended to be male (11/20, 55%); aged 50-69 years (15/20, 75%); Latino, White, or Asian, Indian, or Pacific Islander (6/20, 30% each), and spoke primarily English (16/20, 80%) (Multimedia Appendix 1).

Reported Use and Acceptance of Inpatient Telemedicine From the Patients' Perspective

Telemedicine use varied on the basis of the clinical context and the type of clinician providing care, though it was broadly accepted by patients given the COVID-19–related isolation precautions (Table 1). Predominant use included nonemergency clinical care and bridging to in-person care—such as when a patient triggered the bedside alert button. In this setting, one nurse was reported to initiate a telemedicine encounter to visually connect with the patient while another donned PPE to evaluate the patient in person.

Typical frequency of virtual encounters ranged from 1 to 3 times a day, though one patient reported being contacted up to 10 times per day via the tablet device and 10 times per day in person. Nurses were reported to both enter the room and call on the tablet more frequently than physicians. However, most patients reported at least one in-person encounter daily from their doctor, with a few reporting multiple in-person encounters when their needs were greater. A few patients reported their physician primarily communicated via the tablet device, and a minority perceived there were some days on which they did not speak with their doctor either in person or via the tablet device.

Patients generally accepted the use of inpatient telemedicine given their circumstances requiring isolation precautions. A desire to prevent infection transmission was recognized by several patients: "It's helpful that I can talk to multiple doctors without having to expose them to COVID" [Patient 9]. Some felt that telemedicine offered superior convenience, and the visual component was seen as adding value beyond an audio-only telephone encounter. The virtual interactions provided reassurance, which was reported to positively impact patient mood and mental health: "I love to hear from my doctors, it brought such great comfort for them to be updating me" [Patient 6].

Patients broadly reported that the quality of care they received with the integration of telemedicine into their hospitalization was similar to what they might have received without it.

However, some were in favor of an in-person encounter in accordance with the concern that some aspects of their care could be missed, particularly related to the in-person examination and human connection. Some felt that telemedicine changed the way they communicated with their care team: "In person is better…I can have a more in-depth dialogue, ask questions…When they're physically here, they can be there for me" [Patient 18]. Older patients, in particular, seemed to prefer in-person encounters. Only a handful of patients felt telemedicine did not compromise their connection with their care team.

Table 1. Patient perspectives on the use and acceptance of inpatient telemedicine in the context of the COVID-19 pandemic.

Learnings	Example quotations
Reported use of inpatient telemedicine	
Used primarily for nonemergency care and as a bridge to in-person care	• "We run the visits based on my bladder which is about every hour and a half. They [nurses] bring breakfast and then I pee and then they do my meds and stuff. Normally they don't come in first, [instead] they check on me on [the tablet] and then come in." [Patient 20]
Nurses reported to both enter the room and call on the tablet device	• "Five or six times a day [in-person nurse visits] and they [nurses] also call on the iPad…" [Patient 9]
Physicians sometimes used telemedicine to replace in-person encounters	• "At least once maybe twice a day [in-person physician encounter]. There were some days though where I didn't have any doctors come in and talk to me. They were just conversing with the staff regarding my wellbeing." [Patient 6]
Acceptance of inpatient telemedicine	
Generally accepted given the circumstances surrounding the COVID-19 pandemic	• "Of course there's nothing more effective than the person to person contact, but this is the safest, and the tech is so advanced it's like you're right in front of me" [Patient 15]
Telemedicine seen as improving convenience	• "I think it's great because we have more contact with [the] medical providers than any other time. You normally have to wait till they have time to come and talk to you…[but this way] seems to be a lot more efficient way to handle things" [Patient 2]
Immediate accessibility to clinical team via telemedicine offered reassurance	• "On the first day I went to sleep, woke up with anxiety real bad, feeling as though I was on my last breath. I pushed the [bedside alert] button and the nurses came on and then after that the [tablet] did come on they were looking at me, talking to me, and helped me calm down right away. They were like, 'Just breathe, someone's coming right in'." [Patient 16]
Visual component seen as adding value over a telephone call	• "…they [clinicians] are right there when I need them and I can physically see them versus waiting to talk to them via the phone." [Patient 8]
No perceived impact on quality of care overall with a minority concerned about the reduction in in-person examinations	• "Honestly I don't think it has changed the care because the nurse is always reporting to the doctor and then the doctor looks at all my labs and things so they are pretty on top of it and then they call me to let me know the plan…But I wouldn't say it's better it's like the same." [Patient 1] • "Most of time when we see doctors normally, they use the stethoscope, to listen to lungs, heart…That's the normal way to see a patient, so I just wonder, I'm completely okay with the [tablet], but somehow the doctor can't see [me] in person…the nurse never uses the [stethoscope] to listen to my lungs/heart. So that is something I am not comfortable with." [Patient 4]
Some reported loss of human connection	• "…on the internet you can say whatever you want; telemedicine is close to internet separation…the non-word ways of communication are much different than in person, tone, intonation…like I'm here but I don't see your whole body and vice versa. [It] changes [one's] mood..." [Patient 3]

Technical Factors Impacting Patient Acceptance

In general, the technology was reportedly "very simple to use" [Patient 5]. However, certain technical setup considerations impacted patient acceptability, including audio volume, tablet position both within the room and in relation to the patient, and the automatic turn-on feature. Several patients remarked that despite turning the tablet volume up to its maximum capacity, they still had difficulty hearing the clinical team, particularly if someone was speaking further away from the source microphone.

Furthermore, the tablet location and angle relative to the patient sometimes posed challenges. The tablet device was reportedly moved frequently to allow space for nurses doing their clinical work. This lack of a stable location worsened the experience for some patients:

> Mostly I don't like it. I don't understand them sometimes. Sometimes they move it towards my feet. It's too far from me, it should be near my face... [Patient 19]

There was not a clear consensus on where the tablet should be placed within the room, as another patient preferred it near the feet to optimize the visual component of the encounter.

Finally, patients were asked to comment on the automatic turn-on feature of the tablet device, which did not allow them to screen calls. Nearly all were comfortable with this feature, likening it to standard hospital care in which a clinician would simply walk into the room, only sometimes following a quick

knock. The one patient in his 20s, who expressed some concern over privacy, devised his own solution to turn the camera toward the wall temporarily while he showered.

Care Team Use Factors Impacting Patient Acceptance

The clinical team's use of the technology also impacted patient acceptance, specifically around patient orientation to technology, clinician etiquette regarding encounter introductions and use, and visual connection with each speaker. Patients described minimal or no orientation to the tablet. "They never told me about the iPad; I noticed when they came on-- 'Hello hello hello'" [Patient 10]. Where an orientation was reported to take place, it was minimal: "They pointed it out to me and said…this is the [tablet] for nurses and doctors to call you" [Patient 11]. While this brief orientation would have been preferred, it did not bother most patients. A preference for an orientation was more prevalent among patients who did not have prior familiarity with using tablet devices or web conferencing technology.

Opportunities were also noted for improved etiquette around introducing each member of the team and positioning the tablet toward the speaker:

> *I have a bunch of different doctors on my care team…[it is] much harder to remember each one, [as I] don't have visual clues. I see [them] only as 2D and honestly [there is an] unwillingness for everyone to get in front of the screen…one [clinician] is on the side, I hear their comments but I don't know who that is...* [Patient 3]

This concern was not prevalent among all patients but may have improved acceptability among the few patients who voiced it.

Discussion

Principal Findings

Patients' experience with telemedicine during an inpatient admission for COVID-19 was largely favorable. While most patients expressed a preference for in-person care where possible, telemedicine was an acceptable alternative given COVID-19 isolation precautions. Both nurses and physicians regularly used the technology to communicate with patients, thus validating past work [27] in which the balance of in-person versus telemedicine workflows was guided by acuity of clinical need. Telemedicine appeared to serve as a supplementary point of contact between in-person encounters, which patients primarily saw as a benefit to their overall experience and mental health. The technology reportedly played a meaningful role in mitigating the fear and anxiety associated with isolation precautions [31-37], though additional evaluation is needed to quantify this impact. Finally, with the exception of a desire by some patients for more hands-on examination and in-person interaction, patients felt their quality of care was no different as a result of inpatient telemedicine.

Direct and implied recommendations to improve inpatient telemedicine include increasing audio volume, allowing for a digital "knock" to serve as a warning prior to automatic turn-on, establishing an unobtrusive stable location for the tablet, adding a call-out button to the nursing team, increasing focus on physical touch, improving clinical team introductions, and standardizing patient orientation to the technology (Table 2).

These data are consistent with the past literature, which suggests that providers may overestimate their communication ability [41]. Given that a physician is required to evaluate each inpatient at least once per day, the frequency of physician encounters less than once per day reported by some patient suggests suboptimal communication and role confusion. A strong introduction includes the name, role, and responsibilities of each member of the care team, information that is often not shared even in nondigital clinical settings [42,43]. Training related to the importance of verbal introductions [44,45] and best practices to foster the patient–provider connection in the virtual setting may help mitigate the challenge of role confusion [46]. Clear badges or face cards [38,43,47,48] can also help, but these tools are not available in the digital setting. Instead, facial recognition technology is being explored to solve other problems in health care [49,50] and could be used to automatically display a virtual name badge.

Some patients were also concerned that aspects of their care may be missed owing to the lack of a hands-on examination. The importance of a hands-on physical examination—both for diagnostic and therapeutic purposes—is evidenced in the literature [51,52], but how to best adapt these learnings to patients are under isolation precautions remains an open question. Nurses were reported to use telemedicine more frequently than physicians, while also maintaining a frequent physical presence within the room, which is perhaps unsurprising given that nurses spend approximately 6-fold more time at the patient bedside than physicians in non–COVID-19 settings [53,54]. These COVID-19 data further validate past qualitative work, which suggests that nurses use telemedicine as a bridge to in-person care and "batch" care activities, such that physical assessment, medication delivery, meal delivery, and sanitation protocols all occur in a single room entry [27,55]. The impact of this shift, alongside the reported reduction in in-person physician assessments, on clinical outcomes is an area for future research.

To this end, inpatient telemedicine risks exacerbating pre-existing clinician reliance on technology over hands-on examination. Substitutes for an in-person examination, such as directing patients toward a self-examination with a digital stethoscope [56], pulse oximeter, or other technologies capable of remote transmission of data, even if appropriate from a diagnostic perspective [57], may be less acceptable to patients in the inpatient setting. Additional evaluation is therefore needed to determine the optimal ratio of in-person to virtual encounters.

Table 2. Implied technical and protocol recommendations to improve inpatient telemedicine in accordance with patient interviews.

Patient concern	Possible solutions
Telemedicine technical setup	
Low audio volume	• Improve the audio with more powerful provider-side microphone and patient-side speaker technology
Tablet position is suboptimally angled or too far from the patient	• Stable, unobtrusive "home" for the tablet device within the patient room at an optimal distance and angle; standardized within all patient rooms with telemedicine capabilities
Tablet device automatically turns on without warning	• Announcement of an incoming call with a digital "knock" and a visual and audible countdown prior to automatic web conference turn-on or "entry" into a room
Emergency situation where the patient wants immediate contact with the care team	• Callout button direct to the nurse from the tablet device and the web conferencing system
Care team protocol when using telemedicine	
Desire for physical examination on a regular basis	• Hands-on physical examination by the physician or nursing team with a dedicated stethoscope • Exploration of patient self-exam using enabled devices such as stethoscope with remote transmission capabilities
Poor understanding of who is on the care team and their respective roles when using the web conferencing tool	• Clinical team training emphasizing improved verbal introductions at each virtual encounter • Automatic caption with the name or title based on facial recognition technology
Insufficient patient orientation to tablet use	• Standard orientation to telemedicine, including self-directed exploration

Limitations

Insights from this evaluation are drawn from a small sample of patients within a single institution and therefore cannot be more broadly generalized. These exploratory interviews provide insight into an otherwise difficult-to-reach patient population with currently limited available data, though future work will benefit from expansion to diverse institutions and patient populations. Including patients who required intensive care may be particularly informative; safety and feasibility constraints limited our ability to capture these perspectives in this assessment. In addition, we purposefully sought a diverse set of voices in our sampling protocol, and our final sample overrepresented non-White participants on the basis of local demographics [58]. Increasing sample diversity in terms of languages spoken, given the predominance of English speakers in this sample, may benefit future work. Finally, these qualitative data may also complement and inform ongoing and future quantitative work that explores the impact of inpatient telemedicine on clinician workflows and, by extension, infection control and resource use [59].

Conclusions

Inpatient telemedicine adopted for the purposes of infection control during the COVID-19 pandemic presents a novel use case of the technology, and our understanding of its impact on clinical workflows, patient outcomes, and the patient experience continues to evolve. This qualitative evaluation suggests that while patients still prefer in-person interactions in the hospital setting, inpatient telemedicine is broadly accepted given the need for COVID-19 isolation precautions. Perceived benefits include increased access to the clinical team and reduced anxiety, yet challenges around the technical setup, clinical team introductions, and physical examination remain. Further evaluation is needed to understand the impact on clinical outcomes and the optimal balance between in-person and virtual care in the hospital setting.

Abstract

Background: Centralized drug repositories can reduce adverse events and inappropriate prescriptions by enabling access to dispensed medication data at the point of care; however, how they achieve this goal is largely unknown.

Objective: This study aims to understand the perceived clinical value; the barriers to and enablers of adoption; and the clinician groups for which a provincial, centralized drug repository may provide the most benefit.

Methods: A mixed methods approach, including a web-based survey and semistructured interviews, was used. Participants were clinicians (eg, nurses, physicians, and pharmacists) in Ontario who were eligible to use the digital health drug repository (DHDR), irrespective of actual use. Survey data were ranked on a 7-point adjectival scale and analyzed using descriptive statistics, and interviews were analyzed using qualitative descriptions.

Results: Of the 161 survey respondents, only 40 (24.8%) actively used the DHDR. Perceptions of the utility of the DHDR were neutral (mean scores ranged from 4.11 to 4.76). Of the 75.2% (121/161) who did not use the DHDR, 97.5% (118/121) rated access to medication information (eg, dose, strength, and frequency) as important. Reasons for not using the DHDR included the cumbersome access process and the perception that available data were incomplete or inaccurate. Of the 33 interviews completed, 26 (79%) were active DHDR users. The DHDR was a satisfactory source of secondary information; however, the absence of medication instructions and prescribed medications (which were not dispensed) limited its ability to provide a comprehensive profile to meaningfully support clinical decision-making.

Conclusions: Digital drug repositories must be adjusted to align with the clinician's needs to provide value. Ensuring integration with point-of-care systems, comprehensive clinical data, and streamlined onboarding processes would optimize clinically meaningful use. The electronic provision of accessible drug information to providers across health care settings has the potential to improve efficiency and reduce medication errors.

Introduction

Background

Pharmacological management of chronic diseases and acute illness is common, with over 41% of Canadians reporting using at least one prescription drug [1]. The lack of comprehensive medication information at the point of care can increase the likelihood of an adverse drug event (ADE) [2,3]. A meta-analysis of 46,000 patient records estimated that 20% of hospital inpatients in high income countries have at least one ADE, of which 32% are deemed preventable [4]. In community settings, 5% of patients experience at least one ADE in their lifetime [5], which translates into 16 million Americans or 2 million Canadians based on current population estimates [6,7]. ADEs are often caused by preventable prescribing errors (ie, wrong dose or therapeutic choice) and ineffective monitoring of pharmaceutical care [5,8], costing health care systems an estimated CAD $1.1 billion per year (US $0.89 billion) [9].

Medication reconciliation reduces the likelihood of ADEs [10] and involves a collaborative effort between clinicians and patients to establish a best possible medication history (BPMH) to improve medication safety [11,12]. Medication histories reported by patients during the BPMH process are often verified using secondary sources of information, such as pharmacy or discharge records [13]; however, this process is time consuming and cumbersome at the point of care.

There are several examples of national and international drug repositories, such as the British Columbia Pharmanet [14] or Sweden's National Prescription Drug record [15], which typically contain dispensed medication information, such as the drug name, the dose, allergy, and intolerance information, which can be valuable when constructing a BPMH. A few drug repositories also include information on prescribed medications and private insurance claims to facilitate decision-making at the point of care [16,17]. Access to a centralized drug repository can support the BPMH process and, in turn, reduce inappropriate prescribing [18], improve medication adherence [19], and reduce health care costs [20,21].

Objectives

To achieve these aims, the Ontario Ministry of Health implemented the digital health drug repository (DHDR). The DHDR contains information on publicly funded drugs in Ontario, pharmacy services, and dispensed monitored drugs (ie, narcotics and controlled substances). The DHDR was developed by a provincial agency responsible for creating a public electronic health record system (eHealth Ontario), and access is enabled through one of two provincial clinical viewers (*ClinicalConnect* and *Connecting Ontario*), which provides access to a range of health system data assets. The DHDR was implemented in 2016 and had over 150,000 registered users across over 546 sites at the start of this study (November 2018). Eligible users of provincial viewers include clinicians who require patient medical information as part of the provision of care (eg, physicians, nurses, and pharmacists). Use statistics estimate that approximately 3000 users access the DHDR daily; however, the drivers of engagement and whether the DHDR is achieving its objectives remain unclear.

The overarching aim of this work is to examine the use, drivers of engagement, perceived value, and potential impact of the DHDR. The specific objectives are to (1) understand the perceived clinical value of accessing medication history via the DHDR, (2) identify enablers of and barriers to adoption among eligible users, and (3) understand for which clinician groups the DHDR has current or future potential clinical value and how that value is (or might be) realized.

Methods

Overview

A multi-method approach was used to elicit feedback from users and nonusers of the DHDR and included a cross-sectional electronic survey and semistructured interviews. The approach allowed us to simultaneously collect a breadth of responses from users and nonusers in the cross-sectional survey, whereas the interviews explored more fulsomely individual experiences with the DHDR. Interviews and the survey were conducted concurrently to maximize research efforts, and the results were triangulated and interpreted simultaneously (ie, the qualitative findings were used to help understand the survey findings and vice versa). Informed consent was obtained electronically for participants completing the survey, and verbal consent was obtained for those participating in interviews.

Ethics Approval

Research ethics approval was obtained from the Women's College Hospital using the assessment process for quality improvement projects (WCH APQIP REB #2019-0038).

Study Setting

In Ontario, some prescription drugs were publicly covered by the Drugs and Devices Division of the Ministry of Health (formerly Ontario Public Drug Programs). These include the Ontario Drug Benefit Program for residents aged >65 years, the Trillium Drug Program for residents with high medication costs in relation to household income, and other specialized drug programs for those with complex conditions, such as cancer, inherited metabolic disorders, and those receiving home care [22]. In 2013, over 2.8 million, or approximately 20% of residents, received benefits through these programs to reduce the cost of medications [22]. In addition, the DHDR incorporates the provincial Narcotics Monitoring System, which captures dispensed narcotics (ie, opioids) and controlled substances (ie, methylphenidates, benzodiazepines, and barbiturates) for all residents [23]. The DHDR includes dispensed medication information from the Drugs and Devices Division Programs and the Narcotics Monitoring System; however, it does not include medications paid through private insurance companies; over-the-counter medications; or general purchase medications (eg, acetaminophen), supplements, or medication samples (ie, novel anticoagulants) provided by pharmaceutical companies.

To centralize access to provincial digital assets, the DHDR was embedded into 2 pre-existing clinical viewing portals. These portals allow providers access to a range of patient-level information, including diagnostic imaging reports, dispensed medications, laboratory results, hospital visits, and home and community care information (ie, referral details, risk

assessments, and care plans) in Ontario. Although participants' perceptions of the DHDR were influenced by their experience with the clinical viewer, exploring its functionality was beyond the scope of this study.

Participant Recruitment

Clinicians from all sectors of the health care system were eligible for participation in the survey or interviews, provided they were clinicians who required access to electronic patient records as part of the provision of clinical care. This group includes physicians, specialists, nurses, pharmacists, and other allied health providers employed at health organizations. Allied health professionals employed in the private sector such as physiotherapists, occupational therapists, and paramedics were not eligible.

Recruitment for the survey and interviews was conducted concurrently using a multipronged approach, as no mechanism existed to identify or contact current users directly. Our first strategy involved recruiting participants through Local Registration Authorities (LRAs) working with eHealth Ontario. LRAs are individuals nominated by their organization or site to train users on clinical viewers (ie, *Connecting Ontario* and *ClinicalConnect*) and its connected repositories such as the DHDR. Using aggregate use data obtained from eHealth Ontario, we stratified the data based on the type of health care setting (ie, acute care, long-term care, and community care) and region (eg, Southwest, Northeast, and Central Ontario). Our goal was to recruit from sites with a larger pool of users to maximize the potential for recruitment. Thus, sites with fewer than 20 registered users were excluded (n=308). LRAs were offered a modest honorarium to acknowledge their efforts, and we were limited to include a maximum of 24 sites based on our funding. These sites were selected using a random number generator of the included sites with >20 registered users (n=112). The LRAs from the 24 targeted sites were then asked to distribute recruitment emails.

As the survey was constructed for the purpose of this study, there was no sample size calculation behind our target recruitment. Overall, the selected target sites had approximately 6794 active users and over 15,000 authorized users. We anticipated the LRAs would send the link to the survey to at least 50% (3397/6794) of active users, of which we estimate 30% (1019/3397) would open the email and 20% (203/1019) of which will complete the survey [24,25].

To increase participation, our secondary strategy involved recruitment through the DHDR Clinical Working Group, a group of clinicians who are actively engaged in digital health solutions at their respective organizations and advise eHealth Ontario on how to improve the DHDR. The DHDR working group members circulated a recruitment email detailing the project, contact information of our study team, and a link to the electronic survey through their internal networks. Finally, we recruited individuals through our internal networks and social media outlets (Twitter and LinkedIn). Participants who were interested would click the link to the survey or contact the study coordinator to participate in an interview.

Data Collection

Cross-sectional Survey

A web-based cross-sectional survey targeted authorized users and nonauthorized potential users of the DHDR to understand their knowledge related to the DHDR and how they use its data where applicable. Nonauthorized users are individuals who are eligible for DHDR access but have not been issued secure credentials for access to the repository (ie, still not registered for access through eHealth Ontario via a clinical viewer).

Survey items were informed by previous Ministry of Health benefits and evaluation reports and past surveys conducted by eHealth Ontario. The questions were further modified and reviewed by stakeholders at the Ministry of Health and eHealth Ontario to ensure sufficient alignment to inform decision-making. In addition, to ensure we included questions relevant to our evaluation, face validity in relation to our study objective was assessed using the Clinical Sensibility Questionnaire (Multimedia Appendix 1) [26]. Three stakeholders from eHealth Ontario, 4 clinicians, and 1 researcher (outside of the research team) from Women's College Hospital reviewed the items for inclusion. A total of 10 questions were removed to eliminate redundancy, and several questions were rephrased for clarity based on feedback.

Survey items included a demographic questionnaire followed by questions on the perceptions of the DHDR (Multimedia Appendix 2). DHDR users rated their experience across four key domains: (1) usefulness, (2) quality of data, (3) training, and (4) satisfaction. Participants also rated the perceived value of the 14 data elements currently contained in the repository (eg, strength, dose, and therapeutic class) and their perceptions of the overall value and impact of the DHDR. Finally, the participants ranked the importance of enhancing the DHDR with specific questions currently under consideration for integration: (1) the comprehensive inclusion of all prescribed medications (ie, the addition of those that are not dispensed), (2) privately paid drugs (ie, private insurance or out-of-pocket claims), and (3) additional clinical data (eg, tolerances or allergies). Nonusers of the DHDR were asked to rate their perceptions of the value of centralized repository access and its potential impact. Further questions using open textboxes were used to elicit the reasons why participants did not use the DHDR and the resources used to develop a BPMH.

Survey items were rated on a 7-point adjectival scale with anchors ranging from *1* (*strongly disagree*) to *7* (*strongly agree*) or *1* (*not at all important/valuable*) to *7* (*extremely important/valuable*). The survey was administered and managed on the web using the Research Electronic Data Capture (REDCap) tool hosted at WCH, in Toronto, Ontario [27,28]. It is a secure web-based software platform designed to support data capture for research studies. Participants who completed the survey had the opportunity to enter into a draw for 1 of the 3 CAD $100 (US $79.46) gift cards.

Semistructured Interviews

Interviews were conducted with users and nonusers of the DHDR by trained qualitative research staff with no prior relationship with the study participants (CS and MP), under the

supervision of an experienced qualitative researcher (LD). The interviews focused on mechanisms for accessing the DHDR (ie, type of clinical viewer used), features and functions of the repository, perceptions of the data elements contained in the repository, barriers to or enablers of adoption, and potential impact on clinical workflow and health outcomes (Multimedia Appendix 3). Questions were tailored by user type (users and nonusers of the DHDR) and included a demographic questionnaire. Before conducting interviews, the interview guides were reviewed by an experienced qualitative researcher (LD), a pharmacoepidemiologist (MT), and a researcher (external to the research team with expertise in digital health evaluations). The interview questions were derived directly from the research aims, future features, and functionality of the DHDR. The interviews were conducted in person or over the phone, according to the participant's preference. The interviews were audio-recorded, transcribed, and anonymized by an independent third party.

Analysis

Cross-sectional Survey

Participants were able to skip questions or end the survey early as the survey did not force a response. These incomplete responses were included in the analysis, resulting in different denominators across different questions, and participant responses were aggregated and descriptively analyzed. Items rated on the 7-point adjectival scale using the anchors *strongly disagree* to *strongly agree* were interpreted as disagreement, neutral, and agreement by consolidating responses. Negative statements in the 4 key domains were reverse-scored, and the overall means were calculated for each domain. All the other survey items were aggregated. Subgroup analyses were conducted to assess the impact of gender and user and nonuser perceptions of the impact and value of the DHDR. Differences in gender and user and nonuser responses were evaluated using the Wilcoxon Rank-Sum test. Survey data are presented as means and SD, and statistical significance was considered at the 0.05 level. All analyses were conducted in the R statistical program using the *ggpubr* and *MASS* packages [29].

Semistructured Interviews

Interviews were analyzed using qualitative description, a paradigm that seeks to create an understanding of a phenomenon by accessing the meanings that participants ascribe to it [30,31]. Two coders (CS and MP) independently and inductively coded the first three interviews, after which they met to discuss the data, achieve coding alignment, and establish a codebook. One coder (MP) deductively applied the codebook to the remaining interviews, creating inductive codes as new data emerged. New codes were discussed iteratively (CS and MP), and the second coder (CS) reviewed a random subsample of 3 additional interviews to evaluate consistency. Interviews continued until thematic saturation was achieved (ie, no new themes were identified), at which point 3 additional interviews were conducted to confirm saturation [32]. Two team members (CS and MP) then generated preliminary themes that were discussed with a senior scientist (LD) and a pharmacoepidemiologist (MT). Themes were further refined based on group discussions and finalized once a consensus was achieved. Qualitative data were analyzed using NVivo (version 12 Plus; QSR International) [33].

Results

Overview

The survey and interview data were collected between May and August 2019. The results are first presented for surveys, followed by the data obtained from the interviews.

Survey Results

Of the 161 participants who completed the survey, 80.7% (130) were predominantly female and represented a range of health professions (see Table 1 for demographic characteristics). Approximately 32% (53/161) were not using a provincial viewer for patient information, only 24% (38/161) indicated that they were using the DHDR, and 44% (70/161) indicated they were not using the DHDR. Survey validation findings are detailed in Multimedia Appendix 4 [34-36]. Across the key experience domains, the coefficients were negatively correlated, suggesting that the survey items within each section were slightly convergent; however, the findings were not statistically significant.

Table 1. Survey participant demographics (N=161).

Demographic attribute	Values, n (%)
Sex

[c]DHDR: Digital Health Drug Repository.

DHDR Users

Of the 40 users who reported using the DHDR, 29 were female (73%), 25 were working in acute care (62%), and 27 were located in an urban setting (68%; Multimedia Appendix 5). Most had accessed the DHDR within the last 6 months, although the frequency of access varied (Multimedia Appendix 6).

Across all experience domains (ie, usefulness, quality of data, training received, and overall satisfaction), the average participant response trended toward neutral (neither agree nor disagree), with notable variability in responses (Figure 1). Differences were negligible between male and female respondents; however, female respondents (mean score 4.83, SD 1.61) perceived the DHDR to fit with the workflow to a greater degree than their male counterparts (mean score 2.73, SD 1.85; P=.003; Multimedia Appendix 7).

Figure 1. Mean scores and SDs for digital health drug repository (DHDR) experience among survey respondents.
Of the 14 data elements currently included in the DHDR (Multimedia Appendix 8), DHDR users rated 9 elements as necessary for the development of a BPMH (with a mean rating ≥5, and SD >1.90). In terms of perceived importance, these included the strength of dose (mean 6.41, SD 0.82), generic name of the drug (mean 6.07, SD 1.24), quantity of medication dispensed (mean 5.97, SD 1.13), prescriber contact information (mean 5.90, SD 1.20), estimated supply (mean 5.87, SD 1.11), dosage form (mean 5.87, SD 1.32), dispense date (mean 5.85, SD 1.14), pharmacy contact information (mean 5.77, SD 1.47), and prescription count (mean 5.45, SD 1.36; Multimedia Appendix 8). Participants expressed a desire for private insurance claims for dispensed medications, medication instructions (eg, 50 mg twice daily), and explicit discontinuations in the DHDR to facilitate a comprehensive profile of medication history.

On average, participants perceived having access to all prescribed medications, dispensed medications, private insurance claims, additional clinical data, and integration of the DHDR into current point-of-care systems as moderately valuable, with average scores ranging from 5.90 to 6.32 (Multimedia Appendix 9). However, participants were neutral in their perceptions of the perceived impact of the DHDR on reducing ADEs, improving patient outcomes, and reducing communication with other providers, with average scores ranging from 4.76 to 4.21 (Multimedia Appendix 10).

DHDR Nonusers

A total of 123 participants stated that they were not using the DHDR and had a demographic profile similar to that of the DHDR user group (Multimedia Appendix 5). Most respondents (99/123, 80.5%) had not heard of the DHDR, and 89.4% (110/123) were not familiar with what the DHDR did. Surprisingly, 63.4% (78/123) had access to a provincial viewer, which contained the DHDR, but did not use the DHDR itself (Multimedia Appendix 5). Comments reported in the open textboxes suggest that some DHDR nonusers perceived that there was limited clinically meaningful information in the repository, whereas others believed that the records were incomplete, preferring instead to rely on pharmacy records. Those who did not have access to a provincial viewer cited a lack of availability or the tedious registration process as barriers to use.

Comparison of DHDR Users and Nonusers

Overall, users and nonusers of the DHDR expressed the value in the ability to access all prescribed medications, dispensed medications, privately funded medications, and additional clinical data at the point of care when developing a BPMH (Figure 2), with no significant differences between the groups. All participants agreed that a centralized repository would improve patient outcomes, reduce unnecessary communication between clinicians, and reduce ADEs (Figure 3).

Figure 2. Perceptions of the value of accessing information at the point of care among survey respondents. Bars represent mean scores and error bars represent SDs. DHDR: Digital Health Drug Repository.
Figure 3. Perceptions of the impact of the digital health drug repository (DHDR) among survey respondents. Bars represent mean scores and error bars represent SDs.
Interviews

A total of 33 clinicians were interviewed between May 13 and August 1, 2019. The average length of the interviews was 25 minutes (range 7-53 minutes). Interviewees had a similar demographic profile to that of the survey respondents, apart from a greater gender balance (Table 2). Of the 33 participants, 26 (79%) had access to a provincial viewer and had accessed the DHDR at least once, and 7 (21%) participants neither had access nor wanted to pursue the process to get access because

they believed that they were ineligible for access or were concerned about the administrative process to obtain access. Moreover, nonusers were generally satisfied with current resources, such as calling pharmacists or health care provider to obtain medication information. Themes centered around user experience, training and onboarding, resources used for BPMH, clinical use cases, impact on clinical workflow, lack of awareness of the DHDR, and perceived impact. Additional quotes supporting key themes can be found in Multimedia Appendix 11.

Table 2. Demographics of interviewed participants (N=33).

Demographic attribute	Participants, n (%)

User Experience

Overall, 26 participants accessed the repository a few times a month and were generally satisfied with the available data. Participants found the DHDR easy to use and adaptable to their clinical needs (eg, the ability to filter medication histories over a customizable time). Clinicians valued the basic medication information contained in the repository such as drug name, dosage form, and contact information of the prescriber and dispensing pharmacy as secondary mechanisms to validate BPMH.

Participants felt that the DHDR did not fully achieve its intended role as it did not capture all medication information for Ontario residents (ie, only those covered), restricting its ability to provide a complete and comprehensive understanding of a patient's medication history. Relatedly, notable information was missing from the DHDR, including medication instructions, alternative medication names, drug discontinuations, a comprehensive list of prescribed medications (ie, including those that were not dispensed), and private insurance claims for dispensed medications. None of the participants used the DHDR as the primary source of medication information and only used when it was not possible to call the pharmacy or family physician (ie, after hours). Methods that clinicians used to conduct a BPMH

included reviewing the patient's health record, conducting a patient interview, confirming medications with a pharmacist or family physician, and using other resources such as electronic medical records.

Participants were able to identify issues with medications, such as potential drug interactions, ADEs, or duplicate prescriptions because of the DHDR. Some participants expressed that not having access to this information generates unnecessary costs to the health care system because of duplicate prescriptions and risk of complications.

Onboarding and Training

Obtaining access to provincial viewers (within which the DHDR is contained) presented challenges for participants working in community or long-term care settings. Those working in acute care settings gained access through their organization and delays were relatively small (ie, a few days to weeks). For those outside of acute care, the process of obtaining access was tedious and lengthy, with some participants reporting waiting periods to gain access ranging from 2.5 to 18 months. Delays were often the result of security and privacy assessments or waiting for a response to inquiries during registration. The process of obtaining access to the DHDR for a large hospital was the same as that for a small community practice or a local pharmacy, and

participants were often frustrated at the process. Out-of-pocket overhead costs and resources required to achieve provincial viewer access were a concern to community providers, which served as a deterrent to some:

> You basically go on the website and then you look at the link that talks about getting access for your clinic. Then you contact somebody and they usually will take their time to get back to you, but within maybe a month they'll get back to you and they'll put you on the waiting list and you'll wait another month and then they'll call you back to arrange a time. Kind of works like that. Then, they'll come to your clinic to give you a little bit of orientation and then they'll set it up. [P5]

Clinical Use Cases

Participants agreed that having access to comprehensive medication information at the point of care is valuable for clinical decision-making. Access to medication information was highlighted as particularly useful when conducting a BPMH for geriatric patients, complex patients, and those at high risk for readmission (eg, patients with chronic obstructive pulmonary disorder). The DHDR was particularly valuable in emergency departments at night and during surgical consultations when the ability to contact pharmacies and family physicians was either not possible or limited. Among family physicians, the DHDR was primarily used to support clinical decisions related to antibiotic or narcotic prescriptions for new patients.

Factors Limiting Impact

At times, clinicians with access to the DHDR found integration into their clinical workflow challenging. Inefficiencies were created by the need to log out of their usual point-of-care system to log on to the provincial viewer to access the repository. Both DHDR users and nonusers expressed a desire to have centralized repositories integrated within their point-of-care systems to minimize disruptions to the workflow:

> As you can imagine, somebody...is doing a consult, they're opening up their computer, they're looking through [their EMR]...But then, in order to get to ConnectingOntario you have to actually open up a different window...you actually have to come out of [the EMR] to load up another window, which takes you away from what you were doing before...That takes time. It takes time to load. So, I think you should...actually integrate it into an EMR system, so that the information can be accessed easily instead of through the ConnectingOntario interface. [P5]

Nonusers of the DHDR were unaware of how to register for access to the DHDR, and some participants in community settings highlighted the financial and administrative burden of gaining access to a provincial viewer. Others were unaware of the process of obtaining access, and some community physicians and pharmacists were unclear if they were eligible for access as they worked in independent practices.

Discussion

Principal Findings

To the best of our knowledge, this is the first evaluation of the DHDR repository in Ontario. Previous evaluations of similar national and international repositories have focused on the quality of data contained in the repository and how this affected clinical and process outcomes (eg, inappropriate prescribing, accuracy, and completeness of data elements, medication profiles, and compliance with BPMH documentation) [14,37,38]. Several evaluation studies found drug repositories to be incomplete and contain several discrepancies, thereby requiring use in conjunction with other sources to validate medication histories, and as such, drug repositories may be underused [14,39].

Our results highlight the untapped potential of the DHDR and provide insights into the key elements that are likely to drive future clinical value. Specifically, clinicians found the DHDR valuable in clinical situations where prompt communication with other clinicians or the pharmacy was not feasible, such as in the emergency department. A general lack of awareness was a significant barrier to realizing value at the system level, whereas a lack of comprehensive data was a barrier to consistent use. Moreover, the lack of integration into existing point-of-care systems was highlighted as a challenge to usage. Expanding the DHDR data set to include information on medication instructions and private insurance claims would enhance the clinical value and relative advantage of the DHDR.

The DHDR was most meaningful for clinicians who care for complex or older patients, such as geriatricians, underscoring the value of a comprehensive profile. Most of these patient populations are likely to be supported through publicly funded programs in which complete medication histories are captured within the DHDR. This suggests a potential use case in long-term care facilities, where polypharmacy is a common problem and the prevalence of ADEs is higher than that in other health care settings (ranging from 18% to 82%) [40]. Polypharmacy also increases the likelihood of hospital admission for patients living in long-term care [41], further emphasizing the potential untapped value of a centralized drug repository. Our sample had minimal representation from long-term care facilities, highlighting the need to further explore how to create value for clinicians working in this sector. The lack of medication information for most Ontario residents precluded meaningful use in most other settings. Only 20% of Ontario's 14.6 million residents are covered by public drug programs [22,42], limiting the DHDR's ability to deliver value for most of the population. Inclusion of all prescribed medications (whether dispensed) and the integration of community pharmacy records would support increased medication adherence and the reduction of inappropriate prescribing [43,44].

Despite a clear pathway to comprehensive data, a lack of awareness of the DHDR presents a fundamental barrier to achieving an impact at the population level. Although many participants perceived the data elements to be valuable, they were unaware that the repository existed or had limited knowledge on how to obtain access. This problem is not unique

to the DHDR [45] and highlights the need for active dissemination strategies, such as engaging local clinical champions and increasing awareness and education about the repository through professional organizations (eg, the Ontario Medical Association, the Registered Nurses Association of Ontario, or the Ontario College of Pharmacists), which may increase the uptake [46-48]. Cumbersome access pathways are not unique to the DHDR [45], suggesting that efforts to streamline onboarding, such as bundling it directly to licensure or credentialing processes rather than keeping it as an independent activity, would have positive downstream impacts beyond those realized through the DHDR. Integration into existing point-of-care systems is one such evidence-based strategy that would overcome a key barrier to adoption that plagues a range of digital technologies in health care [39,45,49,50] and has been successfully operationalized for a centralized drug repository [20].

Limitations

This formative evaluation aimed to capture responses from clinicians across multiple health care settings, as well as a broad sample of users and nonusers, to highlight areas for enhancements to the DHDR, which may increase meaningful clinical use. Consequently, our findings cannot speak to the realization of the impact on patient outcomes, experience, and system cost. Our findings are specific to sites with ≥20 registered users and may not reflect the experiences of providers in smaller centers (eg, rural communities). Although more female clinicians participated in our study, we feel this is comparable with the Ontario health care workforce, with over 70% being women. Moreover, we did not know how many individuals were sent the survey link, and as such, our findings may have selection bias because of voluntary self-selection.

As the survey was developed primarily by our project partners to inform decision-making, we sought to evaluate face validity and potential correlation across key domains (Multimedia Appendix 4). No statistical significance was observed, may be because of the limited number of active DHDR users, underscoring the need for further and more robust validity testing.

We were limited in our ability to assess the impact of the perceived shortcomings of the DHDR and associated clinical viewers. Teasing apart users' perceptions of the DHDR from their clinical viewer experience was beyond the scope of the

project; however, it is important to acknowledge. The DHDR was not co-designed by a representative sample of those using the repository, and only contained medication information for a subset of the Ontario population, which limited its clinical value. It is important to note that the DHDR was purposively implemented as an *incomplete* product by eHealth to facilitate the ability to gather data and insights to inform future development and expansion. Limited uptake suggests that future development efforts must consider marketing and implementation efforts to realize the impact. Finally, our objective was to understand health care provider perceptions, usage, and the clinical value of the DHDR to inform strategies to increase its utility and uptake. We determined that the uptake of the DHDR is a necessary precursor to its potential impact on care. Although patient experience is a critical next step in understanding whether and how such a tool can have an impact, it was beyond the scope of this project. An important evolution of this study is understanding how access to comprehensive medication data is valued by patients and how it can be used to enhance patient experience.

Conclusions

Findings from this formative evaluation suggest that the DHDR has untapped value as currently operationalized but that a pathway exists to align with clinician needs. Ensuring comprehensive clinical data and streamlined onboarding processes would facilitate meaningful use, whereas integration with existing point-of-care systems would further enhance efficiency and uptake. Access to a centralized repository that connects currently fragmented health care settings and provides comprehensive medication information at the point of care has the potential to improve efficiency and reduce medication errors if it aligns with the informational needs of clinical decision-making. Stakeholders involved in operationalizing and implementing such repositories (or similar information-sharing systems) should consider broad marketing and dissemination, user engagement, and integration into existing workflows as part of their overall strategy to realize value. Finally, user confidence in the DHDR can be improved by validating the information contained in the repository by comparing multiple sources of BPMH (ie, patient interviews vs pharmacy records vs DHDR records) and documenting the number of medication omissions, inappropriate prescribing, and discrepancies to validate DHDR. The knowledge that DHDR is accurate and complete will increase the uptake.

Authors' Contributions

CS designed the study, collected the data, interpreted and analyzed the data, and drafted the manuscript. MP collected the data and interpreted qualitative findings. MT, TJ, RSB, and LD designed the study and interpreted and analyzed the data. All authors edited the manuscript.

Abstract

Background: It has been suggested that Bayesian dosing apps can assist in the therapeutic drug monitoring of patients receiving vancomycin. Unfortunately, Bayesian dosing tools are often unaffordable to resource-limited hospitals. Our aim was to improve vancomycin dosing in adults. We created a free and open-source dose adjustment app, VancoCalc, which uses Bayesian inference to aid clinicians in dosing and monitoring of vancomycin.

Objective: The aim of this paper is to describe the design, development, usability, and evaluation of a free open-source Bayesian vancomycin dosing app, VancoCalc.

Methods: The app build and model fitting process were described. Previously published pharmacokinetic models were used as priors. The ability of the app to predict vancomycin concentrations was performed using a small data set comprising of 52 patients, aged 18 years and over, who received at least 1 dose of intravenous vancomycin and had at least 2 vancomycin concentrations drawn between July 2018 and January 2021 at Lakeridge Health Corporation Ontario, Canada. With these estimated and actual concentrations, median prediction error (bias), median absolute error (accuracy), and root mean square error (precision) were calculated to evaluate the accuracy of the Bayesian estimated pharmacokinetic parameters.

Results: A total of 52 unique patients' initial vancomycin concentrations were used to predict subsequent concentration; 104 total vancomycin concentrations were assessed. The median prediction error was –0.600 ug/mL (IQR –3.06, 2.95), the median absolute error was 3.05 ug/mL (IQR 1.44, 4.50), and the root mean square error was 5.34.

Conclusions: We described a free, open-source Bayesian vancomycin dosing calculator based on revisions of currently available calculators. Based on this small retrospective preliminary sample of patients, the app offers reasonable accuracy and bias, which may be used in everyday practice. By offering this free, open-source app, further prospective validation could be implemented in the near future.

Introduction

Vancomycin is an intravenous (IV) drug that has been used for over 60 years in the treatment of Gram-positive bacterial infections. Vancomycin has a narrow therapeutic window; thus, therapeutic drug monitoring (TDM) of plasma concentrations is necessary to measure efficacy and to avoid nephrotoxicity. Traditionally, vancomycin dosing consists of giving a patient-weight–based dose, and then checking a trough concentration at an approximate steady state concentration, targeting a range between 10 and 20 mg/L [1]. Dose adjustments

are often made using simple heuristics, clinical intuition, and judgement based on patient factors.

In 2020, the Infectious Diseases Society of America updated the dosing guidelines of vancomycin for severe methicillin-resistant *Staphylococcus aureus* infections. They suggest that vancomycin monitoring via an area under the curve (AUC) approach is the safest and most effective approach to TDM [1]. AUC measurement can be calculated by taking blood concentrations and performing pharmacokinetic (PK) calculations to derive an AUC estimate. This is measured by either the Sawchuk-Zaske method (ie, based on individually calculated PK parameters) or using a Bayesian inference approach (ie, a method of statistical inference using the Bayes theorem to update the probability as more data become available) [2]. According to the Infectious Diseases Society of America, Bayesian-based tools are the preferred approach to vancomycin TDM [1]. Controversy still exists regarding the adoption of AUC-only monitoring of vancomycin [3-5]. Some suggest that adopting this approach may be premature [3], and AUC dosing if carried out by 2-level approach may increase the patient burden by increasing blood draws. There is still some uncertainty on the ideal target AUC or trough level [4].

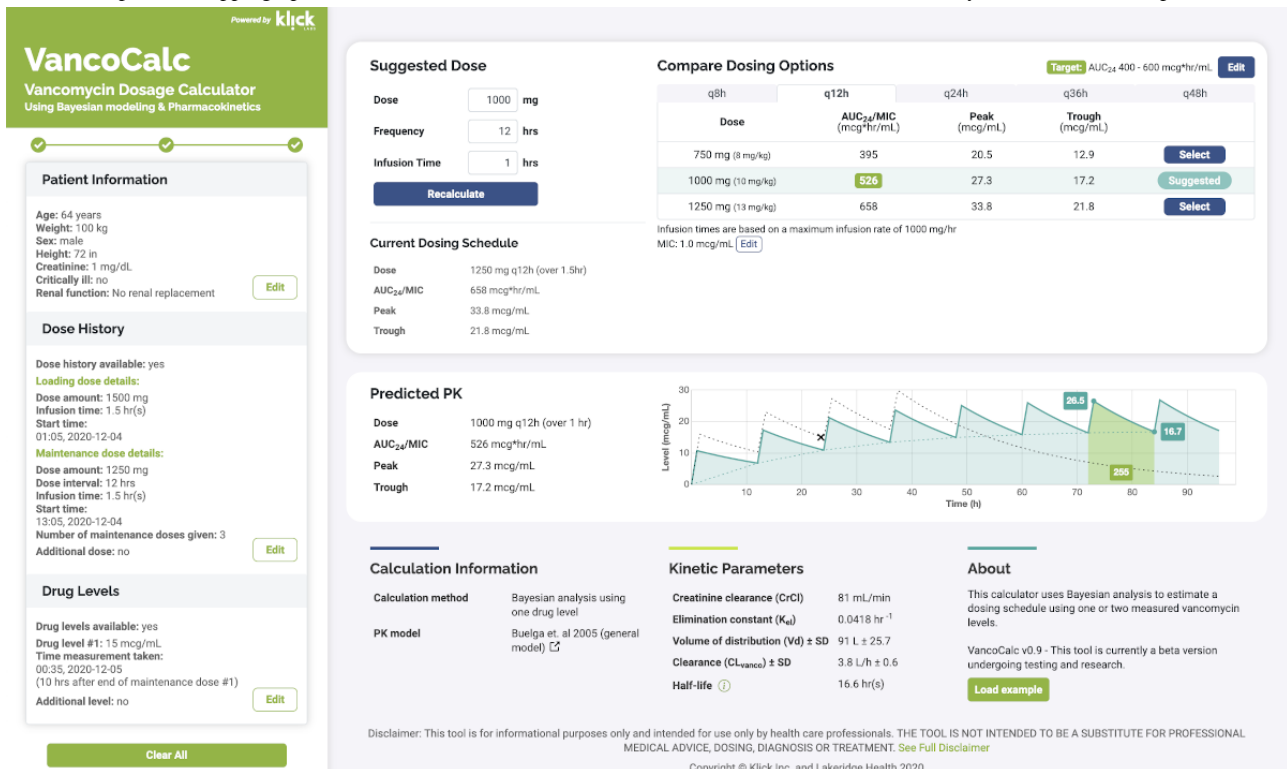
Calls for individualized Bayesian dosing tools have existed for years [6-10]; however, Bayesian TDM has failed to garner widespread adoption for many reasons [7]. The Bayesian TDM approach can require paid computer software programs. These programs typically require multiyear licensing agreements and can be unaffordable to hospital systems. These software packages often use publicly available PK models [11-14] and Bayesian algorithms to derive dosing suggestions. Most apps do not make their code public due to proprietary coding and financial interest. However, it may be assumed that the PK models and Bayesian methods are not proprietary. These Bayesian TDM apps make use of these PK models as a priori to assist in predicting individual patient PK parameters. The

apps conduct mathematical calculations seamlessly without requiring the user to have a knowledge of statistics. The Bayesian inference algorithms were once limited by computing power; however, with advances in technology, they can be performed with any basic software browser via HTML and JavaScript.

As a solution to these paid software programs, we developed a proof-of-concept, free online Bayesian vancomycin dosing app, VancoCalc [15]. VancoCalc allows vancomycin TDM using trough or AUC-based targets. The app uses published PK models and user-inputted patient data as Bayesian priors to estimate vancomycin concentrations and AUC. The app requires no statistical training and is aimed to be user-friendly to assist in the implementation of Bayesian inference in vancomycin TDM. No user data are saved as all calculations are computed locally on the user's device.

Inspiration for our new calculator was fostered from anecdotal user experience with DosOpt [16], ClinCalc [17], and BestDose [18], in hopes of making a more user-friendly app. VancoCalc adds the ability to customize target trough or AUC, permitting 2 different dose or time intervals (plus loading dose) relating to the vancomycin concentration, and the ability to explore various dosing regimens through visualization of the dose and time curve. These updates assist the clinician in assessing the impact a dosing regimen may have (Figure 1). After inputting "Bayesian Vancomycin Calculator" in a search engine, it may appear that there are many Bayesian dosing apps. However, many of these calculators use 2-level trapezoidal calculations and are not truly using Bayesian approaches.

The app's ability to predict a patient's vancomycin concentration (pharmacokinetic parameters) was evaluated using a data set composed of adult patients who received vancomycin at Lakeridge Health. This research aims to describe the development, design, and evaluation of a Bayesian vancomycin dosing app.

Figure 1. Example of the app's graphical user interface. AUC: area under the curve; MIC: minimum inhibitory concentration; PK: pharmacokinetic.


Methods

Development of VancoCalc App

We implemented the app as a static web app using HTML5, JavaScript, CSS, and several open-source projects. The user interface was developed using the jQuery [19], Bootstrap [20]. And Chart.js [21] frameworks. The app uses a custom library for applying Bayesian algorithms that is based on bayes.js [22] and the simple statistics [23] libraries. Markov chain Monte Carlo sampling and model fitting are carried out in the user's browser with no data processing needed from a server or the cloud.

App Design Bayesian Pharmacokinetic Modelling and Fitting

Bayesian dosing strategies employ population models that relate PK parameters, including volume of distribution (VD), clearance (Cl), and creatinine clearance to patient data, including age, weight, gender, serum creatinine, vancomycin dose value, and number of doses given. The Bayesian approach involves the notion of incorporating both a population PK model and measured drug concentrations from the patient to better estimate PK parameters for the individual.

The app selects a population model based on the inputted patient data. If a patient is critically ill and has a BMI of over 30 kg/m^2 and body weight of over 100 kg, the Masich et al [14] model is used; if a patient is critically ill but is not meeting the obese criteria, the Roberts et al [13] model is used; if not critically ill but has a BMI of over 40 kg/m^2 and body weight of over 120 kg, then the Adane et al [11] model is used; if not critically ill and BMI is less than 40 kg/m^2, the Buelga et al [12] general population model is used. The critically ill model parameter is

possible to override. Estimates of the PK parameters (VD and Cl) from the population model, adjusted for patient characteristics, form the starting point of the fitting process. The starting point begins with the mean VD and Cl of the PK model selected. The values are sampled from the parameter space, and first-order PK equations are used to calculate an expected serum concentration, which is compared to the measured concentration. This sampling and traversing of the parameter space are carried out iteratively while taking into consideration the variability of the population parameters and the variability of the serum concentration measurement. By doing this, the modelling process estimates the PK parameters that will be most consistent with drug concentrations predicted by both the population model and the measured drug concentrations.

Complex dose history can be entered involving multiple doses of varying amounts, frequencies, and schedules. Concentrations are not restricted to steady state and can be entered for any infusion and are not limited to trough levels. The calculator's inputs and outputs are shown on the same page, side-by-side, and any modifications to the input are immediately reflected in the calculated output dynamically. The design provides a suggested dose and alternatives, but also encourages exploration and investigation for the patient cases that require it.

App Evaluation

A retrospective observational data set was used to evaluate the app. Information was gathered via electronic chart review (Meditech) and SQL query of Antimicrobial Stewardship data repository.

The data were collected between July 2018 and January 2021 at Lakeridge Health Corporation sites in Oshawa, Bowmanville, or Port Perry, Ontario, Canada. This is a community hospital

system with approximately 800 beds located in the Durham region of Ontario. Inclusion criteria were inpatients, aged 18 years and over, who received at least 1 dose of IV vancomycin and had at least 2 vancomycin concentrations drawn in relation to the vancomycin dose. Patient's sex, age, height, weight, serum creatinine at time of vancomycin, ward, vancomycin dosing history, and vancomycin concentrations were collected. Exclusion criteria were patients who were receiving hemodialysis or continuous renal replacement while on vancomycin, or missing any data as stated in the inclusion criteria.

The first single known vancomycin concentration and matching patient variables were entered into the app. This allowed the app to estimate the patient's individual PK parameters. Subsequent vancomycin concentrations (if available) were not inputted as the app currently only allows 2 vancomycin concentrations to be inputted. This produced a vancomycin plasma concentration time plot where the estimated second vancomycin concentration was compared to the actual concentration.

Ethics Approval

The Research Ethics Board (REB) at Lakeridge Health approved the study (Approval 2020-13) in September 2020, Oshawa, Ontario.

Statistical Analysis and Predictive Performance

Performance of Bayesian prediction of the second vancomycin concentration was evaluated with the median prediction error (MedPE), median absolute error (MedAE), and root mean squared error (RMSE). MedPE, MedAE, and RMSE were calculated according to Equations 1, 2, and 3, and were derived from the study by Sheiner and Beal [24]. MedPE was calculated as an index of bias, MedAE as an index of accuracy, and RMSE as an index of precision. Median was used as the data displayed a nonnormal distribution. All analyses were performed using R (The R Foundation) [25].

Funding

Results

A total of 93 patient charts were reviewed; 41 charts were excluded for analysis. The main reason for exclusion was the patients being on renal replacement therapy. Twenty-five cases were excluded as they were on renal replacement therapy; 2 cases were excluded due to being pediatric; 2 patients were excluded for model fit; and 12 patients had to be excluded where we were unable to reliably input the patient dose parameters (staggered frequency of dose administration or multiple dosing changes; subsequent vancomycin concentration did not correspond with inputted dose). A total of 104 vancomycin concentrations were assessed. The remaining 52 patients were included in the final analysis. This included 24 (46.2%) female and 28 (53.8%) male participants; age range 24-90 years, median age 63 (SD 14) years; median weight 81.2 kg, weight range 43.6-131.7 (SD 20.8) kg; median BMI 30.7 kg/m^2, BMI range 16-54.1 (SD 8.6) kg/m^2. Moreover, 15 (28.8% of the 52 patients were admitted to the intensive care unit.

The median measured concentration was 18.05 (SD 6.83) ug/mL versus the median of the predicted concentration 18.49 (SD 6.40) ug/mL. Using Bayesian estimation, MedPE (bias) was –0.600 ug/mL (IQR –3.06, 2.95), the MedAE (accuracy) was 3.05 ug/mL (IQR 1.44, 4.50), and the RMSE (precision) was 5.34. These results were derived from the following a priori models: Adane et al [11] (n=1); Buelga et al [12] (n=36); Masich et al [14] (n=4); and Roberts et al [13] (n=11; Figure 2). Of note, there were 2 outliers noted in the analysis. One patient was morbidly obese, and the other critically ill. These 2 patients were fit to the Adane et al [11] and Roberts et al [13] a priori models. These outliers were included in the analysis as we could not identify a specific reason for these prediction errors other than their underlying conditions. Performing the analysis excluding these outliers improves median accuracy and precision, with the median bias being largely unchanged. Excluding these outliers, the MedPE was –0.6 ug/mL (IQR –2.9, 2.75), MedAE was 2.95 ug/mL (IQR 1.40, 4.16), and RMSE was 3.86. As other publications have previously reported mean prediction error and mean absolute prediction error [26], we have also included these results. Mean prediction error was –3.13 ug/mL, and mean absolute prediction error was 3.69 ug/mL.

Table 1 displays the bias, accuracy, and RMSE of the individual models. Interpretation of these values is difficult due to the small sample size of some of the patients included in the models.

Figure 2. Observed versus predicted vancomycin concentration and an a priori model selected (N=52 from the following models: Adane, n=1; Buelga, n=36; Masich, n=4; and Roberts, n=11).
Table 1. App performance of individual pharmacokinetic models.

PK[a] model	Unique patients, n (%)	Median prediction error (mcg/mL)	Median absolute error (mcg/mL)	Root mean square error
Adane et al [11]	1 (1.9)	−23.14	23.14	23.14
Buelga et al [12]	36 (69.2)	0.34	3.33	4.18
Masich et al [14]	4 (7.7)	−1.29	1.54	2.30
Roberts et al [13]	11 (21.2)	−2.26	2.59	5.20

[a]PK: pharmacokinetic.

Discussion

Principal Results

We created a free and open-source Bayesian vancomycin dosing app. No statistical or technical knowledge of Bayesian methods are required to use this app. We focused on making this app easy to use for clinicians, with an ability to explore treatment adjustments.

Vancomycin concentrations in second blood samples were predicted by Bayesian analysis and were compared with measured concentrations to assess the app and PK model accuracy of predictions. Our data represent a small sample size of patients in the Durham region of Ontario. Our total patient sample of 52 patients is small. Hiraki et al [26], Turner et al [27], and Nunn et al [28] all used similar sample sizes in their analysis of Bayesian vancomycin dosing software and PK models.

Comparisons With Prior Work

We reviewed the findings of Hiraki et al [26], Turner et al [27], and Nunn et al [28]. We chose to use the methods described by Sheiner and Beal [24] to report our predictive accuracy. Hiraki et al [26] did the same; however, other publications chose alternate approaches to reporting predictive accuracy [27,28]. When comparing our prediction accuracy versus those reported by Hiraki et al [26], we showed similar bias and accuracy. However, our overall results were not as precise as the results shared by Hiraki et al [26] (RMSE 5.34 vs 1.74). We attribute this to the 2 outliers within our data set, and as such, these patients may not be ideal candidates for the a priori model selected. Additionally, our data set included a more heterogeneous population of both critically ill and on the general medicine wards, who were being treated with vancomycin for multiple reasons. The population studied by Hiraki et al [26] was limited to hospitalized patients receiving treatment for methicillin-resistant *S. aureus* infections whose renal function

was very stable. This could also explain the difference in precision.

Interpretation and performance of the individual PK model accuracy and bias in our paper is limited due to the small sample but are included for review (Table 1). Only 1 patient in the validation data set was fit to the Adane et al [11] model, and 4 patients to the Masich et al [14] model. The predicted result of the single patient fit to the Adane et at [11] model and the one fit to the Roberts et al [13] model produced predicted concentrations that were outliers. The Adane et al [11] model is reserved for patients with a BMI greater than 40 kg/m^2 and body weight over 120 kg, while the Robers et al [13] model is reserved for the critically ill. Although there were only 2 data points, this highlights the difficulty in dosing these patients. Based on the small number of patients we enrolled during the time frame of this study, it is unlikely that we will be able to obtain a sufficient sample size to evaluate these models individually.

Limitations

We acknowledge that there are limitations of this app. First, it remains to be determined which a priori PK model is optimal for dosing, since many published vancomycin PK models exist, and choosing the appropriate PK model remains a challenge. It may be unlikely that the wide individual patient PK variability can be captured by a single a priori model. Therefore, it is of utmost importance that the patient be appropriate for the a priori model selected. We chose a one-compartment pharmacokinetic model with individual models for obesity and critical illness. During the development of the app, it appears that a more simplified broadly supported two-compartment model by Goti et al [29] may be more appropriate [30,31].

As trough-based vancomycin dosing was performed at Lakeridge, we are unable evaluate the app's AUC predictions. However, providing this app free of charge for all users allows the potential for further evaluation of this functionality.

The app is not designed to be used in patients receiving renal replacement therapy. Many patients were excluded from the evaluation as they were receiving vancomycin while on renal replacement therapy.

This app was not intended to replace or override the judgement of a clinician. The app relies on accurate user inputs. There are a few checks in place to ensure appropriate user input and model selection (eg, hard limits on input parameters and goodness of fit with the model), but we acknowledge that all possible scenarios or edge cases cannot be addressed. In the development of the app, we attempted to balance user experience and ease of use versus added complexity and customization of the app and a priori PK models. As suggested earlier, a potential solution to this juxtaposition is a more generally applied model similar to that presented by Goti et al [29], or, if suggested, a more customized user-selected model approach or "expert mode."

Future Directions

Bayesian dosing of vancomycin still in its infancy. Vancocalc is available with no restriction. The creation of this free, open-source Bayesian vancomycin dosing app permits this dosing approach to be further explored.

The value of free, open-source software is unquantifiable. Software such as Linux and Python have positively impacted many. We are hopeful that the creation of this app can also have a positive impact and add to the body of work that has already been conducted [16,17].

With increased use and validation of Bayesian dosing apps, it is possible that improved PK models for specific patient populations will be developed. Additionally, larger adoption may eventually permit improved algorithms incorporating other techniques such as machine learning. By open sourcing the app, it can be modified, updated, and improved upon or used as a framework for others to build upon.

Our goal is to share this proof-of-concept app to allow greater awareness and democratization of the Bayesian monitoring approach. The pharmacokinetics of vancomycin are complex. With greater use and awareness of the app and experience from field experts, this will lead to further collaboration and improvement of the app for functionality and vancomycin TDM.

Conclusions

In this paper, we presented a vancomycin dosing app, VancoCalc, including a small evaluation using a real-world retrospective data set. This app leverages previously published research on Bayesian inference calculators. By offering this free, open-source app, further prospective validation could be implemented in the near future. We encourage exploration of the app and collaboration or suggestions for improvement.

Authors' Contributions

TO executed the study, analyzed the data, and contributed to writing the manuscript. AT developed the data modelling, developed the VancoCalc website, and helped analyze the data. AP contributed to literature review and writing the manuscript. YF helped design the study, assisted in data interpretation, and contributed to the writing and editing of the manuscript. All authors contributed to the final review and editing and have approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Myeloproliferative neoplasms (MPNs) are a group of myeloid malignancies associated with significant symptom burden. Despite pharmacological advances in therapies, inadequate management of MPN symptoms results in reduced quality of life.

Objective: This study aims to determine the feasibility of a 12-week global wellness mobile app intervention in decreasing MPN symptom burden. The University of Arizona Andrew Weil Center for Integrative Medicine's global wellness mobile app, *My Wellness Coach* (MWC), guides patients to improve their health and well-being through facilitating behavior changes.

Methods: Of the 30 patients enrolled in a 12-week intervention, 16 (53%) were retained through the final assessment. Feasibility was assessed by the ease of recruitment, participant adherence, and mobile app acceptability. App acceptability was measured using the user version of the Mobile Application Rating Scale. MPN symptom burden was measured at baseline and 12 weeks after the intervention.

Results: Recruitment was efficient, with the participant goal reached within a 60-day period, suggestive of a demand for such an intervention. Adherence was less than the target within study design (75%), although similar to mobile device app use in other studies (53%). The app was deemed acceptable based on the mean user version of the Mobile Application Rating Scale 3-star rating by participants. Finally, there were statistically significant improvements in several MPN symptoms, quality of life, and total score on the Myeloproliferative Neoplasm Symptom Assessment Form surveys.

Conclusions: Our 12-week intervention with the MWC app was feasible and was associated with a decrease in MPN symptom burden. Further investigation of the MWC app for use as a self-management strategy to reduce the symptom burden in patients with MPN is warranted.

Introduction

Background

Myeloproliferative neoplasms (MPNs) are a group of blood cancers and include the diagnoses of myelofibrosis, essential thrombocythemia, and polycythemia vera. These are rare malignancies with an incidence of 0.33, 1.14, and 1.18 per 100,000 persons per year, respectively [1-3]. Although the prevalence is relatively low, the chronicity of MPNs with significant disease-associated symptoms leads to many years of drastically reduced quality of life for patients afflicted with this disease. Disease manifestations vary among individuals, but generally, MPNs are characterized by excessive blood cells leading to an increased risk of blood clots or bleeding, enlargement of the spleen, and a significant symptom burden.

MPN symptom burden is heterogeneous and may be debilitating to afflicted patients. Fatigue is a major contributor to poor quality of life, affecting more than 80% of patients with MPN. Other symptoms include pruritus, night sweats, difficulty sleeping, abdominal discomfort, bone pain, fever, weight loss, decreased memory, poor sleep, inactivity, and psychosocial dysfunction [4-6]. Although the biology of symptoms is complex, it is rooted to the underlying physiologic inflammation associated with the disease and potentially contributing lifestyle factors and, thus, may be modifiable with intervention [7].

The discovery of the *JAKV617F* mutation in 2005 led to the subsequent development of JAK inhibitor therapy, which has revolutionized the treatment paradigm for MPNs. Despite improvements in disease outcomes offered by pharmacologic therapy, patients' symptoms often remain quite high; thus, strategies to address symptoms represent a significant unmet need in the patient population of MPN [6].

Integrative oncology, defined as the use of complementary and integrative therapies in conjunction with conventional oncology care, may offer a unique symptom management tool [8,9]. Previous publications in integrative oncology have largely focused on breast, colon, and prostate cancers, and there is a scarcity of research to support integrative care in patients with MPN [6,10]. Nevertheless, early data using integrative approaches for the treatment of MPNs are promising, including aerobic activity, yoga, meditation, and strength training, to reduce the symptom burden and improve disease-related inflammation [6,11].

As thrombosis is the primary cause of mortality in MPNs, treatment is largely aimed at reducing thrombotic complications. In addition to pharmacologic treatments, lifestyle modifications through integrative methods may be an important tool in decreasing this risk as well. Inflammation is associated with increased risk of thrombotic events through various mechanisms, including elevated white blood cell and platelet counts, together with activated clotting factors and endothelial cells [12]. Regular exercise reduces inflammatory processes and promotes fibrinolytic activity [13,14]. Studies in patients with underlying cardiovascular disease that have established lifestyle change, including increased physical activity and the subsequent lowering of serum cholesterol, can decrease thrombosis risk [15]. It is possible that this same mechanism can decrease thrombotic risk in patients with MPN.

With the evolution of smartphone technology, mobile apps have become useful tools to help manage chronic diseases and may represent an important strategy for wellness-based interventions [16-24]. In oncology, mobile apps have largely focused on patient education and awareness, including such topics as cancer screening, adverse reactions to treatment, disease processes and treatment options, medication compliance, and cancer pain management [16,17,20,21,24,25]. A few mobile apps have emerged to address the symptom burden in endometrial, breast, sarcoma, and lung cancers with lifestyle changes, mindfulness, and coping mechanisms [18,22,23]. Although smartphone-based meditation and web-based yoga have proven some benefit in patients with MPN, with early data specifically suggesting impact on fatigue, depression, and blood inflammation, there has not been a mobile app to specifically address the MPN symptom burden through promoting global behavioral changes [19,26].

Objectives

The University of Arizona Andrew Weil Center for Integrative Medicine has recently developed and successfully piloted a global wellness mobile app, *My Wellness Coach* (MWC), to guide patients to better health and wellness through facilitating behavior changes [27]. The aim of this study is to determine the feasibility of a global wellness mobile app 12-week intervention for decreasing MPN symptom burden. This is meaningful because this app could provide a highly disseminatable and much needed self-management strategy for the MPN symptom burden.

Methods

Ethics Approval

This study was approved by the University of Arizona Human Subjects Protection Program (IRB Number 2004567060).

Recruitment and Enrollment

Patients with MPN were recruited nationally through organizational partners, such as the Myeloproliferative Neoplasm Quality of Life Group. A flyer was posted on the partners' website, and an email describing the study was sent out through approved listservs, with a link to a web-based eligibility consent and survey over a 60-day period. Through this web-based survey, developed in Qualtrics [28], participants consented and answered questions regarding the eligibility requirements of the study. Participants were screened for eligibility using the inclusion and exclusion criteria given in Textbox 1.

Once a web-based questionnaire was returned, it was evaluated for completeness and eligibility based on the responses. A participant was then emailed the consent form and the baseline questionnaire that were required for enrollment in the study. These participants were given approximately 3 days to respond. If they did not respond within the allocated time, then they were deemed as not interested in participating in the study, and the baseline questionnaire was sent to the next eligible participant.

Eligible participants were contacted until our enrollment goal of 30 individuals was met. An optional phone interview was conducted for qualitative analysis at 12 weeks.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Individuals, man or woman, aged ≥18 years

- Individuals able to provide consent

- Individuals who can speak English and is English literate

- Individuals diagnosed of essential thrombocythemia, polycythemia vera, or myelofibrosis

- Individuals identified by a treating physician

- Individuals who have a personal mobile device with an Android (version 4.1 or higher) or iOS (version 12.2 or higher) operating system

- Individuals who displayed satisfactory ability to operate a mobile device and showcase email communication

- Individuals who have reliable internet and cellular access

Exclusion criteria

- Individuals currently participating in a clinical trial

- Individuals who received blood transfusion within the last 6 months

- Individuals with an Eastern Cooperative Oncology Group [29] status of ≥3

Mobile App Intervention

After consent was obtained from eligible participants, they were provided with instructions to download and use MWC. In the app, the participants were prompted to participate in four steps: (1) score, (2) explore, (3) set a goal, and (4) take action. Self-motivation was emphasized by encouraging reflection on why they want to facilitate change. Clinical research staff suggested setting at least two wellness goals. Participants could set goals within seven domains: nutrition, movement, sleep, resilience, environment, relationships, and spirituality. The app provided tips for health improvements and links to curated resources. When setting goals, participants were coached to make them *SMART*—specific, measurable, attainable, relevant, and time-bound—with the value of this technique described in other publications [30-32]. It provided 24- to 72-hour interval reminders before and after each action step and a goal deadline to encourage action throughout the intervention.

Outcome Measures

Feasibility was assessed by ease of recruitment, adherence, and mobile app rating. Successful recruitment was defined as enrolling 30 participants within 60 days. Adherence was defined as a minimum of 75% retention throughout the intervention. The user version of the Mobile Application Rating Scale (uMARS) evaluated acceptability through rankings in four objective categories (engagement, functionality, aesthetics, and information) and was graded on a Likert scale. This included ease of use, intent for continued use, perceived benefit, and overall star rating.

The Myeloproliferative Neoplasm Symptom Assessment Form (MPN-SAF) evaluated common MPN symptoms [33]. The MPN-SAF comprises 18 symptoms plus a total score. Higher scores indicate worse symptom severity. Each symptom was rated according to the level of difficulty a participant had with each item during the past week, scaled from 0 (absent) to 10 (worst imaginable).

The Behavioral Risk Factor Surveillance System (BRFSS) was used to assess physical activity [34]. The 8-item Patient-Reported Outcomes Information System (PROMIS) Sleep Disturbance questionnaire (Short Form 8a) measured perceptions of sleep quality, depth, and restoration within the past 7 days [35]. Mediterranean diet adherence was assessed using a 14-item questionnaire (which has previously shown an inverse association between the Mediterranean diet and obesity in the PREDIMED [Prevención con Dieta Mediterránea] trial [36]). However, the original 14-point scale was revised because 40% of participants were unable to quantify olive oil consumption and responded "don't know/not sure" or left responses blank. At 12-week follow-up, MPN-SAF, BRFSS, PROMIS Sleep, and Mediterranean diet adherence questionnaires were completed in addition to uMARS. Semistructured phone interviews with the research coordinator to provide additional feedback were optional.

Statistical Analysis

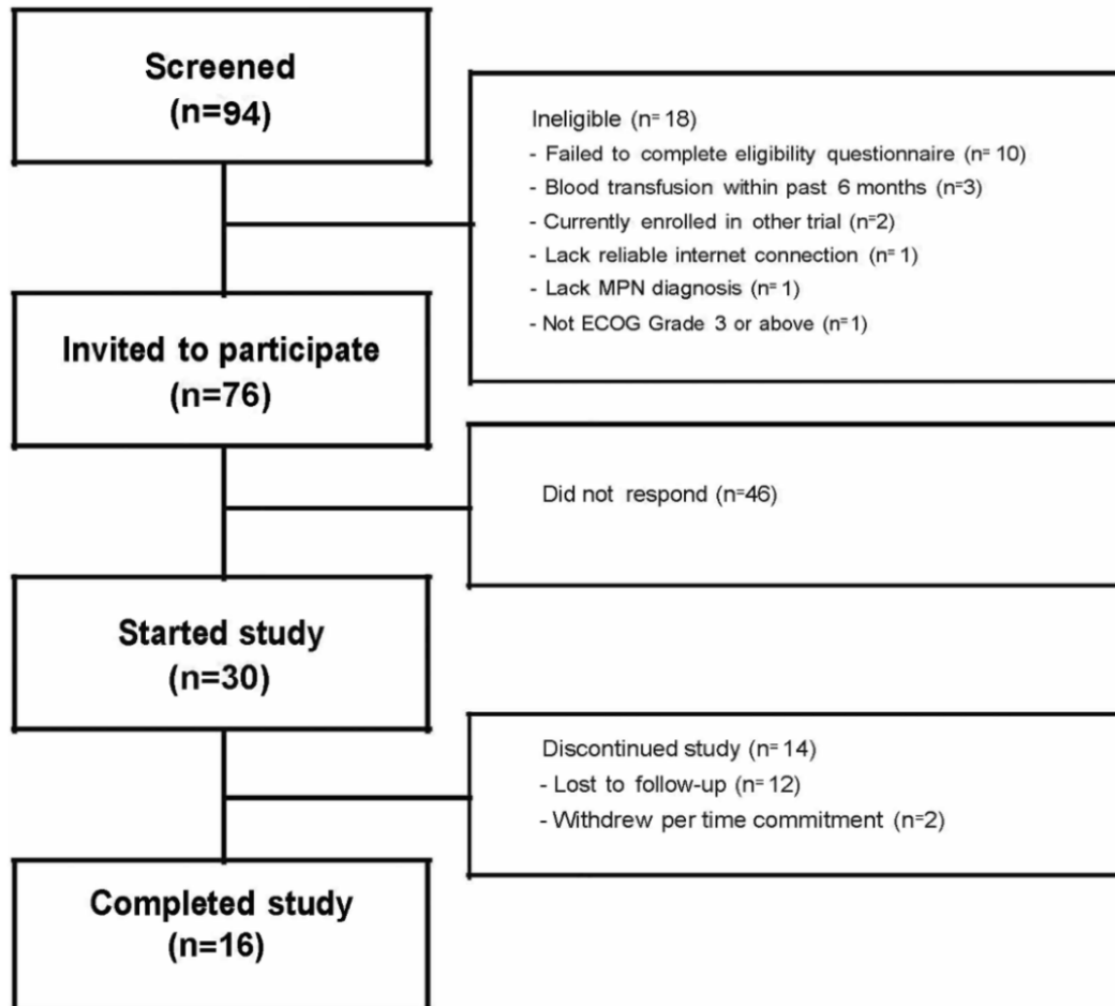
To assess recruitment, acceptability, length of time to accrue, adherence, ease of app use, intent for continued use, and perceived benefit measures were summarized using descriptive statistics. Patient demographics and medical history were summarized using descriptive statistics. Descriptive statistics included proportions for categorical variables and median (IQR) or mean (SD) for continuous variables. Mean changes from baseline to 12 weeks in sleep disturbance, Mediterranean diet adherence, and MPN-SAF symptom scores were tested using linear mixed-effects models, clustered on participants. Such mixed-effects models were used instead of 2-tailed paired t tests to allow all participants (n=30) to contribute to the model, instead of only the subset (n=16) with the end-of-study data. The α level was set to .05, meaning that mean values at 12

weeks were considered significantly different from the mean values at baseline if *P*<.05. All statistical analyses were conducted using Stata (version 16.1; StataCorp). As this is a feasibility study, there were no adjustments made for multiple comparisons because of the small sample size.

Results

Recruitment and Enrollment

Of the 94 interested patients with MPN screened for eligibility, 72 (76%) were eligible to enroll (Figure 1). Emails were sent to eligible patients until 30 were successfully enrolled, which was accomplished within a 3-week period.

Figure 1. Outline of participant enrollment. ECOG: Eastern Cooperative Oncology Group; MPN: myeloproliferative neoplasm.


Patient Demographics

The median age of participants was 62.6 (IQR 54.1-70.2; mean 60.5, SD 12.6) years, and participants were predominantly women (26/30, 87%) and White (28/30, 93%). MPN diagnoses included essential thrombocythemia (11/30, 37%), polycythemia vera (11/30, 37%), and myelofibrosis (8/30, 27%). Most participants (23/30, 76%) were diagnosed with MPN >5 years ago. Of the 30 participants, 11 (37%) reported a known history of splenomegaly, 12 (40%) documented a previous diagnosis of anemia, and 6 (20%) reported a history of blood clots after being diagnosed with MPN. Most participants were being treated with hydroxyurea (20/30, 67%), and some (8/30, 27%) were being treated with ruxolitinib or another JAK inhibitor. Of the 12 participants who completed questions pertaining to the Dynamic International Prognostic Scoring system for myelofibrosis, 1 (8%) was in the high-risk group and 6 (50%) were in the intermediate-1–risk group. There were no statistically significant differences in any of the aforementioned characteristics between participants who were retained in the study (16/30, 53%) and those who were not (14/30, 47%; Table 1).

Table 1. Baseline characteristics of participants.

Characteristic	All participants (n=30)	Retained participants (n=16)
Age (years), median (IQR)	62 (54.1-70.2)	62 (54.9-67.5)
BMI (kg/m^2), median (IQR)	24.5 (21.9-29.8)	23 (20.8-34.6)
Gender, n (%)		
Man	3 (10)	2 (13)
Woman	26 (87)	13 (81)
Prefer not to answer	1 (3)	1 (6)
Race, n (%)		
Asian population	1 (3)	1 (6)
White population	28 (93)	15 (94)
Prefer not to identify	1 (3)	0 (0)
Ethnicity, n (%)

[a]MPN: myeloproliferative neoplasm.

MWC Mobile App Use and Rating

Of the 30 enrolled participants, 7 (23%) failed to make an MWC account, and 10 (33%) additional participants did not set wellness goals within the app. Of the remaining 13 participants, 10 (33%) set at least one or two goals (a total of 5 goals allowed). The uMARS questionnaire was successfully completed by 43% (13/30) of the participants. Most categories had a mean score at ≥3 (Table 2). The highest rated category was aesthetics (mean score 3.4, SD 0.8), and the lowest rated category was behavior change (mean score 2.9, SD 1.2). Most participants (7/13, 54%) gave the MWC app an overall 3-star rating acceptable on the 5-point scale [37].

A total of 6 participants provided additional feedback in an optional phone interview. Participants praised that the app addressed "every aspect of healthy living" and found it resourceful. In addition, 3 participants stated that the app encouraged them to work toward achieving their goals. Then, 1 participant specified that it helped her recognize "that there are definite areas that I need to work on and it helped to get a good start working in the right direction."

Most participants (5/6, 83%) felt that additional guidance in setting up goals would be helpful. Other feedback included the frequency of the reminders seemed "too much" and the tone of the reminders could potentially be adjusted.

Table 2. The user version of the Mobile Application Rating Scale (n=13).

Rating	Values
Category, mean (SD; range)	
Engagement	3.0 (1.1; 1.0-5.0)
Functionality	3.2 (1.3; 1.0-5.0)
Aesthetics	3.4 (0.8; 2.0-5.0)
Information	3.2 (1.4; 1.0-5.0)
Overall quality	3.1 (1.1; 1.0-5.0)
Awareness	3.2 (1.3; 1.0-5.0)
Knowledge	3.2 (1.4; 1.0-5.0)
Attitudes	3.2 (1.3; 1.0-5.0)
Intention to change	3.2 (1.4; 1.0-5.0)
Help seeking	3.0 (1.5; 1.0-5.0)
Behavior change	2.9 (1.2; 1.0-5.0)
Overall star rating (single question), n (%)	
1 star	2 (15)
2 stars	2 (15)
3 stars	7 (54)
4 stars	1 (8)
5 stars	1 (8)

Adherence and Acceptability

All 30 participants were successfully enrolled within the allotted 60-day period. Only 53% (16/30) of participants were retained throughout the 12-week study. Attrition was due to either voluntary withdrawal from the study (2/30, 7%) or loss to follow-up for unknown reasons (12/30, 40%). On the basis of the uMARS score as outlined in the *MWC Mobile App Use and Rating* section, MWC was rated a mean score at ≥3 in many categories, with an overall 3-star rating by most of the participants. The baseline characteristics of participants who completed the study and those who did not were compared, and no statistically significant differences were found.

Patient-Reported Outcomes

The MPN-SAF responses highlighted that not all symptoms were changed by the 12-week intervention, but several (8/18, 44%) significantly improved. Improvements were observed in inactivity, impaired concentration, dizziness, numbness, sexual dysfunction, night sweats, bone pain, and quality of life (Table 3). Furthermore, the mean total score was significantly better at 12 weeks than at baseline (mean 54.8, SD 31.6, vs mean 68.4, SD 30.5; *P*=.001).

The PROMIS Sleep Disturbance (Short Form 8a) responses suggested that mean sleep disturbance scores did not significantly change between baseline (mean 24.2, SD 7.2) and at 12 weeks (mean 22.2, SD 7.4; *P*=.49). Few participants reported moderate or severe sleep disturbance at baseline (5/30, 17%) or 12 weeks (3/16, 19%; Table 4). Furthermore, there was a marginally significant (*P*=.06) difference in Mediterranean diet adherence between baseline (mean 5.9, SD 2.3) and at 12 weeks (mean 6.2, SD 2.7).

Of the 16 participants who completed the BRFSS survey, 16 (100%) responded *yes* to *any physical activities or exercises* at baseline compared with 13 (81%) at 12 weeks. The most frequent types of physical activity or exercise included walking or hiking (8/16, 50% participants at baseline; 7/16, 44% at 12 weeks), yoga, Pilates, or barre (3/16, 19% at baseline; 2/16, 13% at 12 weeks), and gardening (2/16, 13% at baseline; 0/16, 0% at 12 weeks). Participants generally reported a high frequency of engagement in their top physical activity, with most participants reporting 5 to 6 times per week (6/16, 38% at baseline; 6/16, 38% at 12 weeks) or ≥7 times per week (4/16, 25% at baseline; 4/16, 25% at 12 weeks).

Table 3. Assessment of symptom severity based on MPN-SAF using a mixed-effects model.

Symptom	Baseline (n=30), mean (SD)	12 weeks (n=16), mean (SD)	β coefficient	P value
Early satiety	4.5 (2.9)	3.8 (3.1)	−0.59	.21

Mild	10 (34)	3 (19)
Moderate	4 (14)	3 (19)
Severe	1 (3)	0 (0)

Discussion

Principal Findings

There is a high demand in the patient population of MPN for innovative interventions to help alleviate their symptom burden [4,38]. The aim of this study is to determine the feasibility of a 12-week global wellness mobile-based intervention to reduce symptom burden in patients with MPN. This is the first known study to use a global wellness mobile app to address the symptom burden of patients with MPN through advocating self-management strategies focused on facilitating behavioral change. Our results suggest that this study is feasible in terms of the successful enrollment of 30 MPN participants within 30 days and mobile app acceptability by patients. Previous publications, with many recent additions in the medical literature over the last 2 years, have suggested that mobile health apps provide a feasible option to improve quality of life in various patients with cancer, especially through self-care support and behavior modification [22,23,39-41]. However, no mobile health apps have yet to be tested in the patient population of MPN. Most smartphone apps suggest benefit in symptom management; however, none, to our knowledge, have incorporated symptom management and global lifestyle change within 1 app. In small pilot studies, a smartphone-based meditation (CALM) and web-based yoga have previously been shown to be feasible in the population with MPN, with suggested impact on fatigue, sleep, pain, anxiety, and depression [19,26]. Although these pilot studies suggest benefit in symptom management with an isolated behavior intervention (ie, meditation or yoga), the app tested in our study focused on the feasibility of a global lifestyle intervention. A pilot study of MWC showed similar successful recruitment of patients and simple delivery of a nonpharmacologic intervention [27]. The ease and timeliness of this process suggest that this app may be an effective method for providing a self-management strategy for symptom burden in patients with MPN that is highly disseminable to wide groups of individuals.

With most uMARS mean scores at ≥3 points (of a total possible 5), the mobile app was deemed acceptable to this small group of participants [42]. The lowest rated category was behavior change, with a lower mean score of 2.9, close to the mean score in previous studies. Comparatively, the highest rated category was aesthetics, with a mean score of 3.4. The app could potentially be improved by addressing feedback from participants who stated that the mobile app would benefit from additional information describing the process for goal setting, as well as some technical glitches. Furthermore, our study did not achieve the 75% defined target for adherence, with only 53% (16/30) of the participants retained through the 12-week final assessment. However, this finding is quite common; other studies using mobile device health apps note that most users stop use soon after initial use [43] and that approximately half of the 934 survey responders (45.7%) had stopped using a mobile health app [41]. Another study revealed that only 54% of individuals who download a mobile device health app persisted in using it >1 month [44]. Of the 47% who did not complete the final assessment, most participants were lost to follow-up for unknown causes. Retention in future studies could potentially be improved by having more communication with study coordinators throughout the 12-week duration of the intervention check in and assist with any technical difficulties or questions [45].

MWC aims to provide guidance and facilitate wellness goals. By comparing baseline MPN-SAF assessments with 12-week evaluations, improvement was noted in the areas of inactivity, impaired concentration, dizziness, numbness, sexual dysfunction, night sweats, bone pain, and quality of life. Furthermore, the total score improved after the intervention. Thus, the 12-week intervention with MWC suggests a positive impact on our small study group, with improvement in the overall symptom burden. An app feature that may have contributed to the improvement of the symptom burden is the reminder to act on goals. Previous studies have shown that apps that remind participants have better use rate than apps that did not [44,46]. Given our small group of participants, larger studies will be needed to validate the true impact of MWC on MPN symptoms.

The mobile app's impact on diet did not show significant statistical improvement in Mediterranean diet adherence after the 12-week intervention. Limitations in scoring for Mediterranean diet adherence was noted because of participants leaving certain questions blank or responding as "don't know/not sure." In addition, regarding physical activity, the BRFSS survey results were limited in assessing the quantitative change using statistical methods. Therefore, future studies may need to determine a different method for evaluating physical activity that allows for scoring of physical activity. However, participants were noted to engage in their physical activity of choice at high frequency, with 10 participants engaging 5 to 6 times per week or more. However, the impact on sleep was not statistically significant. Although lifestyle changes were not significantly improved in this pilot study, future analysis with a larger patient sample and potentially alternate dietary and physical activity measures may improve the study design. Poor cardiometabolic health is a primary contributor to mortality in patients with MPN, and effective lifestyle interventions and continued study of lifestyle interventions are needed.

Overall, the study exhibited ease of recruitment and acceptability, and although adherence was lower than our goal, it was commensurate with other mobile health app interventions. Finally, the 12-week mobile app pilot study improved the MPN symptom burden and warrants continued study with a larger sample size.

Limitations

The most notable limitation to our study was the small study size. Not achieving the defined level of adherence is a concern; however, the 75% target was likely set too high when compared with the mobile health app use found in the literature and, therefore, may point to a limitation of study design [41,43]. In addition, only 53% (16/30) of the participants completed the study, and 47% (14/30) voluntarily withdrew or were lost to follow-up. On the basis of the completion results in this study, future studies could potentially increase the recruitment goal to ensure a larger sample completing the intervention.

Additional limitations of the study include variability in the proficiency of modern technology by the participants and inability to collect data regarding weekly use of the app. Some participants admitted to discontinuing the mobile app because of confusion and difficulty in understanding how to properly use the app. This limitation could be surmounted by future study design, including frequent coordinator and group engagement for app support. Participants also expressed concerns regarding the frequency of reminders, with a participant stating that it was too frequent and another participant stating that she was not reminded enough. These limitations highlight the importance of a user-friendly mobile app platform with the ability for customization. Perhaps letting the users set their own frequency for reminders can improve adherence. In addition, the study was conducted during the COVID-19 pandemic, when gym closures, self-isolation, and mental health issues could confound the participants' sleep, diet, and physical activity. A participant specifically stated that she "would have used the app for better success if [she] hadn't been self-isolating during this pandemic."

Access barriers, such as patients with MPN who do not possess a mobile device, reliable internet connection, or limited literacy, should also be acknowledged. Although no adaptations for the older patient population were incorporated in this feasibility study, users have the ability within the app to increase the font size on their mobile device for visual limitations. In addition, users can dictate narrative responses (voice-to-text functionality), which can reduce the typing required. App adaptations for the older population will be considered in future design and study of the mobile app. Finally, this study did not investigate which mechanisms were most effective at reducing specific symptoms, as this would require a much larger sample size, and this should be explored in future studies.

Conclusions

Our small feasibility pilot study provided preliminary evidence that the MWC global wellness app intervention is feasible within the population with MPN and may reduce the MPN symptom burden. There was insufficient evidence to show improvements

in physical activity vigor and frequency, healthy diet consumption, and better sleep quality. Future trials evaluating the impact of the MWC mobile app in the population with MPN could be strengthened by a larger sample size, measures to improve adherence and retention (such as coordinator support), and closer consideration of diet and physical activity measures. Overall, this study provides a promising first step toward a self-management strategy to lessen the substantial symptom burden of patients with MPN.

Abstract

Background: The quality of care in labor and delivery is traditionally measured through the Hospital Consumer Assessment of Healthcare Providers and Systems but less is known about the experiences of care reported by patients and caregivers on online sites that are more easily accessed by the public.

Objective: The aim of this study was to generate insight into the labor and delivery experience using hospital reviews on Yelp.

Methods: We identified all Yelp reviews of US hospitals posted online from May 2005 to March 2017. We used a machine learning tool, latent Dirichlet allocation, to identify 100 topics or themes within these reviews and used Pearson r to identify statistically significant correlations between topics and high (5-star) and low (1-star) ratings.

Results: A total of 1569 hospitals listed in the American Hospital Association directory had at least one Yelp posting, contributing a total of 41,095 Yelp reviews. Among those hospitals, 919 (59%) had at least one Yelp rating for labor and delivery services (median of 9 reviews), contributing a total of 6523 labor and delivery reviews. Reviews concentrated among 5-star (n=2643, 41%) and 1-star reviews (n=1934, 30%). Themes strongly associated with favorable ratings included the following: top-notch care ($r=0.45$, $P<.001$), describing staff as comforting ($r=0.52$, $P<.001$), the delivery experience ($r=0.46$, $P<.001$), modern and clean facilities ($r=0.44$, $P<.001$), and hospital food ($r=0.38$, $P<.001$). Themes strongly correlated with 1-star labor and delivery reviews included complaints to management ($r=0.30$, $P<.001$), a lack of agency among patients ($r=0.47$, $P<.001$), and issues with discharging from the hospital ($r=0.32$, $P<.001$).

Conclusions: Online review content about labor and delivery can provide meaningful information about patient satisfaction and experiences. Narratives from these reviews that are not otherwise captured in traditional surveys can direct efforts to improve the experience of obstetrical care.

Introduction

Many hospitals in the United States use the Hospital Consumer Assessment of Healthcare Providers and Systems (HCAHPS) and Press Ganey surveys to evaluate patient experiences [1]. Survey results are standardized and publicly reported to facilitate comparisons of patient experience. However, they are costly and often have low response rates [2,3]. Prespecified domains may miss the concerns of many patients, and aggregated public reporting can obscure differences across specialties [4,5].

Yelp is a website where users share information about their experiences at local businesses by giving a star rating from 1-5 and leaving a narrative review. Yelp is the most used free website in the United States for hospital ratings [6]. In one study, 65% of gynecologists reported being likely to use online ratings to improve patient care, more so than physicians from other specialties [7]. Prior work demonstrates that reviews from online rating services like Yelp are correlated with traditional methods for understanding the patient experience, and the platform's unstructured design provides information not captured in conventional patient experience surveys [2,8-12]. The scale and utilization of these platforms is significant and may provide a

nuanced way to better listen to patients [13]. In this study, we aim to evaluate how the content of labor and delivery Yelp reviews relates to star rating to provide insight into the labor and delivery experience in the United States.

Methods

Obtaining Hospital Reviews

We identified hospitals in the United States that have Yelp reviews using the Yelp Search application programming interface. We included only hospitals listed in the American Hospital Association directory with at least one review. Hospital reviews were then searched for keywords specific to labor and delivery, identified by referencing the Unified Medical Language System database and gathering input from an obstetrician (SKS). The search terms included variations of the same word—for example, "deliver" and "delivery" were both used but counted as one search term. Reviews containing at least one of the specified keywords were characterized as "labor and delivery reviews" and all others as "non–labor and delivery" (Table 1). We used only reviews that received a 5-star or 1-star review for the final analyses, considering the bimodal distribution (Table 2).

Table 1. Characteristics of hospitals with labor and delivery Yelp reviews.

Characteristic	All hospitals on Yelp (N=1569)		All labor and delivery hospitals on Yelp (N=919)	
	Hospitals, n (%)	Average Yelp rating (on a scale from 1-5)	Hospitals, n (%)	Average Yelp rating (on a scale from 1-5)
Bed size				
0-49	223 (14)	3.23	46 (5)	3.44
50-199	577 (37)	2.86	329 (36)	3.31
200-399	487 (31)	2.84	334 (36)	3.24
≥400	275 (18)	2.88	210 (23)	3.33
Region				
Northeast	305 (20)	2.84	191 (21)	3.16
South	617 (40)	2.90	330 (36)	3.23
Midwest	184 (12)	3.12	71 (8)	3.45
West	456 (29)	2.88	327 (36)	3.35
Teaching hospital				
Yes	192 (12)	2.92	157 (17)	3.27
No	1370 (88)	2.85	762 (83)	3.29

Table 2. Distribution of ratings of hospital reviews describing labor and delivery versus all hospital reviews.

Rating (stars)	Labor and delivery Yelp reviews (N=6523), n (%)	Hospital Yelp reviews (N=41,095), n (%)
1	1957 (30)	16,849 (41)
2	522 (8)	3288 (8)
3	457 (7)	2466 (6)
4	913 (14)	5342 (13)
5	2674 (41)	13,150 (32)

Deriving Language Features

After removing stop words, common words of low information content (eg, "the," "as," "a"), we used the MALLET implementation [14] of the machine learning program latent Dirichlet allocation (LDA) to generate 100 topics based on prior work [13]. This machine learning technique automates the identification of co-occurring words whose combination suggests themes or topics [15]. For example, the frequent co-occurrence of "hours," "waiting," "sitting," and "lobby" would define a topic which, on inspection, suggests the theme of long wait times. LDA was used to build a topic model using the corpus of review text; afterward, each review was represented as a weighted mixture of the 100 topics generated from the reviews.

Identifying Differentially Expressed Language Features

Our analysis was aimed at identifying differentially expressed topics in reviews with a 1-star (low) rating versus a 5-star (high) rating considering the bimodal distribution of ratings and based on prior work [11,12]. All statistical analyses were performed in R (version 3.4.1; R Foundation for Statistical Computing). We took a data-driven approach to allow for a more transparent view of the words and phrases that differentiate posts with a high rating (5-star) from those with a low rating (1-star). We isolated the patterns in language topics to obtain correlations in both groups using ordinary least squares (OLS) regression. Treating each review as an observation, OLS regression was performed on standardized LDA derived variables for each review, with the reviews that received 5 stars labeled as 1 and those that received 1 star labeled as 0, and the LDA topic weights of the written review text as the independent variables. Since the variables were standardized, the OLS regression coefficients can be interpreted as Pearson correlations. Topics with a positive coefficient are therefore associated with 5-star reviews, and topics with large negative coefficients are associated with 1-star reviews. We used Bonferroni correction and $P<.001$ for indicating meaningful correlations and the effect size was measured using Pearson r. Most highly correlated topics were labeled independently by two coauthors by examining the top 7 terms in each topic. Adjudication of discrepancies occurred via consensus with a third coauthor reviewer.

Ethical Considerations

The University of Pennsylvania Institutional Review Board deemed the study exempt.

Results

Hospital Reviews

We identified 41,095 reviews from 1569 hospitals listed in the American Hospital Association directory with at least one Yelp rating posted from May 2005 to March 2017. Among those hospitals, 919 (59%) had at least one Yelp rating for labor and delivery (median of 9), contributing a total of 6523 labor and delivery reviews about labor and delivery services. The distribution of ratings is shown in Table 2.

Differentially Expressed Language Features

Themes correlated with favorable ratings included the following: top-notch care ($r=0.45$), expressing gratitude toward staff ($r=0.41$), describing staff as comforting ($r=0.52$), staff having good bedside manner ($r=0.42$), professional and friendly staff ($r=0.43$), the delivery experience ($r=0.46$), modern and clean facilities ($r=0.44$), and hospital food ($r=0.38$; Table 3).

Themes correlated with 1-star labor and delivery reviews included the experience of calling the hospital ($r=0.33$), interactions with reception ($r=0.31$), complaints to management ($r=0.30$), telling others to avoid the hospital ($r=0.32$), a lack of agency among patients ($r=0.47$), and issues with discharging from the hospital ($r=0.32$; Table 4).

Table 3. Yelp differential language analysis topics associated with positive (5-star) labor and delivery reviews.

Yelp domain (determined by Yelp) and Yelp topic (topic terms)	Correlation, Pearson r	Example quote
Positive experience		
Top-notch care (excellent, received, care, top, notch, wonderful, attentive, amazing)	0.448	Thank you to the ENTIRE [hospital name] Pediatric unit. They have taken EXCELLENT care of our baby. Your attention and dedication was top notch. We greatly appreciate it....
Compassionate caring staff		
Grateful (amazing, team, wonderful, grateful, life, love, god, team, saved, bless, remember)	0.405	We are very blessed to have such an amazing team of nurses. The support and caring was priceless. We most likely will have baby 2 in here. If you looking for a happy medium between home-birth or hospital-birth, this place is the answer.
Comforting (made, comfortable, feel, helpful, questions, friendly, caring, pleasant, attentive)	0.521	Both of my daughters gave birth at [the hospital] and raved about the care they got. The nursing staff is compassionate and very skilled!
Bedside manner (great, bedside, dr, manner, awesome, kind, fantastic, sweet, tech, compassionate)	0.416	Delivered my first here. Clean, friendly, knowledgeable staff. Very attentive in Labor and Delivery and until we went home. Made the week long stay as comfortable as possible. Nurses had really good bedside manner. I would recommend this hospital to others.
Professional/friendly staff (friendly, staff, professional, helpful, efficient, service, recommend, highly, courteous)	0.426	Excellent labor/delivery and postpartum experience. Every nurse we encountered was kind and caring. Highly recommended.
Clinical service		
Delivery experience (delivery, labor, baby, amazing, birth, wonderful, maternity, nicu[a], ward, helpful)	0.462	Maternity ward was awesome when I delivered my baby in October everyone was exceptional.
Facilities and amenities		
Modern and clean (facility, rooms, clean, friendly, helpful, nice, super, equipment, modern, beautiful)	0.444	This is hospital is one of the cleanest around! The maternity staff is excellent and so are the facilities!
Hospital food (food, pretty, order, stay, cafeteria, menu, private, dinner, free)	0.380	I delivered my daughter here and absolutely love everything about this hospital from the warm staff, comfortable rooms and amazing kitchen menu for patient meals.

[a]NICU: neonatal intensive care unit.

Table 4. Yelp differential language analysis topics associated with negative (1-star) labor and delivery reviews.

Yelp domain (determined by Yelp) and Yelp topic (topic terms)	Correlation, Pearson r	Example quote
Negative interactions		
Lack of agency (told, asked, didn't, questions, wasn't, couldn't, rude, talk, telling, upset)	0.465	This review is for the prenatal clinic. I called this morning because I had been advised to do so by my Dr. The lady who answered the phone was extremely rude and unprofessional. Her exact words " and your calling us for????" With the rudest tone I have ever heard from a healthcare professional. I was beyond shocked and will never go to their clinic.
Being discharged (information, discharge, medications, papers, husband, refused, stated, physician, attending, signed)	0.321	Beware!!! Don't entrust this incompetent facility with your life!! Intake form - misspelling of name and incorrect recording of birth date so records could not be found until 4phone calls later…
Communication with hospital		
Calls (phone, call, number, person, message, answer, hold, office, transferred)	0.326	Horrible customer service. Called the operator to inquire about setting up a prenatal appointment to find an OBGYN and she told me to google them to find one I like! Ha what a joke.
Reception (desk, front, asked, check, walked, minutes, arrived, paperwork)	0.305	Maternity receptionist is still rude as hell. Wife sent over by office for emergency monitoring.... She told us to wait while she finished putting stickers on a folder.
Complaints to management (complaint, manager, response, letter, lack, contact, advocate, concerns, case, report)	0.296	I had a baby at [hospital name] in 2008. Horrible, scary, TRAUMATIC experience. Incompetence, unprofessionalism, and bad medicine…In spite of numerous conversations with various individuals at the hospital, and a lengthy grievance filed against the hospital with my insurance, no one at the hospital ever said "I'm sorry."
Wait times		
Long wait (hours, waited, hour, finally, worst, sitting, triage, ridiculous)	0.409	Anyone giving this place 5 stars works here. Longest wait ever over 2 hours with a ectopic pregnancy. This place is horrible
Pain meds		
Medication (pain, meds, gave, prescription, morphine, prescribed, migraine, severe)	0.325	If you want to be constantly asked if you're a drug addict while you cry in pain this is your place. Even at 43 under a Sutter West doctors care, had a baby there 3 months earlier have 9 years of [hospital name] medical records, and that still didn't help the staff treat not me like an addict until my x-Rays came back then it's like I'm so sorry here's some pills have a nice day call your doctor. :(
Would not recommend		
Unprofessional staff (worst, rude, terrible, awful, avoid, incompetent, horrible, place, unprofessional)	0.315	This Hospital is one of the worst hospitals in the [county name] county. Their staff is very rude. They almost killed my mother during child birth due to uneducated staff and negligence. DO NOT GO HERE! Not safe.
Specialized medical care		
Tests (test, results, sample, urine, lab, ordered, UTI[a], negative)	0.342	I came in for my 8week old baby he had a temp. Of 101F I came in at 11pm and now it's 4:15 am we are still waiting on some results I know it does not take that long for something to come back about my baby knowing the baby haves a high temp.
IV[b] (arm, hand, needle, IV, put, started, painful, stop, screaming, catheter, veins)	0.339	Never ever would I bring my baby to this hospital walked in my room and found a needle on the floor
Kidney stones (kidney, pain, abdominal, severe, stomach, stone, meds, excruciating)	0.315	I went in for serious stomach pains while I was pregnant, the doctor said I had gall stones that needed to be removed via surgery, scheduled surgery for after my baby was born just to find out later that there was no gall stones, never did find out what sent me to the emergency room in debilitating pain while I was pregnant!

[a]UTI: urinary tract infection.

[b]IV: intravenous.

Discussion

Principal Findings

This study found identifiable themes associated with high and low ratings, offering insights into what patients seeking labor and delivery services care about most. Online reviews about hospitals include comments about the experience of labor and delivery care. Although online reviews are not validated and may attract or amplify the most negative comments [13,16], they reflect raw reports from patients unconstrained by pre-established topics.

Positive reviews on the labor and delivery experience overwhelmingly cited compassionate and attentive hospital staff. Nurses were frequently cited as the most important component of the experience. For 5-star reviewers who criticized their experience in any way, caring and helpful nurses and staff almost always made up for the negative aspects of their stay. In addition, 5-star reviews in our study largely referenced positive feelings about hospital staff and the importance of hospital amenities (often citing spa showers, advanced technology, and appealing decor). Prior work reported that, in the patient-provider relationship in an obstetrics and gynecology setting, patients reported greater satisfaction with their health care experience when they had a positive relationship with their care team, which parallels our finding that patients are more satisfied when providers are caring and attentive [17]. Compassion of staff is not a topic measured in HCAHPS surveys. Additionally, HCAHPS and Press Ganey do not include free-text questions; rather, questions are multiple choice.

Negative reviews of labor and delivery included topics typically inverse to the topics discussed in positive reviews. Raters cited negative interactions and lack of communication with hospital staff, long wait times, and low-quality obstetrics care in 1-star labor and delivery reviews. In a prior review of patient satisfaction in obstetrics care, researchers interviewed patients and compiled a total of 51 items related to patient satisfaction [18]. The list included multiple characteristics related to provider communication style, including compassion/sensitivity, communication, accessibility, support, and positive affirmation of birthing process. Access to and communication with hospital staff contribute to a more positive patient experience in the context of labor and delivery care. Understanding the common themes of positive and negative experiences may help clinical and operational staff create initiatives and protocols that lead to better patient encounters.

Limitations

This study has several limitations. The American Hospital Association data set represents broader obstetrical programs (eg, the Hospital of the University of Pennsylvania) but may miss subsidiary programs (eg, Penn Ob/Gyn & Midwifery Care). The bimodal distribution of reviews may amplify the voices of those with strongly positive and strongly negative experiences, muting the more nuanced and mixed experiences. Clinical terms and procedures may be talked about in slang and ways that are harder to identify using automated techniques. However, using machine learning techniques allows for the analysis of hundreds of thousands of reviews as opposed to what is possible with human coders. In addition, Yelp reviews are not validated and may vary in quality and quantity. To counter this, we eliminated reviews "not recommended" by Yelp (a measure indicating a review is likely to be fake). "Not recommended" reviews are determined automatically by Yelp's proprietary algorithm that considers a number of factors to try and remove fake reviews (eg, one person posting many reviews from the same computer). In the future, including other online review platforms may provide richer insights. The practical application of this data is largely valuable as a supplemental insight into the patient's psychological experience of their labor and delivery care. Understanding the themes that correlate to high and low reviews may provide a place to start when developing standardized surveys for measuring care.

Conclusions

Transparency of hospital performance data is vital to enhancing patient trust and improving health care delivery. Online rating websites may help foster trust and goodwill between hospitals and their consumers, allow consumers to make more informed decisions, and encourage quality improvements [16,19]. Increasing the validity and scientific rigor of these narrative feedback platforms may increase the value of these patient narratives for further improving obstetrics care in the United States [20,21].

Abstract

Background: Behavioral factors, such as lifestyle, have been shown to explain approximately 24% of the excess risk of chronic kidney disease (CKD) among African Americans. However, there are limited intervention studies culturally tailored to African Americans with type 2 diabetes mellitus and CKD.

Objective: The main objective of this study was to examine the feasibility and preliminary efficacy of a culturally tailored lifestyle intervention among African Americans with type 2 diabetes mellitus and CKD.

Methods: A pre-post design was used to test the feasibility of a lifestyle intervention in 30 African American adults recruited from the Medical University of South Carolina between January 2017 and February 2017. A research nurse delivered the manualized study intervention weekly for 6 weeks. Clinical outcomes (hemoglobin A_{1c}, blood pressure, and estimated glomerular filtration rate [eGFR]) were measured at baseline and postintervention. Disease knowledge, self-care, and behavior outcomes were also measured using validated structured questionnaires at baseline and postintervention. Descriptive statistics and effect sizes were calculated to determine clinically important changes from baseline.

Results: Significant pre-post mean differences and decreases were observed for hemoglobin A_{1c} (mean 0.75%, 95% CI 0.16-1.34; P=.01), total cholesterol (mean 16.38 mg/dL, 95% CI 5.82-26.94; P=.004), low-density lipoprotein (mean 13.73 mg/dL, 95% CI 3.91-23.54; P=.008), and eGFR (mean 6.73 mL/min/1.73m^2, 95% CI 0.97-12.48; P=.02). Significant pre-post mean differences and increases were observed for CKD self-efficacy (mean −11.15, 95% CI −21.55 to −0.75; P=.03), CKD knowledge (mean −2.62, 95% CI −3.98 to −1.25; P<.001), exercise behavior (mean −1.21, 95% CI −1.96 to −0.46; P=.003), and blood sugar testing (mean −2.15, 95% CI −3.47 to −0.83; P=.003).

Conclusions: This study provides preliminary data for a large-scale appropriately powered randomized controlled trial to examine a culturally tailored lifestyle intervention in African Americans with type 2 diabetes mellitus and CKD in order to improve clinical, knowledge, self-care, and behavior outcomes in this population.

XSL·FO
RenderX

Introduction

Chronic kidney disease (CKD), categorized as stage 1 to 5 based on the estimated glomerular filtration rate (eGFR), is a major complication of diabetes and is commonly referred to as diabetic kidney disease (DKD) [1]. DKD is marked by persistent presence of albuminuria (albumin excretion rate ≥30 mg/24 hours; urine albumin to creatinine ratio [UACR] ≥30 mg/g) or a decreased eGFR (<60 mL/min/1.73m^2). Approximately 31% of individuals with diabetes have DKD [2]. DKD is associated with significant morbidity, cost, a 4- to 5-fold risk of end-stage renal disease, and an increased risk of death [3-6]. African Americans are disproportionately affected by diabetes and DKD compared with non-Hispanic Whites [7]. Further, African Americans are 3 to 4 times more likely to have end-stage renal disease compared with non-Hispanic Whites [4]. The reason for the accelerated progression of kidney disease among African Americans is not completely understood. However, behavioral factors, such as lifestyle, have been shown to explain approximately 24% of the excess risk of CKD among African Americans [8].

Lifestyle modification comprising one or more aspects, including physical activity, diet change, smoking cessation, exercise, skills training, counseling, and stress management, is an essential component of diabetes and CKD management [9-11]. Evidence of the impact of lifestyle interventions on DKD outcomes is limited and conflicting [12,13]. The largest prospective study until date, the Look AHEAD (Action for Health in Diabetes) study, randomly assigned overweight or obese patients with type 2 diabetes to an intensive lifestyle intervention to achieve weight loss compared with a diabetes support and education condition [14,15]. While the intervention was not effective in reducing cardiovascular events (primary outcome), a post-hoc analysis of this study showed that the intensive lifestyle intervention reduced the incidence of very high–risk CKD [15].

The majority of lifestyle intervention studies in patients with DKD are limited by their study design, limited generalizability, small sample size, low proportion of African Americans, or lack of appropriate predefined renal endpoints [12,13,15,16]. In addition, there is a lack of interventions culturally tailored to African Americans, even though evidence suggests that African Americans have a limited understanding of CKD and CKD risk factors [17,18], and lag behind in hemoglobin A_{1c} (HbA$_{1c}$) control, blood pressure control, and use of statins and glucose-lowering medications [19]. Hence, the main objective of this pilot study was to examine the feasibility and preliminary efficacy of a culturally tailored DKD-focused lifestyle intervention on (1) clinical outcomes, (2) disease knowledge, and (3) self-care and behavior outcomes among African Americans with type 2 diabetes and CKD. The study hypothesized that individuals who receive the study intervention will have improved clinical outcomes, disease knowledge, and self-care and behavior outcomes after the intervention.

Methods

Ethics Board Review

This study was approved by the Institutional Review Board of the Medical University of South Carolina (Pro#00051414; Institutional Review Board approval date: November 9, 2016).

Study Design

A pre-post design was used to test the feasibility of a lifestyle intervention with baseline (preintervention) and 2-month (postintervention) assessments. The study participants were non-Hispanic Blacks with type 2 diabetes and CKD, with an eGFR >59 mL/min/1.73m^2 and a spot UACR of 30-300 mg/g.

Participants and Setting

Participants were recruited from clinics affiliated with the Medical University of South Carolina between January 2017 and February 2017. Non-Hispanic Black participants were identified and recruited using clinic billing records for ICD-10 (International Classification of Diseases, 10th revision) codes consistent with the diagnosis of type 2 diabetes and cystatin C eGFR >59 mL/min/1.73m^2, and through referral from physicians and clinic staff. Institutional Review Board–approved study flyers were posted in the clinics, and letters of invitation signed by the clinic director were mailed to patients.

Screening for Eligibility and Enrollment

Individuals who were aged 21 years or older, self-identified as African American, had a clinical diagnosis of type 2 diabetes and early CKD (stage 1 and 2), were able to communicate in English, and had a telephone (landline or cell phone) were eligible to participate in the study. Individuals who had cognitive impairment, alcohol or drug abuse, acute decompensation of chronic disease conditions, CKD of stage 3 or higher, malignancy, life-expectancy of less than 6 months, and other known disease conditions causing proteinuria were excluded from the study. Transplant recipients, individuals participating in another diabetes or CKD trial, and those who did not have telephone access were not eligible for the study.

A total of 30 participants who met the inclusion criteria were enrolled by a research assistant. Eligible participants received up to US $150 in compensation for completing all the study assessments (screening, baseline, and 2-month study assessment).

Description of the Intervention

The study intervention was adapted from a culturally tailored study, Technology-Intensified Diabetes Education and Skills Training Intervention (TIDES) [20], and was tailored to focus on DKD. The study intervention was based on the Information-Motivation-Behavioral Skills model and provides information, motivation, and behavioral skills training (using motivational enhancement techniques) [21]. Patients were assigned the FORA 2-in-1 Telehealth System at the beginning of the study and provided glucose test strips to allow testing at least once a day.

All intervention sessions were telephone-delivered weekly by a research nurse for 6 weeks. Intervention sessions lasted 30

minutes, and the research nurse was trained in behavioral skills counseling and the study intervention content. The study educational materials were developed based on the National Kidney Disease Education Program [22] and written in lay language for African Americans with DKD. The description of weekly content is provided in Multimedia Appendix 1. All education sessions were audiotaped, and 20% were randomly selected and reviewed by the principal investigator to ensure the research nurse delivered the intervention appropriately. All study participants received behavioral skills training focused on 3 lifestyle behaviors (physical activity, diet, and medication adherence). Target lifestyle behavior goals were set in collaboration with the patients and were guided by current problem areas and preferences.

Study Measures and Data Collection Schedule

Participant information was collected using validated questionnaires administered at 2 time points: at baseline and 2 months postintervention (see Multimedia Appendix 2). Study data were obtained by a trained research assistant.

Feasibility Measures

Feasibility measures were recruitment, session attendance rate, and dropout proportion.

Outcome Measures

BMI was calculated using weight in kg and height in m^2. Blood pressure readings were obtained using automated blood pressure monitors at baseline and 2 months. The device was programmed to take 3 readings at 2-minute intervals, and the readings were averaged. UACR was measured at baseline and 2-month visits using spot urine. Blood samples were assayed for HbA_{1c}, cholesterol, and eGFR at baseline and 2 months by a trained nurse. The Patient Health Questionnaire-9 (PHQ-9), a brief questionnaire that scores each of the 9 DSM-IV (Diagnostic and Statistical Manual of Mental Disorders, fourth edition) criteria, was used to assess for depression [23]. See Multimedia Appendix 2 for details on outcome and process measures.

Process and Behavioral Measures

CKD Self-efficacy Scale

This involved a 25-item instrument that measures disease-related self-efficacy in the following 4 core areas: (1) autonomy, (2) self-regulation, (3) problem solving, and (4) seeking social support [24]. The Cronbach alpha coefficient for the total scale was .94, and the value for each of the 4 subscales ranged from .84 to .90 [24].

CKD Knowledge Questionnaire

This involved a 28-item Kidney Knowledge survey, which has good internal consistency and high reliability (coefficient of 0.72) [25].

Diabetes Knowledge Questionnaire

This involved the 24-item Diabetes Knowledge Questionnaire, which has a reliability coefficient of 0.78 [26].

Health Literacy

This was measured using the 3-item Chew health literacy scale, which assesses the capacity to obtain, process, and understand basic health-related decisions [27]. The 3 questions have been shown to be effective in detecting inadequate health literacy (areas under the receiver operating characteristic curve of 0.87, 0.80, and 0.76, respectively) [27].

Behavioral Skills

This was assessed with the Summary of Diabetes Self-Care Activities (SDSCA) scale [28]. It is a brief, validated, self-report questionnaire of diabetes self-management that includes items assessing diet, exercise, medication adherence, and self-blood glucose testing. The average interitem correlations within scales were high, test-retest correlations were moderate, and correlations with other measures of diet and exercise generally supported the validity of the subscales.

Statistical Analyses

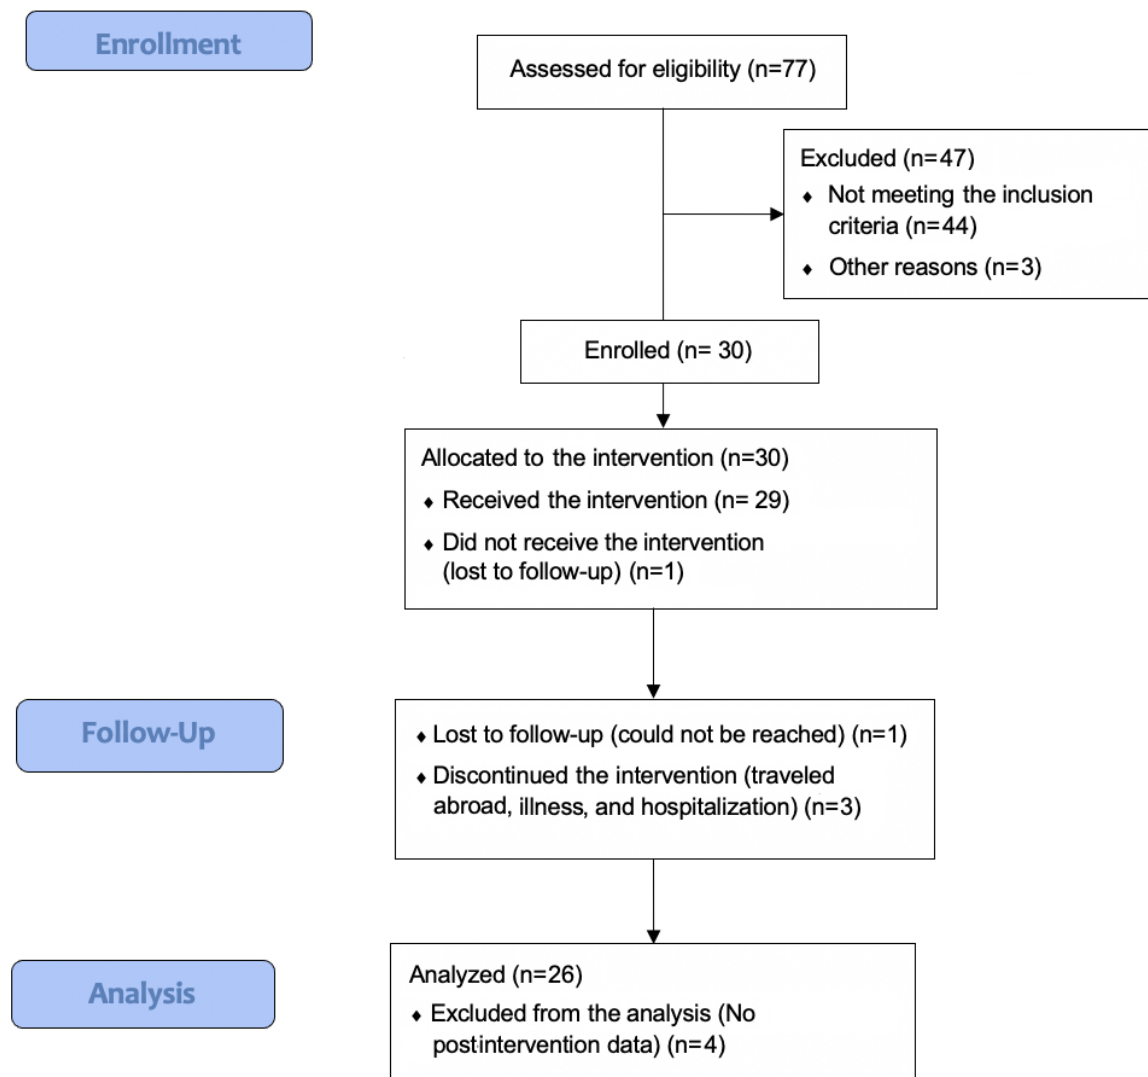
Important measures of feasibility analysis included recruitment, session attendance rate, and dropout proportion. We used 95% CIs for proportions to estimate (1) the proportion of participants who agreed to participate among those who were initially approached, (2) the proportion who were compliant with the treatment intervention, and (3) the proportion who dropped out. In addition, frequency distributions describing the participants' reasons for noncompliance and discontinuation of study participation will be provided.

For quantitative analysis, univariate descriptive statistics and frequency distributions were calculated for the total sample. Pre-post mean differences were tested using paired t tests. Effect size, a measure of treatment effect, was used to interpret the effects of the intervention. An effect size of 0.2 was considered small, 0.5 was considered moderate, and 0.8 was considered large. In addition to effect sizes, which demonstrated clinical relevance, a statistically significant difference was noted for the primary measurement. All statistical analyses were performed using Stata software (StataCorp).

Results

Study Profile

Between January 9, 2017, and April 28, 2017, 77 patients were screened, and 30 eligible patients were enrolled into the study (Figure 1). All 30 (100%) patients completed the baseline assessment, and 26 (87%) completed assessments at 2 months. Four (13%) participants were lost to follow-up; hence, the analytical sample included 26 participants.

Figure 1. Study flow diagram.


Baseline Demographic Profile

Table 1 shows the baseline characteristics of the study participants. The mean age of the study participants was 57 years, and the mean duration of diabetes was 14 years. The majority were female (21/30, 70%), unmarried (17/30, 57%), unemployed (20/30, 67%), and insured (30/30, 100%). Over half of the participants reported having a "good" health status (16/30, 53%) and not using any special equipment (16/30, 53%).

Table 1. Baseline sample demographic characteristics of African Americans with type 2 diabetes and chronic kidney disease enrolled in the pre-post study.

Variable	Value (N=30)
Age (years), mean (SD)	56.7 (13.5)
Sex, n (%)	
Female	21 (70)
Marital status, n (%)	
Married	13 (43)
Employment status, n (%)	
Employed	10 (33)
Income, n (%)	
<US $25,000	18 (60)
Smoking status, n (%)	
Smoker	9 (30)
Insurance status, n (%)	
Insured	30 (100)
Health status, n (%)	
Fair/poor	14 (47)
Use of special equipment, n (%)	
Yes	14 (47)
Physical activity days per week, n (%)	
0	16 (53)
1+	14 (47)
Years of education, mean (SD)	12.6 (1.7)
Work hours per week, mean (SD)	14.3 (24.0)
Duration of diabetes (years), mean (SD)	14.2 (9.1)

Feasibility Findings

Overall, 33 out of 77 (43%) participants contacted were eligible for the study, and 30 participants were successfully recruited for this study. Among the 30 participants, 21 (70%) completed all 6 sessions, 26 (87%) completed assessments at 2 months, and 1 (3%) dropped out of the study. The reasons for incomplete sessions were death in the family, illness, or hospitalization. One participant dropped out after enrollment because of hospitalization for pneumonia.

Preintervention and Postintervention Differences in Clinical Outcomes

Table 2 presents preintervention (baseline) and postintervention (2 months) differences in clinical outcomes. Significant preintervention and postintervention mean differences and decreases were observed for HbA_{1c} (mean 0.75; P=.01), total cholesterol (mean 16.38; P=.004), low-density lipoprotein (LDL) (mean 13.73; P=.008), and eGFR (mean 6.73; P=.02). We observed nonstatistically significant increases in BMI (mean −0.48; P=.05), systolic blood pressure (mean −1.77; P=.61), diastolic blood pressure (mean −3.42; P=.21), and the UACR (mean −18.63; P=.79). There were also nonstatistically significant decreases in the PHQ-9 score for depression (mean 1.30; P=.17), high-density lipoprotein (mean 1.70; P=.23), and triglycerides (mean 4.03; P=.62).

Table 2. Preintervention and postintervention mean differences in the clinical outcomes of African Americans with type 2 diabetes and chronic kidney disease enrolled in the pre-post study.

Variable	Baseline[a], mean (SD)	2 months[a], mean (SD)	Mean difference (95% CI)	P value
BMI (kg/m^2)	35.9 (8.1)	36.4 (8.4)	−0.48 (−0.96 to 0.01)	.05
Systolic blood pressure (mmHg)	131.2 (17.9)	133.0 (15.2)	−1.77 (−8.84 to 5.30)	.61
Diastolic blood pressure (mmHg)	77.0 (10.2)	80.5 (9.5)	−3.42 (−7.80 to 0.96)	.12
Hemoglobin A_{1c} (%)	9.1 (2.5)	8.3 (1.9)	0.75 (0.16 to 1.34)	.01
Total cholesterol (mg/dL)	199.5 (44.9)	183.1 (34.6)	16.38 (5.82 to 26.94)	.004
Low-density lipoprotein (mg/dL)	122.2 (41.4)	108.4 (31.1)	13.73 (3.91 to 23.54)	.008
High-density lipoprotein (mg/dL)	50.4 (11.0)	48.7 (12.8)	1.70 (−1.14 to 4.52)	.23
Triglycerides (mg/dL)	134.3 (58.3)	130 (61.6)	4.03 (−12.80 to 20.88)	.62
Microalbumin-creatinine ratio	264.8 (375.5)	283.5 (557.6)	−18.63 (−168.83 to 131.58)	.79
Glomerular filtration rate (mL/min/1.73m^2)	93.4 (21.9)	86.7 (21.7)	6.73 (0.97 to 12.48)	.02
Patient Health Questionnaire-9 (PHQ-9) score	5.2 (4.9)	3.9 (4.5)	1.30 (−0.62 to 3.23)	.17

[a]Baseline is preintervention and 2 months is postintervention.

Preintervention and Postintervention Differences in Knowledge, Self-care, and Behavior Outcomes

Table 3 displays participant responses to questions related to knowledge, skills, self-care, and behavior outcomes. Significant preintervention and postintervention mean differences and increases were observed for CKD self-efficacy (mean −11.15; P=.03), CKD knowledge (mean −2.62; P<.001), exercise behavior (mean −1.21, P=.003), and blood sugar testing (mean −2.15; P=.003). We observed nonstatistically significant increases in diet (mean −0.42; P=.49), special diet (mean −0.43; P=.23), and foot care (mean −0.21; P=.60). A nonstatistically significant decrease in diabetes knowledge (mean 0.77; P=.25) was also observed, while no significant change in health literacy (mean 0.04; P=.66) was seen.

Table 3. Pre-post mean differences in knowledge, self-care, and behavior outcomes of African Americans with type 2 diabetes and chronic kidney disease enrolled in the pre-post study.

Variable	Baseline[a], mean (SD)	2 months[a], mean (SD)	Mean difference (95% CI)	P value
Knowledge				
CKD[b] self-efficacy	208.9 (36.0)	220.0 (27.4)	−11.15 (−21.55 to −0.75)	.03
DM[c] knowledge	16.2 (3.8)	15.4 (3.7)	0.77 (−0.59 to 2.14)	.25
CKD knowledge	18.4 (3.8)	21.0 (2.1)	−2.62 (−3.98 to −1.25)	<.001
Health literacy	0.3 (0.5)	0.3 (0.5)	0.04 (−0.14 to −0.21)	.66
Self-care and behavior				
Diet	3.9 (2.1)	4.4 (2.1)	−0.42 (−1.68 to 0.83)	.49
Special diet	4.0 (1.4)	4.4 (1.2)	−0.43 (−1.16 to 0.30)	.23
Exercise behavior	1.8 (1.7)	3.0 (1.6)	−1.21 (−1.96 to −0.46)	.003
Blood sugar test	3.7 (2.6)	5.9 (1.8)	−2.15 (−3.47 to −0.84)	.003
Foot care	4.9 (2.2)	5.1 (2.1)	−0.21 (−1.05 to 0.63)	.60

[a]Baseline is preintervention and 2 months is postintervention.

[b]CKD: chronic kidney disease.

[c]DM: type 2 diabetes.

Discussion

Principal Findings

This study examined the feasibility and preliminary efficacy of a culturally tailored DKD-focused lifestyle intervention in African Americans with type 2 diabetes and CKD. With 100% recruitment, a 70% session attendance rate, and a 3% drop-out rate, the study findings suggest that the design, recruitment, and delivery of a culturally tailored lifestyle intervention for high-risk African Americans with type 2 diabetes and CKD are feasible. This study was also designed to examine preliminary changes in clinical outcomes, disease knowledge, self-care, and

XSL•FO

RenderX

behavior outcomes. We observed statistically significant changes in the clinical outcomes of HbA_{1c}, total cholesterol, LDL, and eGFR following the study intervention. In addition, there were statistically significant increases in CKD self-efficacy, CKD knowledge, exercise. and blood sugar testing.

Comparison With Prior Work

Behavior lifestyle intervention trials have conflicting results on the impact of lifestyle interventions on clinical outcomes [12]. Consistent with our study findings, a systematic review by Van Huffel et al evaluating the impact of exercise and diet on health outcomes in individuals with diabetes and CKD concluded that exercise and diet interventions have beneficial effects on glycemic control, BMI, and quality of life [13]. Similarly, large trials, such as the "Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan (RENAAL)," "Action to Control Cardiovascular Risk in Diabetes (ACCORD)," "Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT)," and "Action in Diabetes and Vascular Disease: Preterax and Diamicron Modified Release Controlled Evaluation (ADVANCE)," demonstrated that aggressive risk factor control in African Americans using antihypertensive, antihyperglycemic, or lipid-lowering medications is beneficial [29-33]. However, these studies focused on risk factor control using medications and did not emphasize lifestyle modification, which is a core component of diabetes and CKD management [3,9,10].

Contrary to our study findings, a systematic review and meta-analysis of self-management support interventions for people with diabetes and CKD showed that these interventions may improve self-care activities, HbA_{1c}, and systolic blood pressure [34]. While we observed a significant increase in CKD self-efficacy, disease knowledge, exercise behavior, and blood sugar testing, our study did not show a significant difference in blood pressure; however, it was not powered to confirm or refute a hypothesis, which could explain the lack of statistical significance in most clinical outcomes. The impacts of lifestyle interventions on kidney function are also inconsistent, with some studies demonstrating no effect, or a negative or positive effect [12,13]. We observed a significant negative effect (decrease) in the eGFR postintervention in our study population. Glomerular hyperfiltration often mediated by hyperglycemia results in a high eGFR in type 2 diabetes and is a hallmark finding in DKD [35]. Nonpharmacological interventions, such as decreases in body weight, and salt and protein intake, have been shown to ameliorate diabetic hyperfiltration [35]. It is unclear why we observed these findings given the lack of a significant difference in BMI or dietary habits. Future large-scale and more rigorous behavior lifestyle randomized controlled trials in this population should explore measuring changes in salt and protein intake, and examine the impact on outcomes.

Recent evidence demonstrates that glucose-lowering medications, such as glucagon-like peptide 1 receptor agonists and sodium-glucose cotransporter-2 inhibitors, are of particular benefit in the prevention and treatment of CKD in patients with type 2 diabetes [36]. However, despite the strengths of these large clinical trials [37-44] and limited data on the efficacy of lifestyle interventions in African Americans [12,15,34], African Americans remain poorly represented. It is established that African Americans with CKD are poorly represented in clinical trials [45], and low inclusion of African Americans in clinical trials limits the generalizability of study findings. This potentially propagates existing disparities in a high-risk high-cost population. Low participation of African Americans in clinical trials is often attributed to poverty, lack of accessibility, lack of information on clinical trials, and chronic disease–related stigma [45,46]. There is a need to overcome these barriers and increase the participation of African Americans in clinical trials. Ongoing clinical trials are exploring novel community-based screening recruitment methods for African Americans with CKD [46,47]. More intervention studies that focus on high-risk patients incorporating such novel recruitment strategies are needed. In addition, behavioral lifestyle interventions that account for contextual factors facing high-risk African American populations with diabetes and CKD are needed [48].

Strengths, Limitations, and Future Direction

The findings of this study are promising and have important clinical implications. Significant changes observed in clinical outcomes, such as a decrease in HbA_{1c}, and improved CKD knowledge, self-care, and behavior, can prevent or delay the progression of CKD to renal failure, and improve quality of life and survival in this study population. This could potentially reduce the economic burden associated with renal failure and the life-threatening complications of renal failure. Despite these promising findings, some limitations are worth noting. First, the relatively small sample size, limited intervention duration, and lack of a control group might have affected the findings. However, the goal of this feasibility pilot study was to generate information needed for planning and designing a future large-scale study. Second, eGFR was estimated using creatinine and cystatin C equations with race. Recent evidence suggests that the inclusion of race in eGFR estimation overestimates measured eGFR, which potentially exacerbates health disparities and contributes to systemic racism. While it is unlikely that the eGFR equation used for this study influenced the study findings, future studies will use new creatinine and cystatin C equations without race to ensure accuracy. Third, although majority of the study participants completed all intervention sessions, some weekly intervention sessions were delayed. The main reasons for delayed intervention sessions were travel abroad, hospitalization, and death in the family. Future studies will incorporate a run-in period to establish expectations and processes for timely completion of intervention sessions in the event of hospitalization or unanticipated events. In addition, we will account for loss of information due to dropout when calculating sample size. Fourth, the study findings may not be generalizable to other populations since the study was primarily designed for African American/non-Hispanic Black populations.

Conclusion

This study clarifies the feasibility and preliminary efficacy of a culturally tailored DKD-focused lifestyle intervention in African Americans with type 2 diabetes and CKD in terms of clinical, knowledge, self-care, and behavior outcomes. Statistically significant changes in the clinical outcomes of

HbA_{1c}, total cholesterol, LDL, and eGFR were observed following the study intervention. In addition, there were statistically significant increases in CKD self-efficacy, CKD knowledge, exercise, and blood sugar testing. Based on the results of this study, a trial to determine the efficacy of this intervention would be feasible in African Americans with type 2 diabetes and CKD. The findings from this study will also serve as preliminary data to inform the design of a large-scale appropriately powered randomized controlled trial to examine the efficacy of a culturally tailored lifestyle intervention in African Americans with comorbid diabetes and CKD in terms of clinical, knowledge, self-care, and behavior outcomes.

Abstract

Background: The qualification and order of authorship in scientific manuscripts are the main disputes in collaborative research work.

Objective: The aim of this project was to develop an open-access web-based platform for objective decision-making of authorship qualification and order in medical and science journals.

Methods: The design science process methodology was used to develop suitable software for authorship qualification and order. The first part of the software was designed to differentiate between qualification for authorship versus acknowledgment, using items of the recommendations of the International Committee of Medical Journal Editors. The second part addressed the order of authorship, using the analytical hierarchy process for objective multiple criteria decision-making and ranking. The platform was evaluated qualitatively (n=30) and quantitatively (n=18) using a dedicated questionnaire, by an international panel of medical and biomedical professionals and research collaborators worldwide.

Results: Authorships.org represents an open-access software compatible with all major platforms and web browsers. Software usability and output were evaluated and presented for 3 existing clinical and biomedical research studies. All 18 international evaluators felt that the Authorships.org platform was easy to use or remained neutral. Moreover, 59% (n=10) were satisfied with the software output results while the rest were unsure, 59% (n=10) would definitely use it for future projects while 41% (n=7) would consider it, 94% (n=16) felt it may prove useful to eliminate disputes regarding authorship, 82% (n=14) felt that it should become mandatory for manuscript submission to journals, and 53% (n=9) raised concerns regarding the potential unethical use of the software as a tool.

Conclusions: Authorships.org allows transparent evaluation of authorship qualification and order in academic medical and science journals. Objectified proof of authorship contributions may become mandatory during manuscript submission in high-quality academic journals.

KEYWORDS

authorship; writing; dissent and disputes; research ethics; software design

Introduction

Next to the presentation of scientific results, authorship in academic journal articles is a means for scholars to communicate the intellectual contributions of their work, take public responsibility for it, build reputation among peers, and convey their professional benefits [1]. However, scholars frequently encounter disputes concerning authorship, with the qualification and order of authorship remaining the main controversial issues in most collaborative work worldwide [2]. In other words, most dissents involve "Who are the authors, who should be acknowledged, and what should the order of the authors be in a given manuscript?" Numerous types of authorship abuses are considered scientific misconduct, with coercion (ie, intimidation tactics to gain authorship), guest, mutual support, ghost, and denial of authorship being the most frequent ones [3].

To address these issues, the International Committee of Medical Journal Editors (ICMJE) [4] established authorship guidelines including items related to study conception, execution, and documentation, which are adopted by many prominent institutions and journals worldwide [5]. While providing specific definitions regarding the roles of individual authors, the ICMJE guidelines do not allow a quantitative objectifiable assessment of individual author contributions within a body of authors, and disputes regarding authorship and the order of appearance frequently remain [6,7].

With the interest of promoting the highest ethics in medical and science publications, the aim of this project was to develop a user-friendly, open access, web-based software platform for the objective assessment of authorship qualification and order, in an attempt to reduce and hopefully eliminate authorship disputes.

Methods

Study Design

The design science research methodology was used to develop a suitable software for achieving our objective, as previously described [8]. Briefly, this is an established set of analytical techniques for performing research in information systems, involving the design of innovative products. The design science research methodology typically involves the problem identification, solution design, and evaluation phases [9].

Settings, Developers, and Collaborators

The software was designed by DAR located in Switzerland and developed together with AR located in Athens, Greece, starting on May 7, 2016. A group of collaborators worldwide contributed in the design, development, and evaluation of the software, and were selected based on personal contacts and through personal interest, with a full list of names available in the Acknowledgments and on Authorships.org. A subset of 18 of these collaborators were selected for formal software evaluation as described below, with eligibility for selection being a scientific background in medicine or other biomedical areas, regardless of the grade. The characteristics of the collaborators who formally evaluated the software can be found in Table 1. The overall software design and development duration was from May 2016 to December 2019. The software evaluation took place between March and October 2016, with the headquarters of software evaluation located in Zurich, Switzerland.

Table 1. Characteristics of the collaborators formally evaluating the software.

Software Design and Development

The free web-based software is built on Drupal version 7 [10], an open-source content management system written in PHP and distributed under the GNU General Public License [11], as previously described [8]. An Apache server with a MySQL database was used [12]. The most advanced firewalls were installed for monitoring and prevention of malware. The costs for the server rental, domain name purchase, and software development were set at 2160 CHF (US $2332). These costs were successfully covered through a Kickstarter campaign by the collaborators on April 4, 2016 [13]. The website and software compatibility for different platforms, internet browsers, and devices were assessed using BrowserStack [14].

The first part of the software design focused on identifying and differentiating individuals whose work qualifies them as authors as opposed to contributors for acknowledgment. Items of the International Committee of "Medical Journal Editors Uniform Requirements for Manuscripts Submitted to Biomedical Journals," including conception, execution, and documentation of research, were used to design the first part of the software (Figure 1) [4].

The second part was designed to address the order of the qualifying authors using the analytical hierarchy process (AHP) method for objective multiple criteria decision-making and ranking [15]. Briefly, the AHP first decomposes the decision-making problem into a hierarchy of subproblems. Then, the relative weight of importance of the different criteria is assessed by pairwise comparisons. These weights are then used to calculate a score for each selection alternative. Information is decomposed into a hierarchy of alternatives, and criteria information is then synthesized to determine the relative ranking of alternatives. Both qualitative and quantitative information can be compared using informed judgements to derive weights and priorities. The consistency index measures the extent to which the decision-makers were consistent in their responses (Figure 2) [16].

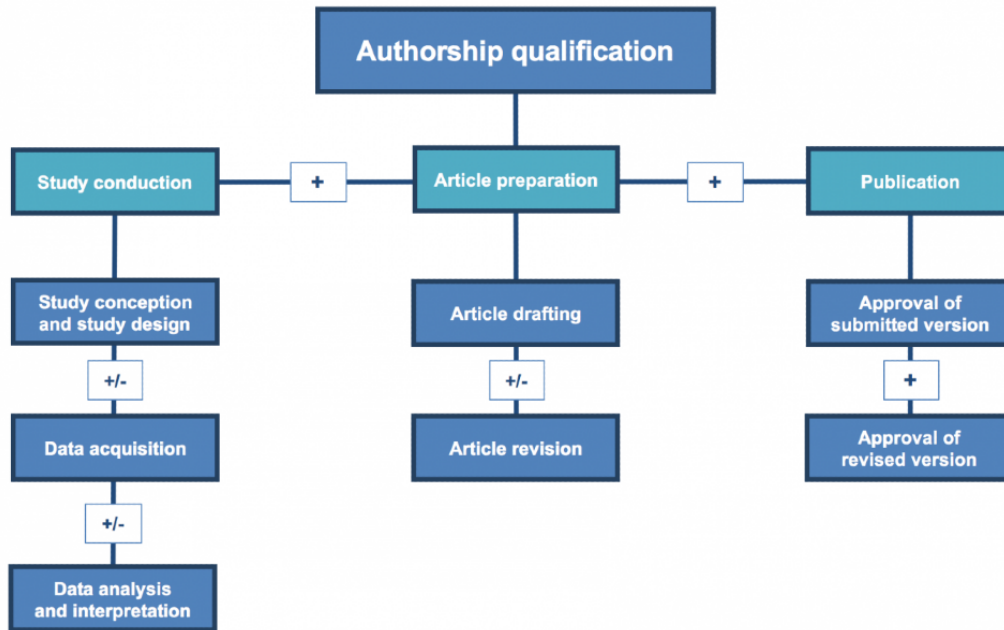
Figure 1. Qualification for authorship versus acknowledgment.


Figure 2. Analytical hierarchy process method for multiple comparisons and ranking of authors' contributions.
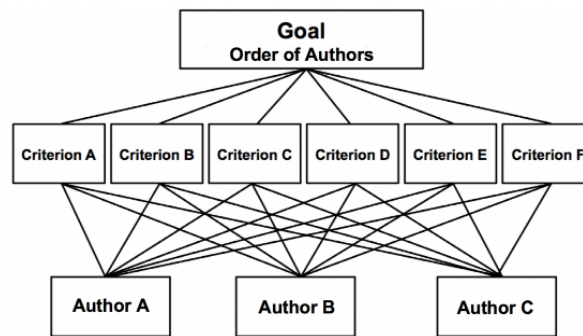

Software Evaluation

The software was evaluated and re-evaluated during the design phase as described above. At the end of software development, 18 collaborators (Table 1) assessed software usability and output in 3 existing clinical and biomedical research projects. The collaborators were chosen from the international panel of medical and biomedical professionals, based on the availability of a current research manuscript ready for submission and willingness to apply Authorships.org to evaluate their choice and order of authors. Collaborators were further asked to complete an online questionnaire (Multimedia Appendix 1). The evaluation questionnaire was designed by the authors, focusing on assessing the collaborator's attributes regarding authorship disputes, software functionality and usability, and the need for improvements [17]. Descriptive statistics were used to report results using rBiostatistics [18].

Results

Software Design

The developed software, named Authorships.org [19], is freely available online and is compatible with all major platforms, web browsers, and mobile or tablet devices [14]. Authorships.org performs server-side calculations and graphical rendering, which eliminates any hardware requirements or incompatibilities at the user side.

First, the user is requested to add the number and names of the individuals who participated in a particular research project. Next, their contribution to the work is assessed based on the generally agreed upon ICMJE criteria, such as conception, execution, documentation, and final approval for publication (Figure 3) [4]. The user is also given the choice to give equal or different weights to these criteria, in order to respect local norms at different institutions worldwide.

Based on the existing ICMJE guidelines, the software then indicates which individuals qualify for formal authorship versus for acknowledgment as a contributor. The user is subsequently asked to indicate a senior/last author of the manuscript, if required (Figure 4).

In the second part, the user assesses the extent of the individual contributions of all qualifying authors, except the one defined as senior/last author. A ranking of each author's extent of contribution to each ICMJE criterion is performed by using the AHP multiple comparisons method. Thereby, each author is compared to each other author in pairwise comparisons, using a decision matrix for ranking of the extent of contribution (Figure 5).

After all pairwise comparisons are made, a consistency ratio is provided to the user to ensure the input data are consistent and logical (Figure 6). This ratio should typically be below 0.10; however, values as high as 0.30 are acceptable, especially when large numbers of authors and their contributions are being assessed [15]. In case of severe inconsistency, the user is required to repeat the evaluation steps of the second part, ensuring comparisons are meaningful (eg, A > B, B > C, A > C).

Based on these quantitative and objective evaluations, the software defines the appropriate order of author appearance in a publication at a medical or science journal (Figure 7).

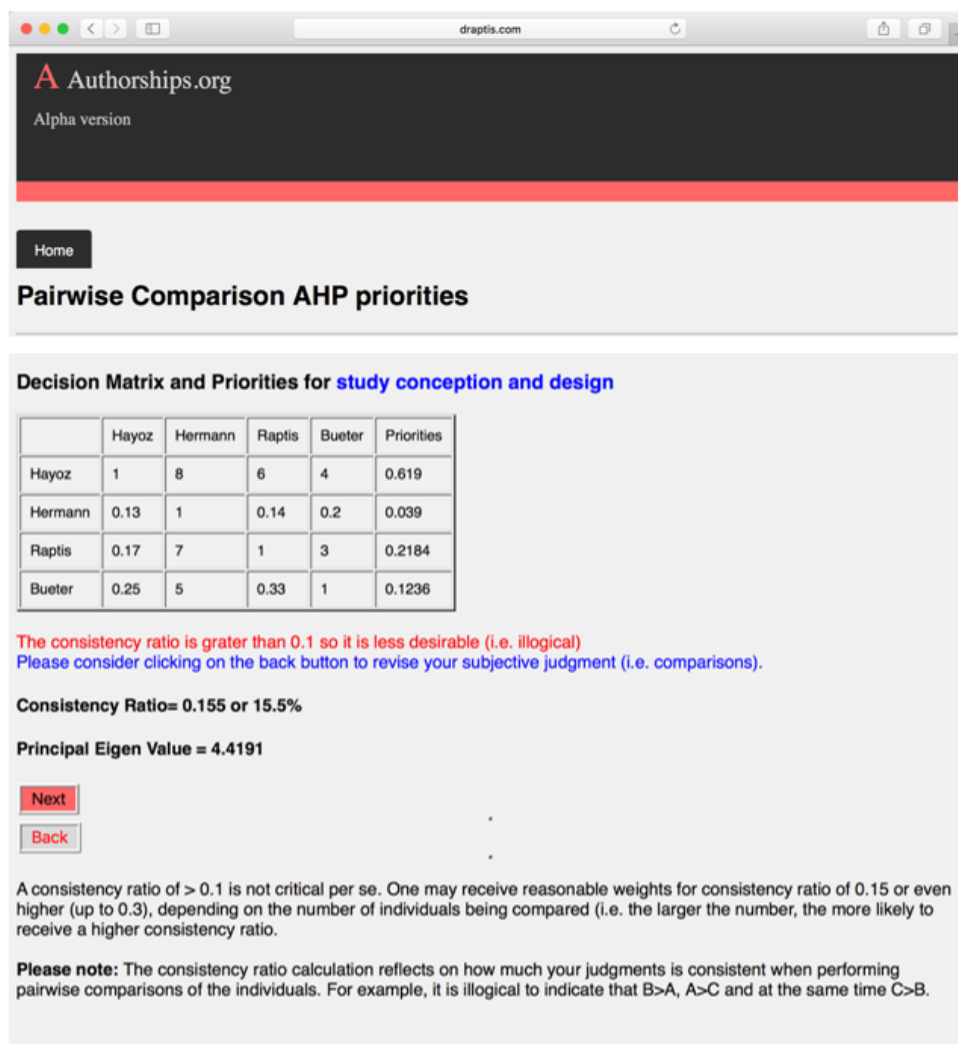

Figure 7. Software output on final author contribution ranking.
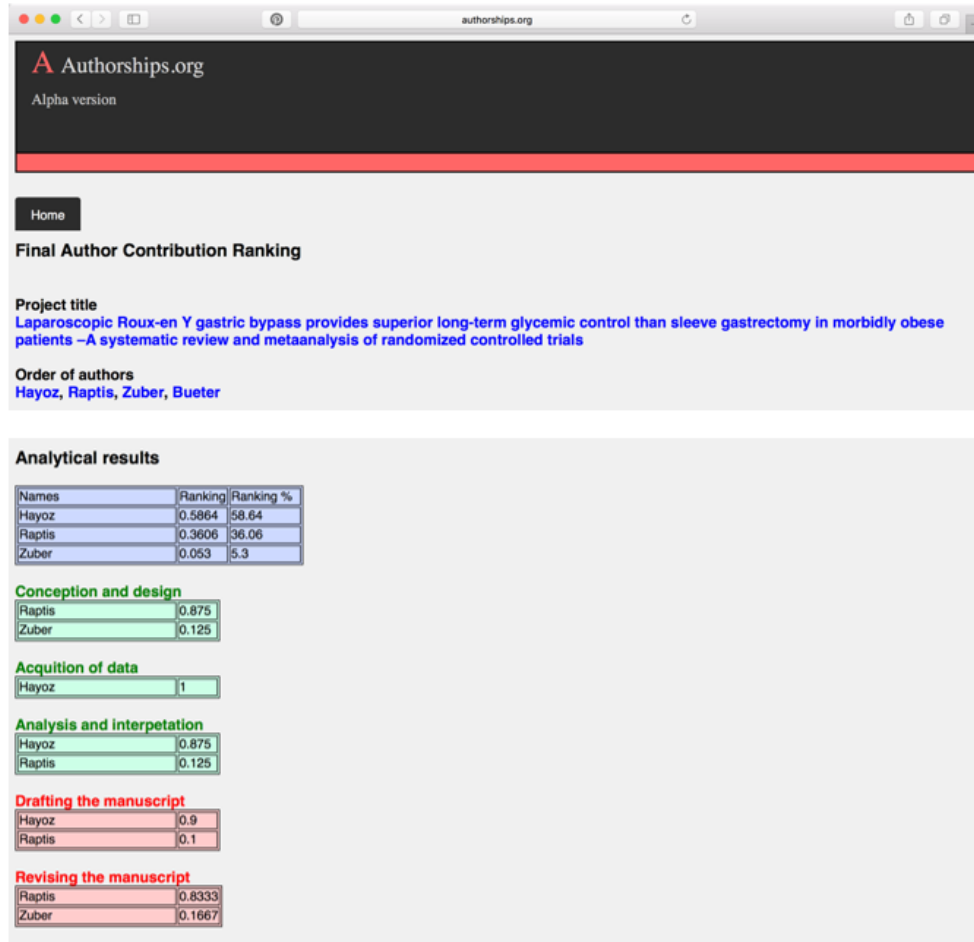

Software Evaluation

Questionnaire

Eighteen international collaborators evaluated the software using the specially designed questionnaire. Of these, 88% (n=15) felt that the software was easy to use, while 12% (n=3) remained neutral. Additionally, 59% (n=10) were satisfied with the software output results, feeling that it objectively reflects reality, while 35% (n=6) were unsure and 6% (n=1) were dissatisfied. The reason stated for dissatisfaction was that the collaborator felt "one very important contribution (ie, outstanding critical manuscript revision) may be sufficient to qualify for authorship;" however, authors with such contributions were disqualified when using Authorships.org. Fifty-nine percent (n=10) stated they would definitively use the software in future projects, while 41% (n=7) would potentially consider it. Moreover, 94% (n=16) felt that it may prove useful to eliminate disputes regarding authorship, and 82% (n=14) felt that it should become mandatory for manuscript submission to journals. Fifty-three percent (n=9) raised concerns regarding potential unethical use of the software as a tool for authorship evaluation. Reasons given were concerns that Authorships.org may represent one more tool to "justify" unethical authorship behavior. The quantitative results are summarized in Figure 8.

Figure 8. Results from the software evaluation questionnaire survey.
Case Study 1

In an attempt to objectify authorship disputes, 6 collaborators contributing to a clinical study were asked to provide the authors' order and reasoning behind it for a manuscript not yet submitted. The results of this survey were analyzed in a particular form developed at Authorships.org. Although they all agreed 100% regarding the authorship qualification of all 6 collaborators, a 0% total agreement on the order of author appearance was noted (Fleiss kappa: –0.10, 95% CI –0.18 to –0.01). In retrospect, the authors felt that the main reasons for this discordance were misconceptions on the amount of work conducted by their colleagues, lack of adherence to the "International Committee of Medical Journal Editors" recommendations, and some form of bias. Authorships.org was then applied to review the authorship order, yielding complete agreement of the collaborators. The collaborators felt that the platform was a transparent and objective tool for assigning authorship order, and justified the use of Authorships.org for their work.

Case Study 2

Seven authors of a biomedical engineering manuscript based on clinical and medical imaging data were asked to provide the order of the authors for the paper they all contributed. All authors agreed on their own qualification for authorship, and 2 (28%) authors agreed about the collaborator order for the manuscript. Authorships.org was used to assess author qualification and the order of authorship. Thereafter, 5 out of

the 7 authors justified the use of Authorships.org and thought that it is a robust and objective tool to assign the order of authors. The reason for the disagreement of the remaining 2 authors was a feeling that Authorships.org did not sufficiently acknowledge the seniority level of individual authors. They further disagreed to the design that authors should fulfil at least one green item, one red item, and the blue item to qualify for authorship in Autorship.org (based on the ICMJE recommendations) (Figure 3).

Case Study 3

Eight members of an international research group conducted a systematic review and meta-analysis regarding the use of comprehensive enhanced recovery protocols in the setting of liver transplantation. Individual tasks included study design and methodology, screening of titles and abstracts of studies identified in the literature search, data extraction and analysis of selected works, manuscript writing, and critical review. Authorships.org was applied after drafting the manuscript and before submission to a peer-reviewed scientific journal. The objective author qualification and order were applied directly in the manuscript as suggested by the software output and accepted by all authors.

Discussion

This study reports on the development and evaluation of a novel software tool for the objective assessment of authorship qualification and order, in an attempt to reduce authorship

disputes. To the best of our knowledge, Authorships.org represents the first open-access web-based software to quantitatively and thus objectively indicate the qualification and order of academic authorship in medical and science journals.

The majority of collaborators assessing the usability of Authorships.org found the software helpful and easy to use, and felt that the software could have a high impact in the scientific community in a short period of time. The concerns of the remaining collaborators regarding software output results focused on the criteria required for authorship qualification and therefore on the internationally accepted ICMJE criteria applied in the proposed software algorithm. While the qualification for authorship has been standardized in the ICMJE criteria [4], varying approaches of determining the order of authorship are currently applied across scientific disciplines, research groups, and countries. Examples of authorship policies include descending order of contribution, placing the person who took the lead in writing the manuscript or performing main research tasks first and the most experienced contributor last, or using an alphabetical or random order [1,20,21]. While the significance of a particular order may be understood in a given setting, the order of authorship is not generally agreed upon [22]. Attempts to reduce inaccuracies in author lists include models similar to the film credit concept, with mandatory contribution statements replacing the author's list, such as Credit Taxonomy [23]. However, these could lead to a shift in importance from the authors who actually produced the science to a more confounding way of giving credit to each research co-operator. Autorships.org not only represents a quantifiable and thus objectifiable approach, but also could provide a solution for the correct interpretation of the respective contributions of individual authors. Since the indication of specific author contributions has become mandatory in most scientific journals with a mid to high impact factor [22], the submission of a separate document objectifying the assessment of author qualification and contributions, such as provided by Authorships.org, may become obligatory in the future. To this end, Authorships.org must be formally validated in future projects worldwide, including a randomized controlled study comparing the levels of disputes.

One main hypothetical advantage obtained by the implementation of an objective instrument in academic authorship, as presented herein, is a reduction in the number of disputes. Academic authorship of papers arising from complex research projects, involving multiple centers and with potential valuable impact on the scientific community, can nowadays be considered as a currency for career development. These scenarios represent feeding terrains for conflicts between authors, which can sometimes even result in the retraction of a manuscript from publication or, if remaining unresolved due to failed mediation among authors, in rejection by the journal. Another known issue is the abuse of power exerted by certain authors inflicting the order of authors in their own interest, which can be avoided by using an objectifiable tool such as Authorships.org. We believe that the most reasonable attempt to resolve such disputes is undertaken primarily among the authors themselves, and in case of failure to compromise, the

disputes are taken up by the authors' affiliating institutions. Moreover, Authorships.org allows authors to evaluate the extent of contribution provided by each author to individual phases of manuscript preparation, representing the main advantage of using the AHP over other ranking models. Another main advantage of the proposed algorithm is the possibility to "customize" the relevance of each area of performance according to the contributors' previous agreement or the institution's internal guidelines. The use of the software could prompt a prearranged settlement and, consequently, help the team working on the project on the basis of mutually approved rules (eg, first authorship for a PhD candidate or last authorship for professorship title). This further allows maintaining the "motivating" aspect of a researcher to perform at her/his highest level when aiming to keep a certain position within the authorship list. Most of the collaborators evaluating the software further felt that the added consistency ratio supported them in reflecting their own contributions to a project in a quantitative way. A progressive improvement in consistency ratio values with increasing use of the software is further expected, as a result of ongoing education on the use of a mathematical way to evaluate each participant's contribution.

An important aspect of the Authorships.org design is the time point of the assessment of the qualification and order of authorship. While in many research groups worldwide, author roles are defined *prior to* the start of a research project, Authorships.org was deliberately designed to be applied *after* the execution and writing of a manuscript but before submission to a scientific journal, preferably in a discussion by all contributing members of the research team [1]. Hence, authorship qualification and order reflect the actual tasks performed by each individual rather than preset rigid orders potentially prone to abuse. It is essential to note that if not applied at the correct time point, Authorships.org may not be beneficial or, if abused, may even lead to erroneous results, which might represent a limitation to the current methodology. A further potential conflict of the proposed software is the option to change the weight of assessment for different parameters, which may increase the possibility of manipulation of weights toward personal interests. This was added to address the different needs across scientific fields. For example, in clinical research, more weight might be placed on the researcher who wrote the manuscript, whereas in basic science, more weight might be placed on the researcher performing the laboratory work. In general, we recommend giving equal weight to all assessment parameters. The acknowledgment of the seniority level of individual authors has been raised as a critical point by several collaborators evaluating Authorships.org. The software was designed such that 1 senior/last author could be specifically chosen based on her/his a priori qualification as the senior project leader. This was deliberately limited to 1 person to avoid multiple senior authors being listed for "political" reasons, acknowledging internal hierarchical structures rather actual contributions to a scientific work. While abusive authorship selections may still remain when using Authorships.org, the use of the proposed software has the potential to make such conflicts more transparent, raise awareness among authors, and therefore contribute to open discussions about conflicts in authorship contributions. Finally, views of the authorship disputes and

attributes, as evaluated by the collaborators, might not reflect generalizable views across researchers. However, with the selected collaborators originating from countries across the world and from varying areas of science, this potential selection bias might have been alleviated.

In conclusion, Authorships.org represents a novel approach to quantify and objectify the qualification and order of authorship in academic literature. It may become a mandatory tool for objectified proof of author contributions in scientific publications. Further randomized studies are needed to validate the potential of using such a tool for reducing or eliminating authorship disputes.

Abstract

Background: At the very beginning of the COVID-19 pandemic, information about fear of COVID-19 was very limited in Chinese populations, and there was no standardized and validated scale to measure the fear associated with the pandemic.

Objective: This cross-sectional study aimed to adapt and validate a fear scale to determine the levels of fear of COVID-19 among the general population in mainland China and Hong Kong.

Methods: A web-based questionnaire platform was developed for data collection; the study instruments were an adapted version of the 8-item Breast Cancer Fear Scale ("Fear Scale") and the 4-item Patient Health Questionnaire. The internal construct validity, convergent validity, known group validity, and reliability of the adapted Fear Scale were assessed, and descriptive statistics were used to summarize the participants' fear levels.

Results: A total of 2822 study participants aged 18 years or older were included in the analysis. The reliability of the adapted scale was satisfactory, with a Cronbach α coefficient of .93. The item-total correlations corrected for overlap were >0.4, confirming their internal construct validity. Regarding convergent validity, a small-to-moderate correlation between the Fear Scale and the 4-item Patient Health Questionnaire scores was found. Regarding known group validity, we found that the study participants who were recruited from Hong Kong had a higher level of fear than the study participants from mainland China. Older adults had a higher level of fear compared with younger adults. Furthermore, having hypertension, liver disease, heart disease, cancer, anxiety, and insomnia were associated with a higher fear level. The descriptive analysis found that more than 40% of the study participants reported that the thought of COVID-19 scared them. About one-third of the study participants reported that when they thought about COVID-19, they felt nervous, uneasy, and depressed.

Conclusions: The psychometric properties of the adapted Fear Scale are acceptable to measure the fear of COVID-19 among Chinese people. Our study stresses the need for more psychosocial support and care to help this population cope with their fears during the pandemic.

Introduction

In December 2019, the novel coronavirus disease 2019 (COVID-19) emerged in Wuhan City, China [1]. The outbreak rapidly evolved into a global pandemic [2], affecting more than 190 countries and regions [3]. The COVID-19 pandemic continues to spread on a global scale. As of December 20, 2021, there have been more than 271 million confirmed cases of COVID-19 worldwide, with more than 5 million deaths [4]. The COVID-19 pandemic has lasted for almost 2 years and is still ongoing. With time, an increasing number of COVID-19 variants was reported globally [5].

COVID-19 is not only life-threatening, but it also leads to psychological distress [6-10]. The concomitant public health measures such as quarantines, social distancing, and lockdowns can also increase psychosocial distress. Since the start of the COVID-19 pandemic, a plethora of research studies have been conducted to examine the psychological status of people during the pandemic. A meta-analysis of 55 peer-reviewed studies found that the prevalence of depression was 16%, the prevalence of anxiety was 15%, the prevalence of insomnia was 24%, and the prevalence of posttraumatic stress disorder was 22% [11]. Another meta-analysis of the prevalence of stress, anxiety, and depression among the general population during the COVID-19 pandemic found that the prevalence of stress was 29.6%, that of anxiety was 32%, and that of depression 34% [12]. Moreover, compared with studies conducted in Europe, those conducted in Asia found a higher prevalence of anxiety (Asia 33% vs Europe 24%) and depression (Asia 35% vs Europe 32%) [12]. These studies suggest that the pandemic substantially jeopardizes the psychological well-being of the general population [11,12].

In addition to anxiety, depression, and stress, fear is also a common psychological response to COVID-19 [13]. In brief, fear is an adaptive emotion that helps defend against potential danger [14]. Fear may occur in response to specific stimuli in the present environment or in anticipation of future or imagined situations that pose a threat to oneself [15]. During the COVID-19 pandemic, people may experience the fear of contracting the infection and a feeling of uncertainty. Fear can be beneficial because it can motivate people to engage in preventive behaviors, such as hand hygiene and mask wearing [16]. However, excessive fear can be maladaptive, leading to psychological distress. For example, fear of COVID-19 may exacerbate preexisting mental health and psychiatric conditions [17]. In extreme situations, fear may lead to suicidal ideation [18]. Excessive fear can cause irrational behaviors, such as panic buying [19].

It is noteworthy that the COVID-19 pandemic has reignited the fear resulting from the 2003 severe acute respiratory syndrome outbreak for many people in mainland China and Hong Kong. This adverse experience was unique to those populations. The fear levels of people in mainland China and Hong Kong may therefore be different from those in populations that did not undergo that adverse experience. Assessing and managing fear is a crucial component of outbreak control and health promotion [20].

In this study, the 8-item Breast Cancer Fear Scale developed by Champion et al [21] was used. We chose this instrument to measure fear levels for several reasons. First, at the very beginning of the pandemic, there was no standardized and validated study instrument specifically developed to measure fear levels related to COVID-19. For example, the Fear of COVID-19 Scale developed by Ahorsu and colleagues [13] was not available when we planned this study. Second, the 8-item Breast Cancer Fear Scale ("Fear Scale") was one of the few instruments available to measure fear among the Hong Kong Chinese population [22]. Furthermore, even though the Fear Scale was originally developed to measure fear related to breast cancer, the question items are generic and comprehensive. The Fear Scale covers common responses to fear such as feeling scared, nervous, upset, depressed, jittery, uneasy, and anxious, as well as having heart palpitations. According to a study in Canada, many participants felt uneasy, distressed, anxious, and nervous due to the COVID-19 pandemic [23]. A study in Slovakia reported an overall increase in negative feeling such as feeling upset, scared, and afraid during the COVID-19 pandemic [24,25]. The items of the Fear Scale should be applicable and appropriate to measure the fear related to COVID-19.

This study aimed to adapt and validate the Fear Scale to determine the levels of fear of COVID-19 in mainland China and Hong Kong. With the information on how an individual fears COVID-19, health care providers can design appropriate psychosocial interventions to meet the public's needs.

Methods

Study Design, Participants, and Sampling

An international study was conducted, which aimed to examine the global impact of the COVID-19 pandemic on lifestyle behaviors, fear, depression, and perceived needs of communities [26,27]. The study was conducted in 30 countries across the globe. It is a cross-sectional web-based survey design. Moreover, a web-based questionnaire platform was developed for data collection [28].

For this analysis, only data collected in mainland China and Hong Kong between July 2020 and January 2021 were used. Study eligibility criteria included (1) aged ≥18 years; (2) being able to read and understand Chinese; and (3) having an internet access. To recruit more people with diverse sociodemographic backgrounds, multiple recruitment strategies were used to recruit study participants. The study participants were recruited by survey service providers, social media platforms such as Facebook, WeChat, and Twitter, and snowball sampling, in which the existing study participants helped to recruit additional participants to join this study. To encourage more people to complete the survey, for each completed questionnaire, HK $1 (US $0.13) would be donated to the Red Cross in the respondent's region.

The study protocol has been published elsewhere [26]. The study was approved by the institutional review board of the University of Hong Kong/Hospital Authority Hong Kong West Cluster (reference UW 20-272). All the procedures involving

human participants in this study were conducted in accordance with the ethical standards of the institutional review board and the 1964 Declaration of Helsinki and its later amendments. Electronic informed consent was obtained from each study participant.

Outcomes and Instruments

The primary outcome of the study was the fear of COVID-19. To measure the fear of COVID-19, we adapted the 8-item Breast Cancer Fear Scale developed by Champion et al [21] for this study. The study instrument was originally developed to measure women's emotional responses to breast cancer. In the scale developed by Champion et al [21], a 5-point Likert scale is used (1=strongly disagree, 2=disagree, 3=neutral, 4=agree, and 5=strongly agree); a higher score indicates a higher level of fear. The total score of the instrument is the sum of each item. In this paper, we changed the words "breast cancer" to "COVID-19" in all of the following 8 items: (1) the thought of COVID-19 scares me; (2) when I think about COVID-19, I feel nervous; (3) when I think about COVID-19, I get upset; (4) when I think about COVID-19, I get depressed; (5) when I think about COVID-19, I get jittery; (6) when I think about COVID-19, my heart beats faster; (7) when I think about COVID-19, I feel uneasy; and (8) when I think about COVID-19, I feel anxious.

The face validity of the adapted instrument was evaluated by an expert panel of this study.

The 4-item Patient Health Questionnaire (PHQ-4), which measures anxiety and depressive symptoms, was administered to evaluate the convergent validity of the Fear Scale. The PHQ-4 includes the 2-item Generalized Anxiety Disorder scale and the 2-item Patient Health Questionnaire (PHQ-2). A 4-point Likert scale is used (0=not at all; 1=several days; 2=more than half the days; and 3=nearly every day). The summary score of the PHQ-4 ranges from 0 to 12, with a higher score indicating greater anxiety and depressive symptoms. The PHQ-4 was validated in Chinese adults [29]. The study supported its 2-factor model and reliability [29]. Cronbach α coefficient was .87 for the PHQ-4, .80 for the 2-item Generalized Anxiety Disorder, and .80 for the PHQ-2 in this study.

A structured questionnaire was used to collect sociodemographic factors such as age, gender, and comorbidities.

Data Analysis

The internal construct validity, convergent validity, known group validity, and reliability of the Fear Scale were assessed. The internal construct validity was evaluated using the corrected item-total correlation; a correlation coefficient of ≥0.4 indicated adequate internal construct validity. The convergent validity of the Fear Scale was determined by calculating the Pearson correlation coefficient between the total score of the Fear Scale and the total score of the PHQ-4. It was hypothesized that an absolute value Pearson correlation coefficient of at least 0.3 was required [30]. To evaluate the known group validity, independent t tests were used to compare the mean score of the Fear Scale between (1) people recruited from mainland China and people recruited from Hong Kong [31]; (2) people aged 18-59 years and people aged 60 years or older [15]; and (3) male and female participants [32]. A study among Chinese university students reported that students in mainland China had lower fear of instability related to the COVID-19 pandemic when compared with students in Hong Kong [31]. Another study among pregnant women and new mothers reported that compared with the study participants in mainland China, the level of fear related to the COVID-19 pandemic was significantly higher among study participants in Hong Kong [33]. A study in Singapore found that older age was associated with greater fear of COVID-19 [15]. Another study in the Spanish population found that fear was higher among women than among men [32]. Besides, a study in Turkey reported that the COVID-19 fear scores were higher among people with a chronic disease [34]. Therefore, we also compared the mean score of the Fear Scale between people with and without the following chronic diseases, which were highly prevalent in Chinese populations: (1) hypertension; (2) diabetes; (3) liver disease; (4) heart disease; (5) stroke; (6) chronic obstructive pulmonary disease; (7) cancer; (8) depression; (9) anxiety; and (10) insomnia. Cohen d effect sizes were also calculated. The interpretation of the effect sizes was as follows: trivial (<0.2), small (≥0.2 to <0.5), moderate (≥0.5 to <0.8) and large (≥0.8). Finally, descriptive statistics were used to describe the fear levels of the study participants. Furthermore, multiple linear regression analysis was used to explore the known associations between sociodemographic and clinical factors, on the one hand, and the Fear Scale, on the other.

Results

Participants' Characteristics

A total of 2822 study participants aged 18 years or older were included in the analysis, of whom 61% (n=1721) were female and 38.8% (n=1096) were male. Three-quarters, 75.6% (n=2133), were recruited from Hong Kong while 24.4% (n=689) were recruited from mainland China. Almost half (1450, 51.4%) of the participants were married. Hypertension (294, 10.4%) was the most prevalent reported chronic disease, followed by diabetes (155, 5.5%), insomnia (90, 3.2%) and heart disease (62, 2.2%). Table 1 shows the participants' characteristics of the study.

Table 1. Sociodemographic and clinical profile (N=2822).

Characteristics	Values, n (%)
Geographical areas	
China	689 (24.4)
Hong Kong	2133 (75.6)

Insomnia	90 (3.2)
Depression	43 (1.5)
Anxiety	44 (1.6)

Reliability and Validity of the Fear Scale

The mean score of the Fear Scale was 23.60 (SD 6.64), and the Cronbach α coefficient was .93. The corrected item-total correlations were >0.7 for all items. Table 2 shows the results of the internal consistency and internal construct validity. The Pearson correlation coefficient between the Fear Scale and PHQ-4 scores was 0.23 (P<.001). Table 3 shows the results of the convergent validity.

Table 2. Descriptive statistics, internal construct validity, and reliability of the Fear Scale (N=2822).

	Corrected item-total correlation (n=2821)	Mean (SD)[a]	Strongly disagree, n (%)	Disagree, n (%)	Neutral, n (%)	Agree, n (%)	Strongly agree, n (%)	Missing, n (%)
The thought of COVID-19 scares me	0.71	3.27 (0.98)	151 (5.4)	451 (16)	890 (31.5)	1145 (40.6)	185 (6.6)	N/A[b]
When I think about COVID-19, I feel nervous	0.73	3.11 (0.99)	187 (6.6)	527 (18.7)	1076 (38.1)	862 (30.6)	170 (6)	N/A
When I think about COVID-19, I get upset	0.75	2.99 (1.02)	225 (8)	642 (22.8)	1083 (38.4)	694 (24.6)	178 (6.3)	N/A
When I think about COVID-19, I get depressed	0.80	2.99 (1.03)	235 (8.3)	656 (23.3)	1007 (35.7)	760 (26.9)	163 (5.8)	1 (0.04)
When I think about COVID-19, I get jittery	0.71	2.63 (1.04)	449 (15.9)	810 (28.7)	992 (35.2)	480 (17)	91 (3.2)	N/A
When I think about COVID-19, my heart beats faster	0.70	2.64 (1.04)	426 (15.1)	823 (29.2)	1006 (35.6)	463 (16.4)	104 (3.7)	N/A
When I think about COVID-19, I feel uneasy	0.78	3.03 (1.04)	256 (9.1)	560 (19.8)	1003 (35.5)	854 (30.3)	149 (5.3)	N/A
When I think about COVID-19, I feel anxious	0.80	2.95 (1.03)	279 (9.9)	585 (20.7)	1101 (39)	719 (25.5)	138 (4.9)	N/A
Cronbach alpha	0.93	N/A	N/A	N/A	N/A	N/A	N/A	N/A

[a]A higher score means a higher level of fear.

[b]N/A: not applicable.

Table 3. Convergent validity of the Fear Scale (N=2822).

Scale	Population, n	Mean (SD)[a]	Pearson correlation coefficient	P value
PHQ-4[b] anxiety subscale or GAD-2[c]	2822	1.22 (1.26)	—[d]	—
PHQ-4 depression subscale or PHQ-2[e]	2821	1.10 (1.30)	—	—
PHQ-4 total score	2821	2.32 (2.37)	—	—
Fear Scale total score	2821	23.60 (6.64)	—	—
PHQ-4 anxiety subscale or GAD-2	2821	—	0.25	<.001
PHQ-4 depression subscale PHQ-2	2820	—	0.19	<.001
PHQ-4 total score	2820	—	0.23	<.001

[a]A higher score means a higher level of fear or anxiety or depression.

[b]PHQ-4: 4-item Patient Health Questionnaire.

[c]GAD-2: two-item Generalized Anxiety Disorder scale.

[d]Not available.

[e]PHQ-2: 2-item Patient Health Questionnaire.

With respect to the known group comparisons, the results of the independent t tests showed that the study participants who were recruited from Hong Kong had a higher level of fear compared with the study participants from mainland China (Cohen d effect size 0.24). Furthermore, older adults (60 years or above) had a higher level of fear than younger adults (Cohen d effect size 0.39). Study participants with cancer (Cohen d effect size 0.58), heart disease (Cohen d effect size 0.44), hypertension (Cohen d effect size 0.36), liver disease (Cohen d effect size 0.33), insomnia (Cohen d effect size 0.33), and anxiety (Cohen d effect size 0.28) had a higher level of fear than those without such conditions. Table 4 and Table 5 show the results of the known group comparisons by independent t test.

The results of multiple linear regression are shown in the Multimedia Appendix 1.

Table 4. Known group comparison: sociodemographic factors (N=2822).

Sociodemographic factors	n (%)	Fear Scale, mean (SD)	P value	Cohen d effect size
Location			<.001	0.24
Mainland China	688 (24.4)	22.40 (6.49)		
Hong Kong	2133 (75.6)	23.98 (6.64)		
Gender			.80	0.01
Female	1720 (60.9)	23.58 (6.60)		
Male	1096 (38.8)	23.64 (6.69)		
Age (years)			<.001	0.39
18-59	2546 (90.2)	23.34 (6.56)		
≥60	275 (9.7)	25.98 (6.86)		

Table 5. Known group comparison: clinical factors (N=2822).

The Fear Levels of the Study Participants

In total, 47.1% (n=1330) of the participants reported that the thought of COVID-19 scared them. Moreover, 36.6% (n=1032) of the study participants reported that they felt nervous when they thought about COVID-19. About one-third of the participants reported that they felt uneasy (1003, 35.5%) and became depressed (923, 32.7%) when they thought about COVID-19. The descriptive statistics of the Fear Scale are shown in Table 2.

We also separated the analysis between data collected in Hong Kong and those collected in China. Those results are shown in Multimedia Appendix 1.

Discussion

Principal Results

In the first part of this study, we assessed the psychometric properties in terms of internal construct validity, convergent validity, known group validity, and reliability of the Fear Scale. The Cronbach α coefficient was .93, which is far larger than the recommended cut-off value of .7. This finding supports the general agreement between the 8 items that make up the composite score of the scale to measure the fear related to COVID-19. Moreover, we found that all the coefficients of the item-total correlation, corrected for overlaps, were larger than 0.4, supporting the internal construct validity of the modified scale. These results supported the suggestion that all individual items measured the same construct as that measured by the other items. With regards to the study's convergent validity, we found a small-to-moderate correlation between the total score of the Fear Scale and the total score of the PHQ-4. Another important finding of this study was that participants with a chronic disease had a higher fear level than those without a chronic disease. Particularly, we found that hypertension, liver disease, heart disease, cancer, anxiety, and insomnia were associated with a higher fear level.

Limitations

There were some limitations in this study. First, the study was conducted in mainland China and Hong Kong. Therefore, the study findings may not be transferable to other geographic areas in which the severity of COVID-19, case fatality rate, and infection control measures are different. We expect that the fear level would be even higher in areas where the severity and case fatality rate of COVID-19 were more severe. Second, we could not explore the trajectory of the fear levels over time due to the cross-sectional nature of the study. Third, we adapted the Breast Cancer Fear Scale in this study; thus, some of the constructs related to COVID-19 could not be measured. However, as previously mentioned, there was no validated fear scale specific to COVID-19 when we planned our study. Fourth, regarding the reliability of the scale, we only evaluated its internal consistency. We were not able to evaluate the test-retest reliability of the scale due to the cross-sectional design of the study. Fifth, regarding the known group comparison, the sample size of some subgroups was small such as that of patients with diabetes and depression. There might be insufficient statistical power to detect the differences between groups. Finally, we

used a web-based questionnaire platform to collect the data. People with low computer literacy would probably be excluded from the study. Accordingly, the potential sampling bias should be noted.

Comparisons With Prior Work

We found that the total score of the Fear Scale had a higher correlation with the PHQ-4 anxiety subscale than with the PHQ-4 depression subscale. In fact, there are distinct differences in psychological features between fear and depression. According to Witte [35], fear is conceptualized as negatively toned emotion accompanied by a high level of physiologic arousal stimulated by a threat. Fear can be expressed as a physiological arousal, such as feeling "jittery" and "heart beating faster," through verbal self-reports of fear (eg, "I feel scared") and overt acts that exhibit fear, such as facial expression [21]. These emotional and physiological reactions to perceived threats are fundamentally different from those of depression, which is manifested through the following 4 symptom clusters: (1) emotional symptoms such as feeling sad and worthless; (2) cognitive symptoms such as a negative view of the self and hopelessness; (3) motivational symptoms such as a lack of incentive; and (4) somatic symptoms such as a loss of appetite and sleep disturbances [36,37]. Additionally, it was suggested that fear and anxiety are largely distinct emotions. A meta-analysis reported only a moderate (r=0.32) relationship between measures of trait fear and anxiety [38]. Fear is an aversive psychological state during which an individual is motivated to escape a specific and imminent threat. The characteristics of fear include short-lived arousal that quickly dissipates after the threat is avoided. By contrast, anxiety is an aversive psychological state that occurs while an individual approaches an ambiguous and uncertain threat. Hypervigilance and hyperarousal are the typical behaviors characteristic of anxiety [38]. The small-to-moderate correlation between the Fear Scale and the PHQ-4 further supported the need for this study, which adapted and validated the Fear Scale to measure the fear of COVID-19. Besides, compared with study participants recruited in Hong Kong, those recruited from mainland China had a higher PHQ-4 score but lower Fear Scale total score. This finding further suggested that the constructs of fear and anxiety are different.

Participants with a chronic disease had a higher fear level than those without one. This finding was consistent with that of a matched case-control study, which found that the prevalence of anxiety symptoms and depressive symptoms and the level of stress were significantly higher among those with preexisting chronic health conditions (59%, 71.6%, and 73.7%, respectively) compared with controls (25.6%, 31.1%, and 43.3%, respectively) [39]. Evidence has suggested that the presence of comorbid chronic conditions would increase the risk of death from COVID-19 [40-42]. Moreover, one major concern with the COVID-19 pandemic was its impacts on the routine use of health care services especially for individuals with comorbidities [43]. Service disruptions due to cancellations of elective care and lockdowns hindering access to health care facilities, in addition to the diffidence of patients with a chronic disease in seeking assistance for fear of risking iatrogenic exposure, altogether increased the psychological burden of patients with

a chronic disease. Thus, it was not surprising that people with a chronic disease had a higher fear level than those without.

In this study, more than 40% of the study participants reported that the thought of COVID-19 scared them. About one-third of the study participants reported that when they thought about COVID-19, they felt nervous, uneasy, and depressed. No doubt, the COVID-19 pandemic was very stressful for people and the communities in general [7]; the fear of infection was very common during the pandemic. Furthermore, people were worried that the health care system could not cope with the COVID-19 pandemic, that there were not enough hospital beds and ventilators to handle the rising number of COVID-19 cases. Another concern weighing on people's minds was the COVID-19 recession. Fear of the COVID-19 pandemic can be overwhelming and cause strong emotions [7]. It was also noteworthy that the COVID-19 pandemic rekindled fears of the 2003 severe acute respiratory syndrome epidemic in mainland China and Hong Kong.

Implications

First, based on the psychometric evaluation, we found that the adapted scale was a valid and reliable measure to assess the level of fear related to COVID-19. Further studies can use this scale to longitudinally monitor the fear level in different communities. Second, given the high fear levels found in the study sample, it is required to provide psychosocial care for the general public to diminish the psychological burden of the pandemic. Third, the findings call for the need to provide more psychosocial care for chronic disease patients and older adults.

Conclusion

This study found that the psychometric properties of the Fear Scale were acceptable to evaluate the fear level of the general Chinese population. Our descriptive analysis found that more than 40% of the study participants reported nervousness when they thought about COVID-19. About one-third of the study participants reported that when they thought about COVID-19, they felt nervous, uneasy, and depressed. Additionally, we found that people with a chronic disease reported a higher fear level than those without. The findings call for the need to provide more psychosocial care for chronic disease patients and older adults.

Abstract

Background: Social media has become widely used by individual researchers and professional organizations to translate research evidence into health care practice. Despite its increasing popularity, few social media initiatives consider the theoretical perspectives of how social media works as a knowledge translation strategy to affect research use.

Objective: The purpose of this paper is to propose a conceptual framework to understand how social media works as a knowledge translation strategy for health care providers, policy makers, and patients to inform their health care decision-making.

Methods: We developed this framework using an integrative approach that first involved reviewing 5 long-standing social media initiatives. We then drafted the initial framework using a deductive approach by referring to 5 theories on social media studies and knowledge translation. A total of 58 empirical studies on factors that influenced the use of social media and its messages and strategies for promoting the use of research evidence via social media were further integrated to substantiate and fine-tune our initial framework. Through an iterative process, we developed the Social Media for ImpLementing Evidence (*SMILE*) framework.

Results: The *SMILE* framework has six key constructs: developers, messages and delivery strategies, recipients, context, triggers, and outcomes. For social media to effectively enable recipients to use research evidence in their decision-making, the framework proposes that social media content developers respond to target recipients' needs and context and develop relevant messages and appropriate delivery strategies. The recipients' use of social media messages is influenced by the virtual–technical, individual, organizational, and system contexts and can be activated by three types of triggers: sparks, facilitators, and signals.

Conclusions: The *SMILE* framework maps the factors that are hypothesized to influence the use of social media messages by recipients and offers a heuristic device for social media content developers to create interventions for promoting the use of evidence in health care decision-making. Empirical studies are now needed to test the propositions of this framework.

Introduction

Social Media Use in Health Care

Social media has been extensively used worldwide to communicate health-related information. For example, in China, one-third of the users of the social media platform WeChat—which is widely used for instant messaging and social networking [1]—receive and read health information through the platform [2]. In the United States, 32% of social media users post messages about friends and family members' health experiences on social media [3]. Health care professionals use social media to provide health information and answer medical

questions [4], and patients and caregivers use social media for self-care and health literacy [5]. In health care research, social media platforms such as Twitter, Facebook, and YouTube are increasingly used for participant recruitment, intervention implementation, data mining and collection, and the sharing of research findings [6].

Social media, with its free access, interactive features, and widespread reach, has become increasingly used by individual researchers and professional organizations who wish to translate research evidence into health care practice. For example, the Joanna Briggs Institute (JBI) at Fudan University in China has been using WeChat to disseminate nursing evidence since 2014. In the first 2 years, their WeChat account reached 22,369 followers from 34 provinces in China [7,8]. The Cochrane Child Health groups in Canada and Portugal used social media strategies to disseminate child health evidence to health care providers, and within 6 months of initiating the strategy, their blog received 2555 visitors and 3967 page views, and their Twitter account gained 469 new followers from a geographically diverse population [9]. A social media initiative called *It Doesn't Have to Hurt*, led by health care researchers in Canada, developed a short YouTube video on evidence-based strategies, such as distraction and using topical anesthetics for reducing procedural pain in children. Their video received 237,132 unique views from 182 countries 5 years after its launch, with patients and health care providers reporting strong acceptance and high intention to use the strategies [10]. The number of parents reporting the use of topical anesthetic creams to reduce pain increased from 18% to 63% after watching the video [11].

There has also been a surge in social media initiatives during the COVID-19 pandemic, which are aimed at helping health care professionals, patients, and the public better understand the coronavirus and cope with its impacts. Global evidence synthesis networks such as Cochrane, JBI, and Campbell Collaboration use social media to disseminate rapid review findings related to COVID-19. In China, the Beijing University of Chinese Medicine (BUCM) Cochrane Center, together with 20 evidence-based health care research teams and organizations, launched the *Fighting COVID-19 with Evidence* initiative. They collect urgent clinical questions about COVID-19 diagnosis, treatment, and nursing care through WeChat and share recommendations after a rapid search and synthesis of research evidence [12]. In England, the Center for Evidence-Based Medicine at Oxford University uses Twitter (@CebmOxford) to share COVID-19 relevant recommendations to a global audience. In Canada, the COVID-19 Evidence Network to support Decision-making initiative (@COVID_E_N_D) collects the best available evidence related to COVID-19 and shares this information on Twitter to support decision-making.

Theoretical Understandings of Social Media as a Knowledge Translation Strategy

Despite its popularity, many researchers and organizational decision-makers upload research findings onto social media platforms without deliberately planning how to facilitate its use by recipients in policies, programs, or practices. In their systematic review, Webb et al [13] concluded that theory-based internet interventions had greater impacts on health behaviors

than non–theory-based interventions, with interventions based on the *theory of planned behavior* having larger effects than those based on the *transtheoretical model* or *social cognitive theory*. However, despite these benefits, theoretical frameworks are rarely used to guide the development of social media interventions aimed at facilitating research use. In their systematic review, Arguel et al [14] only identified 15 experimental studies published between 2005 and 2016 that applied theoretical approaches to guide the development of social media interventions.

Ngai et al [15,16] classified 31 theories used in social media studies into three categories: personal behavior theories, social behavior theories, and mass communication theories. Personal behavior theories (eg, the *theory of planned behavior* and *technology acceptance model*) focus on personal factors that affect user behavior on social media. Social behavior theories (eg, *social capital theory* and *social cognitive theory*) identify key social factors that stimulate individuals to participate in collective actions on social media. Mass communication theories (eg, *parasocial interaction theory*) reveal the distinct characteristics of social communications that can assist in the use of social media for communication and marketing [15,16]. These theories provide valuable insights into social media's role in behavior change; however, the following two limitations exist in fully understanding the research use process:

1. They only consider 1 of the 2 latent and indispensable layers of social media use: social media and messages. Recipients must first use social media before they can engage with messages (eg, the *technology acceptance model* emphasizes the platform, and the *social cognitive theory* and *theory of planned behavior* focus on the message). Theories that do not address both layers fail to fully explain the process of research use through social media.
2. They neglect multilevel contextual factors, such as the virtual–technical, organizational, and system contexts, particularly in relation to the features of the social media platform in shaping behavior. This may lead to the development of knowledge translation strategies solely from an individual perspective, without taking into account the contextual determinants that affect recipients' behaviors.

These 2 limitations were partially addressed by Ritterband et al [17], who developed a *behavior change model for internet interventions*, which posited that website use was influenced by support, characteristics of the websites and users, and environmental factors. Behavior change from information on websites is then influenced by various mechanisms (eg, knowledge and motivation). This model has been used to guide the development and evaluation of internet interventions in health care [18,19]. Although not exactly the same, websites that allow for multiway interaction are normally considered to be social media [20,21], and the Ritterband et al [17] model has been used in the social media context [22]. It addresses the limitations of the aforementioned social media theories, as it considers the platform—which in this case is the website—and accounts for the multilayered contexts in shaping behavior, such as personal, professional, and community contexts, as well as the health care system [17]. However, the Ritterband et al model [17] does not make mechanisms of change explicit and presents

a linear process for using the internet to change behavior when real-world practice is often complex [17].

Despite its extensive use for disseminating health care research evidence, social media is rarely used in a well-planned way with end users in mind, which largely limits its potential to bridge evidence–practice gaps and contribute to health care practices. Studies on the use of research evidence through social media are sparse [14]. Large theoretical gaps exist in understanding how social media interventions affect health care practices and decision-making. Unpacking the process by which social media works as a knowledge translation strategy is important to not only advance science but also inform interventions for improving health care practices and patient outcomes.

Objective

The purpose of this paper is to propose a conceptual framework to understand how social media works as a knowledge translation strategy for health care providers, policy makers, and patients to inform their health care decision-making.

Methods

We used a 3-step process based on the approach described by Meleis [23] to develop our conceptual framework. Meleis suggested that practice, theory, and research are important sources for patterning real-world phenomena and informing theory development [23]. Our approach was iterative and flexible and built a preliminary understanding of the process through which social media works for knowledge translation.

To get a sense of how they operate, we first reviewed five long-standing social media initiatives that have a large number of followers: the Fudan University JBI Center Nursing Evidence Dissemination Initiative (ie, Fudan JBI Initiative) [7,8,24], BUCM Cochrane Evidence Dissemination Initiative (ie, BUCM Cochrane Initiative) [25], *It Doesn't Have to Hurt* initiative [10,26], *Be Sweet to Babies* initiative [27], and Translating Evidence in Child Health to Enhance Outcomes (ECHO) program [28]. For each social media initiative, we specifically reviewed the topics and interface of their social media channels (including format and structure of content); the number of readers, followers, and comments; intervals between posts; and the length of videos and papers published relating to each initiative.

Second, we drafted the initial framework using a deductive approach based on existing theories and our team members' expertise in knowledge translation and social media. We primarily drew on five well-known and widely cited theories, frameworks, and models: *integrated Promoting Action on Research Implementation in Health Services (i-PARIHS)* [29]; *capability, opportunity, motivation, and behavior (COM-B)* [30]; *Fogg behavior model* [31]; *theory of innovation diffusion* [32]; and *behavior change model for Internet interventions* [17]. We built the basic structure of our framework based on the *i-PARIHS framework*, which argues that successful knowledge translation relies on the interactions among four constructs: innovation, recipients, context, and facilitation. In addition to the *i-PARIHS* constructs, we added one construct for social media content developers (hereafter referred to as *developers*)

in recognition of the crucial role they play in ensuring that recipients get relevant and appropriate messages. We added the virtual–technical context to the 3-layer contexts described in *i-PARIHS* (ie, local, organizational, and external) to capture the unique features of social media platforms, which is substantiated by the *behavior change model for internet interventions* (described above). We also included three types of knowledge translation outcomes—conceptual, instrumental, and persuasive research use [33,34]—in recognition of the fact that not all evidence on social media was appropriate for practice or behavior change. Rather, we recognize that a large amount of social media evidence affects understanding, attitudes, or collective actions.

The other four theories and models were used to develop two further aspects of our framework: using social media and using the messages. In the first aspect, the four theories and models were employed to understand social media use from two main construct levels: recipients and the virtual–technical context. In the second aspect, derived from the *COM-B model* and the *Fogg behavior model*, we built subconstructs for the active ingredient of message use, named as *trigger* in our framework.

We then reviewed published papers that incorporated the 5 long-standing social media initiatives (described earlier) and used strategies such as citation tracking from the papers we reviewed. The forward citation search was conducted using Google Scholar, and the backward citation search was conducted by screening the reference lists. We also conducted a citation snowballing search using Google Scholar and consulted experts from the 5 social media initiatives and our team members to further locate relevant empirical studies. The studies we identified were primarily about factors that influenced people's use of social media and its messages and strategies for promoting message use. We used the key findings of these studies to substantiate and fine-tune our initial framework. Through an iterative process, we went back and forth from the initial framework to social media initiatives, theories, and empirical studies and developed the Social Media for ImpLementing Evidence (*SMILE*) framework. *Implementation* in the *SMILE* framework refers to instrumental, conceptual, and persuasive knowledge translation.

Results

Overview

Through a review of social media initiatives (n=5), theories (n=5), and empirical studies (n=58), including papers (15/58, 26%) relevant to the 5 social media initiatives [7,8,10,24,26,27,35-43] and papers (43/58, 74%) [9,13,15,44-83] from citation tracking, snowballing, or consultation, we developed the *SMILE* framework (Figure 1). Table 1 summarizes the key constructs and their supporting evidence. The *SMILE* framework provides a preliminary understanding of how social media can be used as a knowledge translation strategy to inform health care practices and decision-making. It has six key constructs: (1) developers, (2) messages and delivery strategies, (3) recipients, (4) context, (5) triggers, and (6) outcomes. For social media to enable recipients to use research evidence in their practice or decision-making, the framework proposes that

developers respond to the needs and context of target recipients to develop relevant messages and appropriate delivery strategies. Recipients' use of social media messages is influenced by the virtual–technical, individual, organizational, and system contexts and can be activated by different types of triggers, described as sparks, facilitators, and signals. Next, we describe the constructs of the *SMILE* framework.

[f]COM-B: capability, opportunity, motivation, and behavior.

Developers

Developers are individuals, groups, and organizations responsible for the management of social media contents. Developer activities may include designing and periodic uploading of information, monitoring operations, collecting data on impact, and answering questions or comments from viewers. Developers can be health care researchers who produce research evidence and share it directly via social media for public access. Barton [78] proposed a new research-to-practice continuum where researchers not only disseminate research findings through traditional journal publications but also create multimedia messages and disseminate them to the public. Developers can also be intermediaries who serve as a link between research producers and end users by translating research evidence into user-friendly messages for dissemination on social media.

Although it might be simple for individuals to develop and upload research findings to social media, a fast, frugal, and *hope-the-change-happens* approach has limitations. One of the propositions embedded in the framework is that the composition of the development team, availability of resources, scope of topics, and vision of impact influence the development of relevant and appropriate social media interventions, thus affecting recipients' engagement with and use of the messages.

We suggest bringing together a multidisciplinary collaborative team of health care professionals, target users, social media experts, and audiovisual technicians (eg, camera operators and video editors) to best support the development of social media

interventions [9]. Health care professionals can assist with the identification of different types of evidence resources; target users can strengthen the relevance and accessibility of messages; social media experts can contribute to the operation of the platform; and audiovisual technicians can provide support when the team wants to deliver messages using videos or animations. For example, the *It Doesn't Have to Hurt* initiative has built a large interdisciplinary collaborative team of researchers, trainees, patients, and other stakeholders to facilitate the stable operation of their social media program [10,26,85]. Similarly, the ECHO research program has created various videos, animations, and posters on child health with a multidisciplinary team [28]. With different knowledge, skills, and perspectives, the team can generate high-quality and influential social media products. The long-term collaborative approach can additionally promote the sustainability of these initiatives.

The availability of resources to develop and manage social media initiatives, such as time and budget, must be taken into consideration when planning it. In the *It Doesn't Have to Hurt* initiative, it cost the team Can $15,000 (US $11,802) and considerable efforts to develop and promote their YouTube video, and the developers stated that financial and time costs could be a hindrance for individual researchers to undertake the work [10]. In their social media initiative to disseminate Cochrane Child Health evidence, Dyson et al [9] also found that the team invested enormous time and human resources in managing the platform. Therefore, we suggest that adequate time and budget be allocated to social media initiatives before their commencement.

The scope of topics covered is closely linked to the amount of time and resources invested. Some initiatives, such as the Fudan JBI Initiative [7,8,24] and BUCM Cochrane Initiative [25], have broad scopes that are open to a range of topics in nursing and medicine. Some initiatives focus only on specific topics; for example, the *It Doesn't Have to Hurt* [10,26] and *Be Sweet to Babies* initiatives [27] target reducing procedural pain for children and infants, respectively. Other initiatives center on a certain field, such as the ECHO initiative, which covers common childhood conditions. The topics covered should be balanced with the consideration of practical issues. Dyson et al [9] suggested that starting from a specific content area and engaging with a stable social media community was more effective for developing a social media network.

It is also essential that the development team builds a shared vision of the impact they are looking to achieve and tracks the performance of their social media initiatives [51]. Building and sustaining a social media initiative is demanding work that requires collaboration and investment. An explicit team vision of the impact of social media can motivate the team to work toward a common goal. For example, since 2016, the Fudan JBI Initiative has openly shared its social media vision in its annual center report and at conferences [84]. Gates et al [79] also emphasized the importance of setting goals and tracking achievements after the evaluation of their social media initiative.

In the *SMILE* framework, we propose that the engagement of a multidisciplinary team, time, and resource investments are essential for developing relevant and appropriate social media

interventions to influence research use. Developers should balance the topics covered with practical considerations and create a shared vision of the goals of their social media initiatives.

Messages and Delivery Strategies

Overview

The second construct in the *SMILE* framework is messages and delivery strategies. Developers should respond to recipients' needs and their context to create messages and delivery strategies. Through a systematic literature review, Schein et al [57] observed that collaborating with target users to create social media interventions contributed to heightened authenticity of messages and improved trust in developers. Korda and Itani [51] suggested that social media messages should account for user characteristics and information preferences and should be customized through an iterative interaction with target users. On the basis of 4 years of experience in social media operations, the Fudan JBI Initiative recommended that developers could improve the usability and uptake of research evidence on WeChat through the full use of WeChat's interactive functions to capture users' needs [7,24].

Messages

To date, a limited number of studies have investigated the attributes of social media messages that influence its uptake, despite the development of tools and models to assess the quality of web-based information [44,47,49,54,59,61-63,80]. On the basis of the content of these tools and models, as well as the unique features of social media platforms, we posit six interrelated attributes that influence the uptake of social media messages: relevance, aesthetics, readability, findability, credibility, and usability.

A *relevant* message is directly related, connected, or pertinent to target users. The more relevant messages are to the target users, the higher their level of engagement and the likelihood of being used. In their systematic review, Schubart et al [58] concluded that internet interventions that addressed the primary concerns of patients with chronic health conditions were the most successful.

An *aesthetic* message is characterized by the artistic design and visual appeal of the social media content; for instance, the layout of content, color and size of words, and graphics [17]. A first impression is made after a brief glimpse of the format and structure of content, and a user will quickly decide whether to stay on it or leave [56]. For example, ECHO uses art-based approaches, such as animations and e-books, to disseminate child health evidence on social media [43]. As many social media platforms impose restrictions on the design and presentation of messages, flexibility with visual appeal is often limited. For example, Twitter only allows 140 characters and 4 pictures per tweet.

A *readable* message is easy to follow. The US National Institutes of Health recommend that the readability of content on websites be at the sixth- to eighth-grade level [44]. Readability also encompasses accessibility and understandability. Health information that is hard to read will

be hard to understand and therefore remain inaccessible, particularly for people with low health literacy [52]. For example, the *It Doesn't Have to Hurt* initiative developed YouTube video storyboards and scripts in collaboration with a communication company, which was further verified by parents for its readability [10,26].

The messages must also be *findable*, meaning that they are easy to locate. Search boxes, navigation menus, and links are likely to improve the findability of health information on social media [62,63]. Both the Fudan JBI Initiative [7] and BUCM Cochrane Initiative used the navigation function in WeChat to organize and categorize the evidence sources, which allowed users to easily locate the specific evidence item they wanted.

A *credible* message refers to the trustworthiness of the message and is described as accurate, believable, and factual [59,63,80]. The *Journal of the American Medical Association* considers four elements to judge the credibility of medical information on the internet: currency of information; declaration of authorship; presentation of a list of references; and the disclosure of any conflicts of interest, funding, or sponsorship [60].

Finally, the *usability* of a message is the extent to which it can be actionable in practice. For the purpose of affecting research use, clear behavioral recommendations or prescriptions within the message can promote its usability [44]. Together, the six attributes of relevance, aesthetics, readability, findability, credibility, and usability influence the use of a social media message in practice.

Delivery Strategies

Delivery strategies are the ways through which social media messages are conveyed to recipients. We conceptualize them as comprising three distinct layers: the social media platforms, modes of delivery, and specific parameters. One of the first decisions that developers need to make is which social media platform to use. Although social media platforms have burgeoned in recent years, only a few are popular for disseminating health care information, such as Facebook, YouTube, and Twitter in Western countries and WeChat and Weibo in Asia. Messages are delivered on social media platforms through different modes of delivery, such as text, infographics, videos, audios, animations, vignettes, testimonials, and stories [17]. The modes of delivery differ in their impact on users' engagement with the messages, and research has found that visual abstracts attract a significantly greater number of engagements than basic texts [82,83]. Webb et al [13] conducted a systematic review in which they classified the modes of delivery of internet-based behavior change interventions into three types: automated functions (eg, automated tailored feedback), communicative functions (eg, access to an adviser to request advice), and the use of supplementary modes (eg, SMS text message). It should be noted that the options for the mode of delivery vary for different social media platforms. The specific parameters of the delivery strategy are the characteristics of the mode of delivery, such as the length of videos, size, color and limits of words, frequency, and interval of message uploading. In the 5 initiatives we reviewed, all used a variety of social media platforms such as WeChat, YouTube, and Twitter. In addition, they used diversified modes of delivery,

such as videos, podcasts, animations, stories, and texts, to deliver their social media messages.

Overall, the attributes of messages and delivery strategies affect the reach and successful use of messages by people and are a key construct in the *SMILE* framework. The 6 attributes of messages and the 3 layers of delivery strategies should be considered during the social media content development process to promote the likelihood of message use.

Recipients

Recipients are the target audience of social media messages and have the potential to direct, influence, or be affected by messages. In our framework, we consider health care providers, policy makers, and health care consumers as recipients. We also propose that using social media messages in health care decision-making involves two distinct, interconnected layers: using the social media and then using the message. It is a prerequisite for recipients to first accept and use the social media before they can engage with the messages. We distinguish between these 2 layers and consider the factors that influence each layer separately. We contend that the characteristics of recipients and the virtual–technical context are the two main domains that influence people's use of social media, and the individual, organizational, and system contextual domains shape the message use.

Together with frameworks from the social media and technology research field [15,48,55,65], the *i-PARIHS framework* [29], *behavior change model for internet interventions* [17], *COM-B model* [30], and *Fogg behavior model* [31] have provided valuable insights into the characteristics of recipients that influence social media use. On the Basis of their theoretical constructs, four aspects of recipients' characteristics were incorporated into our framework: demographics, personal traits, motivation, and capability.

Demographics include age, gender, geography, socioeconomic status, ethnicity, and lifestyles [15,17,55]. Large quantities of research data from Twitter and Facebook revealed differences in social media use by gender, ethnicity, and geography [45,53]. Personal traits of openness, conscientiousness, extraversion, agreeableness, and neuroticism—rooted in genetics—are perceived as one of the fundamental theories that explain personal behavior [15]. They are closely associated with social media use [64]. In a national survey in the United States, Correa et al [46] found that although extraversion and openness were positively related to social media use, emotional stability—a central measure of neuroticism—was a negative predictor. These findings differed by gender and age [46].

Motivation and capability are 2 summative characteristics of social media recipients that the *SMILE* framework identifies as affecting social media use. These characteristics are based on the *Fogg behavior model* [31] and the *COM-B model* [30]. Within motivation, perceived needs [65], attitude [50], intention [48,50,55], self-efficacy [17], and goals [55] are factors motivating individuals to use social media. Within capability [48,50], knowledge and skills [17,31] enable individuals to use social media. Together, all four characteristics of recipients (demographics, personal traits, motivation, and capability) are

determinants affecting social media use in the *SMILE* framework.

Context

Overview

In the *SMILE* framework, context is defined as "a set of characteristics and circumstances that consist of active and unique factors that surround the implementation... (It) interacts, influences, modifies and facilitates or constrains the intervention and its implementation" [81]. We identify four interrelated layers of contextual factors that influence social media use and further message use: virtual–technical, individual, organizational, and system contexts.

Virtual–Technical Context

The virtual–technical context is the context surrounding the social media platform. Dawot and Ibrahim [69] summarized its composition into three core elements: individual-level, conversation-level, and community-level elements. Through a systematic review, Elaheebocus et al [70] created a taxonomy of social media features that included identity representation, communication, peer grouping, data sharing, competition, activity data viewing, and web-based social networks.

We posit that seven characteristics of the platform influence social media use: relative advantage, complexity, observability, compatibility, usefulness, interactivity, and playfulness [48,65,75,77]. Relative advantage, complexity, observability, and compatibility originate from the *theory of innovation diffusion* [32] and are all considered important factors influencing social media use [65]. *Relative advantage* is the degree to which one social media platform is perceived to be better than other alternatives. *Complexity* is the extent to which social media is perceived as being difficult to use. *Observability* is the degree to which the benefits of social media use are visible to others. *Compatibility* is the degree to which social media is perceived as consistent with the existing values, past experiences, and needs of potential users [65]. Each of these factors is positively associated with social media use, except for complexity [75]; the more complex the social media is perceived, the lower the level of engagement by users. *Usefulness* is the degree to which social media can directly or indirectly benefit individual performance. Data show that usefulness can predict up to 62% of the intention to use social media [48]. *Interactivity* is the degree to which social media enables 2-way communication rather than 1-way transmission or distribution of information. Multiple research studies have demonstrated the positive effects of interactivity on social media use [75,77]. *Playfulness* is the hedonic value of social media and can influence the perceived usefulness and direct use of social media [48]. In the 5 social media initiatives included for developing the *SMILE* framework, all of them use popular platforms that contain these 7 characteristics, attesting to their importance. We posit that all 7 aspects of the platform in the virtual–technical context affect social media use.

Individual Context

The context of an individual plays a crucial role in shaping one's behavior of message use. Brouwer et al [67,68] found that being motivated to visit the web-based intervention, being curious about the content, and perceiving the web-based intervention as personally relevant were important influencers for participants to engage with the web-based intervention. In a qualitative and a cross-sectional study conducted by Hu et al [39,40] to understand the barriers of implementing the *Be Sweet to Babies* pediatric pain management strategies in China, they found that insufficient knowledge, beliefs, and self-efficacy of health care providers were common individual-level barriers hindering the implementation of social media messages in clinical practices by nurses.

Organizational Context

Organizational context is considered an indispensable layer of the context affecting one's use of a social media message in practice. In the *Be Sweet to Babies* initiative, the hierarchical managerial system, low authority of nurses, and staff shortage were factors impeding nurses from changing their practice and incorporating the evidence in China [40]. In the *It Doesn't Have to Hurt* initiative, researchers found that the cost for using topical anesthetic cream [10] and the unit routines of disallowing parental presence during painful procedures [26] hindered the implementation of pain management strategies for children. The Fudan JBI Initiative also stated explicitly in every WeChat post that users should consider the local context to determine the appropriateness of implementing the evidence.

System Context

People's use of social media messages in health care practices is also influenced by the broader system context, namely the social, political, economic, and cultural environment. From a social perspective, one study found that popular opinion leaders on the internet played a positive role in changing sexual behaviors among men who have sex with men [71]. Some countries impose restrictions at the judicial level on accessing certain social media, which may be attributed to ideological, political, or economic reasons. Culturally, Hu et al [40] found that the negatively escalating relationships between patients and health care professionals in China made nurses reluctant to introduce the *Be Sweet to Babies* pain management strategies, despite a strong evidence base for the practices.

As illustrated above, we have made distinctions between the four types of contexts that influence social media and its message use in the *SMILE* framework. Specifically, the virtual–technical context concerns the determinants of social media use; the individual, organizational, and system contexts are considered as the micro-, meso-, and macro-level factors shaping message use.

Triggers

Overview

The concept of the *trigger* in the *SMILE* framework describes the strategies adopted to activate social media message use. On the basis of the *i-PARIHS framework* [29], for social media to be effective in facilitating research use, there needs to be an active ingredient to energize the message implementation process, in addition to having relevant messages. The trigger is derived from the *Fogg behavioral model* [31] and includes

behavior change techniques (active triggers) or events (passive triggers) that activate a recipient to use social media messages. One behavior change technique, as an active trigger, is an "observable, replicable, and irreducible component of an intervention designed to alter or redirect causal processes that regulate behavior" [73]. Michie et al [73] created a behavior change technique taxonomy to standardize the reporting of the active content of behavior change interventions. These techniques have been widely adopted in social media interventions. Webb et al [13] found, in their systematic review, that internet interventions that incorporated more behavior change techniques had larger effects than interventions that incorporated fewer techniques. In a systematic review of the characteristics of internet-delivered healthy lifestyle promotion interventions, Brouwer et al [66] reported that feedback, interactive elements, and email or phone contact were the most commonly used techniques. In a recent systematic review in 2020, Simeon et al [74] conducted a detailed analysis of the behavior change techniques used in social media interventions. They found that 46 techniques had been used in the identified 71 studies. An event, as a passive trigger, is an emergent, unexpected, or accidental incident that pushes recipients to use social media messages in a passive way. These events require people to think and act in alternative ways, and social media provides relevant information to perform an alternative behavior. Fogg [31] classified triggers into three different types in persuasive technology design: sparks, facilitators, and signals. We adopted these 3 types of triggers and enriched their connotations in our framework, as discussed in the following sections.

Spark for Motivation

A spark is a trigger that motivates recipients to use a message. It can be used when recipients' motivation to use a social media message is low or needs to be further enhanced. Developers can apply various behavior change techniques such as problem solving, feedback and monitoring, and social support and reward [55,74] to help activate behavior change. For example, Modanloo [41] used motivational interviewing to improve parents' use of *Be Sweet to Babies* pain management strategies for infants during vaccination. Although no significant differences were found between the 2 comparative groups, approximately all participants used at least one strategy in the vaccination [41]. Through a Delphi study approach, Brouwer et al [67] identified that two behavior change techniques—the provision of tailored feedback on behavior and credible information source [73]—were related to an extended engagement with internet interventions. After implementing their social media initiative, Gates et al [79] suggested that web-based opinion leaders' endorsements would be a promising strategy for motivating recipients to use the messages.

Facilitator for Capability

A facilitator is a trigger that improves recipients' capability to use social media messages, such as knowledge and skills. Social media interventions that incorporate different behavior change techniques, such as instructions on behavior performance and demonstrating the behavior [73], are likely to improve the capability of recipients. In the Clinical Excellence Through

Social Media trial, Tunnecliff et al [76] linked every tendon management practice point on Twitter and Facebook to supplementary information to enhance the knowledge of recipients. Webb et al [13] found that the use of communicative functions within internet interventions to provide access to and schedule contacts with an adviser could have a small to medium effect on behavior. Developers made full use of the visualization function of a YouTube video in the *Be Sweet to Babies* initiative to demonstrate pain management techniques and help the recipients build skills [27]. Watching this video doubled the chance of using an analgesic strategy and increased breastfeeding 1.5 times and skin-to-skin care 4.6 times by parents in a nonrandomized pragmatic trial in Brazil [42].

Signal for Reminding

A signal indicates or reminds recipients of social media messages. This type of trigger is useful when recipients need external reminders to use messages or, in other cases, when events emerge, and the developers want to push recipients to use the messages, such as wearing masks during the COVID-19 pandemic. The signal can be an active prompt or cue in the form of an SMS text message delivered by developers [31,55]. Among the 71 included studies in the systematic review by Simeon et al [74], 10 studies reported the use of prompts or cues as a behavior change technique in self-directed social media programs. Webb et al [13] also found that SMS text messages were highly effective for behavior change in internet interventions when they provided cues to action. A signal, on the other hand, is an event that is emergent, accidental, or unexpected such as an adverse event that happened on a unit, a new health care regulation or policy, or a global pandemic. These events remind people of the relevant resources on social media platforms that can help tackle the situation. Together, the *SMILE* framework proposes sparks, facilitators, and signals as triggers to activate recipients to use social media messages.

Outcomes

In the *SMILE* framework, we specify the knowledge translation outcome as research use, which is a multidimensional concept that involves conceptual, instrumental, and persuasive use of research findings [33,34]. Conceptual research use refers to using research evidence to change the levels of knowledge, understanding, or attitude of a recipient. Both the *It Doesn't Have to Hurt* initiative [10,26] and *Be Sweet to Babies* initiative [27,35-39] have demonstrated that when recipients receive relevant and appropriate messages on social media that respond to their needs and context, they are highly likely to improve conceptual research use. Instrumental research use involves the direct application of research evidence in practice to change behavior. Modanloo et al [41] and Tunnecliff et al [76] have shown, in their randomized controlled trials, that different types of triggers, such as sparks or facilitators, are essential for the active uptake of research evidence and behavior change by recipients. Persuasive research use refers to using research evidence as a political or persuasive tool to justify an action, attain power, or achieve goals [33,34]. One of the most typical examples is the #WearingMasks social media campaign during COVID-19, which has made a huge impact on public behavior and government policy making.

Discussion

Principal Findings

In this paper, we present the *SMILE* framework, which is based on a review of 5 social media initiatives, 5 theories, and 58 empirical studies. The framework provides a preliminary understanding of how social media works as a knowledge translation strategy for health care providers, policy makers, and patients to inform their health care decision-making.

The *SMILE* framework has implications for research by offering a heuristic device for the development of social media interventions to promote evidence use. We suggest that it be used in combination with process frameworks, which provide step-by-step guidance on implementing web-based knowledge translation interventions [86] or evaluation frameworks to evaluate the multilevel outcomes and impacts of social media interventions [54].

Implications for Social Media Strategy Development

On the basis of this framework, we offer several suggestions for researchers and organizations who intend to use social media to promote research use. First, in the preparation stage, it is important for developers to assess their readiness to start a social media initiative. Some probing questions may be considered during this stage, such as is there an explicit topic to be covered? Does the team have enough time, resources, and expertise to develop the intervention and monitor the operation?

Once the infrastructure has been built for the social media initiative, the team begins developing a message and delivery strategy. Developers should recognize target users' needs and their context and, if possible, engage them in the development process. The six attributes of messages (ie, relevance, aesthetics, readability, findability, credibility, and usability) and three dimensions of delivery strategies (ie, social media platform, mode of delivery, and specific parameters) need to be taken into account when creating the social media interventions.

The team can then start the activation stage, where they make efforts to embed triggers into the social media delivery mechanisms for recipients to use the messages. Developers may interact with multilevel stakeholders and investigate the enablers of and barriers to recipients' use of the messages. By tailoring behavior change techniques to identified barriers and enablers, the development team can develop a social media strategy that has the greatest potential to affect message use in practice.

Acknowledgment of Complexity Within This Framework

We fully acknowledge the complexity of developing and implementing social media interventions and incorporate the notion of complexity within this framework in several ways. As information and communication sciences are fast-growing fields, new features and functions for social media platforms are continually emerging. Consequently, the approaches to developing messages and delivery strategies may become more diversified as technology advances. The dynamic interactions between constructs within the *SMILE* framework, such as the interaction between developers, recipients, and their situated contexts, make it challenging to undertake firm predictions [87,88]. Developers should immerse themselves in the human–social media system and capture underlining interactive patterns to inform the development of the most relevant and targeted activating techniques.

We also acknowledge the nonlinear aspect of the social media implementation processes, in which different levels of context influence and shape behavior. Promoting research use through social media is not a linear, straightforward process, and constant adaptations should be expected and embraced to optimize interventions. Finally, as each construct within this framework does not have a fixed and predetermined effect, and the interactions between constructs are dynamic and complex, we recognize that the framework has not been empirically validated and may not reveal all of the mechanisms at play for social media to influence research use. Nevertheless, the framework is based on current empirical evidence and well-recognized theories to provide plausible explanations for the successes and failures of social media interventions. Overall, the framework explicates the complexities of using social media in real-world practice and elucidates the key domains that developers, recipients, and researchers should attend to when developing or evaluating social media interventions.

As Maloney et al [72] suggested, "rather than looking at whether or not social media is effective for health professional education, it may be time to look at how various modalities can be optimized, both in terms of how the messages are delivered and how learners can be supported to engage." Using social media to disseminate research evidence has become such an inexorable global trend that researchers should go beyond the investigation of the effectiveness of social media interventions and delve into the theoretical field on how to make it effective. The next stage of our project will be to test and refine the *SMILE* framework through a realist methodology that unpacks the mechanisms of how and under what circumstances social media works as a knowledge translation strategy for health care professionals to improve the delivery of research-based care.

Limitations

The *SMILE* framework and its development process have 2 limitations. First, because of the multiple interactive components involved in developing and using social media for knowledge translation, as well as the massive amount of literature available from the relevant disciplinary fields, it was challenging to retrieve all pertinent theories and studies using a full systematic review approach. Instead, we used a targeted and flexible approach to select studies that allowed us to prioritize articles based on our framework's development needs. It is possible that we missed some research and embedded our own values into the propositions by using this approach; thus, our next step is to test and refine the framework. Second, as the use of social media for knowledge translation in real-world practice is still in its infancy, we could not locate studies that captured all the *SMILE* framework's propositions. More empirical studies of social media initiatives are needed to test the propositions of this framework.

Conclusions

In this paper, we propose the *SMILE* framework based on a review of social media initiatives, theories, and empirical studies as a preliminary understanding of how social media works as a knowledge translation strategy in health care decision-making. We provide a detailed description of each construct in the framework and offer suggestions for researchers and developers who intend to develop social media initiatives and interventions. For social media to be effective in enabling recipients to use research evidence in their practice decision-making, the *SMILE* framework purports that developers respond to target recipients' needs and context to develop relevant social media messages and appropriate delivery strategies. Recipients' use of messages is influenced by the virtual–technical, individual, organizational, and system contexts and can be activated by three types of triggers: sparks, facilitators, and signals. The *SMILE* framework maps the factors that are hypothesized to influence recipients' social media message use and offers a heuristic device for social media developers and researchers to develop social media interventions. More empirical studies and social media initiatives are needed to test the propositions of the *SMILE* framework.

Abstract

Background: Mindstep is an app that aims to improve dementia screening by assessing cognition and risk factors. It considers important clinical risk factors, including prodromal symptoms, mental health disorders, and differential diagnoses of dementia. The 9-item Patient Health Questionnaire for depression (PHQ-9) and the 7-item Generalized Anxiety Disorder Scale (GAD-7) are widely validated and commonly used scales used in screening for depression and anxiety disorders, respectively. Shortened versions of both (PHQ-2/GAD-2) have been produced.

Objective: We sought to develop a method that maintained the brevity of these shorter questionnaires while maintaining the better precision of the original questionnaires.

Methods: Single questions were designed to encompass symptoms covered in the original questionnaires. Answers to these questions were combined with PHQ-2/GAD-2, and anonymized risk factors were collected by Mindset4Dementia from 2235 users. Machine learning models were trained to use these single questions in combination with data already collected by the app: age, response to a joke, and reporting of functional impairment to predict binary and continuous outcomes as measured using PHQ-9/GAD-7. Our model was developed with a training data set by using 10-fold cross-validation and a holdout testing data set and compared to results from using the shorter questionnaires (PHQ-2/GAD-2) alone to benchmark performance.

Results: We were able to achieve superior performance in predicting PHQ-9/GAD-7 screening cutoffs compared to PHQ-2 (difference in area under the curve 0.04, 95% CI 0.00-0.08, P=.02) but not GAD-2 (difference in area under the curve 0.00, 95% CI –0.02 to 0.03, P=.42). Regression models were able to accurately predict total questionnaire scores in PHQ-9 (R^2=0.655, mean absolute error=2.267) and GAD-7 (R^2=0.837, mean absolute error=1.780).

Conclusions: We app-adapted PHQ-4 by adding brief summary questions about factors normally covered in the longer questionnaires. We additionally trained machine learning models that used the wide range of additional information already collected in Mindstep to make a short app-based screening tool for affective disorders, which appears to have superior or equivalent performance to well-established methods.

Introduction

Depression was among the 12 modifiable dementia risk factors identified by the Lancet commission [1]. The relationship between depression and dementia is complex, with depression being a risk factor for dementia, a prodromal symptom [2] and a differential diagnosis known as pseudodementia [3]. Anxiety is a highly comorbid condition with depression and is an important feature in the diagnosis of dementia [4]. Anxiety has independent effects on cognition [5] and plays a role in driving health-seeking behavior in individuals without deficits [6]. Furthermore, depression and anxiety symptoms are common in older adults with an estimated prevalence of around 13% [7]. Therefore, appropriate screening for depression and anxiety is of importance when screening for dementia. Mindstep is a new app that aims to holistically screen for cognitive impairment and dementia while gathering information on important dementia risk factors. It achieves this by integrating the analyses of important risk factors such as depression and anxiety with cognitive screening tests in a conversation interface. It is important that the methods used within this app are accurate and easy to integrate within the wider structure of the app.

Both the 9-item Patient Health Questionnaire for depression (PHQ-9) and the 15-item Geriatric Depression Scale are widely used in clinical settings to screen for depression in older adults [8,9]. However, despite being shorter, PHQ-9 performs at least as well as the Geriatric Depression Scale in screening older adults across multiple populations, and therefore, we decided to incorporate PHQ-9 into the app [10,11]. The optimal cutoff point for the diagnosis of depression in PHQ-9 is ≥10 with an associated sensitivity and specificity of 88% [8]. Similarly, the 7-item Generalized Anxiety Disorder Scale (GAD-7) assessment has been used for anxiety screening with high sensitivity (92%) and specificity (76%) in those of working age with cutoff points ranging from ≥7 to ≥10 [12-14]. Further research has established effectiveness in screening older adults, with lower cutoffs of 5 recommended for better sensitivity [12,13].

Although these questionnaires are individually brief, they can become lengthy when nested within an app that aims to screen for multiple other risk factors and utilize multiple tests. Longer questionnaires cause higher rates of fatigue and dropouts, and hence, we aimed to limit the duration of total software use to 5 minutes [15]. This is especially key for individuals with affective disorders who are likely to experience deficits in attention, concentration, motivation, and fatigue [16,17]. We therefore considered PHQ-4 that combines PHQ-2 (which consists of the first 2 questions of PHQ-9) and GAD-2 (which consists of the first two questions of GAD-7) [18]. Although this shortens the time spent on the questionnaires, PHQ-4 does not have a severity scale, and commonly used cutoffs can result in prioritizing sensitivity or specificity at the expense of the other [19]. Consequently, this requires follow-up questions; for example,

completing the whole PHQ-9 following a positive screen on PHQ-2 [20]. We wanted to develop a method that would have both the brevity of PHQ-4 and the accuracy of the longer PHQ-9/GAD-7 in addition to a severity scale. To achieve this, we adapted PHQ-4 by adding questions about factors normally covered in the longer questionnaires. We trained machine learning models that used the wide range of additional information already collected in Mindstep. Therefore, this study aims to assess the performance of our models when benchmarked against full-length standardized PHQ-9 and GAD-7 questionnaires. If performance was equivalent to that of these longer questionnaires, this would enable the app to have a screening method of equivalent efficacy while minimizing completion time.

Methods

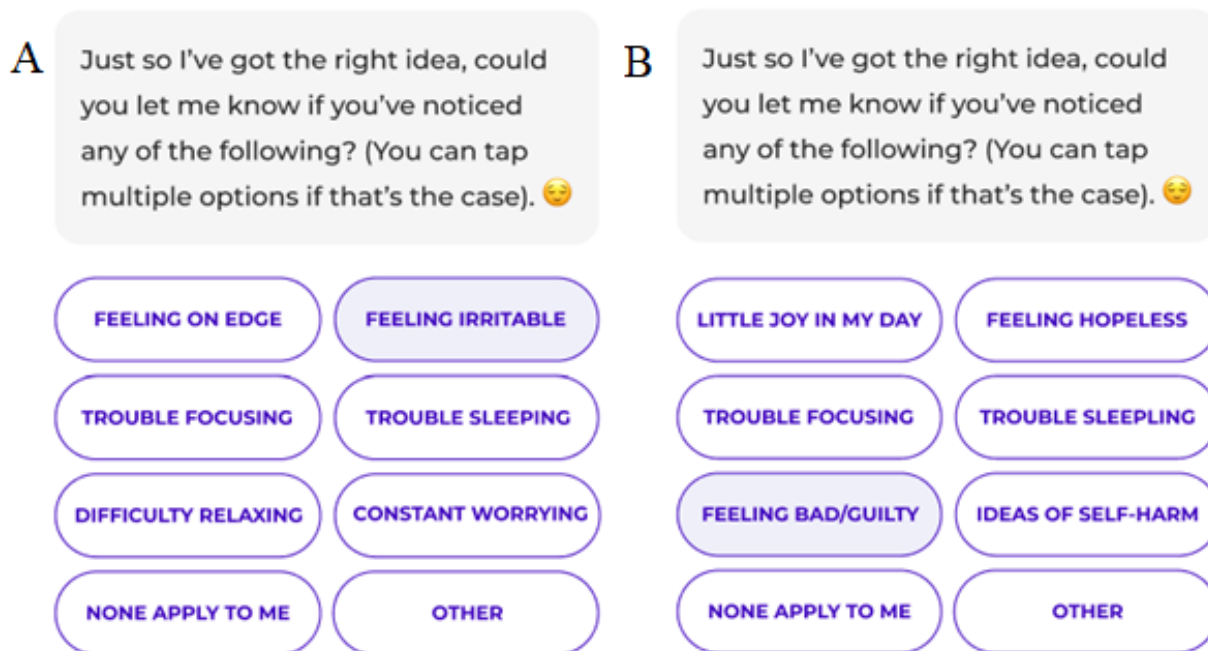
App Data Collection and Users

Data of users of the Mindstep app were used for this study in a convenience sample. The app consists of a 5-minute conversational style questionnaire where information on common dementia risk factors is gathered. Cognitive performance is assessed through modified versions of 2 common cognitive tests: the Stroop test and Symbols Digit Modalities test. The dementia risk factors queried include medical history, age, alcohol consumption and dependency, concussion, smoking, and self-reported functional impairment. Analogous to medical consultation, further screening is then performed in response to answers that would elicit concern. Only those who reported feeling depressed or tired were screened with PHQ-9, while only those who reported feeling anxious or worried were screened with GAD-7. As a control group, for a short time, those who answered that they felt fine or great were also screened for anxiety. Apart from age, no other personal information was gathered from users.

New Question Design

New questions were created based on the longer versions of PHQ-9 and GAD-7, each for depression (Mindset Depression Question [MDQ]) and anxiety (Mindset Anxiety Question [MAQ]) to encompass symptoms of depression and anxiety in the Diagnostic and Statistical Manual of Mental Disorders that would normally be excluded from the shortened questionnaires. In 1 question, users were asked to select in a binary manner if any of several options applied to them—a method of collecting a wide range of information in a rapid manner. The questions are shown below (Figure 1). A mixture of categorical and continuous features from the app was used. The features were selected by unsupervised recursive feature elimination. Both models included age, alcohol dependency (as assessed by CAGE) [21], and a functional impairment question. For the PHQ models, the MDQ, PHQ-2, alcohol/drugs/smoking (currently/past/never), weekly alcohol consumption in drinks

(<3/4-7/7-14/>14), feeling (depressed/tired), and joke data (yes/no/didn't get it) were included. For the GAD models, MAQ, GAD-2, and the cognitive scores (MStroop/MSymbols) were included.

Figure 1. (A) Screenshot of the Mindset Anxiety Question. (B) Screenshot of the Mindset Depression Question.


Benchmarks

Outcomes of interest were compared to those of the full-length PHQ-9 and GAD-7. For the binary classification task, a cutoff value of ≥10 was used in both cases to represent commonly used screening cutoffs for these tools [14,22]. The total PHQ-9 and GAD-7 scores were also used for the regression task where the full-length screening score was predicted from PHQ-4 plus Mindset features.

Data Preprocessing and Analysis

As part of the preprocessing pipeline, the categorical inputs were one-hot encoded. As only self-reported heavy drinkers were asked to complete the CAGE questionnaire, most users did not register a CAGE score and their score was assumed to be 0. For users who chose not to complete the Stroop or Symbols test, a mean value was used for their results. We divided the data into 80% training and a 20% holdout testing sets for PHQ (n=432,108) and GAD (n=408,103) with 10-fold cross validation. The holdout test set remained unseen throughout model training, hyperparameter tuning, and model selection.

Machine Learning Models

Four distinct machine learning models were trained in both classification and regression task. The models used were logistic regression (linear regression was used in the regression task), support vector machines, TabNet [23], and extreme gradient boosted trees. The models were evaluated based on 10-fold cross validation scores (area under the curve [AUC] for classification, R^2 for regression). The weaker models were discarded (AUC<0.9 or R^2<0.7), and the final result was a median ensemble of the remaining models. Only the ensemble model was tested on the testing set. The performance on the training set of this ensemble model compared to that on the individual models can be found in Table S1 of Multimedia Appendix 1.

Benchmarking

To guide interpretation and benchmarking of results, the final ensemble model was compared to logistic/linear regression models built using only the PHQ-2 and GAD-2 questionnaires. This was done on the unseen holdout test set. Confidence intervals and *P* values were generated to assess for the significance of differences by comparing model performance via a 1000-times bootstrap of the test set.

Model Explainability

To interpret the predictions of the final ensemble model, model agnostic Shapley Additive Explanations (SHAP) scores were calculated to determine the relative feature importance [24]. SHAP scores determine which features are important to the model across the entire testing set and enable local interpretations such as why a particular prediction was made for a given user.

Ethical Approval

This paper was a secondary data analysis of robustly anonymized data with minimal demographic information collected (only age) where there is no chance of data being linked to any individuals. On using the app, users agreed to transparent terms and conditions, which included having their data stored and anonymously used for further research. Therefore, ethical approval was not strictly required for this research. Out of an abundance of caution, we applied for and

were granted retrospective ethical approval for the use of these data for research: West Midlands, Solihull Research Ethics Committee, Reference 21/WM/0202.

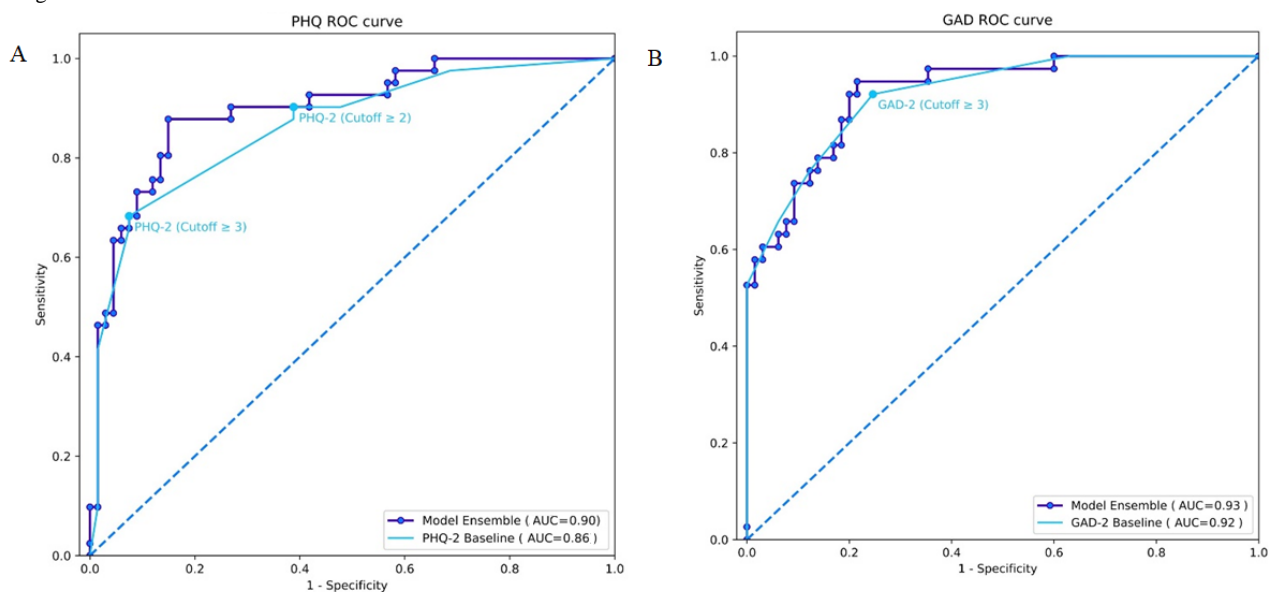
Results

Participant Data

Of the 2235 Mindstep users, 540 completed the PHQ and 511 completed the GAD. The mean age of the total Mindstep users was 50 (SD 14.1) years; for the PHQ subset, it was 49.3 (SD 13.1) years; and for the GAD users, it was 49.1 (SD 13.6) years. Of the 540 targeted users selected to take PHQ-9, 233 (43.1%) screened positive for depression. Of the 511 targeted users selected to take the GAD-7, 173 (33.9%) screened positive for GAD. These high rates likely represent the enriched selection of users who had already reported feeling negatively valenced emotions. Only a small number of users did not complete the Stroop (28/2235, 1.3%) or Symbols tests (26/2235, 1.2%) and had data imputed.

Questionnaire Characteristics

All questionnaires had excellent reliability as measured by the Cronbach interitem correlation [25]: PHQ-9 (α=.84), PHQ-2 (α=.77), GAD-7 (α=.90), and GAD-2 (α=.84). The test set AUC for the ensemble model for PHQ-9 (0.90) was a significant improvement on the PHQ-2 baseline (difference 0.04, 95% CI 0.00-0.08; P=.02). The test set AUC for the ensemble model for GAD-7 (0.93) was equivalent to the GAD-2 baseline (difference 0.00, 95% CI –0.02 to 0.03, P=.42) (Figure 2). By altering thresholds, the sensitivity and specificity of the ensemble models can be optimized for particular situations. The selected optimal sensitivity and specificity for the PHQ model was 88% and 85%, respectively, achieving a good compromise compared to the highly sensitive PHQ-2 cutoff ≥2 (90% and 61%, respectively) or highly specific PHQ-2 cutoff ≥3 (68% and 93%, respectively). The positive and negative predictive values for the PHQ model were 78% and 92%, respectively. The sensitivity and specificity of the GAD model (95% and 78%, respectively) were substantively similar to the clinically used GAD-2 cutoff ≥3 (92% and 75%, respectively). The positive and negative predictive values for the GAD model were 69% and 96%, respectively.

Figure 2. Receiver operating characteristic curve for prediction of (A) Patient Health Questionnaire for depression and (B) Generalized Anxiety Disorder Scale of the model ensemble and their respective baselines. GAD: Generalized Anxiety Disorder; PHQ: Patient Health Questionnaire; ROC: receiver operating characteristic.


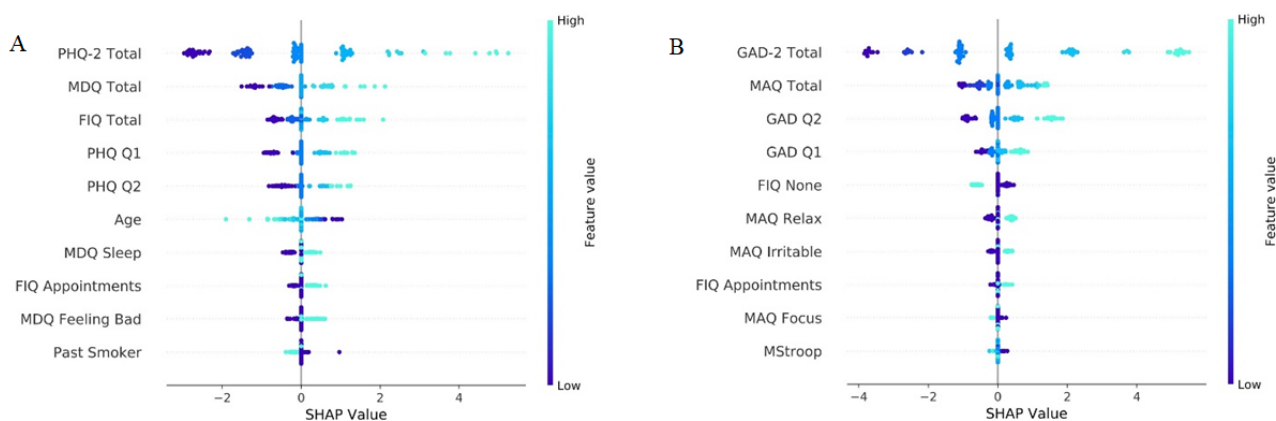
Regression Analysis

Figure 3 shows the regression model ensemble predictions for the test set PHQ-9 and GAD-7 scores. Both models (Figure 3) were able to achieve good prediction of the full-length questionnaire scores: PHQ-9 (R^2=0.655, mean absolute error [MAE]=2.267) and GAD-7 (R^2=0.837, MAE=1.780). The PHQ model showed a significant improvement in MAE over the PHQ-2 baseline (difference 0.35, 95% CI 0.06-0.65, P=.01) and a nonsignificant improvement in R^2 (0.08, 95% CI –0.02 to 0.21, P=.06). The GAD model showed a nonsignificant improvement in MAE over the GAD-2 baseline (0.08, 95% CI –0.10 to 0.26, P=.20) and a significant improvement in R^2 (0.04, 95% CI 0.01-0.08, P=.01) (Table S1 in Multimedia Appendix 1). For PHQ, by breaking the scores into categories of increasing severity [8], 0-4, 5-9, 10-14, 15-19, and ≥20, an intraclass correlation was calculated to be 0.76 (95% CI 0.67-0.83, P<.001). For GAD, categories of 0-4, 5-9, 10-14, and ≥15 were used [14]. An intraclass correlation was calculated as 0.87 (95% CI 0.81-0.91, P<.001).

Figure 3. The regression model ensemble predictions for the test set (A) 9-item Patient Health Questionnaire for depression and (B) 7-item Generalized Anxiety Disorder scale scores. GAD-7: 7-item Generalized Anxiety Disorder scale; MAE: mean absolute error; PHQ-9: 9-item Patient Health Questionnaire for depression.
Feature Importance

Figure 4 shows the beeswarm SHAP summary plots of the 10 most important features as determined by SHAP values for predicting the PHQ-9 and GAD-7. The greater the magnitude of the SHAP values, the larger was the influence on the model with positive numbers, indicating that the user is more likely

to have the condition. In both cases, the most important features in the prediction of the full-length questionnaires were the PHQ-2 and GAD-2 followed by the MDQ and MAQ, respectively. The functional impairment question was also shown to be important in both sets of models. Age and smoking were important in the depression models, and the Stroop test was important in the anxiety models.

Figure 4. Beeswarm Shapley Additive Explanations summary plots of the 10 most important features as determined by Shapley Additive Explanations values for predicting the (A) 9-item Patient Health Questionnaire for depression and (B) 7-item Generalized Anxiety Disorder scale. Ordered by importance (top to bottom). The greater the magnitude of the Shapley Additive Explanations values, the larger the influence on the model with positive numbers, indicating the user is more likely to have the condition. FIQ: functional impairment question; GAD-7: 7-item Generalized Anxiety Disorder scale; MAQ: Mindset Anxiety Question; MDQ: Mindset Depression Question; PHQ-9: 9-item Patient Health Questionnaire for depression; SHAP: Shapley Additive Explanations.


Discussion

Principal Results

We have shown that the combination of PHQ-4, additional questions, and risk factor information are able to accurately predict the severity score of the longer questions with an R^2 of 0.655 on PHQ-9 and R^2 of 0.837 for GAD-7. This is a novel finding, as previous studies have only looked at agreement

between the binary cutoffs of the shorter questionnaires compared to that of the longer. This suggests that even these ultrashort questionnaires may be responsive to change, although this will need to be explored in future work. In addition to this, compared to using the PHQ-2 alone, our model achieves significantly better performance on both classification and regression models. The SHAP analysis suggests that the MDQ and MAQ can capture some of the variance missed by the shorter PHQ-4. The benefit of our model is less clear in anxiety

with little difference compared to utilizing the GAD-2 alone. This may be in part, as GAD-2 alone achieves very high performance on both the binary classification and regression task. This is in line with meta-analyses, which show that GAD-2 achieves very similar performance to GAD-7 [12-14]. The strength of our developed model for depression is not just an enhanced accuracy of prediction but also our ability to choose any threshold to best balance sensitivity and specificity. This enables us to choose a cutoff that best balances sensitivity and specificity rather than having to choose between a PHQ-2 cutoff, which prioritizes a high sensitivity or specificity. Furthermore, the fact that we collect age will enable us to personalize the cutoff for screening in line with evidence by using less stringent cutoffs in older adults to maximize sensitivity [12,13]. Our regression model with good intraclass correlations enables us to sort users into multiple categories. For example, initial validation studies of PHQ-9 demonstrated that while 10 represented the best cutoff for sensitivity and specificity, higher scores had much better discriminative values with scores above 15 highly specific for depressive disorders and 10-15 representing an important grey zone [8]. Therefore, sorting users in multiple categories such as unlikely (<10)/possible (10-15)/probable (>15) depression is achievable and will assist in optimizing the accuracy of advice we can offer. Data suggest that longer questionnaires incur more fatigue and dropout [15]. This is especially important, as our app is self-administered and there is no clinician to encourage the user. The benefit of using ultrashort questionnaires is that it allows for many different risk factors to all be assessed with a single app and in a single sitting without significant fatigue and dropout. This enables a comprehensive review of many risk factors for dementia.

Limitations

Although these questionnaires are filled out unsupervised on an app, the validity of the computerized forms of PHQ-9 and GAD-7 has been demonstrated to be valid across format types [26], and the excellent reliability achieved in this study negate this as an issue. A limitation of this study is the use of PHQ-9/GAD-7 as our ground truth. This is an indirect measure compared to clinician-assessed diagnosis or structured diagnostic questionnaires such as the Structured Clinical Interview for Diagnostic and Statistical Manual of Mental Disorders-IV (SCID). This both means that we cannot train our model on a definite diagnosis of depression. However, previous studies that have looked for proxies of depression diagnosis achieved AUCs of 0.77 [26] and 0.79 [27], which are low compared to the accuracy of the full PHQ-9 (AUC 0.87) [28]. This suggests that PHQ-9 is a valid ground truth to use. An additional limitation of the use of PHQ-9/GAD-7 as our ground truth means that our model can never outperform these questionnaires. Considering that we collect data on a wider variety of factors including

functional impairment, it may be that comparison to diagnostic measures would allow enhanced performance. Indeed, by capturing functional measures, including cognitive performance and self-perceived deficits, our app captures important elements missing from the PHQ-9 and GAD-7 questionnaires. Interestingly, the SHAP analysis shows that the questions around functional deficits are especially important in the PHQ-9 model, suggesting this information is important to the model's outperformance of the PHQ-2 alone. The next step to address this limitation would be to use the app in a population with gold standard validated measures of mental illness such as a SCID conducted by a mental health professional. This would both allow refinement of factors in the model and allow assessment of true sensitivity and specificity when it comes to the diagnosis of depression. However, it is important to note that the intent of the app is to use this function strictly in a screening and not a diagnostic role, with identified individuals being signposted for further assessment by their primary care doctors. Therefore, correlation to an already extremely well-validated questionnaire is likely to be adequate for its purpose.

Owing to the need for the app to collect anonymized data, we do not have basic demographic data such as gender, ethnicity, sociodemographic status, or educational background, which is an important limitation of this study. This makes it difficult to explore biases in the model, which may result in differing performance across demographic groups. Further work will need to be done to explore the algorithm's performance in a diverse range of groups to guard against differential performance. In addition, this limitation makes it hard for us to generalize these findings to a specific group outside of users of our app. However, the MAQ/MDQ are based on widely accepted symptoms that are likely to maintain their validity outside of this setting. Another limitation of this study was the relatively small sample size; future investigations could expand to larger data sets. In this vein, an important future step is to test the effectiveness of this algorithm in a setting with participants with well-labelled characteristics—an essential follow-on to the initial validation [29]. A future trial is planned to assess this in a group of older adults, an especially important group, since evaluating depression and anxiety are in the context of dementia risk factors and screening.

Conclusion

In summary, our results suggest that by using the PHQ-4, in line with the other measures collected in the Mindstep app, we can achieve accuracies similar to full-length PHQ-9 and GAD-7 questionnaires. This suggests that the app can be used to reliably screen for these conditions. Further work in populations with validated diagnoses whose demographics are known will further strengthen the evidence underlying these models.

Authors' Contributions

RPRZ and NK conducted the data analysis and devised this project. RPRZ and NK wrote the manuscript. MM, MJ, IP, HS, YY, and AAM reviewed the draft manuscript and provided editorial input.

Abstract

Background: In times of COVID-19, we are challenged to experiment with alternative platforms or software to connect people. In particular, the struggle that arose in health research was how to interact with patients and care professionals. The latter is additionally faced with an extreme workload to fight the pandemic crisis. Creative strategies have been developed to continue research among patients and care professionals to improve quality of care. This paper addresses the issue of synchronous, online, nominal group sessions, a common consensus method used for group brainstorming.

Objective: The purpose of this study was to share our experiences with performing online, nominal group sessions using the video conference software Microsoft Teams. In addition, we aimed to create a practical guide with recommendations for researchers.

Methods: We critically analyzed the procedures for the online nominal group technique, according to the Fishbone methodology.

Results: Performing synchronous, online, nominal group sessions is challenging but offers opportunities. Although interaction with and among the attendees complicates the process, the major advantage of online sessions is their accessibility and comfort because of reduced barriers to participation (eg, lower time investment). The role of the moderators is of major importance, and good preparation beforehand is required. Recommendations for future online, nominal research were formulated.

Conclusions: Online, nominal group sessions seem to be a promising alternative for the real-life commonly used technique. Especially during the COVID-19 pandemic, the benefits must be highlighted. More expertise is needed to further refine the practical guide for using digital software in research and to achieve optimal performance.

COVID-19; fishbone diagram; nominal group technique; video conferencing; primary health care; qualitative research

Introduction

The COVID-19 outbreak has posed multiple challenges. Not only has the pandemic caused major loss of human life globally, the impact on mental and psychosocial health should not be underestimated [1-4]. Apart from the major impact on human health, it also has an impact on health research. More specifically, the limited accessibility of research sources and

XSL•FO
RenderX

participants obliges researchers to seek for alternatives to pursue research projects. Due to strict regulations to control transmission of the virus, researchers have to rely on creative strategies to involve the research population [5]. In-depth interviews and focus groups are conducted by using video conferencing software and platforms, but more complex group-based participatory methods have not yet been fully explored online [6-8]. The nominal group technique is one of these unexplored methodologies in research. This technique is commonly used to solve problems, determine priorities, or generate ideas [9]. The main challenge is cooperation in a strict and formal procedure [10]. Guidance is provided to a limited extent for face-to-face sessions, but the online setting remains unclear [9-11]. There are 2 different strategies for organizing online sessions: asynchronous sessions using an online platform to communicate in a nonsimultaneous way or synchronous sessions using video conference software in which participants join simultaneously. Since the nominal group methodology has not yet been extended fully online, very few researchers have utilized it [12,13]. Guidelines for recruiting participants, giving informed consent, and doing qualitative research with individuals are all based on the assumption of in-person interactions [14]. Therefore, there is a need to investigate in-depth the methodological issues of an online setup. In this paper, we describe the challenges and opportunities of the online form based on our experiences with 3 synchronous, virtual, nominal group sessions. In addition, participants' experiences were explored. Finally, a practical guide with recommendations for researchers has been created.

The online sessions were part of a larger study by the Primary Care Academy (PCA) that aims to implement self-management support into primary care practice. Self-management is "the individual's ability to manage the symptoms, treatment, physical and psychosocial consequences and lifestyle changes inherent in living with a chronic condition" [15]. Self-management of a chronic disease is a process in which health care professionals play a crucial supportive role [16-18]. The COVID-19 pandemic has highlighted the importance of self-management since the lockdown of many services resulted in more responsibility regarding handling of chronic diseases [19]. Online nominal group sessions were organized to brainstorm how health care professionals can support patients in this self-management process.

Methods

We critically analyzed different aspects of synchronous, online, nominal group sessions, according to the Fishbone methodology. The nominal group sessions aimed to formulate specific actions to support patient's self-management and were part of research to reinforce Flemish primary care.

Data Collection

Data were collected during 3 online, nominal group sessions with health care professionals and experts by experience (ie, patients with knowledge based on personal experiences). Two qualified moderators conducted all the sessions, by use of the video conference software Microsoft Teams. With the participants' consent, all 3 sessions were audio- and video-recorded and transcribed verbatim afterwards for qualitative analysis. At the end of each session, participants were offered the opportunity to share their experiences verbally, by use of the chat box, or by email afterwards.

Online, Nominal Group Sessions

Similar to the classical nominal group technique, the online sessions were structured in 4 key stages: silent generation, round robin, clarification, and ranking [9]. A PowerPoint presentation was used to support this structure and the accompanying storyline. In advance, this slideshow was uploaded in Microsoft Teams instead of sharing the presentation, with the advantage of seeing the participants on the call. The protocol was developed specifically for online use and based upon comprehensive debate within the research group.

Sampling and Recruitment

Maximum variation purposive sampling was used to recruit the nominal group participants by email or through health care organizations and practices. A registration link was embedded in a flyer. In addition, a call for participants was announced on the internet (website of the PCA). Participants included health care professionals and experts by experience from around Flanders. The aim was to have a minimum of 5 and a maximum of 10 participants per session [20].

Procedure

Each session started with a short introduction, including explaining ground rules (which had also been communicated in advance by email) and a roundtable introduction by the attendees. Afterwards, information was provided on the topic of the session (self-management support) and the brainstorming procedure. These initial stages took 20 minutes and were followed by the active nominal group brainstorming. It started with the presentation of a specific question, related to self-management support, that gave rise to the formulation of ideas during the silent generation phase. This idea generation question (ie, "What concrete action/interventions can be designed to help patients fit chronic disease(s) into their lives in the most optimal way?") was the impetus for brainstorming. Participants were asked in advance to have their pen and paper ready while brainstorming. To keep everyone's attention, no more than 15 minutes were provided for generating ideas on self-management support. Additionally, the round robin stage in which ideas were exchanged filled in the next 20 minutes. Both moderators took notes during this stage. The formulated ideas were then rephrased by the moderators to make sure everyone gained a full understanding. Then, during a 15-minute clarification phase, there was time to clarify the ideas upon request of the participants. Finally, the nominal group sessions ended with a ranking stage of 5 minutes to 10 minutes, depending on the number of ideas formulated. More specifically, a ranking system created with the online service "Poll Everywhere" (San Francisco, CA) was included in the slideshow to prioritize the ideas generated according to the participants' preferences. A short break of 10 minutes after the generation of ideas gave the moderators the opportunity to process them in the ranking system. The second and third sessions had an additional phase just before the polling in which the ideas

previously formulated were quickly reviewed and included in the ranking system. Each session was planned to last no longer than 1.5 hours.

Analysis of the Content Related to Self-Management Support

Processing the output of the brainstorming sessions (ie, formulated ideas on self-management support) was performed analogous to the regular methods of the nominal group technique. In summary, the generated ideas were (after performing 3 brainstorming sessions) organized in themes by qualitative coding of the transcripts and processed in a survey. Participants were asked to identify their favorite idea and to rank the ideas based on their preferences by defined theme. Afterwards, ideas were grouped by the main researcher (LT) following a self-management support model into 5 categories according to the type of primary care action (ie, supporting, involving, listening to, coordinating, or questioning patients). Ideas that were not chosen as favorites were excluded. Subsequently, the table was reviewed by the research team during multiple rounds to reach a consensus on the categorization. Finally, ideas were further refined according to the survey results and processed for use in a primary care practice intervention related to self-management support. The results of the analysis related to the formulated ideas of the online sessions are beyond the scope of this research paper and will be reported elsewhere.

Ethical Approval

Ethical approval for the brainstorming sessions was obtained from The Ethics Committee Research UZ/KU Leuven (S63890). An informed consent document was sent to the participants in advance by email. It explicitly stated that conversations were video- and audio-recorded during the online sessions. In addition, participants were informed that the content remained internal for scientific research purposes.

The return of a signed copy was required to participate in the online sessions. After confirmation of participation and signing the informed consent form, attendees obtained an invitation link to a Microsoft Teams live event. Access to the recorded sessions (audio, video, and shared slideshow) was limited to the research group. The entire study was conducted in accordance with the Helsinki Declaration.

Outcome Measures

We defined 6 different process outcomes to characterize the online nominal group sessions: guidance, engagement, interaction, timing, technology, and participants' experiences. These categories were initially described by the main researcher based on literature analysis and further refined by the research team.

Analysis of the Online, Nominal Group Procedure

Audio and video recordings, together with written data (ie, transcripts, Teams chat, and email data) from the nominal group procedure, were analyzed for the purpose of this study. A deductive "top-down" approach was applied to collect meaningful data from these sources, by exploring the predefined outcomes. More specifically, a Fishbone diagram was used to

explore all possible challenges researchers and participants faced when performing or attending the online, nominal group sessions, as this methodology helps team members visualize the potential problem sources. The analysis starts by defining a central problem, which is then deeply examined by formulating several causes, organized in different categories [21]. A literature search revealed that an online, nominal group technique has rarely been performed (and reported); only very few research articles explored this online methodology. This resulted in the definition of our central problem: low uptake of synchronous, online, nominal group sessions in research practice. The final Fishbone diagram incorporated in the study was reviewed by the entire research team to manage bias and ensure the validy of our findings.

Trustworthiness

To ensure rigor, we applied different strategies to increase trustworthiness of the data. First, maximum variation sampling was applied to recruit the participants for the nominal group sessions. Participants of different ages, sexes, regions, educational levels, and employment were chosen. Second, the 3 nominal group sessions were fully recorded and transcribed verbatim. In addition, field notes were taken. Third, dependability of the findings was established by providing a detailed description of the online, nominal group procedure. Finally, the analysis was checked by qualitative experts in the field.

Research Team

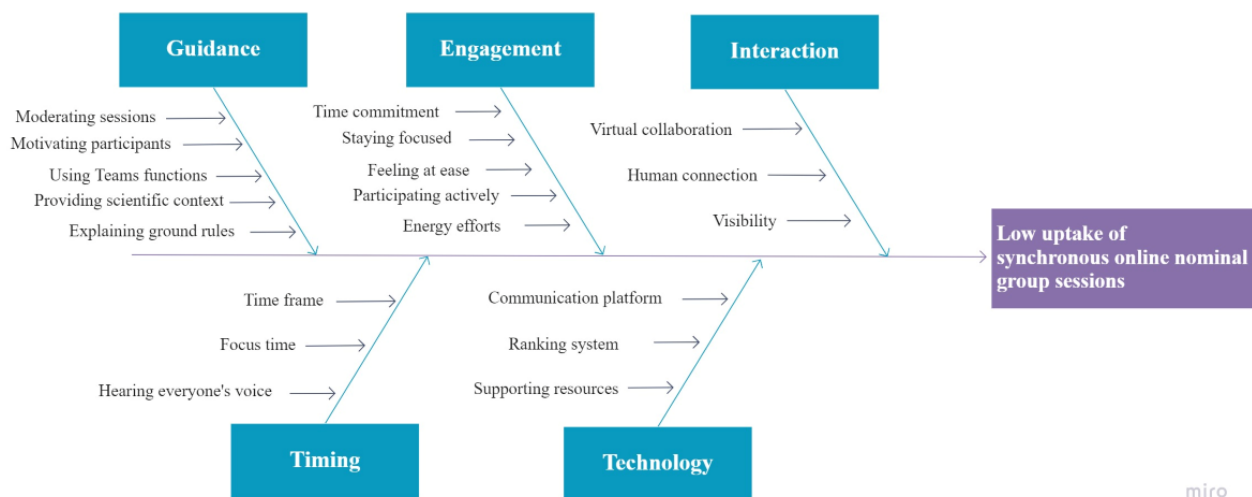
LT and IH performed the online nominal group sessions and collected the data. LT analyzed the data and designed the Fishbone diagram, in close collaboration with supervisor BS. The entire research team (IH, PD, VF, AVH, MV, and BS) reviewed the final diagram that was incorporated in this manuscript. This group consists of experienced members in qualitative health research. Before project initiation, the moderators received additional intensive training on the principles and methods in qualitative research to assure a certain level of standardization. Both moderators had previous expertise in quantitative and qualitative data collection in a group setting.

Results

After performing 3 synchronous, online, nominal group sessions in which individuals brainstormed on specific actions to support patients' self-management, a Fishbone analysis was undertaken. A total of 24 persons participated in the online sessions and therefore contributed to the data collection.

Challenges for Online, Nominal Group Sessions

Various causes were identified that positively or negatively challenged the online performance. These causes were clustered under the predefined outcome measures: guidance, engagement, interaction, timing, technology, and participants' experiences. Each outcome measure was thoroughly examined by audio and video analysis, supplemented with input from the chat and email, to identify the potential causes of the low uptake of online, nominal group sessions in research practice. Figure 1 represents the final Fishbone diagram.

Figure 1. Fishbone diagram representing identified causes challenging the uptake of synchronous, online, nominal group sessions. Template retrieved from an online collaborative whiteboard [22].


Guidance

Moderating the online sessions challenged the research team in various ways. The moderators' role was of major importance since they had to guide the discussion in an online setting. The main barrier was managing participants during the brainstorming while not being able to interact directly, neither verbally nor nonverbally. Participants were encouraged to provide input by elevating a virtual hand using the hand icon of Microsoft Teams. A moderator then appointed the person to speak at an appropriate time during the session. The importance of guiding participants was especially expressed during the round robin and clarification stages. To ensure everyone could provide their input, participants were indicated one by one to express their ideas on the topic of self-management. Examples of formulated ideas included the following: introducing a buddy system among peers, organizing interactive sessions on chronic disease coping strategies, integrating communication aids and strategies in primary care practice. This structured approach while exchanging the ideas seemed to have positively contributed to an equal involvement of all participants, even those who had told us beforehand they were not very articulate. Questions to each other when sharing ideas could often not be answered immediately. In these cases, the use of a chat box could act as an intermediate communication medium. Although instructed, this medium was rarely used by the participants.

During the entire nominal group session, attention was paid to expressing the scientific context and methodology in simple terms—for example, the moderators did not use the word self-management itself when guiding conversations and asking the idea generation question. This resulted in an overall understanding of the background information, setup, and aim of the nominal group technique. Based on the participants' feedback we received, we can conclude that the absence of real-life interaction emphasized the importance of strictly guided sessions. Also, clear instructions before and at the start were necessary given the simultaneous use of the chat box, hand icon, and PowerPoint presentation by the moderator, while interacting with the audience.

Engagement

During the sessions, engaging participants was challenging because of the online setup. Some actions by the moderators were observed as a remarkable help, since they triggered the audience to contribute to the conversation. First, the sessions began with a roundtable introduction, encouraging participants to get to know each other in an accessible way. This introduction revealed a variety of backgrounds: project officers of care organizations, general practitioners, nurses, patients with chronic conditions and informal caregivers, representatives from patient associations, lecturers, and researchers in primary care. Second, the use of informative PowerPoint slides during the idea generation phase seemed a welcome addition, since all participants indicated they had a full understanding of the brainstorming procedure after reading a concise information sheet on the general topic and the idea generation question. Third, to give participants time to think and feel at ease, they were asked to switch off the camera during the silent idea generation phase. Fourth, regarding the engagement while exchanging ideas, the use of a round-robin questioning format allowed each participant to provide input. Attendees were motivated to actively participate by emphasizing that all input was valuable. However, we noticed the online setup demanded extra effort from the participants. This was mainly observed at the end of the sessions, when there was reduced active contribution to the brainstorming. This could be attributed to the long period of attention on the computer screen.

Interaction

The online design challenged the interactive process of brainstorming since participants could not rely on human interaction and the use of sticky notes, both key elements in real-life nominal group sessions. Nevertheless, some elements did contribute to a relatively vibrant process. Slides with strong visuals, including images to supplement content, engaged participants online and resulted in virtual collaboration. Participants also used pen and paper to write down their thoughts. In addition, the hand icon was used to interact with the research team. Unfortunately, active interaction or conversation among participants was not enhanced by the online setup. The only stage in which participants were able to

communicate with each other in a coordinated way was the clarification stage.

A remarkable aspect of the online setup was how the camera use influenced the level of interaction. A sense of interconnectedness was created when participants were asked to switch on their webcams, determined by the observation that attention increased and the conversation became more lively. Noteworthy is that when sharing the PowerPoint presentation, this connected feeling diminished as the screen was taken up by the shared slides instead of the video streams. To overcome this barrier, screensharing was interrupted while actively brainstorming during the round robin and clarification stages.

Timing

Overall, the timing of the virtual sessions turned out well, although moderators were challenged to stick to the schedule in the foreseen period. To maintain the timetable, the entire nominal group session was precisely structured, and every part was delineated according to a strict time frame. The timing was tuned to the PowerPoint slides. For the moderators, staying within the time frame was rather challenging since they had to find a balance between providing enough time versus sticking to the strict time frame. To make sure sessions were not too strenuous, a break of 10 minutes was incorporated in between and appeared to be sufficient. However, the time frame was very tight, resulting in a rushed feeling among the moderators and reduced room for unforeseen circumstances (eg, delayed start). We also noticed that there was not enough time to prioritize the ideas with the external ranking system. To resolve this, we provided the opportunity to rank immediately afterwards up to a few hours after each session. However, this function was rarely used.

Technology

The online nominal group design challenged the participants since they had to have access to reliable technology to successfully engage within the sessions. In addition, necessary skills for using the various instruments (ie, Microsoft Teams, Poll Everywhere) were expected. Likewise, the moderators had to be able to manage the interaction with the audience, processing of ideas (ie, submitting in a ranking system), and navigation through the slideshow. This emphasized the need for guidance from 2 moderators. Unfortunately, due to the large number of participants (between 7 and 10 in each session), not all the faces were visible at the video bar while presenting the slides. This was a disadvantage because visual interaction appeared to contribute to participants' engagement.

Participants' Experiences

I would like to compliment you (ie, the main moderator/researcher) on the way you took the lead in the session. You gave enough guidance so that it was pleasant to follow at a smooth pace. That is not always evident online. [Participant]

Based on voluntary feedback in the chat, by email, or orally, participants' experiences regarding the online sessions were positive overall. Furthermore, participants explicitly indicated they wished to cooperate further on the research project. The only negative feedback was received regarding the large number of ideas that had to be prioritized using the ranking system (Poll Everywhere). Participants verbally indicated that they did not have enough time to rank the ideas in the foreseen time frame. This resulted in confusion for some participants and failure to reach a full consensus at the end of each session, since consensus can only be reached when everyone gives their input. It is possible that participants preferred to have more time in a relaxed atmosphere to rank ideas. This resulted in the development of an additional short survey in Qualtrics (Provo, UT) after completion of the 3 sessions, in which all participants had the opportunity to cast their vote on the entire group of ideas (total of 3 sessions).

Discussion

Practical Guide With Recommendations

Guidance for performing online nominal group studies is missing. However, it has been stated that results of the same quality can be achieved with an online approach [23]. In addition, studies show that there is no specific need to perform real-life sessions [13]. We used a Fishbone diagram to identify all possible challenges that researchers face when performing online, nominal group sessions. Based on our findings and experiences with the online setting, we developed a practical guide with recommendations for researchers interested in this type of work. The recommendations were pooled into the main stages of the nominal group: silent generation, round robin, clarification, and ranking (Figure 2). In addition, some general recommendations were formulated.

Figure 2. Recommendations for planning and implementing synchronous, online, nominal group sessions.

Recommendations for online nominal group sessions

Silent generation
1. Ask to have pen and paper available
2. Display initial question on screen
3. Make sure everyone understands the concept
4. Keep an eye on the chat box
5. Ask to turn off the camera
6. Set up a short time frame

Round robin
1. Provide enough time
2. Stop sharing slideshow and focus on interaction (camera on)
3. Discourage the use of the chat box
4. Act as a neutral moderator
5. Let each person pass his or her ideas to the group
6. Coordinate by indicating participants

Clarification
1. Make sure everyone understands the ideas
2. Rephrase the ideas
3. Stimulate the use of the hand icon
4. Check chat box regularly
5. Determine the end point in advance

Ranking
1. Present a clear overview of the generated ideas
2. Include a user-friendly ranking system
3. Give clear and understandable instructions
4. Finish by reporting some results

Silent Generation

At the beginning of the session, the moderators should clearly explain the concept. During the brainstorming, pen and paper are indispensable. Taking notes helps the participants to explore ideas. Instead of classical notes, an online platform or whiteboard can help participants brainstorm but can be more complicated. Displaying the initial question on the screen during the generation process adds value. We recommend keeping this phase short, to avoid losing someone's attention. Moderators should encourage participants to use the chat box when personal issues occur. Oral interventions are not recommended. This results in disruption of the individual reflection. An exception should be made for communications that are relevant to the whole group. In addition, switching off the cameras also contributes to thinking in serenity. However, disabling cameras can be discussed as a negative element, as participant's behavior can no longer be interpreted. In addition, seeing each other visually can result in increased commitment to the idea generation.

Round Robin

To engage participants during the round robin, we recommend stopping screen sharing. Switching on the video camera leads to a more interactive conversation. To further increase the level of interaction, try to minimize the use of the chat box while exchanging ideas. If still used during this stage, motivate the chat box user to ask the question out loud. We suggest providing enough time to exchange the ideas generated so that everyone can have their say and the moderators have time to take notes. Furthermore, it is essential that moderators act as neutral as possible to avoid judgment and criticism. They should monitor the participants' engagement. Coordination is crucial for every person to pass their ideas to the group.

Clarification

Collaboration and interaction are highly affected in the online setup since there is less nonverbal communication. This challenges participants to speak more out loud during the clarification round. Unfortunately, not everyone feels comfortable doing so. The use of the chat box as an intermediate communication platform can counteract this but was rarely used. Moderators should make sure everyone understands the ideas formulated. It helps to reformulate ideas in different ways and to check that those present understand them. Make sure the use of the Microsoft Teams hand icon is encouraged to avoid a chaotic conversation. Analogous to the regular methods of the nominal group technique, we advise determining the end point of this research phase in advance to prevent clarification from becoming an ongoing process.

Ranking

Some participants are overwhelmed by a multitude of information. Providing a clear overview of the generated ideas at the beginning of the ranking process is helpful. This procedure should be user-friendly, and instructions should be incorporated into the accompanying slideshow. The time it took to rank the ideas generated seemed to be person-dependent. Therefore, it is valuable to familiarize oneself with the audience while preparing the online sessions. To finish the brainstorming in a pleasant way, let the participants take a sneak peek at the results. This can be done by reporting the most favorite idea so far (ie, ranked as number 1).

General Recommendations

Organizing synchronous, online, nominal group sessions requires thorough preparation. Guidance by at least two moderators is necessary. Due to the online complexity, moderators can benefit from special training. Not only are skills required from the research team but participants also need to develop online competencies. Unfortunately, not everyone is able to deal with online platforms. In Belgium, more than 15% of the adult population has a low level of health literacy, and in addition, 10% of households do not have an internet connection [24,25]. This must be considered when setting up online research with lay participants. Communication with the participants is essential to operate efficiently. More specifically, moderators should provide clear instructions before, at the start of, and during sessions. Furthermore, it is important to make a detailed schedule and monitor time. To engage participants as much as possible, more emphasis should be put on enhancing human interaction. The format of the nominal group technique is well adapted to empower attendees [13,26]. However, it should be mentioned that due to a strict pattern and guidelines, the nominal group technique never allows a lot of interaction. Not being able to ask each other questions immediately, due to the strict design, might also challenge participants' patience. Starting with a roundtable introduction, switching on the video cameras, and using interactive slides with visual components seem to make attendees feel comfortable. In addition, the possibility can be offered to contact the research team afterwards. Researchers should aim for a meeting moment that works best for the target population, and the importance of attending at the scheduled time needs to be emphasized.

Computer screens have been proven to negatively influence the activity of the human brain [27]. Therefore, the duration of the meeting should be limited. By contrast, online sessions are less subject to distractions, which means less time is lost and researchers can better stick to the schedule. Unfortunately, the strict timing can result in a rushed feeling. In our opinion, this cannot be compensated by allowing more time for the brainstorming, as we noticed focus decreased the longer the session lasted. A second break could be a possible solution.

The main advantage of performing online sessions seems to be the flexibility and comfort for both researchers and attendees. The online setup increased the accessibility for participants who otherwise might have experienced barriers to participation, such as feelings of discomfort in a group setting, transportation issues, or time [13]. Especially for health care professionals, who were in the middle of the battle during COVID-19 pandemic, it was a great opportunity to actively participate in research. The flexibility might explain the large turnout and few cancellations. This is in striking contrast to real-life sessions in which organizational issues seem the main limitation [10].

Strengths and Limitations

Some limitations should be mentioned. First, performing only 3 online sessions limited the generalizability of the results.

However, after performing 3 sessions, we reached a point of saturation regarding both the findings on the topic of self-management support and on the methodological challenges and opportunities. Moreover, we did not compare our findings with real-life nominal group sessions. This paper only elaborates on the synchronous, online technique. Based on the performance of 3 sessions, we were able to gain sufficient input to analyze challenges. Knowledge of the real-life setup was gained through literature analysis. Furthermore, participants' experiences were not deeply surveyed or explored. However, we achieved a notion of participants' satisfaction by voluntary feedback in the chat, by mail, or orally. In addition, the research team reflected critically about the objectivity of the observations during multiple review rounds. Finally, the use of sophisticated online brainstorming tools was not included in our brainstorming procedure. These platforms can increase engagement during brainstorming. However, we deliberately chose simple operating systems (ie, Microsoft Teams, Poll Everywhere), because not everyone is able to work with such tools. By choosing low-threshold systems, a wide target group could participate in the online, nominal group sessions.

Practical Implications

Online, nominal group sessions seem to be a promising alternative to the commonly used real-life technique. This paper provides researchers with recommendations for conducting online sessions, considering the various challenges. In our experience, the online format is highly recommended when looking for research procedures that are very accessible and consume little time. Especially during the COVID-19 pandemic, the benefits must be highlighted.

Future Research

Future research should focus on refining the online, nominal group technique. More expertise is needed to optimize the practical guide and to achieve optimal performance. Comparative studies between the real-life and virtual setups are required to make statements about the efficiency. Researchers should consider participants' experiences in the design of future online sessions.

Conclusion

Performing synchronous, online, nominal group sessions is challenging but offers opportunities. One should be aware of the differences between real-life and online sessions. Good preparation is needed to overcome the barriers of the online technique. Our practical guide for researchers offers recommendations to facilitate the process. The role of the moderators is of major importance during brainstorming. Further research should refine the online procedure and make it more accessible for both researchers and the research population.

Abstract

Background: Ecological momentary assessment (EMA) has been used with young people experiencing homelessness to gather information on contexts associated with homelessness and risk behavior in real time and has proven feasible in this population. However, the extent to which EMA may affect the attitudes or behaviors of young adults who are currently or were formerly homeless and are residing in supportive housing has not been well investigated.

Objective: This study aims to describe the feedback regarding EMA study participation from young adults who are currently or were formerly homeless and examine the reactivity to EMA participation and compliance.

Methods: This mixed methods study used cross-sectional data collected before and after EMA, intensive longitudinal data from a 7-day EMA prompting period, and focus groups of young adults who are currently or were formerly homeless in Los Angeles, California, between 2017 and 2019.

Results: Qualitative data confirmed the quantitative findings. Differences in the experience of EMA between young adults who are currently or were formerly homeless were found to be related to stress or anxiety, interference with daily life, difficulty charging, behavior change, and honesty in responses. Anxiety and depression symptomatology decreased from before to after EMA; however, compliance was not significantly associated with this decrease.

Conclusions: The results point to special considerations when administering EMA to young adults who are currently or were formerly homeless. EMA appears to be slightly more burdensome for young adults who are currently homeless than for those residing in supportive housing, which are nuances to consider in the study design. The lack of a relationship between study compliance and symptomatology suggests low levels of reactivity.

Introduction

Background

Ecological momentary assessment (EMA), also known as the *experience sampling method*, is an intensive, longitudinal, real-time sampling strategy with widespread adoption in public health research and social sciences [1-4]. EMA, which leverages advancements in mobile computing to deliver repeated surveys throughout a specified measurement period, often by using cell phone technology [5], can reduce recall biases and improve the ecological validity and environmental representativeness of the collected data [6]. Given that young adults experiencing homelessness, of which the prevalence is estimated to be 1 in 10 annually in the United States [7], live relatively unstable lives that are highly affected by their immediate environment [8,9] and have high rates of mobile phone technology adoption [10], EMA may be well suited for use with young adults experiencing homelessness [11,12]. In addition, this method may overcome existing limitations in homelessness research that has relied on methods using retrospective reporting, including cross-sectional designs (eg, single point-in-time measurement) [13] and longitudinal study designs with infrequent measurement points (eg, monthly follow-ups) that include issues with attrition [14]. However, although EMA is likely to be a useful method in homelessness research, it is important to better understand the feasibility and acceptability of EMA in this population.

To date, few studies have used EMA to investigate the daily life experiences of young adults who have experienced homelessness, and several studies have shown the feasibility of EMA in this population. Santa Maria et al [15] provided smartphones to 66 young adults who were homeless aged 18 to 25 years to collect EMAs over 21 days and found daily drug use to be predicted by discrimination, pornography use, alcohol use, and urges for substance use and stealing behaviors. In a different study, Tyler et al [16] distributed mobile phones to implement EMA via SMS text messaging with 150 youths who were homeless aged 16 to 22 years over a 30-day period and found that experiencing physical or sexual victimization on a specific day was positively associated with drinking alcohol later that day. Both studies reported high compliance with completing EMA prompts, and the latter study also reported that participants perceived the study to be of low burden [17].

Another important aspect of EMA feasibility is reactivity. Reactivity is understood to be the extent to which the frequency or quality of behavior changes as a result of being monitored [18]. Understanding the potential reactivity is critically important as it suggests that EMA could serve as a possible intervention or manipulation. The literature has generally found low reactivity when using EMA [19-23], including in college and clinical samples [24,25]. Acorda et al [26] found that young people experiencing homelessness were highly receptive to EMA but may have experienced limitations regarding the use of technology and that the repetition of EMA prompts may have affected some behaviors of those participating. However, the extent to which EMA may affect the attitudes or behaviors of young adults experiencing homelessness during a time of identity formation and instability, especially when examining risk behaviors, including sex risk and substance use, has not been well investigated.

Objective

More research is needed to understand the daily experiences of young people who have experienced homelessness, including those who have transitioned into supportive housing, which is a primary intervention being applied to homelessness. Previous work has identified ways in which housed and unhoused young adults differ, including abuse at home [27], which affects mental health [28,29] and substance use [30]. To understand the environmental influences on young adults who have experienced homelessness, it is imperative to examine both those who are currently experiencing homelessness and those who have transitioned from homelessness to supportive housing environments. This study seeks to address this gap by using a mixed methods approach to examine whether there are differences between young adults who are currently (ie, unhoused) versus were formerly homeless (ie, housed in supportive housing) in terms of acceptability, compliance, and reactivity to EMA.

Methods

Study Design

This mixed methods study examines the experiences of EMA in a sample of young adults currently experiencing homelessness and young adults who were formerly homeless who have been placed into supportive housing programs. Specifically, as described in a previously published research protocol paper, young adults participated in a study on health risk behaviors using geographic EMA through a smartphone app that allowed for the collection of time-stamped geographic location data along with EMA behavioral data. Consistent with previous literature [15-17], high compliance with completing EMA prompts (80.2% across the entire sample) over a 1-week study period for the combined sample has already been reported [31]. For this study, we first compared the feedback of housed and unhoused participants regarding their experiences of participating in the EMA week. Responses were then used to examine rates and predictors of EMA compliance and survey responses regarding acceptability and feasibility, comparing those in housing with those who were currently homeless (ie, unhoused). Reactivity was examined using reported anxiety and depression symptomatology before and after the EMA week. Next, we used a qualitative approach to analyze the focus group data of participants who are current or were formerly homeless to better understand their experiences with EMA, which may help explain our quantitative findings.

Participants

Participants (N=231) in transitional living programs or permanent supportive housing (ie, *housed* sample; n=122, 52.8%) and participants not in housing programs (ie, *unhoused* sample; n=109, 47.2%) were enrolled in the study in Greater Los Angeles using stratified convenience sampling. Unhoused participants were recruited via drop-in centers and emergency shelters, including individuals who were explicitly homeless or

unstably housed with temporary living situations that were not reliable beyond 30 days (eg, temporarily crashing with a friend or family member or couch surfing). Participants who consented to the EMA component of the study received up to US $90 in scaled compensation based on response rates and were given the choice of using a study phone with an unlimited data plan or their own smartphone, with an additional US $10 compensation for using their own data plan.

Ethics Approval

All protocols and procedures were approved by the institutional review board at the University of Southern California (review number: UP-16-00046) [31].

Quantitative Component

Overview

Participants were enrolled in a 7-day EMA study comprising questions that asked participants to report on current and previous 2-hour experiences, which were delivered approximately every 2 hours during waking hours using a custom-built app for smartphones using the Android operating system (Google). This study used custom EMA software written by the investigative team. Phones were programmed to only deliver prompts during the waking day, which was determined using the participants' individual estimated sleep and wake times. Prompted surveys asked about physical and social environments, as well as affect and substance use. Participants received an average of 5 EMA prompts per day.

In addition to the EMA prompts, participants completed a daily survey for each EMA day. Daily diaries captured the risk behaviors of the previous day and infrequent behaviors that may be missed by EMAs. Daily survey prompts were scheduled to be delivered at a participant's preferred time but were also available to access via the app at any time during the day to report on the previous day. Daily surveys inquired about participants' social environments, sex behaviors, and substance use.

Before the EMA week, participants completed a baseline interview that took an average of 60 minutes to gather demographic information and data on their histories of homelessness, mental health, and other behaviors. Following the EMA week, participants participated in an exit survey, in which their thoughts and feelings regarding their participation in the EMA study were gathered. The exit surveys lasted approximately 30 minutes. Participants returned the phones and were paid for study participation at the conclusion of the exit survey. The Patient Health Questionnaire-9 was used to assess depression symptomatology [32], and the General Anxiety Disorder-7 was used to assess anxiety symptomatology [33] at both the baseline and exit surveys.

To reduce missed surveys, there were multiple push notifications for both the EMA and daily survey prompts. EMA prompts required a response within 10 minutes after the first prompt, which comprised a chime and vibration. During this 10-minute window, push notifications were sent every 3 minutes. After 10 minutes, the EMA prompt became inaccessible to ensure momentary reporting of the current time and day. Daily surveys

were programmed to send push notifications at 3 time points during the day; however, they could be answered at any point within the day; when answering the daily surveys, participants reported on the prior waking day. The complete study methods are available for further review elsewhere [31] (see Multimedia Appendix 1 for the complete EMA questionnaire and Multimedia Appendix 2 for the daily survey questions).

Analyses

Quantitative analyses in this study included chi-square analysis to compare results by housing status and bivariate linear regressions to predict EMA and daily compliance. Compliance measures the total number of prompts answered out of those received. As the aim of this study was to examine personal factors, such as housing status, rather than artifacts associated with EMA technology, which are associated with compliance, we chose to calculate compliance based on the number of prompts received instead of prompts possible (ie, scheduled). Furthermore, between-subject mixed effects regressions assessed reactivity using the Patient Health Questionnaire-9 [32] and General Anxiety Disorder-7 [33], with random intercepts for each participant.

Qualitative Component

Overview

A total of 4 separate focus groups were conducted to better understand participants' experiences with EMA, each of which occurred within 2 weeks of their last day in the study and lasted approximately 1 hour. Focus groups were chosen as a time-saving way of easily measuring and capturing wide-ranging reactions to EMA. A total of two focus groups included participants recruited from housing programs (one with n=12 transitional living program residents and one with n=6 permanent supportive housing program residents) and 2 focus groups (n=6 and n=7) recruited from youth drop-in centers. Focus group facilitators began by asking participants about their general experiences in the study (eg, "What did you like? What did you not like?"). Additional probing questions included specific aspects of study participation (eg, whether EMA interfered with their daily lives), perceived reactivity to EMA surveys, how accurate they thought their reporting was, level of comfort reporting about sensitive topics such as drugs and alcohol, timing and density of survey prompts, and suggestions for similar studies in the future.

Analyses

Focus group recordings were transcribed and evaluated by 2 independent reviewers, one of whom was the focus group facilitator. Coding and case summaries took a deductive approach using exit survey questions focused on experiences of study participation as a guide (see Multimedia Appendix 3 for the focus group interview guide). Co-coder consensus was achieved through the codevelopment of 4 individual case summaries that summarized each item, including quotations, with 1 for each focus group. Case summaries were then analyzed, first considering housed and unhoused groups separately and then together, to see what might account for and expand upon the differences found.

Results

Quantitative: Exit Interview by Housing Status

Table 1 describes the sample characteristics by housing status, and Table 2 describes the exit surveys and responses, also by housing status. Approximately two-thirds of the participants had an overall positive experience with the study, >90% reported they would be willing to participate in the study again, and approximately 67.5% (156/231) reported that the study took place during a typical week. Approximately 69.7% (161/231) did not feel judged about their sex or drug use, and approximately half of the participants would prefer to use their own phone in a new study provided they owned a phone compatible with EMA technology. As a result of personal choice and incompatibility, only 9% (21/231) used a personal phone

in this study, and significantly more unhoused individuals opted for personal phone use. Housed and unhoused participants also reported statistically significant differences in their experiences of charging the phones, behavior change because of EMA content, being open and honest about EMA survey questions, and whether EMA interfered with their daily life. Compared with those in housing, unhoused participants reported greater difficulty charging their phones ($P=.007$ to overall $P=.02$), greater self-perceived behavior changes in response to EMA ($P=.001$ to overall $P<.001$), that EMA interfered more with their daily life (specific and overall $P<.001$), and more stress or anxiety because of EMA surveys ($P=.008$ to overall $P=.02$), whereas housed participants reported that they were more comfortable answering EMA survey questions openly and honestly (overall $P=.03$).

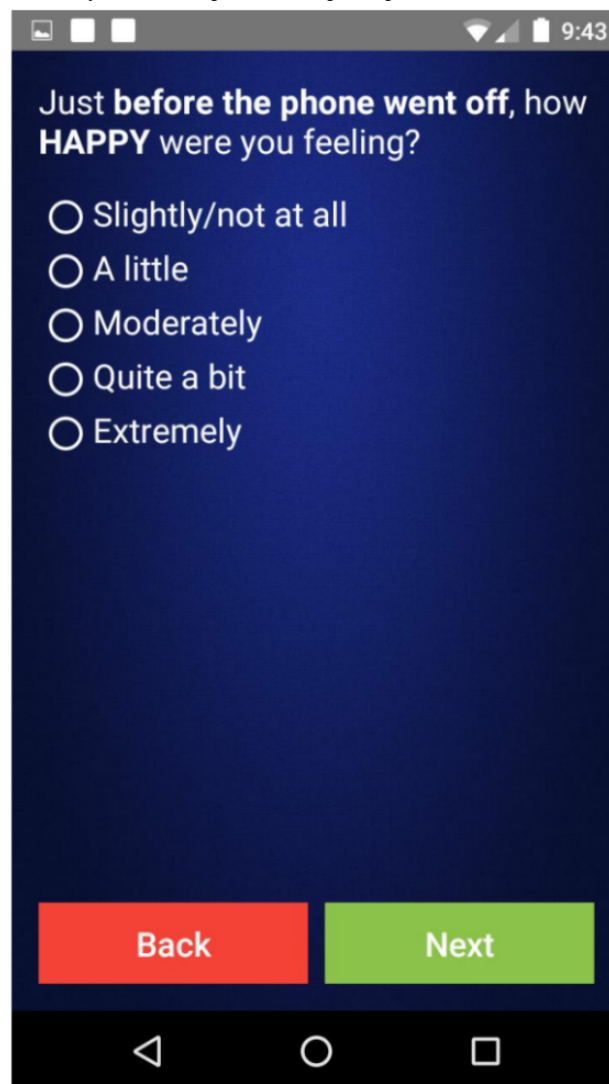
[a]Combined for specific *P* values.

Quantitative: Delivery and Compliance

Out of a theoretical maximum of 20,076 prompts, 17,944 (89.38%) prompts were scheduled for delivery by the custom software. The discrepancy of the 10.62% (2132/20,076) of prompts may be explained by hardware issues (eg, low battery), software issues (eg, app crashing), or schedule timing (ie, where a participant was enrolled at midday and would not have received earlier prompts). Of the scheduled prompts, approximately 39.57% (7101/17,944) were not delivered as the app detected that the prompt time was within sleep parameters specified by the participant. Of the 17,944 prompts, 679 (3.78%) scheduled prompts were not delivered because of Android system features designed to conserve battery life and memory, and 138 (0.77%) prompts were not delivered as the phone was intentionally turned off. The remaining undelivered scheduled prompts, which was an average of 46, were missing because of unknown software or hardware errors. In all, of the 17,944 prompts, the participants received 9980 (55.62%) prompts and completed 8001 surveys upon answering the prompts (8001/9980, 80.17% EMA completion). Participants failed to answer 18.24% (1820/9980) of prompts and answered but did not complete 1.59% (159/9980) of surveys. Participants took, on average, 97 (SD 70, range 19-599) seconds to complete the EMA surveys and completed 13.8 (SD 6.4, range 0-25) questions per EMA survey (see Multimedia Appendix 1 for the EMA survey questions and Figure 1 for an example screenshot of the app).

Figure 1. Screenshot of the ecological momentary assessment presented to participants.


Approximately 3% (7/231) of participants did not receive 2.93% (49/1673) of daily survey prompts, and an additional 6.69% (112/1673) of daily survey prompts were not delivered, out of the theoretical maximum number of prompts, because of possible hardware, software, or schedule timing issues. Of the 1512 scheduled daily survey prompts, 5 (0.33%) were not delivered because of Android system battery conservation issues, and 5 (0.33%) were not delivered as the phone was turned off by the participant. Out of 1502 prompts that were received, participants answered and completed 1376 (91.61% daily compliance) daily prompts; of the 1512 surveys, participants failed to fully complete 6 (0.4%) surveys. Participants took, on average, 89 (SD 61, range 14-570) seconds to complete daily surveys, and they completed 12.2 (SD 5.1, range 0-45) questions per daily survey (see Multimedia Appendix 2 for the daily survey questions).

The results of the analyses of compliance are presented in Table 3. Neither daily compliance nor EMA compliance was associated with housing status ($t_1=-0.38$, $P=.71$ and $t_1=-0.86$, $P=.39$, respectively). Only 9.1% (21/231) of participants chose to complete the study on their own phone, with no difference in compliance between those who used a personal versus a study phone ($t_1=1.15$, $P=.25$ and $t_1=0.74$, $P=.46$, respectively). Compared with those reporting negative or neutral experiences, participants who reported a *very positive* or *somewhat positive* experience with the study had 6% (SE 0.03%) greater EMA compliance ($t_1=2.49$; $P=.01$). Furthermore, those reporting *not at all* or *a little bit* of difficulty charging their device had 6% (SE 0.03%) greater EMA compliance than those reporting more difficulty charging their device ($t_1=2.41$, $P=.02$).

Daily survey compliance was not associated with general experience with the study ($t_1=0.97$; $P=.33$), nor was participants' self-report of honesty regarding survey responses associated with EMA or daily compliance ($t_1=0.92$, $P=.36$ and $t_1=1.23$, $P=.22$, respectively). Compared with those reporting somewhat or greater interference with the study protocol in their lives, participants who reported not at all to a little bit of interference had 8% (SE 0.02%) greater EMA compliance ($t_1=-3.83$; $P<.001$) and 6% (SE 0.02%) greater daily compliance ($t_1=-3.42$; $P=.001$). Similarly, participants experiencing little or no stress or anxiety from surveys had 7% (SE 0.03%) greater EMA compliance ($t_1=2.62$; $P=.009$) and 5% (SE 0.03%) daily compliance ($t_1=2.05$; $P=.04$) than those experiencing greater stress or anxiety from surveys. Compared with those who indicated feeling judged by surveys, participants who did not endorse feeling judged by the surveys had 6% (SE 0.03%) greater EMA compliance ($t_1=2.38$; $P=.02$) and 9% (SE 0.02%) greater daily compliance ($t_1=4.02$; $P<.001$). Participants who reported having a typical week had 8% (SE 0.02%) greater EMA compliance than those who reported having an atypical week ($t_1=3.58$; $P<.001$); however, those with typical weeks only had marginally greater daily compliance ($t_1=1.79$; $P=.08$). Willingness to participate again was not associated with EMA or daily compliance ($t_1=0.34$, $P=.74$ and $t_1=-0.05$, $P=.96$, respectively).

[a]EMA: ecological momentary assessment.

[b]Indicates percentage change in compliance.

[c]N/A: not applicable.

Quantitative: Reactivity Analyses

Table 4 displays the results from the mixed effects models to examine reactivity to EMA participation, specifically regarding anxiety and depression symptomatology. Both anxiety and depression scores decreased from baseline to follow-up (β=−1.77, *P*<.001 and β=−1.10, *P*=.03, respectively). However, no significant effects for EMA compliance were detected for either anxiety or depression; thus, the decrease in symptomatology was not associated with compliance. Both models controlled for age, gender, sexual orientation, race and ethnicity, and housing status.

Table 4. Mixed effects regressions for reactivity (N=231).

Qualitative Findings

Overview

The qualitative findings that were generated independently of the quantitative findings were categorized under the 5 main emergent themes. The first theme explains how participants felt the study design *increased mindfulness and reflection*, whereas the second theme captures those negative instances when the participation in the study resulted in *causing stress and anxiety*. The third theme discusses the ways in which study participation incited behavior change, whereas the fourth theme addresses participants *responding honestly* to questions. The final theme captures participant suggestions about future study designs. We note that a comparative analysis of the housed and unhoused samples indicated that these themes apply to both groups, as shown in Table 5.

Table 5. Qualitative findings by housing status.

Themes	Housed focus groups (n=18)	Unhoused focus groups (n=13)
Increased mindfulness and reflection	• "You get to know yourself. Like how many times do I do these things a day? Who am I around every day? What am I doing every day? So, it gave me insight on who you are and what you do every day. Because sometimes we'll just do things. And we don't keep track of those things. They kind of keep you on track a little bit." [SP[a]102] • "Some stuff I forgot about, that...It just opened my mind more. I was, 'Okay, I need to start paying more attention to that. I need to start paying more attention to this. I am around certain people who do stuff like this.'" [SP209]	• "It was the shit to me. It actually calmed me down on most occasions." [SP305] • "It makes you feel good. You want to get up and answer the questions that, how you feel, how you feel going out today, and shit like that. It made me feel good, honestly." [SP306] • "Yeah 'cause I forgot to do my chores and as soon as that survey come on, and be like, 'Oh snap. I forgot to do my chore.'...But then I'm right back on it." [SP403] • "It also gave me a good understanding of how when I hang out with these certain people, yeah, I am smoking more. And if I hang out with this certain people, I am drinking more...Gonna be like, okay dude, I'm hanging out with you but just because we're hanging out doesn't mean we have to drink. You know? If they're drinking it's their choice. Alright man, I'm noticing I can't be hanging out with you every day. You're drinking every day, I'm hanging out with you every day, I'm probably gonna be drinking every day." [SP406]
Causing stress and anxiety	• "Well, it was irritating, like once or twice. I thought it was going to ask different questions. I didn't know about the repetition thing." [SP106] • "Sometimes it would annoy me, like, 'How do you feel?' Like, 'Oh, I feel annoyed now.'" [SP207]	• "I got paranoid sometimes, like if I was hanging out with these people and it was asking me, 'who are you with?' 'Did you do any drugs with them?'...It was just about the whole street thing; it feels like snitching." [SP301] • "I got annoyed sometimes. If I was going through something and the survey went off, I just didn't want to answer it sometimes." [SP302] • "I did [feel uncomfortable] at first. I thought it was like the Feds or something. I was like oh shit, I'm not gonna lie, I was doing all types of lies though. A few of the surveys I feel like I failed them or something. I don't know. That's just how my mentality think. I felt like the phone was recording. Something. On everything. Yeah, I felt like the Feds was watching. And taking video at the same time. I let the phone die for like a day and a half...I'm like I don't know, I'm gonna keep the phone off. I was just annoyed about it because like they know oh really alerted when I got a text that 'we see your phone hasn't been charged.' [laughs] You guys are watching me! I know what you can do with technology. It's a simple program, there's no telling what's written in that program that I don't see." [SP403]
Inciting behavior change	• "I'm not going to drink today, because they're going to ask me how many drinks I drank." [SP102] • "I had kind of like a Pavlov's dog affect, where every time it went off, I'm like, 'Ooh, I could really use some alcohol right now.' I'm like, 'Ooh, this is reminding me that alcohol is not a great option, but it is an option.' [SP206]	• "Have you smoked yet today? Okay? I haven't, mostly because I haven't got my weed so hold on, thanks for letting me know I have to go get weed. That's what I'm saying. Reminding me to go get my marijuana when I run out." [SP305] • "On the alcohol and drink question I went like...the repetitive asking you another question and just mentioning a drink, made me want to drink. I never had that many drinks in a week." [SP403]

Themes	Housed focus groups (n=18)	Unhoused focus groups (n=13)
Responding honestly	• "I tried to be as honest as possible. Because I knew that it was a study. So I tried to be as honest...Because you guys are going to look at it and try to get real answers from people. It was hard. But I tried to be honest about it." [SP102] • "The thing about surveys too, is it's a non-judgemental environment that you're telling your information to." [SP105] • "Yeah, I feel like if anything it makes me feel more comfortable, because the phone, you don't have to give a fuck...I'm going to be real today, and I'm going to be real to myself. It's kind of like a diary if you think about it. That survey was like a diary for a week...If you have time for that." [SP205] • "To be honest, I lied on a few questions...I lied because- It just reminded me of what a whore I am, because like...so it would be like 'How many times did you have sex today?' And stuff like that, I'm like 'Ooh.' [SP202]	• "...it was just about the whole street thing, it feels like snitching. Yep." [SP301] • "I say it depends on the mood of how people will feel when I'm doing the surveys." [SP306] • "A lot of them I tried to be honest some, some of them I kind of like, I don't think I put the right answers, like it would say, where you at, and sometimes I'd put like, or what are you doing, and I'd say hanging out, but really I was eating, still hanging out a little bit, so kind of lie about that, I need to be more honest, cause you know, I don't want them to know exactly what I'm doing." [SP404] • "I thought it was like the Feds or something. I was like oh shit, I'm not gonna lie, I was doing all types of lies though." [SP403]
Suggestions for future studies	• "I think [using my own phone] was more convenient. It was a lot easier than having to have a second phone. Losing track of it." [SP105] • "I thought it was interesting. It was cool. I think I prefer it to be on my actual phone than another phone. Because it was kind of hard to keep up with it." [SP104] • "It felt extra for me but that's because...I'm really bad about keeping my regular phone on me, so I said I was a bad millennial. I'm a bad millennial." [SP204] • "It's hard to remember to carry two phones." [SP208] • "But even if I went from my bedroom to the dining room, and thirty minutes went by and I was like, 'I have to go get my phone.' Then I saw that I missed one survey." [SP204] • "I feel like I have bigger problems than carrying two phones. It wasn't the hardest thing in my life, but sometimes I would forget it and be like, 'Aw, crap.' That's it." [SP207] • "It was hard for me. I was literally driving. I always keep my phone away. I'm over there trying to jump in the purse like: Where is this phone? And then, another thing, my neighbor...My neighbor [who was also in the study] always comes over...And my other neighbor...So he'd be like: 'Who's phone is who's? Who got that...' And I'd be like: 'Do you have my phone? That's my phone?' How did we know it was our phone?...It took me about a day, or maybe two, to actually [get used to it]." [SP104]	• "[Borrowing] the phone...actually helped me with my daily life, bro. Because I didn't have a phone at the time, so it helped me to get phone calls." [SP404] • "Oh yeah, me too. Google maps." [SP408] • "I hadn't had a phone since that one. I do want a phone for another week though." [SP404] • "Because it would ask have you did this in the past 2 hours and I might forget. Or how many cigarettes, how many times do you think you used tobacco products. Like, I don't know, let me count the cigarettes in my pack right now...I might forget and I just smoked a cigarette 5 minutes before it happened. So more every time you smoke a cigarette, log it in the phone. Tally it." [SP402]

^aSP: study participant

Increased Self-reflection and Self-awareness

Self-reflection and awareness while participating in EMA were common points of discussion in the focus groups. In fact, this idea came up in all 4 focus groups. Many participants noted increased self-awareness regarding how their own thoughts, feelings, and social or physical contexts influenced their engagement in protective or risky behaviors.

For example, several participants noted that the EMA helped them stay on track over the course of the day, including triggering better awareness of time, what has been accomplished, and what has yet to be done. A participant discussed being able to keep track of what they were up to:

You get to know yourself. Like how many times do I do these things a day? Who am I around every day? What am I doing every day? So, it gave me insight on who you are and what you do every day. Because sometimes we'll just do things. And we don't keep

track of those things. They kind of keep you on track a little bit. [Study participant (SP) 102, housed]

Similarly, another participant specifically talked about how EMA kept them productive and on top of their chores, saying the following:

Yeah 'cause I forgot to do my chores and as soon as that survey come on, and be like, "Oh snap. I forgot to do my chore."...But then I'm right back on it. [SP403, unhoused]

Several participants realized that they were using drugs and alcohol more than they thought by logging their substance use every 2 hours:

Oh my gosh, I was shocked how many times I actually put down how much I drank alcohol, and truthfully, I have been trying to stop. [SP408, unhoused]

Furthermore, substance use was also linked to social and physical environments for some:

It also gave me a good understanding of how when I hang out with these certain people, yeah, I am smoking more. And if I hang out with certain people, I am drinking more...Gonna be like, okay dude, I'm hanging out with you but just because we're hanging out doesn't mean we have to drink. You know? If they're drinking it's their choice. Alright man, I'm noticing I can't be hanging out with you every day. You're drinking every day, I'm hanging out with you every day, I'm probably gonna be drinking every day. [SP406, unhoused]

Questions about drug use and sexual activity were often considered sensitive topics—topics that others might not ask the participants about because of their sensitive nature. Some participants felt that the EMA prompts provided a safe and comfortable opportunity to check in:

I think you get to know more about yourself by...You're being asked questions that a whole lot of people wouldn't ask you. So I found it interesting for a device or a system, that's not human, obviously, to ask you those questions. I was like: Wow. They were pretty insightful. Even if they were like the same old questions over and over and over. "How much drugs do you take?" Or "Who do you sleep with?". It's information that you want to keep private. You don't want to share it with anybody. And also, it's kind of a comfortable feeling too. [SP105, housed]

In addition, the *check in* and ability to confide in the surveys seemed to provide a sense of calm for participants: such as who stated:

It took me a little break, too. That was my little break, with the alarm going off. I was like oh shit, I'm on my little couple seconds break. [SP403, unhoused]

Self-reflection Negative Case Analysis: Causing Stress and Anxiety

Although self-reflection and self-awareness were common in focus group discussions, which seemed to promote a sense of calmness among participants, aspects of the EMA protocol also seemed to trigger stress, anxiety, and paranoia, particularly in response to location tracking. Approximately 16% (37/231) of participants reported EMA caused *somewhat* or *quite a bit* of stress or anxiety in the exit survey (Table 2). Although some participants liked the personal nature of the questions, allowing them to check in with themselves regarding personal behaviors that were otherwise likely to go unchecked, others felt that the questions were too personal. In fact, a participant discussed paranoia as a result of the prompts:

I got paranoid sometimes, like if I was hanging out with these people and it was asking me, "who are you with?" "Did you do any drugs with?"...It was just about the whole street thing; it feels like snitching. [SP301, unhoused]

Similarly, another participant spoke of the discomfort they felt regarding the nature of the questions and location monitoring:

I did [feel uncomfortable] at first. I thought it was like the Feds or something. I was like oh shit, I'm not gonna lie, I was doing all types of lies...I felt like the Feds was watching. And taking video at the same time. I let the phone die for like a day and a half...I'm like I don't know, I'm gonna keep the phone off. I was just annoyed about it them because like they know oh really alerted when I got a text that "we see your phone hasn't been charged." [laughs] You guys are watching me! I know what you can do with technology. It's a simple program, there's no telling what's written in that program that I don't see. [SP403, unhoused]

Fears regarding the personal nature of questions and location tracking, such as those discussed by participants SP301 and SP403, who were unhoused and both enrolled via drop-in centers, were more common among young adult participants who were actively homeless (ie, focus groups 3 and 4 [see Table 5 for more quotes by focus group and housing status]).

Further stress appeared to arise from the repetitive nature of the prompting schedule, with EMA prompts approximately 2 hours apart with the same array of questions. A participant commented on this by saying the following:

Well, it was irritating, like once or twice. I thought it was going to ask different questions. I didn't know about the repetition thing. [SP106, housed]

Some participants felt that the prompting occurred too frequently and reported that the prompt changed their mood and what they reported as the prompt itself annoyed them:

Sometimes it would annoy me, like, "How do you feel?" Like, oh, I feel annoyed now [SP207, housed]

A similar response was recorded by another participant, who commented the following:

Damn, this alarm's going off and now I'm irritated. Like I was doing fine before but now I'm irritated as fuck. [SP202, housed]

An additional point about the prompting scheme focused on the concept of negativity in survey items, as a few participants noted that the surveys did not ask about positive things in their lives, such as work, school, or other productive aspects of their lives. A participant commented the following:

It seemed to always be focused on like, what did you do that wasn't productive today. How much weed did you smoke how many did you smoke, how much did you drink, did you fuck anybody for drugs, what time did you wake up, did you even go to sleep tonight—it didn't ask anything like I don't know did you have a good day or did you...Did anything positive happen to you today. It was just all focused on, I'm not going to say negativity...I guess how often homeless youth use drugs and trade that for sex or whatever else. Being on the streets, just assuming being on the streets that's all that you do. [SP403, unhoused]

Despite these concerns, the participants seemed to become used to the prompting schedule over the course of the week.

Specifically, a participant discussed their experience of becoming familiar with the surveys, which made the experience easier:

> I got used to it...At first it was kind of slow, for me. So it'd take a while, maybe five or ten minutes. I'm taking forever on this thing until eventually it was two minutes. And after a while it wasn't really bothering me. [SP404, unhoused]

Considering the demands of the prompting schedule, participants had to juggle their study responsibilities with the responsibilities of their daily lives. Remaining stresses that resulted from study participation focused on having to comply (ie, answer a certain number of prompts) to get paid; needing to keep track of their study phones and answer surveys when at work or school; and not being comfortable with answering in front of others, such as SP408 when in the company of their case manager:

> I know I didn't want to miss one because you're not gonna get your money. I want to get to a good percentage, high percentage [SP404, unhoused]

> If I was working or if I was at school...I want to get the survey done, but I really have to pay attention to what I'm doing. So it's like let me just get it over with [SP103, housed]

> A few times it ringed off when I was in a meeting with my case manager. I was like "oh...no." I couldn't just pull out my phone and start doing a survey in front of my case manager. I was like, why you gotta hit at this hour. [SP408, unhoused]

On occasion, these demands resulted in participants clicking through the surveys. A participant described this as "going into default":

> I did find myself going into a default and then just changing it if it was different because my mood was fairly stable throughout the day and I'd be like, "This one, this one, this one, this one." Then I'm like, "Eh, this one's actually over here now." I definitely would go into a default but then I'd adjust it. [SP202, housed]

Inciting Behavior Change

Approximately 22.9% (53/231) of the SPs thought that their behaviors had changed because of study participation. Most notably, behavior change was focused on drug and/or alcohol use and more often reported by unhoused participants than those residing in supportive housing. On some occasions, EMA promoted positive change, such as the intention to consume less of a substance, such as with one participant's alcohol consumption:

> I'm not going to drink today, because they're going to ask me how many drinks I drank. [SP102, housed]

However, on the other hand, prompting regarding drug or alcohol consumption also had negative impacts, resulting in cravings or the desire to consume. A participant explains the effect as follows:

> I felt a little like after a day or two, I had kind of like a Pavlov's dog effect, where every time it went off, I'm like, "Ooh, I could really use some alcohol right now." I'm like, "Ooh, this is reminding me that alcohol is not a great option, but it is an option." [SP206, housed]

Similarly, another participant stated the following:

> On the alcohol and drink question...the repetitive asking you another question and just mentioning a drink made me want to drink...It kept asking me how many drinks I have had and I'm like, none, but I don't know, I kind of want one now, shit. [SP403, unhoused]

In addition, the subject matter, combined with the annoyance of the prompting schedule, brought on an increased desire to use:

> Especially since it was that ringing and a little bit of an irritant, and it's like, "Ooh, a drink would be really nice to kind of just not deal with this right now" [SP206, housed]

Responding Honestly

Across the 4 focus groups, the participants discussed honesty in their survey responses. Although 81.8% (189/231) of focus group participants agreed with being open and honest, others expressed greater distrust and, therefore, less honesty. Some participants oscillated between providing an honest picture of their day and, at times, lying. One of the participants provides a good example of the latter:

> I should say...I was just trying to be as honest as possible. But some days you just don't feel like explaining yourself or completely answering. [SP103, housed]

Here, fluctuations in fatigue and social engagement influenced honesty in survey responses.

The occasions where participants reported dishonesty, which occurred more often among unhoused participants, were largely related to the personal nature of the questions. One of the participants noted that the more specific and personal the questions got, the harder they were to answer honestly. This participant continued by providing a specific example:

> It was asking me to put a nickname down for someone you had sex with, I was like, I don't really want to do that. [SP103, housed]

Furthermore, another participant described their experience with honest survey responses as follows:

> To be honest, I lied on a few questions...I lied because it just reminded me of what a whore I am. It would be like "How many times did you have sex today?" And stuff like that, I'm like it's clocking me. I had the times I was cheating on my boyfriend with this boy, and you know how it asks you like the five people that you hang out with mostly or whatever? Then it would be like, "Who were you with?" I'd be like, "Ooh." [SP202, housed]

Despite these circumstances, many participants discussed why they chose to respond honestly to the survey items. A participant shared their respect for the study by stating the following:

> *I tried to be as honest as possible. Because I knew that it was a study. So I tried to be as honest...Because you guys are going to look at it and try to get real answers from people. It was hard. But I tried to be honest about it.* [SP102, housed]

Others noted that responding via the phone provided some comfort:

> *The thing about surveys too, is it's a non-judgmental environment that you're telling your information to.* [SP105, housed]

Another participant also had similar feelings about using their phone to answer the surveys honestly:

> *Yeah, I feel like if anything it makes me feel more comfortable, because the phone, you don't have to give a fuck...I'm going to be real today, and I'm going to be real to myself. It's kind of like a diary if you think about it. That survey was like a diary for a week.* [SP205, housed]

Suggestions for Future Studies: Technology

The largest perk for many participants in the study without a phone of their own was receiving a phone with a full data plan for the whole week, which most participants chose to do. Only 9.1% (21/231) of participants used their own phones for the study. Participants from focus group 4 (unhoused) discussed the following:

> *[Borrowing] the phone...actually helped me with my daily life, bro. Because I didn't have a phone at the time, so it helped me to get phone calls.* [SP404]
>
> *Oh yeah, me too. Google maps.* [SP408]
>
> *I hadn't had a phone since that one. I do want a phone for another week though.* [SP404]

Some others with their own personal devices preferred using their own phones rather than needing to keep track of 2 phones for the duration of the study:

> *I think [using my own phone] was more convenient. It was a lot easier than having to have a second phone. Losing track of it.* [SP105, housed]
>
> *I thought it was interesting. It was cool. I think I prefer it to be on my actual phone than another phone. Because it was kind of hard to keep up with it.* [SP104, housed]

In addition, some with their own personal phones chose to borrow a study phone to keep the study separate from their personal lives or because the software was incompatible with their phones. This, most often, resulted in difficulty keeping track of the 2 phones, as discussed in focus group 2 (housed):

> *It felt extra for me but that's because...I'm really bad about keeping my regular phone on me, so I said I was a bad millennial. I'm a bad millennial.* [SP204]
>
> *It's hard to remember to carry two phones.* [SP208]

> *But even if I went from my bedroom to the dining room, and thirty minutes went by and I was like, "I have to go get my phone." Then I saw that I missed one survey.* [SP204]
>
> *I feel like I have bigger problems than carrying two phones. It wasn't the hardest thing in my life, but sometimes I would forget it and be like, "Aw, crap." That's it.* [SP207]

Another discussion point stemming from this issue occurred in friend groups in which multiple people were enrolled in the study at the same time. One of the participants mentioned the difficulty of keeping track of their phone when interacting with others also in the study:

> *It was hard for me. I was literally driving. I always keep my phone away. I'm over there trying to jump in the purse like: Where is this phone? And then, another thing, my neighbor...My neighbor [who was also in the study] always comes over...And my other neighbor...So he'd be like: "Who's phone is who's? Who got that..." And I'd be like: "Do you have my phone? That's my phone?" How did we know it was our phone?...It took me about a day, or maybe two, to actually [get used to it].* [SP104, housed]

To this point, another participant in an unhoused focus group offered a potential way of distinguishing study phones in the same friend group, recommending the following:

> *Maybe have a choice of different ringtones, because when you're in a group of people and the ringtone goes off, but everyone thinks it's theirs...Everyone's like, "Hold on, I think it's mine."*

Finally, and perhaps most notably, SPs recognized the value of EMA as an intervention. Participants wanted more, such as prompts to support them in cutting back on their substance use, with many participants noting the benefits of study participation in terms of mindfulness:

> *I feel like sometimes you're doing stuff and then...Like, say somebody says yes, to something on the list. Like some serious drugs...Meth or something like that. Which you know is a serious drug. You can tell them like: "Maybe you shouldn't do it." Or something like that. I'm not sure about the whole thing. I'd have to sit down and go over it myself. If I was designing the app or something.* [SP101, housed]

Mixed Methods

In comparing the quantitative and qualitative arms of this study via a convergent parallel design, we found qualitative responses from both housed and unhoused participants to confirm the quantitative findings (see Table 6 for an integration of the quantitative and qualitative findings). The findings regarding the previously discussed difficulties with charging devices were found to be convergent. Qualitative findings regarding study-induced stress and anxiety, as well as interference with daily life, provided additional contextual information to the quantitative findings, offering an expansion in the interpretation of results. As previously stated, unhoused participants self-reported greater, statistically significant study-induced

stress and anxiety. However, the qualitative findings highlight that housed individuals, at times, also noted stress and anxiety related to study participation; however, this stress and anxiety seemed to be contextually different from that experienced by unhoused participants, which was often connected to paranoia, fears of snitching, and being *watched by the Feds*. The latter stress and anxiety could be directly related to street culture and economy. Similarly, quantitative findings showed increased

reporting of study interference in daily life among unhoused individuals; however, qualitative findings showed that both unhoused and housed participants noted interference. Housed participants most often talked about interference in terms of school or work responsibilities, whereas those unhoused discussed needing to answer to make the money for survey compliance, which made it more likely to interfere with what they were doing.

Table 6. Results of convergent parallel design based on housing status.

Quantitative findings	Qualitative findings	Merged findings outcome
Compared with housed participants, unhoused participants were more likely to report that the *study caused them stress or anxiety* (*P*=.02).	Although both housed and unhoused participants reported stress accompanying the study, unhoused participants discussed stress related to paranoia and snitching.	Confirmatory; expansion
The study was reported to have *interfered with daily life* among those unhoused compared with those in housing (*P*<.001).	Although surveys appeared at inopportune times for both housed (eg, while at work or school) and unhoused (eg, while visiting with a case manager) participants, unhoused participants discussed more stress regarding needing to answer to make the money for survey compliance, which made it more likely to interfere with what they were doing.	Confirmatory; expansion
Unhouse participants reported greater *difficulty charging* their devices (*P*=.02).	Housed participants were more likely to be in locations with outlets. Charging had to be sought out by unhoused participants.	Confirmatory; convergent
More unhoused participants reported that the study caused *changes in their behavior* (*P*<.001) than those in housing.	Although both housed and unhoused participants noted increased awareness of substance use related to substance use questions, unhoused participants more often reported increased substance use, whereas housed participants seemed to mention the awareness of substance use and trended toward a reduction in their use.	Confirmatory; complementarity
Compared with those in housing, unhoused participants reported being less likely to *be open or honest* when answering survey items (*P*=.03).	Housed participants seemed to feel more comfortable with honest responses, whereas unhoused participants again noted paranoia and fear of snitching.	Confirmatory; convergent

Additional statistically significant differences between housed and unhoused participants occurred regarding reported behavior changes and honesty in the survey responses. Although both housed and unhoused participants noted increased awareness of substance use related to substance use questions, quantitative findings showed that more unhoused participants reported that the study affected their behavior during the week. Qualitatively, we obtained complementary findings in that those who were unhoused more often reported increased substance use, whereas housed participants seemed to mention the awareness of substance use and trended toward a reduction in their use. Finally, convergent findings emerged regarding honesty in the responses. It was clear that housed participants seemed to feel more comfortable answering openly and honestly, perhaps as a result of the newfound freedom associated with transitioning from homelessness to housing [34]. This is contrasted by unhoused participants once again noting paranoia and fear of outing peers on the street.

Discussion

Principal Findings

The results of this mixed methods study illuminate the experiences of housed and unhoused young adults enrolled in an EMA for a 1-week period. Although no statistically significant differences in compliance by housing status were found, statistically significant differences were found regarding

the impact of study participation. Housing status was found to affect young adults' engagement with EMA. Differences in housing status were found regarding the ability to keep their device charged, interference with daily life, stress and anxiety associated with participation, behavior change as a result of EMA, and the ability to respond openly and honestly to prompts.

In terms of compliance, those who had difficulty charging also had lower survey compliance when the phone was charged, and unhoused participants reported greater difficulty in charging. Perhaps the unhoused participants had difficulty charging but made sure to find some way to charge it, possibly because of the importance of the incentive. Similarly, less interference with daily life was associated with greater study compliance in both the daily and EMA surveys, and unhoused individuals noted greater interference. A thought here is the significant correlation between difficulty in charging the device and interference in daily life. Research apps may drain battery life more quickly than other apps and disrupt typical charging patterns based on their usual phone use. If unhoused participants struggled to find a power source and spent much time consumed with finding ways to charge the phone [35] to maintain compliance (ie, get paid), this could interfere greatly with one's day. This could also explain why unhoused participants reported greater stress and anxiety associated with study participation. Again, status was not associated with compliance rates; however, greater stress and anxiety resulting from study participation produced worse compliance rates.

Overall, study compliance was approximately 80%, with no significant detected differences explicitly related to housing status. However, this does not imply that housing status does not need to be considered in the study design. The findings clearly reveal greater impacts, and perhaps burden, for unhoused participants, which was confirmed in the qualitative interviews. Future use of EMA, particularly with unhoused individuals, should consider barriers to using technology in research. Although entirely possible, a study design that relies on the use of technology such as a mobile device should consider issues related to access and how this may create increased burdensomeness. We observed how increased burden could produce additional stress in an already stressful environment, particularly with regard to being tracked. In some cases, the awareness of being tracked has the potential to exacerbate the underlying mental health or substance use issues. Greater efforts to ensure comfort with protocols, including an enhanced focus on confidentiality, could be beneficial, especially because of the histories of marginalization that have led to a deep-seated distrust of systems, including social service systems. Taking more time at the outset of EMA studies to ensure understanding and consent could promote greater trust and decrease the associated stress and anxiety. This could also increase honesty in responses, particularly among unhoused individuals who reported being less honest in their responses compared with those in supportive housing, potentially because of perceived impacts on securing housing or other needed services and resources. Other methods to potentially increase data quality and assurance are to use a lead-in period where participants would get a day or two of practice with the app and EMA questions before recording their responses for analysis.

In testing for reactivity using anxiety and depression symptomatology before and after EMA the week, results show compliance to not be significantly related to the degree of anxiety and depression symptomatology reported. However, a decrease in reported symptoms occurred from before to after the test. This is particularly interesting as some participants, particularly unhoused participants, discussed increased stress and anxiety because of study participation. This indicates that the momentary stress of being prompted did not affect symptomatology and perhaps was fleeting. Although participants may have frequently thought about the bother of the study and became momentarily overwhelmed, it seems to have not been a lasting experience with long-term impacts, despite 22.9% (53/231) of participants feeling that the study affected their behaviors. The fact that compliance was not significantly related to symptomatology (ie, more prompts completed were associated with increases in symptomatology) indicates low reactivity to EMA prompting and participation. More work is needed to effectively examine the overall decreases in symptomatology that may be associated with EMA, as the results cannot definitively be ruled as reactivity, echoing previous literature [36].

The study's implications include support for using intensive longitudinal methods such as EMA with housed and unhoused young adults. Acorda et al [26] explored the impact and acceptability of EMA among 18 youths experiencing homelessness, making recommendations for use with young people who are actively homeless. The results produced by Acorda et al [26] reinforce the findings of this study, most notably the effects of increased self-awareness and the potential for behavior change as a result of EMA. Given the discussion regarding perceived behavioral change and behavioral intentions, EMA also presents possible opportunities for intervention work. It is clear from both their work and the additional support offered from these analyses that EMA is highly acceptable for young adults who have experienced homelessness, both housed and unhoused, with several special considerations, particularly around housing status and confidentiality.

Limitations

Despite the strengths of analyzing this innovative method for vulnerable young adults, there are several limitations that must be acknowledged. The results suggest that some participants did not always answer honestly. We do not have a way of knowing the responses to trust or not using this method with this population. Future work may want to design studies to test the validity of this method with this population, perhaps adapting the study design to include *self-checks* within survey protocols and questions about honesty at the conclusion of each EMA survey. In addition, relying on focus groups as the qualitative methodology could potentially lead to group think more than individual interviews, particularly regarding sensitive topics where group interactions could be detrimental to the discussion. Inquiring about sensitive topics is needed for epidemiological studies; however, a focus solely on what may be perceived as *negative* aspects without the inclusion of a strengths-based perspective lacks an equity lens and was felt by some SPs. Finally, we considered the difference between completion and compliance within the EMA context and ultimately decided to use compliance as the number of prompts completed out of those received based on the study aims. Care should be taken when interpreting findings, specifically if the interest is in distilling information regarding the technological aspects of EMA methods, as this study did not consider technical issues as a focus of analysis, although it is briefly reported.

Conclusions

Although with caveats, this study produced evidence in favor of the use of intensive longitudinal designs with young adults who were formerly and are currently homeless. Intensive longitudinal methods are well suited to capture experiences associated with the chaotic and unstable environments of homelessness, addressing the limitations of cross-sectional and traditional longitudinal designs. However, the findings of this study show that chaotic and unstable environments must be considered at every step of the research process. These findings have implications for research development and design, data collection, and analysis.

Abstract

Background: Currently, there is no holistic theoretical approach available for guiding classification development. On the basis of our recent classification development research in the area of patient safety in health information technology, this focus area would benefit from a more systematic approach. Although some valuable theoretical and methodological approaches have been presented, classification development literature typically is limited to methodological development in a specific domain or is practically oriented.

Objective: The main purposes of this study are to fill the methodological gap in classification development research by exploring possible elements of systematic development based on previous literature and to promote sustainable and well-grounded classification outcomes by identifying a set of recommended elements. Specifically, the aim is to answer the following question: what are the main elements for systematic classification development based on research evidence and our use case?

Methods: This study applied a qualitative research approach. On the basis of previous literature, preliminary elements for classification development were specified, as follows: defining a concept model, documenting the development process, incorporating multidisciplinary expertise, validating results, and maintaining the classification. The elements were compiled as guiding principles for the research process and tested in the case of patient safety incidents (n=501).

Results: The results illustrate classification development based on the chosen elements, with 4 examples of technology-induced errors. Examples from the use case regard usability, system downtime, clinical workflow, and medication section problems. The study results confirm and thus suggest that a more comprehensive and theory-based systematic approach promotes well-grounded classification work by enhancing transparency and possibilities for assessing the development process.

Conclusions: We recommend further testing the preliminary main elements presented in this study. The research presented herein could serve as a basis for future work. Our recently developed classification and the use case presented here serve as examples. Data retrieved from, for example, other type of electronic health records and use contexts could refine and validate the suggested methodological approach.

Introduction

Background

Classifications are applied for various purposes in clinical contexts, including patient documentation and more specific domains, such as the patient safety incident reporting of technology-induced errors. However, the availability of methodological frameworks and research evidence is limited for developing and maintaining clinical classifications [1-3]. Typically, classification development has practical goals in a specific clinical setting or documentation context. Accordingly, the results of practice-driven classification work are not necessarily transferable to other organizations, clinical domains, or purposes [4,5].

According to literature, severe challenges have arisen from the emergence of safety issues involving newly innovated and existing implemented health information technologies (ITs) [6-8]. Regarding patient safety in health IT, previous classification development-related research on technology-induced errors is available [3,9,10]. Magrabi et al [3] identified categories for populating the classification of IT problems with the aim of providing a clinical method for classifying computer-related patient safety incidents. This classification was then tested with patient safety incident data in a setting with 100% coverage of electronic health records (EHRs). The results indicated a need for classification development from the perspective of a sociotechnical approach [1]. Moreover, a recent study summarized that organizations today do not have rigorous, real-time approaches for routinely assessing the safety of EHRs or for identifying safety hazards [11]. This constitutes the underlying rationale for why we have recently developed and validated a classification of technology-induced error types from a social-technical perspective [12]. A guiding assumption in our research was that despite previous research introducing relevant themes in this area, further research is needed to capture the fast-developing clinical working environment. Health IT and EHRs advance in ways that require the identification and classification of new types of phenomena. Classifications evolve as new evidence arises [13].

On the basis of our experience when researching classification development, this focus area benefits from a more systematic approach. Although valuable theoretical and methodological approaches have been presented, some of the literature concentrates on a specific part of the classification development, such as validation within a specific domain [14] or maintenance and implementation of international classifications [15]. No holistic approach is provided to guide classification development. In addition, although some valuable research on patient safety incidents and respective classifications has been conducted, there is relatively scarce documentation of detailed classification development that could guide future development. It is suggested [16] that publishing methodological and theoretical approaches applied in classification development cases increases the validity and quality of development outcomes. This contributes in building a systematic approach to classification development. Currently, for example, some

practical guidelines and web-based resources are available regarding large-scale international examples, such as the World Health Organization's International Classification of Diseases and Systematized Nomenclature of Medicine–Clinical Terms [17,18]. However, the gap between practical guidelines and theory-based systematic classification development presents a challenge when the aim is to develop most sustainable, well-grounded classifications, which can also be assessed in a transparent way against a set of common development principles [16,19].

Objectives

To benefit future classification work, in this paper, we present preliminary results on methodological considerations based on previous research evidence and our case research on classifying EHR-related patient safety incidents [12]. Our preliminary results are intended to inform future research on classification development research protocols with different use cases. We characterize typical elements of classification development and suggest a methodological approach [20] to achieve more systematic classification development after testing it with other use cases. Therefore, our main research question is as follows: what are the main elements for systematic classification development based on research evidence and our use case?

Methods

Evidence From Previous Research Informing Our Study Design

Sociotechnical theory has been a basis for the development of health IT-related models [21]. Pioneering theorists of the sociotechnical approach emphasized that technical and social systems should be optimized simultaneously and that organizations should comprise a relationship between nonhuman and human systems [22,23]. More specifically, the theoretical background for developing our classification was the Health IT Safety measurement framework proposed by Sittig and Singh [9,24]. The starting point of the Health IT Safety framework is that safety incidents must be understood within the full context of the *sociotechnical work system*. This refers to the interacting technical (eg, hardware and software) and nontechnical (eg, clinical workflow, people, and the physical environment) variables that affect health IT-related patient safety. The framework responds to the fundamental conceptual and methodological gaps related to both defining and measuring health IT-related patient safety. The aim is to provide a conceptual foundation for health IT-related patient safety measurement, monitoring, and improvement [10]. The following three domains were created to describe the range of risks and opportunities of health IT to influence patient safety: Safe Health IT, Safe Use of Health IT, and Using Health IT to Improve Safety. The latter includes using technology to identify and monitor patient safety incidents, risks, and hazards and to intervene before harm occurs [24].

EHR-related classifications for the purpose of incident reporting have been developed for specific clinical settings and problem areas. For example, the French Nuclear Safety Authority scale for classifying incidents was applied in oncology to inform the

design and potential utility of an incident reporting system. All incidents during the research period were reviewed and graded according to potential severity by the consensus of a committee, including physicians and physicists [25]. However, the aim of the research was not to provide a detailed description of the development process of IT-related error-type categories from a methodological classification development perspective. Another example of classification-related development work in a specific IT-related error area is the development of a usability-related error ontology by Elkin et al [26]. Here, initial semantics for usability error types were derived from a literature review and an expert opinion. Then, a participatory design method was used to obtain input and feedback from multi-professional stakeholders. According to Elkin et al [26], with use and experience, the ontology would grow and evolve toward more standard and interoperable reporting. Intrinsically, ontologies have become important resources, because they can be applied to integrated EHR infrastructures to improve possibilities of data acquisition and storage, standardization, interoperation, data analysis for clinical research, and routine clinical documentation [27,28].

The classification developed by Magrabi et al [3] is a rare example of EHR-related classification development research that is not restricted to a specific EHR problem area. It was developed by using safety incidents and was further refined by analyzing data from incident reports submitted to a regulatory database. The methodology of classification development was based on the free-text descriptions of a quarter of the incidents retrieved (n=123), which were used to identify *natural categories* for the classification. A simple classification of the reported problems related to computer use was developed. The incidents were classified using the classification. An interrater reliability analysis was performed using the κ statistic to determine consistency among researchers. The classification developed by Magrabi et al [3] underwent testing in the United Kingdom after the preliminary development phases. In subsequent research, a limitation of the classification was documented: it was not possible to demonstrate the clinical relevance of all incidents by using this classification [29]. However, the study focused on case data–driven development of the classification, not on describing the underlying methodological aspects of classification theories.

In a recent study [12], a classification for patient safety incident reporting associated with the use of a mature EHR was developed, which was validated using a data set of 501 patient safety incidents. Here, a mature EHR is defined according to the Electronic Medical Record Adoption Model, which was developed by Healthcare Information and Management Systems Society Analytics. This universally recognized maturity model is an 8-stage model that reflects hospitals' electronic medical record capabilities, ranging from a completely paper-based environment (stage 0) to a highly advanced paperless and digital patient record environment (stage 7). Regarding these data, the maturity level of the EHR system is 6 to 7 [12]. The classification development was based on research into commonly recognized error types. Further, a multi-professional research team used iterative tests on consensus building to develop a classification and preliminary descriptions of the classes. The final classification was validated using incident report data to evaluate its characteristics and applicability for purposes of patient safety incident reporting. The development focused on applying the theoretical aspects of classification development, for example, by defining concepts and the exclusiveness of categories and forming descriptions for all categories with the quality and usability of the resulting classification as a guiding principle. This classification development and validation research was used as a use case in this research to strengthen the fragmented methodological support for this type of research.

Methodological Background and Study Design

This study applied a qualitative research approach that is applicable for identifying, characterizing, and interpreting a phenomenon. Qualitative methodology relies on data and their interpretation according to respective conceptualization [20,30]. To increase the reliability of qualitative research, applying a varied methodology is suggested [20,30-32]. For our use case [12], this involved retrieving clinical patient safety incident reporting data and conceptualizing technology-induced errors based on previous research, selecting relevant reports, analyzing incident data to define categories and hierarchies for the emerging classification, and applying a multidisciplinary panel within our research team to reach agreement over ongoing classification development (Multimedia Appendix 1). We have already documented the study design for data analysis and validation [12], and in this paper, our study design concentrates on specifically capturing classification development characteristics (Textbox 1) and related observations from the use case of our classification development. By creating a holistic methodological approach for classification development, there is potential to expand use to different kind of contexts and use cases.

Textbox 1. Main elements of classification development based on previous research.

1. A concept model: a concept model supports the data analysis required in classification development. A model includes, for example, the name and version of the classification, names of each category and their descriptions, possible translations, types of relations among categories, and mapping data regarding terminology harmonization [4,33,34].

2. Documentation of classification development: documenting the elements and progress of classification development in sufficient detail adds to the understanding of concept analysis and building relationships among categories, with an emphasis on clear separation among categories [4,16,33].

3. Multidisciplinary expertise: for example, clinical, terminological, informatics, and technical expertise used in the analysis and development process ensures relevant and usable outcomes [4,12,16,26,27].

4. Validation of results: development result validation based on study design and expertise or, for example, the translation of concepts and categories to ensure that the chosen concepts remain unchanged and the clinical meaning prevails. This supports interoperability and is especially relevant for small languages, such as Finnish [12,20,35,36].

5. Classification maintenance: after developing a classification, the formal governance model or informal maintenance process should include feedback from the clinicians (ie, the users) [34,37,38].

Classification development research is considered more practical than theoretically oriented, which results in development outcomes that might not necessarily be scalable to other research or use contexts [16,39,40]. Unsystematic and partial descriptions of classification development steps render it difficult to understand the underlying theoretical grounds for created structures and characteristics [33]. Applying a qualitative approach allows us to use somewhat limited research literature both as an analytical tool and to provide a source of concepts, theories, and hypotheses [20,31]. For qualitative research, a systematic review of literature is not typically required, although familiarity with relevant literature may increase sensitivity to subtle nuances of data [20,32]. In line with the qualitative approach [20], we identified key elements of classification development from the previous literature. The main literature consists of 12 research papers, and the results are summarized in Textbox 1. With this use case, we applied the elements found in the literature by researchers who described such elements and stages of classification development. Therefore, before embarking on classification development, typical elements based on the previous literature were compiled as guiding principles in the research process. These guiding principles were used and tested in practice during our recent study [12] (Textbox 1). However, these elements were not described in-depth in our publication.

According to the available literature, the classification development process begins with a careful, in-depth concept analysis to support the need for structured and controlled data representation (cf the study by Watson et al [16]). This is for documentation purposes [27] and for increasing the usability of data by ensuring improved data quality and comparability [41]. Reconciling clinical needs for documentation requires content analysis and mapping, which can be costly in both financial and temporal respects [4]. An important observation for classification development is that incomplete or overlapping conceptualizing, naming, and descriptions of categories and their relations within a classification may challenge resulting data quality owing to heterogeneity and indistinctness of concepts and terms used [4,33]. We have defined the concepts used in our research in the previous paper [12]. Our core concept regarding the phenomenon of the use case is a technology-induced error that results from the design and

development of technology (Multimedia Appendix 2), the implementation and customization of technology, and the interplay between the operation of a technology and the new work processes that arise from the use of technology [42,43]. Regarding the classification category and subcategory building, our process was both qualitative and iterative [20]. The category building consisted of systematic analysis and labeling of varied phenomena illustrated in our data [20]. By examining differences and similarities in our data, we divided the data first into categories, iteratively refined distinctive differentiation between categories and within a category, and continued to define subcategories with an in-depth analysis.

From a methodological perspective, regarding the aim of improving systematic classification development, the potential strengths and weaknesses encountered during the process should be documented in research. Cornet et al [4] stated that content shortcomings encountered during classification development, for example, concept coverage and gaps, can be solved relatively easily. However, some formalism issues are more difficult to resolve. These include, for example, how relations among the categories are arranged, the overall structure or concept model, and how the classification is applied by the clinical users [27,41]. The United Nations suggests the following similar requirements in their practical guideline for classification development, for example, a consistent conceptual basis, a flat or hierarchic structure, categories that are mutually exclusive and exhaustive, and definitions that are clear and unambiguous and define the content of each category [44]. Furthermore, classifications should be relevant to users and sufficiently robust to last for a period of intended use. They should also provide comparability over time and among collections and provide guidelines for the coding and output of any data collected [36,38].

To summarize, as described in our study design, these elements form the basis for testing them in our use case.

Results

Overview

Our results provide examples of selected categories of our use case analysis to illustrate the development of technology-induced problem classification. During the analysis [12], we reviewed

all patient safety incidents (N=1486) to identify technology-induced ones and continued to categorize the remaining incidents (n=501) with the concepts based on previous research. We added both main categories and subcategories to develop the initial content toward the context of mature EHRs according to evidence from the patient safety incident data. This required close cooperation between clinical and informatics experts within the research team to ensure that the categories captured identified phenomena correctly and were relevant for clinicians.

We provide the following four examples from our use case [12]: a description of the reasoning behind 2 categories, which were expanded to increase the potential accuracy of patient safety incident reporting, and 2 new categories, which were added to reduce ambiguities and any duplication of the original categories.

Category of Usability Issues

The first example is illustrated by the category of usability issues (73/501, 17.1%). To start with, this category had no description, and the initial subcategories included features that were more closely related to other categories, such as documentation problems (60/501, 14.1%; Multimedia Appendix 2). With the help of clinical experts, we defined usability problems as situations in which the used EHR is difficult to use. For example, this complicates finding the required patient data or does not guide the clinician as expected, meaning that the system does not support the clinician's work processes as expected according to care guidelines. In contrast, the documentation problems were defined to include a lack of data structure, errors, and ambiguities when entering data. After the analysis, we added 4 subcategories to usability issues, resulting in a 2-level hierarchy. Two of these subcategories (problems with decision support, n=2, and printing problems, n=11) were easily defined. For the other two subcategories (problems and deficiencies related to alarms, n=29, and problems with finding data, n=30), we added additional third-level subcategories. In addition, we added missing, incorrect, or difficult-to-interpret alarm and alarm fatigue to the first subcategory. For the second subcategory, we added that the information is difficult (illogical) for the user to perceive and the information is laborious to find and has to be dug up. These third-level subcategories were easily identified by the clinicians in our research team and are documented in previous research. Although they concern separate usability issues, only future use of the classification would reveal if the third-level subcategories are suitable for reporting. In an ideal situation, third-level subcategories could guide the reporting clinician to identify a usability issue more easily, based on the category-specific name and description. However, a deeper hierarchy of categories and additional subcategories could increase the reporting burden in fast-paced clinical work. To determine the most suitable level of accuracy for reporting, the pilot use of the developed classification would be required.

Category of EHR Downtime

Regarding the category of EHR downtime (8/501, 1.9%), the starting point for classification development was a flat hierarchy, that is, a single-level main category, after which our development progressed iteratively. This category was identified

as a relatively well-defined entity with no connection to other categories in the classification. Furthermore, it was known from the literature that domain coverage (including only planned and unplanned downtimes based on previous research at this stage) was insufficient to provide classification benefits. However, we sought a relatively simple 3-level hierarchical structure to facilitate clinical use. In addition to the literature, available real-world data in the form of patient safety incident reports guided more precise identification of new subcategories, including the completely new phenomenon of *the problem of logging on to a single application partly or entirely* (n=5). At this point, we divided the subcategory of the system logging problem in relation to the whole or part of the system in use to capture issues with a high-maturity EHR more effectively. The harmonization of concepts for known phenomena based on previous literature was relatively straightforward. However, the concepts for optimizing the new range of categories for clinical users required more reconciliation. Our aim is that categories would be mutually exclusive and exhaustive. During classification work with our data, we noticed that not all incidents fitted with existing subcategories. At this point, attention was given to content according to the feedback of clinicians as users. Without incorporating multidisciplinary knowledge, it would have been difficult to create and define content clearly and comprehensively, especially for the category *data entry during and after a downtime*.

Category of Clinical Workflow Problems

During classification development, we added clinical workflow problems (33/501, 7.7%) as a new main category for two main reasons: the original classification addresses this phenomenon ambiguously, and mature EHRs implement clinical procedures according to defined workflow descriptions and guidelines. In other words, although building a workflow into EHRs is a well-established practice, the original classification left the issue either unidentified or partially identified. On the basis of the use case and the views of clinical experts, workflow problems can disrupt work procedure continuity. For example, although fundamental process steps such as a patient transfer or discharge should be carried out, the EHR renders it impossible to complete the procedure or does not otherwise support the clinician's work as expected according to hospital guidelines. Moreover, owing to the lack of an integrated, functional, and logical workflow, the system may attract ways of clinical use that are not aligned with the guidelines when the expected EHR functionalities cannot be obtained. This can result in deviant work processes and workarounds. On the basis of our case data, the phenomena of workflow problems could be accurately identified and tentatively described. However, this could still benefit from insights from other use cases and data to confirm the correctness of our interpretation based on these specific data. Moreover, identifying workflow problems as a new main category can reduce the corruption of reported data caused by the weak distinctiveness of the original classification and its categories.

Category of Medication Section Problems

We noticed that the original classification did not cover incidents related to the medication management section adequately, especially given that many of these cases were documented in

the research data. Thus, a new main class of medication section problems (89/501, 20.8%) was added. These problems can result in situations where prescription and patient record information is not stored as intended, or where apparent changes occur because of an unidentified system-related reason. This is often a problem that hinders the management of overall medication. With this particular category based on its appearance in our research data, we wish to illustrate that there are some preconditions for classification development. First, the problems in the medication section appeared more difficult to delimit and describe compared with workflow problems. However, we recognized that these problems are closely related to the clinical workflow category features (eg, functionality of closed-loop medicine administration) and documentation category. Regarding medication section incidents, our research team concluded that there were still complex unresolved issues in the implementation of the new EHR from the implementation perspective, where immediate modification and mitigation appears to be necessary. Thus, it is likely that some of the system-specific problems will be solved. Moreover, when identifying real root causes to develop new subcategories, a more detailed examination would have been required, for example, through root cause analysis. In this case, it was too early to develop subcategories based on the research data; hence, the problem type could be identified but not unambiguously described. For this category, we found that a major functional change period, that is, system implementation in progress, may be a suboptimal time for developing a classification.

To conclude the insights from the use case, several iterations of category names and descriptions were required to ensure shared and sufficient understanding of the reasoning behind a specific category. Further, we used research literature to determine how the same or similar categories had been conceptualized. During classification development, clinician insights provided clinical understanding of a phenomenon through a clinical lens. However, informatics and IT expertise were required to identify and analyze system-specific starting points and boundaries of a specific phenomenon. Overall, our classification development was conducted through a sociotechnical lens to ensure comparable reasoning of both human and nonhuman factors that attribute to a specific technology-induced patient safety incident. However, when new categories or subcategories were constructed, the clinical perspective of relevant and usable classification content development remained a prevailing guideline. This was particularly true regarding clinical reporting and the optimal versus redundant level of accuracy for reporting based on the available categories and time available for reporting in hectic clinical work. To summarize, essential key elements, such as content analysis, category building, the definition of hierarchy among categories, and classification validation, provide requirements for systematic classification development.

Discussion

Principal Findings

On the basis of the study design, a set of guiding principles and preliminary elements for classification development were identified and applied in our use case. Next, we gathered evidence of the process for classification development and captured common elements based on previous research and our own experience of classification development. Finally, we processed these elements and explored examples from our recent research [12] in the *Results* section to illustrate the details of both the classifying process and elements to build sustainable and well-defined classifications in the future.

Our classification development and validation research [12] was used as a use case in this research to strengthen the fragmented methodological support for this type of research. In practice, we revealed incident-related gaps of conceptualization within the area of research. During classification development, filling these gaps meant analyzing various technology-induced patient safety incidents within our multidisciplinary research team. The incidents were analyzed with a sociotechnical lens to avoid bias when building the categories. Clinician insights into the incidents and the rationality of the clinical working environment played significant roles when identifying the categories.

Owing to the scarcity of research evidence, challenges when conducting this kind of research are recognized [4,12]. Accordingly, our main purpose is to fill a methodological gap in classification development research to promote well-grounded classification development. Although we ground these recommendations on the use case, the available research literature indicates similar challenges in other classification development cases. First, a concept model informing the classification development promotes systematic category building with structural formalism. In a way, such a model provides fundamental requirements for the development of each category. Second, in addition to conceptualizing category building, documenting agreements on other main elements can constitute guiding principles for the whole classification development. Furthermore, documenting common agreements can also support quality control and ensure the understanding of common goals for the development. Third, ensuring multidisciplinary expertise is crucial for guaranteeing that the intended clinical meaning prevails and for facilitating the validation of emerging classes. Moreover, regarding the future use of a classification under development, multidisciplinary expertise can be used to define the required level of category robustness and to review sufficient levels of clinical domain coverage and comprehensiveness. By reviewing clinical relevance and documenting practices during classification development, the development outcome might be feasible for clinical use. Fourth, terminological harmonization or systematic translation of concepts and terms representing the categories can be used to ensure that the clinical meaning remains unchanged during the development and that the chosen concepts remain relevant in the specific domain or clinical context. Fifth, planning ahead is a requirement of classification maintenance, especially when the clinical context in which the classification is used is constantly changing and evolving. In this regard, planning for user feedback or other routes for receiving and processing development needs emerging from the clinical context and users in the future can provide a means of classification maintenance.

Limitations

Any method of qualitative or quantitative analysis is not a purely technical process, as it is inevitably influenced by the scientific background and experience of researchers. Accordingly, critical reflection throughout the research process is of considerable importance. The multidisciplinary research team with prior training and experience in qualitative analysis worked closely to follow up on research progress analytically and critically to ensure the quality of the conduct of the study. However, there are many known weaknesses associated with the qualitative research approach in particular [20,30-32]. In this study, the approach was iterative, the analysis was interpretative, and the results were consequently descriptive, which is typical of this research approach. Therefore, the results should be considered from the outset of these facts. The most difficult methodological question arose from the situation where the researchers determined that a systematic review of the literature in this area does not necessarily produce such results that would benefit the achievement of the research goals. Moreover, the researchers have been working on governmental and international classification development for many years, which contributed to the decision to proceed in a way that deviated from the original research plan, which relied on the possibilities provided by the qualitative research literature. Furthermore, the literature was studied and adopted cumulatively.

The theoretical framework for our classification development was the sociotechnical model [9,10]. It should be noted that classification development can be based on many starting points and can occur within many themes. As a result, we cannot conclude from this use case alone that our approach would be applicable to all subject areas. This is why further research is still required, in which our observations could be tested with new data.

Lessons Learned and Implications for Future Work

There are many possible aspects for future classification development work and related research based on our study results. Based on our observations, for the continuum of classification development in each context, we suggest that sufficient multi-professional analysis and review should be part of classification development and maintenance. Overall, the classification development should place more emphasis on terminological and clinical subject area expertise.

Moreover, classifications can be regarded as a representation framework among evolving practices, meaning they must be followed by new knowledge. Furthermore, more case or pilot studies with real-world contexts are required. Our use case and developed classification serve as an example here: patient safety incident data retrieved from other source EHRs and use contexts could strengthen the methodological approach or it might contribute to further development of our classification based on user feedback.

As we became acquainted with the classification literature, preliminary observations were made about promising future possibilities, specifically of ontologies. Although we excluded the topic from our own research, we highlight the potential for future research. Hancock [41] described a study that demonstrates the demand for instant data and information is enabled through innovative and newer ways of classifying information. From a system perspective, much of the development process can now be automated, content can be contributed and approved on the web, and computer programs are sufficiently advanced to consider more human-thinking methodologies. Although it will take time to replace traditional approaches to classification development and theory with innovative, technological solutions, we suggest re-examining the classification development process we have described, starting with the concept definition phase. It would be particularly interesting to determine whether machine learning can be used in this context, especially if the aim is to analyze extensive data sets.

Conclusions

Although classifications remain significant tools for clinical documentation and for producing clinical data in various clinical domains, limited research literature is available that illustrates classification development systematically or from a methodological perspective based on previous research. Owing to the role of classifications in data production, theoretical and systematic reviews could also contribute to the transparent development of a future health care knowledge base. Thus, we recommend the main elements based on this study for systematic classification development. Furthermore, the research presented herein could serve as a basis for future work. To conclude, there is a need for the scientific assessment of whether classifications in different domain areas can be developed from theoretical and systematic perspectives.

Abstract

Background: The research marketplace has seen a flood of open-source or commercial mobile health (mHealth) platforms that can collect and use user data in real time. However, there is a lack of practical literature on how these platforms are developed, integrated into study designs, and adopted, including important information around cost and effort considerations.

Objective: We intend to build critical literacy in the clinician-researcher readership into the cost, effort, and processes involved in developing and operationalizing an mHealth platform, focusing on Intui, an mHealth platform that we developed.

Methods: We describe the development of the Intui mHealth platform and general principles of its operationalization across sites.

Results: We provide a worked example in the form of a case study. Intui was operationalized in the design of a behavioral activation intervention in collaboration with a mental health service provider. We describe the design specifications of the study site, the developed software, and the cost and effort required to build the final product.

Conclusions: Study designs, researcher needs, and technical considerations can impact effort and costs associated with the use of mHealth platforms. Greater transparency from platform developers about the impact of these factors on practical considerations relevant to end users such as clinician-researchers is crucial to increasing critical literacy around mHealth, thereby aiding in the widespread use of these potentially beneficial technologies and building clinician confidence in these tools.

(JMIR Form Res 2022;6(3):e29988) doi:10.2196/29988

Introduction

Interest in integrating mobile technology into research has grown exponentially over the last 2 decades, particularly as a means of collecting real-time observational data and intervention outcomes [1]. A newer, but equally growing area of research involves Just-In-Time Adaptive Interventions (JITAIs) [2], which use data collected via mobile/wearable devices, such as symptoms and behaviors, to identify opportune moments for delivering personalized interventional content in real time.

These increasingly popular techniques have created a thriving marketplace for mobile health (mHealth) platforms designed to aggregate mobile app data, deliver intervention content, and observe outcomes. For example, the open-source AWARE

framework is an Android platform designed to address the lack of availability of open and reusable software for creating context-aware apps on mobile devices [3]. Similarly, Remote Assessment of Disease and Relapse-base is a scalable, fully functional, remote Internet of Things data collection platform for real-time remote sensor data collection [4]. Such platforms allow clinicians and researchers to collect (1) ecological momentary assessment (EMA) data, for example, active self-report surveys collected on a mobile or wearable device; (2) sensor data from external devices, such as data collected by a wrist-worn device like a Fitbit [5] or a mattress sensor like the Withings Sleep Analyzer [6]; and (3) sensor data directly collected from participants' smartphones, including step counts, geolocation data throughout the day, and so on.

Clinician-researchers seeking to integrate mobile app data into their research or practice either to deliver interventions or to monitor existing interventions have a plethora of options. However, very few apps include all these features, and implementing these apps on a large scale can be problematic without specific technical and implementation knowledge [4,7]. Should one wish to learn these skills, there is limited documentation with respect to understanding the pragmatic processes required for setting up these studies, building new features, and assessing the feasibility of technical solutions to these research questions. Furthermore, for many clinician-researchers, this is a decision that is outside of their realm of expertise. A wrong decision can dramatically impact the feasibility of meeting a given set of research aims. Indeed, despite the availability of several mHealth platforms, guidance for integrating intervention aims with technical capabilities—from a combined technical and implementation perspective—is difficult to find and would be valuable to researchers working with these tools.

To contribute to this body of knowledge, this paper describes the programmatic processes involved using our experiences with developing an mHealth platform, Intui. The mHealth platform is described with a particular focus on the decisions and choices of relevance to health services and clinician-researchers, including the procedure, cost and effort, and design choices at the product and project levels. To illustrate this further, we present the software results of these processes in action, namely a practical example of the adaptation of Intui to a behavioral activation therapy context, adding practical depth and detail to our procedures.

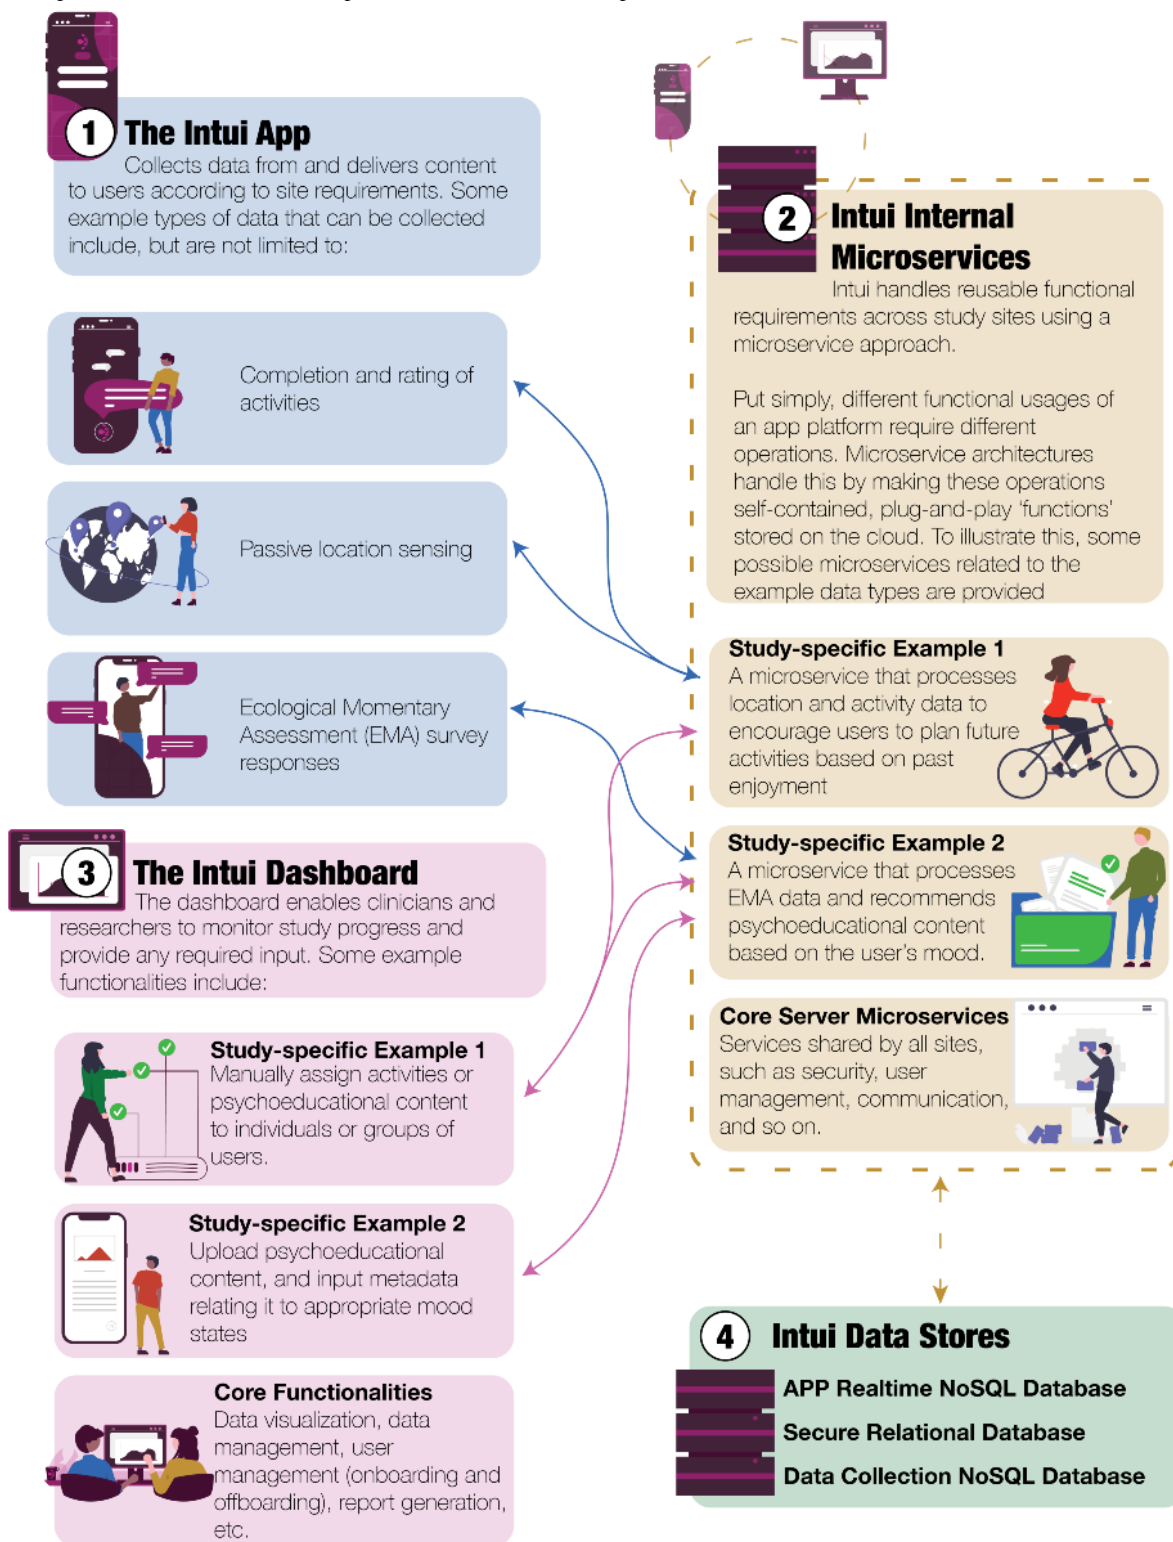
Methods

Materials

Intui Platform: Design Decisions and Features

The Intui platform is a configurable cloud-based service designed to support mHealth data collection and intervention studies (Figure 1). The 4 core software elements of the platform are (1) the Android and iOS smartphone apps for participant use; (2) lightweight cloud functions, also known as microservices, to handle reusable functional requirements provided in the app and the dashboard—for example, security, user management, communication, data management and data analysis—in isolation and at scale; (3) the web-based data dashboard for clinician-researchers to manage study participants and data; and (4) cloud storage on Amazon or Google data centers.

The app and dashboard user interfaces are implemented in a cross-platform app development framework, Ionic, which allows us to create and implement modular components that can be reused in multiple projects as required. Ionic also supports easy integration of third-party plug-ins, which can enable rapid development of new features [8]. For back-end functionality and data storage, Google and Amazon cloud services are used owing to their easy scalability and ability to integrate functionalities implemented in a number of programming languages as microservices.

Figure 1. Components, architecture, and example functionalities of the Intui platform.


Study Design and Initiation

The process of initiating a new study within the Intui platform consists of three parts, guided by the Intui platform software development team: (1) setting up data hosting, (2) configuring Intui to the study-specific requirements, and (3) developing and implementing any custom study components.

Data Hosting Setup

The data hosting setup begins with an Intui software developer preparing the study-specific databases. The Intui platform is designed such that each study has a separate set of databases, 1 set for storing deidentified study data and another for securely storing personally identifiable participant details in an encrypted format. This provides an assurance that data segregation exists from 1 study to another for privacy and ethical considerations,

as discussed in detail later. At this stage, a unique study code is also generated for registered clinician-researchers.

Study-Specific Configuration

Once the hosting setup is complete, registered clinician-researchers receive a welcome email with details to access the web-based data dashboard, as well as the study code to share with prospective participants using the app. Researchers can also use the data dashboard to perform administrative functions, such as inviting participants, removing participants, downloading data, viewing summary statistics, and monitoring study progress.

Based on the unique requirements of each study, Intui software developers extract the study-specific configurations. These configurations define the inclusion of existing functionalities and components of the Intui platform as well as any parameters required for them to operate within the research design. For low-complexity studies, this includes the data collection requirements for phone sensor data and external device sensors, the definition of EMA question sets with branching logic, and protocol details such as the length of the study and timing of reminders related to the proposed data collection.

Development and Implementation of Any Custom Study Components

High-complexity studies often involve the implementation of custom study components. These components may include app user interface (UI) elements for intervention delivery, custom-built data gathering functionalities, and the implementation of microservices to handle the functional logic requirements of more complex study designs. Intui software developers work with researchers to define, design, and implement these components, or integrate those developed by third parties. This flexibility allows researchers to retain full software development control over aspects of more complex study designs.

In addition, UI components that encompass visual elements (styling and display), data (what is shown), and logic (what needs to be stored and any conditional functionality) may need to be developed. These can be designed by the Intui platform developers or by an external developer. Once a prototype UI component is available, the Intui platform developers integrate the component into the Intui app and release an updated version of the app with all added functionalities.

When a study has completed the initiation process, Intui software developers collaborate with the study researchers to run a short technical pilot. The pilot period validates the functional components and configured settings for the study ahead of participant recruitment. Technical pilots ensure that the right data are collected and that the study design has been correctly implemented to reduce the risk of participant dropout as a result of technical faults.

Measures

EMA Delivery

The design of the Intui mHealth platform permits the administration of various EMA question types and tailoring of the question flow and timing. For each study, the EMA question set(s) are defined within a study-specific configuration, and the schedule for question delivery is set up within the study protocol microservice of the Intui platform. EMA question types can include numerical sliders, Likert scales, single choice (eg, yes/no), multiple choice, and free-text input. Branching logic can be used to set conditions on which questions are shown. For example, if poor sleep is self-reported in the app, an additional question may appear asking for further information to differentiate difficulties in falling asleep.

Sensor Measures

The sensor data types and sources collectible through Intui are, essentially, unlimited. Sensors can be integrated with Intui at the application programming interface (API) level and through manual data entry methodologies, for example, participants entering results from an analog medical device.

Procedure

Participant Onboarding

Study participants are invited to download the Intui app from the respective Apple-iOS or Google-Android app stores. Participants register on the Intui app using the provided study code. The unique study code enables the study-specific configuration and features within the app and may also be used to link or segregate participant data. For example, a study may require the use of a patient app that feeds data into a clinician dashboard. In this scenario, clinicians are assigned a unique study code that they provide to participants, thereby linking multiple patient apps to an individual clinician's dashboard. This ensures that only authorized clinicians can access patient information linked to their study code, maintaining data segregation.

Collection of EMA Data

The timing of administering EMAs may be based on time-contingent, event-contingent, or answer-contingent schedules. Time-contingent schedules are configured at a predetermined time of the day/week (for example, a survey getting sent at 2 PM every Monday) or within a range of possible times (for example, a prompt being set to be sent at some point between 9 AM and 3 PM). Event-contingent schedules deliver a tailored prompt in response to characteristics, trends, or threshold values identified in the collected data (when event X occurs, nudge Y). Event-contingent nudges can be delivered in response to active data (when a self-reported threshold value is recorded or a trend is observed over several days) or passive data (like arriving at a specific location, reported through a smartphone's GPS sensor). The type of questions posed in the app and the schedule for delivering those questions can be customized to the requirements of each specific study. Additionally, the appearance of questions may be conditionally based on responses to previous questions (eg, if response is A, ask B). For example, if poor sleep is self-reported in the app, an additional question may appear asking for further information to differentiate difficulties in falling asleep.

The EMA question set(s) are defined within study-specific configuration settings and the schedule for question delivery is

set up within the study protocol microservice of the Intui platform for each study.

Delivery of JITAIs

Access to data in real time is critical to the implementation of JITAIs, as is the development of the necessary UI components to enable this implementation. External and internal programmers can access data gathered in real time through the secure data RESTful APIs in Intui. This can facilitate rapid and collaborative intervention development, as programmers can prototype approaches to process data in any environment (Python, R-Studio, Java, JavaScript) and schedule algorithms to run as independent applications (microservices) that use the same Intui database to read data and store processed results. Programmers can also use the Intui API, which can control push notifications to users and set up reminders to access interventions within the app. Such interventions can include brief text within push notifications, multimedia content within the app, or a set of EMA questions.

Data Extraction for Ongoing Analysis

The collected participant data may be downloaded at any time from the clinician-researcher dashboard or using the Intui API. Clinician-researchers can download data in the CSV format for offline analysis at any time from the data dashboard. Alternatively, separate data analytic applications can be implemented to programmatically read and process the gathered study data through APIs in real time and initiate study features (eg, present new content or messages to participants).

Considerations Unrelated to the Study Design

Support

Researchers can expect to receive stable support for the duration of their study from the Intui platform development team. Owing to the monthly support and maintenance fee, researchers (and study participants) can submit bug reports and expect support and resolution within reasonable time frames to ensure the continuous and uninterrupted progress of their study. The Intui platform development team includes app and cloud computing software developers who hold grant-funded project positions and are also working in the industry. These developers work with the lab on 1 or more projects in an ongoing manner.

Privacy and Ethics

Researchers need to establish an agreement with Flinders University to use the Intui platform that will outline the terms of hosting and sharing of data between the Intui development team and researchers. All data collected by the Intui app are transferred to and stored in 2 databases to lower the impact of a potential data security breach "at rest." Personal identifiable data (eg, names, email addresses used for registration, and logins) are stored in an encrypted user management database in Amazon Web Services data centers. Data collected and used in the study such as questionnaire/survey data and passive data streams are stored on Google Cloud Firestore. Due to the possibility of identifying individuals through their location data coordinates, all raw location data are encrypted before leaving the phone and remain encrypted during storage within the database in a format not readable by humans.

Cost and Effort

In the interest of transparency, we have provided the following example data in Australian Dollars (AUDs) associated with previous projects. The following conversion rate was used: AUD $1=US $0.72. In short, setup costs depend on the functionalities required by the study, the associated software development effort required for the app, and for any back-end development required on the functional database. This is further influenced by the complexity of the project, its duration, and the number of participants.

A low-complexity study that makes use of existing functionalities and components incurs the standard Intui platform study setup effort of 12 hours, roughly costed at AUD $100 per hour for the example in this paper, leading to a total of AUD $1200. This includes advice on study design and consultation with the team to determine study requirements. The baseline costs associated with technical support and maintenance efforts are 3 hours per month (approximately AUD $300) for studies involving up to 2000 participants.

In addition to these labor hours, infrastructure costs—like data hosting and cloud services—start from an AUD $100 per month allocation for studies of up to 2000 participants. Infrastructure costs for serverless environments are often difficult to estimate a priori but are based here on the Google Cloud Platform hosting costs at the time of printing (2021). Free credit tiers may influence infrastructure costs, for example, Cloud Function free tier of 2 million invocations per month, and Firebase free tier of 50,000 reads and 20,000 writes per day. The baseline allocation set here is used to cover Google Cloud resources used by App Engine for storage, logging, and reading operations, or where Cloud Function and Firebase usage exceeds free tier levels on heavy use days; however, this should be monitored closely during the early stages of any project to adjust for redundant usage and identify infrastructure cost savings at scale.

For a practical example involving a simple study, Intui was used to collect third-party device data over a 6-month observational study investigating the relationship between mental health and device data of at-risk young adults for a total cost of AUD $3000 [7]. In this study, participants installed the Intui app on their phone that extracted daily, passively recorded active time, and administered EMAs addressing participants' mood, sleep, and eating habits.

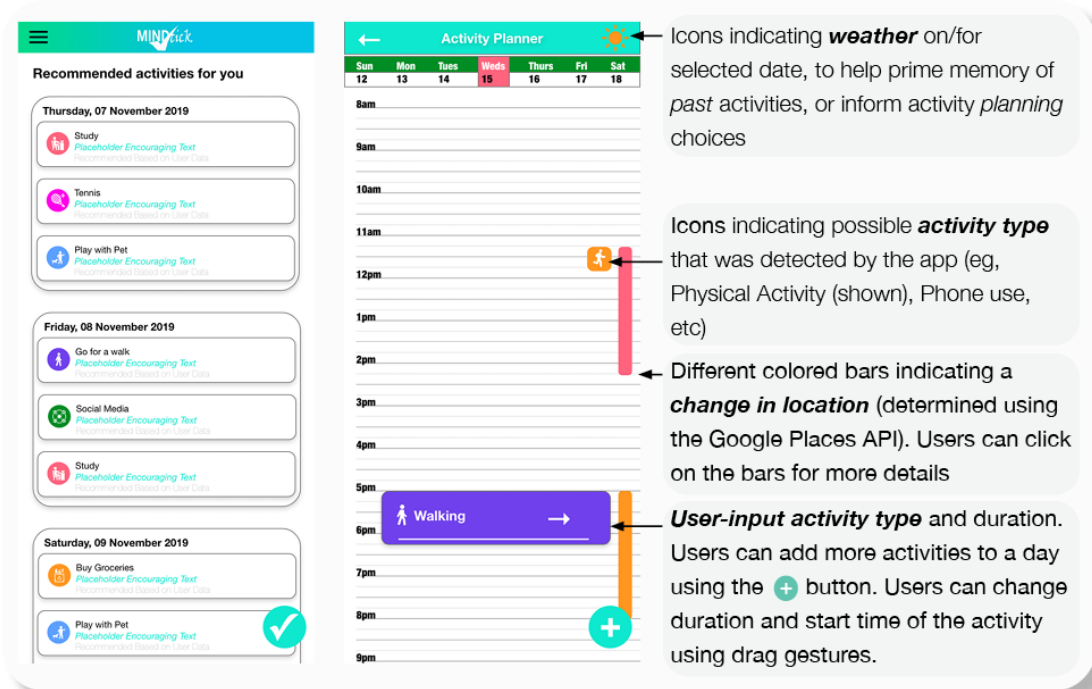
Higher complexity studies are costed on a time and effort basis. In this context, complexity can include the development and integration of custom UI elements, developing and ensuring high-quality integration of microservices that can handle custom intervention logics, or any other request that requires substantial effort beyond the hours outlined in the more basic worked example. The case study presented later in this paper provides a good worked example of the costs associated with a more complex project. Additional costs may also be incurred for alterations to the study design and data collection while a study is running, technically referred to as change requests. Studies with over 2000 participants incur additional monthly costs to account for more extensive support, maintenance, and infrastructure requirements.

Results

App Implementation Using Intui

To make these considerations less abstract, we illustrate how the Intui platform was used to implement an app to support a behavioral activation (BA) intervention. BA is an evidence-based technique used predominantly to manage depressive symptoms. The aim of BA is to increase engagement in behaviors that promote feelings of pleasure and mastery [9]. This technique requires participants to keep an accurate record of activities undertaken over a period and report their mood while undertaking that activity. The goal of this technique is for participants to learn to identify and schedule enjoyable and mastery-oriented activities. However, compliance is a recognized barrier to this treatment method, and few participants complete the prescribed protocol [10].

We implemented a BA app within the Intui platform with adaptive interventions to reduce the burden of monitoring and planning (Figure 2). This was achieved through adaptation of existing components and through the development of two new interventional components: (1) a nudging intervention to improve recall, planning, and adherence for self-monitoring; and (2) machine learning–assisted activity planning.

Figure 2. Intui behavioral activation implementation, including an activity recommendation (left) and a planning/logging (right) interface.


Study Design and Initiation

Data Hosting Setup

We configured a study-specific database on Google Firestore. User-reported data are stored in and recommended activities are fetched from the same study database. Additionally, we configured the app to collect location coordinates every few minutes and store them in the study database. We used a secure data API to read from and write to the study database. Next, we implemented 2 internet-based algorithms (described below) to read from and write to the study database to operationalize the 2 real-time intervention components.

Study-Specific Configuration

Pre-existing EMA components within Intui, as well as much of the back end and UI components of the app and dashboard, were reused or adapted for this project.

Development and Implementation of Any Custom Study Components

The BA app offered 2 interventional components using real-time data, namely nudging to improve recall and adherence to self-monitoring, and machine learning–assisted activity planning. These interventional components were designed specifically for this study, and they were crucial to its success. Outside of the algorithm development, the implementation and development of the custom app UI calendar elements, app UI location context detail elements, and the implementation of microservices to handle the logic for the recommender algorithm as well as the location clustering algorithm also contributed substantially to the development effort.

Interventions Developed

The first intervention component aims to enhance the user's ability to retrieve previously experienced activities and moods as part of self-monitoring. It achieves this by nudging relevant spatial and behavioral cues, involving push notifications and

in-app cues to predictably alter user behavior in a way that is predictable but without specifically forbidding any options or producing disincentivizing effects [11]. Using a calendar or list view interface in the app, users keep a detailed log of their past activities and associated moods. When a user clicks in the calendar to make an activity entry for any given day and time, contextual cues mined from the mobile phone location and usage data are displayed. The cues, shown as visual elements (Figure 2), correspond to where the users were (derived from location data, as described below), what activities they were doing (derived from movement sensor data), and the environment (weather of the location); all these are possible, thus aiding more accurate recall [12,13].

For cueing users to recall their activities and mood more accurately when they were recording data, we displayed visited places as vertical bars in the daily calendar view. Each bar visualized the start and end times of 1 visited place (Figures 2-3). When the bar was clicked, the users were able to see a map and the details of each location, including the precise start and end times. These vertical bars were generated daily, using the results of a k-means clustering algorithm that was set to run at midnight. This algorithm works by taking a continuous stream of location coordinates gathered from the phone sensors, clustering them into locations, and then outputting them as a list of visited places. Entries for the start and end times of each location, and the central GPS point of the cluster marked as the visited place were made into the database. Once users confirm the type of activity they have completed, they are asked to evaluate the activity through a short questionnaire (Figure 3).

The second intervention component aims to assist with planning activities by making personalized activity recommendations learned from the users' self-monitored data and that of other users with similar behavioral patterns. The planner interface displays a ranked order list of activity recommendations drawn from a mix of previously recorded activities and random activities (Figure 2). Users select an activity and schedule when to undertake it in the future. Users' responses to the suggested activities and their evaluation are processed through a bilinear model to refine the ranked order listing of future recommendations [14]. Over time, the recommender interface personalizes the ranked order list with higher-order ranking for activities that reflect long-term user preferences; that is, activities that have resulted in better mood outcomes are the most likely ones to be completed.

To ensure that activity suggestions were personalized to user circumstances, the order of activities displayed in the planner view were dynamically ranked based on past data (Figure 3). To achieve this, we implemented the linear upper confidence bound algorithm, which weighs activities reaping the most rewards (in terms of mood and likelihood to be completed) when exploring new options that may be equally or more rewarding; this is a very important consideration in the context of BA, where targeting reward responsiveness is crucial [15]. The algorithm takes user activity preferences from past data entries and a batch model trained using the first 8 weeks of data from all the users, and it outputs a ranked list of activities to help users prioritize activities that may reward them. A second microservice was scheduled to refresh the batch model daily at midnight after an 8-week period.

Figure 3. Intui behavioral activation app activity evaluation questionnaire. After inputting an activity or clicking on a machine learning–generated activity suggestion in the planner view (Step 1), users are asked to confirm the details of the activity (Step 2), and then answer 3 short questions evaluating the activity (Step 3). API: application programming interface.
Cost and Effort

These algorithms were implemented in Python and run as independent microservices on an Ubuntu instance. This work was carried out independently by a research assistant with a background in data science and Python programming. The specifications for storing the results of the algorithms were established by the platform developers. Additionally, these platform developers designed and implemented the UI elements that incorporated the outputs of these algorithms into the clinician-researcher dashboard. This case study was completed in 62 hours (costed at AUD $100 per hour for $6200).

Discussion

Principal Findings

The clinician-researchers seeking to integrate mobile app data into their research either to deliver interventions or to monitor existing interventions have a plethora of options. As evidenced by the overall process of developing Intui and the case study outlined in this study, the considerations clinician-researchers must bear in mind when setting out to perform this research are extensive. However, Intui represents just 1 approach to designing, developing, and implementing these tools, and regardless of the platform, there is a need to reflect on the ability of clinician-researchers and their teams to meet the logistical and technical requirements underpinning the success of these platforms in their contexts.

Ecological studies, especially longitudinal studies, often require extensive infrastructure and information technology support that demand careful planning to ensure high-quality development, implementation, and maintenance [16]. The frequency at which extremely granular data are stored, received, segmented, analyzed, and presented is also a challenge that can be underestimated, thus affecting the ability of platforms to be used for multiple research outcomes. All these decisions drastically impact the feasibility of delivering projects, are difficult to plan for and cost without a nontechnical background, and can either limit or enable the possibilities of a project. Indeed, this is critical to the provision of the support we have integrated into our operations as nonnegotiable for Intui.

These issues are not confined to our experiences in developing Intui and supporting trials using it; indeed, cost and effort—including the up-front and opportunity costs due to the perceived loss of time in learning new tools—training, and support, were listed as prescient concerns by de Grood and colleagues in their scoping review of eHealth technology adoption by physicians [17]. Open-sourcing projects claims to address these concerns in many respects, namely through literal transparency by sharing the bare bones of software for all to scrutinize [18]. In an age of WebMD self-diagnoses, we are assured that our medical audience requires little convincing that open-sourcing data only results in transparency of the pragmatic type if it is received by an audience able to understand, contextualize, and critique it [7,19,20]. In the same sense that health consumers are ultimately justified in their desire to combat medical gatekeeping and the harm it can cause [7,19], health professionals have every right to question the authority and hegemony of software developers and technology companies on eHealth, especially given the questionable quality of these software packages sometimes [21-23]. However, the solution in both cases lies on a middle ground; solutions can be developed through new models with transparent collaboration and through the development of a critical audience capable of engaging with these digital realities in a reflexive and an ongoing manner [7,20,24]. Through providing insights into the cost, effort, and processes involved in developing and operationalizing Intui in this paper, we hope to have contributed to the development of this critical audience as well as to more transparent norms in mHealth platform development and operationalization in a broader sense.

Conclusions

Enabling researchers to rapidly implement mobile data collection and intervention studies can ultimately lead to increased understanding and access to evidence-based behavioral and mental health interventions. Based on a case study involving our own platform and on critical reflection, this paper has outlined some practical considerations for those hoping to engage in these technologies. Greater transparency in terms of the cost, effort, and support across the board in this field will only enable the widespread use of these beneficial methodologies and build clinician confidence in these tools.

Abstract

Background: Psychological resilience has been extensively studied by developmental researchers, and there is a growing body of literature regarding its role in psychiatry and psychopathology research and practice. This study contributes to this growing literature by providing real-world evidence on the relationship between resilience and clinical symptoms among a large sample of employed Americans.

Objective: This study aimed to describe resilience levels in individuals accessing Ginger, a virtual mental health system, in addition to the association of resilience with demographic characteristics, baseline depression, and anxiety symptoms.

Methods: We conducted a retrospective observational study of 9165 members who signed up for Ginger and completed a baseline survey between January 1 and August 5, 2021. We used multivariate regression models to test for associations between baseline resilience and other member characteristics.

Results: Baseline resilience scores centered on a mean of 23.84 (SD 6.56) and median of 24 (IQR 8) out of 40, with 81.0% (7424/9165) of the sample having low resilience at baseline. Despite having relatively higher resilience scores, members with no or mild depression or anxiety still had low resilience scores on average. Self-reported suicidal ideation was associated with lower resilience.

Conclusions: Overall, members had low baseline resilience, similar to resilience levels observed in trauma survivors in prior studies. Younger members and those with higher levels of depression and anxiety at intake reported lower levels of resilience at baseline. Notably, members with no or mild depression or anxiety still had low resilience scores on average, suggesting a need for mental health support among individuals who might not typically be recommended for treatment based on traditional clinical assessments, such as the 9-item Patient Health Questionnaire (PHQ-9) and the 7-item Generalized Anxiety Disorder scale (GAD-7). Two suggestions for topics of future research are to develop treatment recommendations based on the Connor-Davidson Resilience Scale and to understand the interaction between resilience levels and symptom-based outcome measures, such as the PHQ-9 and the GAD-7.

Introduction

Resilience and Adaptability

Psychological resilience, subsequently referred to as resilience, represents the personal qualities that enable an individual to thrive in the face of adversity. It can be viewed as a measure of the ability to cope with stress and is potentially an important target of treatment for anxiety, depression, and stress reactions, such as posttraumatic stress disorder (PTSD). Research has shown that resilience is a multidimensional characteristic and that it may vary with context, time, age, gender, and cultural origin, as well as different life circumstances [1,2].

The construct of resilience has long been of interest to developmental psychologists [3]. Considered a personal strength, resilience can contribute to positive functioning and optimal development and can prevent negative emotions, thoughts, and behaviors [4]. While it does not imply total invulnerability to the development of psychiatric disorders, resilience serves as a protective factor against the development and onset of psychopathology [3]. An evaluation of hypotheses about the relationship of resilience to personality traits, coping, and psychiatric symptoms found that it demonstrates strong positive correlations with extraversion and conscientiousness, and it can moderate the relationship between retrospective reports of childhood emotional neglect and current psychiatric symptoms [3]. Researchers have also pointed out that resilience is not necessarily a feature of an individual's internal psychological processes but can be a product of an individual's social and psychological ecosystem, including individual, family, community, and cultural factors [5].

There is a growing body of literature on resilience in the fields of psychiatry and psychopathology, which tends to be more focused on disease and pathology. A new approach in psychopathology research, advocated by some authors, focuses on positive adaptation in response to stress [3]. As part of this approach, there is interest in moving beyond an emphasis on pathology and focusing on prevention through human strengths and protective factors [6]. The importance of resilience as an inherent ability to manage daily stresses, as well as to overcome severe trauma, has increasingly been recognized [7]. Studies of frontline health care workers during the beginning of the COVID-19 pandemic and responders to the September 11, 2001, attacks have shown that resilience is important for both risk of PTSD and the ability to overcome trauma [8,9]. Further, researchers have made progress modeling the neurobiological components of resilience, pointing to both physiological processes and genetic factors that shape a person's resilience [10].

COVID-19

The COVID-19 pandemic presented the need for a prolonged period of social distancing and potential isolation, a changing and uncertain time frame for improvement in conditions and lifting of restrictions, and uncertain political and economic implications. Recent studies have shown that individuals with lower resilience scores experienced increased odds of mental distress and expressed greater difficulty coping with the emotional challenges of the pandemic crisis [11,12]. Given these unique challenges to resilience and mental well-being, more attention is being given to increasing resilience from both research and clinical perspectives. In particular, health systems have recognized the need to promote resilience among both health care workers and patients. As New York City became the epicenter of the pandemic in the United States, the Mount Sinai Health System created the Center for Stress, Resilience, and Personal Growth in order to address the pandemic's psychological impact on the health care workers in the system; they also created a resilience app, the Wellness Hub, as a standalone digital platform offering users a suite of tools that they could interact with on a daily basis [13]. Furthermore, the pandemic has spurred increased interest in not only

understanding the neurobiological and cultural process that shape resilience but also in developing interventions that improve resilience, as individuals around the globe cope with the implications of the COVID-19 pandemic [14]. In this regard, digital health platforms can play an important role in delivering such interventions.

Study Objectives

Given current events, increased demand for mental health services, and newer disciplines like behavioral health coaching, it is important to understand individual needs, particularly those that might not be captured in traditional clinical assessments, such as the 9-item Patient Health Questionnaire (PHQ-9) and the 7-item Generalized Anxiety Disorder scale (GAD-7). With this in mind, Ginger, an on-demand mental health system, began collecting self-reported resilience data from its members beginning in December 2020. These data are used in this study, which aims to describe resilience levels in individuals accessing virtual mental health services, a population that is less understood given the relatively nascent industry. In particular, we aim to answer the following research questions: (1) What is the distribution of baseline resilience? and (2) To what extent are baseline scores correlated with demographic characteristics and concurrent depression and anxiety symptoms?

Methods

Overview

This is a retrospective observational study of individuals who accessed Ginger. Data were collected from Ginger members between January 1 and August 5, 2021.

The Ginger System

Ginger provides virtual on-demand mental health services, primarily through employee or health plan benefits. Via a mobile app platform, Ginger members can access behavioral health coaching, teletherapy, and telepsychiatry, as well as self-guided content and assessments. This system has been described in more detail in prior publications evaluating depression and anxiety outcomes as measured by the PHQ-9 and the GAD-7 [15,16].

Participants

Study participants had access to the Ginger system as part of their employer or health plan benefits. Internal clinical protocols include the following exclusionary criteria where self-directed telehealth is likely not appropriate and where more specialized and urgent psychiatric services are required:

1. Active suicidal ideation.
2. Active high-risk self-harm behavior.
3. Two or more hospitalizations within the past 6 months or one hospitalization in the past month for psychiatric reasons.
4. Certain symptoms of psychosis that are poorly managed (eg, member is not medication-compliant or symptoms are unresponsive to treatment) and are likely incompatible with telehealth.
5. A primary diagnosis of a substance use disorder or moderate to severe substance abuse issues, due to the high complexity,

severity, and risk frequently associated with such members, as well as the need for specialized care.

6. Active eating disorders with symptoms considered to be high risk.

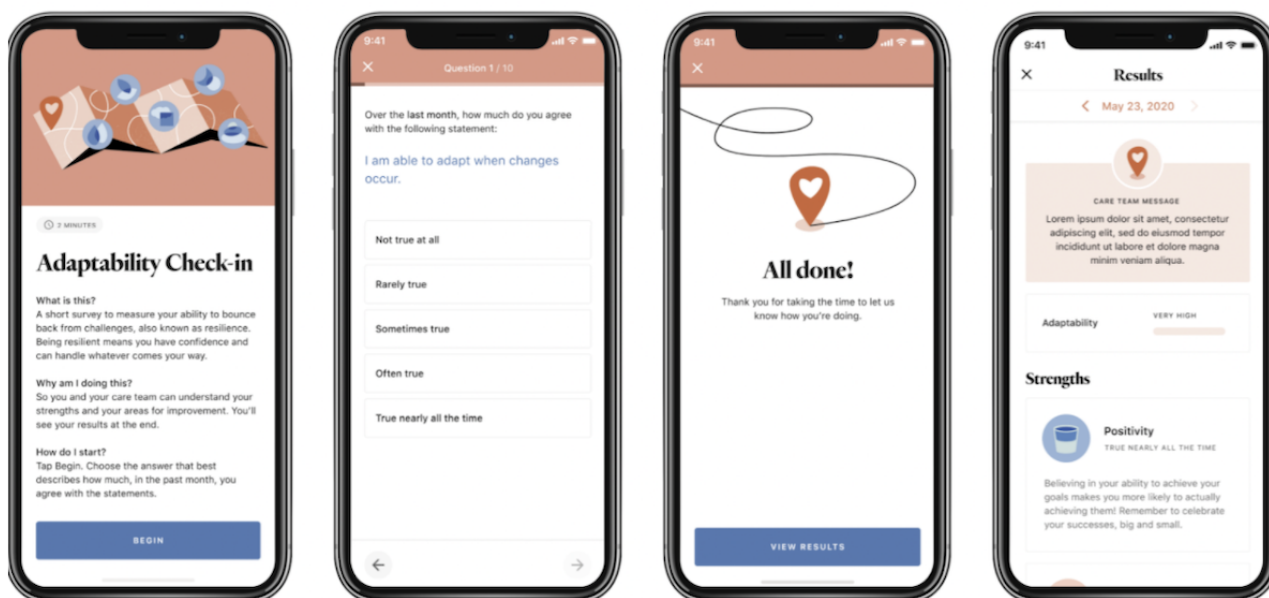
7. Ongoing grave disability, including certain patients who are bipolar with active mania, hypomania, or mixed episodes; are unmedicated; or have poor compliance with a medication regimen over time.

8. Two or more medical hospitalizations in the last month, due to the high likelihood that the individual has a poorly controlled medical condition that requires close monitoring.

For this study, we included Ginger users aged 18 years or older who joined during the study data collection period.

Data Collection

As part of its measurement-based care system, Ginger uses various assessments, including the PHQ-9 and the GAD-7. Since December 2020, Ginger has used the 10-item Connor-Davidson Resilience Scale (CD-RISC 10), also referred to as an adaptability check-in, to track progress beyond depression and anxiety symptoms. This is particularly relevant to understand needs of "subclinical" members (ie, those members who screen negative for depression or anxiety at intake). This measure was selected due to behavioral health coaching's focus on building resilience and its strength-based focus in contrast to more traditional symptom measures, such as the PHQ-9 and the GAD-7. The CD-RISC 10 was sent to members 1 week after they signed up, and a follow-up survey was sent to members every 30 days. Importantly, members who signed up but did not engage with the app past the 1-week mark did not complete the baseline survey. In this way, members with a low likelihood of meaningful engagement, which is a proxy for behavioral health need, were excluded from the sample. Visuals of how this survey appeared to members are shown in Figure 1.

Figure 1. Screenshots of the Ginger mobile app showing the 10-item Connor-Davidson Resilience Scale.


Measures

The Connor-Davidson Resilience Scale

As mentioned above, Ginger uses the CD-RISC 10 to measure self-reported perceived resilience. The development of the Connor-Davidson Resilience Scale (CD-RISC) [1] arose from the researchers' extensive treatment of individuals suffering from PTSD. They initially developed a 25-item scale to measure resilience, or how well one is able to adapt to change and bounce back after stressful events, tragedy, or trauma. Two briefer versions, the CD-RISC 10 [17] and the 2-item CD-RISC [18], were subsequently developed by other research teams. The CD-RISC 10 has demonstrated robust validity, reliability, and practicality [1]. Since its development in 2003, the CD-RISC has been translated into many different languages and studied in a variety of populations [1].

The CD-RISC 10 contains 10 of the original 25 items from the CD-RISC. The 10 topics included in the CD-RISC 10 are as follows: confidence, determination, flexibility, focus, grit,

perseverance, personal growth, positivity, self-reliance, and weathering emotions. For each of the 10 items, respondents were asked to select one of the following responses to a statement (eg, "I am able to adapt when changes occur"): not true at all (0), rarely true (1), sometimes true (2), often true (3), and true nearly all the time (4). A respondent's total score could range from 0 to 40. Results from the US population indicated that the quartiles for this measure are as follows: quartile 1, 0 to 29 points; quartile 2, 30 to 32 points; quartile 3, 33 to 36 points; and quartile 4, 37 to 40 points [17].

Baseline Characteristics

For each member, the following data were either collected at baseline or were fixed characteristics of members: age group, gender, geographic region, PHQ-9 score, and GAD-7 score. The demographic and location data were not self-reported. Instead, they were reported by a member's parent organization, which was either their employer or their health insurance plan. The baseline PHQ-9 and GAD-7 data were collected within the Ginger system. Baseline PHQ-9 and GAD-7 scores were

selected by looking at the window from 1 week before to 1 week after a member's baseline CD-RISC 10 score was collected and choosing the first PHQ-9 and GAD-7 scores in that window.

For many Ginger members in this study, baseline characteristics were missing. Data were missing due to one of two reasons. First, a member's parent organization may not have shared the member's demographic information. Thus, missing demographic data is a signal of a member's parent organization and not necessarily a signal of information specific to a given member. For example, of the 249 parent organizations represented in this study, 116 (46.6%) reported all of their members' gender information and 121 (48.6%) did not report their members' gender information. The remaining 12 (4.8%) reported gender information for some but not all of their members. Second, there may not have been a PHQ-9 or GAD-7 score within the 1-week window around the collection of a member's baseline CD-RISC 10 score. This could be due to a member not completing the PHQ-9 or the GAD-7 at all or due to the timing of their completion of surveys falling outside the 2-week window.

Analyses

Sample

This study included 9165 Ginger members who completed a baseline survey at any point from January 1 to August 5, 2021. This sample will be referred to as the baseline sample.

Summary Statistics and Subgroup Analysis

Our descriptive analysis summarized baseline resilience scores and presented the mean (SD) and median (IQR) of baseline scores. We used a Welch t test to analyze differences in means across subgroups of members with unequal variances when a category had two groups (eg, gender). For categories with more than two groups (eg, census regions), we used an F test as part of an analysis of variance to test for significant differences in means across the groups. Further, to understand whether members with missing data had significantly different outcomes than those without missing data, we performed Welch 2-tailed t tests comparing means across the two groups.

Descriptive Multivariate Regressions

In order to understand the associations between resilience and specific covariates, we leveraged a multivariate regression model as part of our descriptive analysis of baseline scores. This methodology accounted for possible correlations among covariates and isolated the relationship between each covariate and resilience, holding all other covariates constant. We estimated an ordinary least squares (OLS) linear regression predicting baseline scores. The following categorical independent variables were included in the model: gender, age group, census region, and indicators for whether a member's baseline PHQ-9 and GAD-7 scores were each above 10. For each of these independent variables, a category for members with missing data was included. No interaction terms were included, although, theoretically, there could be significant differences at a more granular level. Additionally, self-reported suicidal ideation (ie, indicating more frequently than "never" on question 9 of the PHQ-9) was included as an indicator

variable. Homoscedasticity was not assumed, and robust standard errors were computed.

Ethical Considerations

This study represents a secondary analysis of pre-existing deidentified data. The study team does not have access to the participants or to the participants' identifying information and does not intend to recontact participants. This study protocol was reviewed by the Advarra Institutional Review Board (IRB) and determined to be exempt from IRB oversight, as deidentified secondary data analysis is generally not regarded as human subjects research; this is in accordance with the US Department of Health and Human Services regulations for the protection of human subjects in research (45 CFR 46) [19].

Results

Using the baseline sample of 9165 members, Figure 2 shows the distribution of baseline scores. The scores are centered on a mean of 23.84 (SD 6.56) and a median of 24 (IQR 8) out of 40, but there is significant variance in these scores. A total of 81.0% (n=7424) had a resilience score of less than 30. Table 1 shows the mean response scores across the 10 items. Responses were highest for the questions about confidence, flexibility, and perseverance, and scores were lowest for determination and weathering emotions.

Table 2 presents the number of members and baseline score statistics for the overall sample and subgroups based on demographic characteristics and mental health outcomes at baseline. Demographic data were missing for a large portion of the sample due to irregular reporting by members' employers or health plans. Of those without missing demographic data, the majority were female and between 18 and 34 years old. Members were most likely to live in the West and South, but all four census regions were represented in the baseline sample.

For each category (gender, age, etc), a P value is presented in the category's first row testing whether the difference in mean scores across the category was statistically significant. For all categories except gender and census region, the mean baseline score was statistically different across groups at the 1% level. In the row for groups with missing data, the P value corresponds to a t test of the difference in mean baseline scores between those with and without data.

For all categories, members with missing data had significantly different scores than those without missing data. The mean scores for those with missing demographic data were lower than for those who were not missing data. While we do not have direct evidence regarding why this is the case, we can at least conclude that the resilience of members with parent organizations (ie, employers or health plans) that did not send demographic data was lower than for members with parent organizations that did report these data. The mean resilience scores for members with missing PHQ-9 and GAD-7 scores followed a different pattern in that they fell between the mean scores for clinical and subclinical members. For both the PHQ-9 and the GAD-7, the mean scores for members with missing data were considerably closer to those of subclinical members, suggesting that the set of members with missing PHQ-9 and

GAD-7 data were disproportionately subclinical, relative to the sample overall.

A significant portion of the sample screened positive for moderate to severe depression, based on the PHQ-9, or moderate to severe anxiety, based on the GAD-7. While anxiety and depression symptoms correlated with baseline scores (Table 3),

there was significant overlap in the distribution of resilience scores for members with and without clinical depression or anxiety. Figures 3 and 4 display these distributions. Notably, a significant portion of members without clinical depression (3659/4841, 75.6%) and members without clinical anxiety (3907/5130, 76.2%) had low resilience.

[d]GAD-7: 7-item Generalized Anxiety Disorder scale.

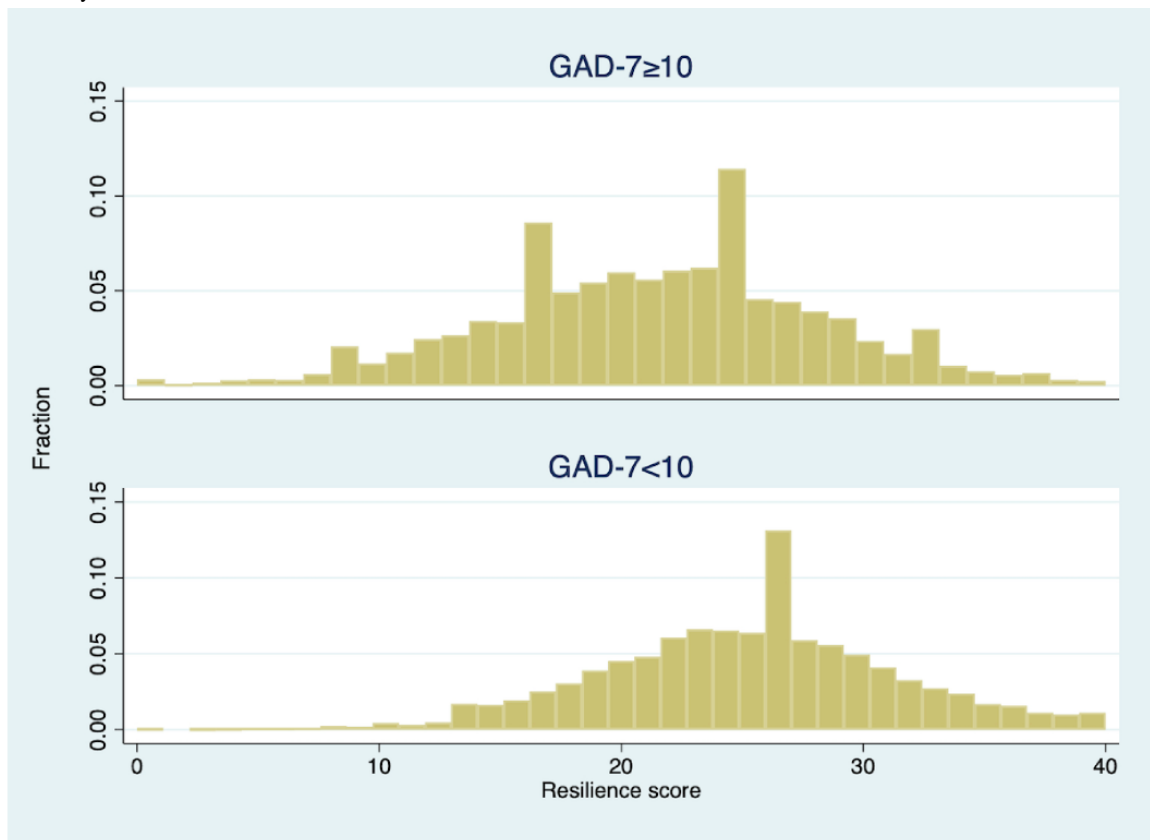
Figure 3. Distribution of CD-RISC 10 resilience scores by PHQ-9 threshold. CD-RISC 10: 10-item Connor-Davidson Resilience Scale; PHQ-9: 9-item Patient Health Questionnaire.
Figure 4. Distribution of CD-RISC 10 resilience scores by GAD-7 threshold. CD-RISC 10: 10-item Connor-Davidson Resilience Scale; GAD-7: 7-item Generalized Anxiety Disorder scale.


Table 3 presents results from a multivariate OLS regression using demographic and baseline mental health outcomes to predict baseline resilience scores. Point estimates and standard errors are included in the table. Holding all else constant, gender does not significantly predict scores. The youngest members (aged 18 to 24 years) had significantly lower scores than those aged 25 to 64 years and higher scores than those aged 65 years and above; the latter difference was not statistically significant. There were no statistically significant differences across census regions. Baseline scores for members with no or mild depression or anxiety were 2.3 or 2.0 points higher, respectively, than those with moderate to severe depression or anxiety. Consistent with the hypothesis that members with missing PHQ-9 and GAD-7 scores are more similar to subclinical members, the scores for these members were 4.3 points higher than for members with clinical depression (ie, the leave-out comparison group). Self-reported suicidal ideation was associated with a significant reduction of 2.1 points in baseline resilience.

Discussion

Principal Findings

This study found that individuals accessing the Ginger system had, on average, low baseline resilience levels (median CD-RISC 10 score of 24), well below prior benchmarks of the US general population and in line with studies of veterans with PTSD and depression [20]. This is not surprising given that the sample includes individuals seeking out mental health services and the data collection period, which coincided with spikes of COVID-19 cases and other disruptive world events. A significant portion of the sample screened positive at baseline for moderate to severe depression (3641/8482, 42.9%, based on the PHQ-9) and moderate to severe anxiety (3352/8482, 39.5%, based on the GAD-7). A total of 81.0% of members had a baseline resilience score of less than 30.

Our descriptive analysis shows that younger members tended to have lower resilience, which is consistent with several studies of adolescents and young adults in the United States [3,21]. Baseline resilience scores for members with no or mild depression or anxiety were higher than those for members with moderate to severe depression or anxiety. This association was even stronger for members who reported suicidal ideation. This is consistent with findings from other studies showing that self-reported mental health diagnoses were negatively associated with higher resilience, and adults with reported low or normal levels of resilience were more likely to experience mental distress compared to those with high resilience [11,21]. However, it is interesting to note that despite having relatively higher resilience scores, members with no or mild depression or anxiety still had low resilience scores on average. This highlights the need for mental health support among individuals who might not typically be recommended for treatment based on traditional clinical assessments, like the PHQ-9 and the GAD-7.

Strengths and Limitations

A major strength of this study was the large number of participants; this is one of the largest studies using the CD-RISC 10 measure, which allows for certain subgroup analyses. This is also one of the first applications of this measure in a large-scale real-world setting, in contrast to smaller controlled research settings. Incorporating a strength-based measure like resilience, in contrast to symptom-based measures like the PHQ-9 and the GAD-7, allows us to better understand the needs of individuals seeking mental health services.

There are several limitations to this study. Of the 9165 Ginger participants in the study, 43.6% had missing data for gender, and 44.1% had missing data for age. Typically, these demographic data are shared by members' organizations through which they access Ginger services (eg, employers). Some organizations do not share demographic data. Given the amount of missing data in our sample, we acknowledge the need for further research that focuses on the relationship between resilience and demographics. In part due to incomplete data reporting by parent organizations, Ginger has launched the capability for members to elect to self-report their demographic information in the app. These self-reported data will supplement the parent organization–reported data and will be available for future research projects. This functionality had not been launched by the time of this analysis. For the purposes of this study, we presented results for members with missing data and we controlled for whether a member's demographic data were missing in any regression analyses. However, because the Ginger platform is offered through employers, the survey respondents were working-age adults, which suggests that these findings may generalize to the professional workforce and those enrolled in health benefits through their employer. Further, the current data did not include information on other sociodemographic or contextual factors (eg, marital status, family composition, significant life events, sources of social support, and educational level) that might be related to resilience and mental health, and that may have been of particular significance during the pandemic.

Future Research

Given that behavioral health providers often focus on clinical symptoms, such as those measured by the PHQ-9 and the GAD-7, a deeper understanding of nonclinical outcomes, such as resilience, is increasingly important to the growing digital behavioral health industry. This is especially true given that many members seeking behavioral health support do not experience clinical symptoms. For example, the majority of members in this study screened negative for depression and anxiety, signaling a need to not only track other outcomes that are associated with members' well-being but also to understand which specific interventions have an impact on these outcomes, the expected size of these impacts, and which subpopulations may respond differently. This study points to many directions for future research, primarily looking at how these scores evolve over time, with a particular focus on whether the interaction of resilience and clinical symptoms (eg, depression and anxiety) impacts members' responses to behavioral health interventions. Given that this data set included PHQ-9 and GAD-7 scores, future studies could examine the relationship between resilience and symptoms of anxiety and depression, for example, whether increased baseline resilience is associated with a higher likelihood of symptom improvement and faster time to improvement (ie, less use of care services). Additionally, future

research could look at more detailed classifications of use and conversational features extracted via natural language processing of text messages to better understand which factors have stronger associations with increased resilience.

Conclusions

Resilience is a construct often referred to but less often defined and measured, particularly in clinical settings that tend to focus more on symptom-based measures. In this study, we found that members accessing mental health services from January to August 2021 had extremely low baseline resilience, in line with prior studies of trauma survivors, which highlights the need for expanding access to care. Overall, younger members and those with higher levels of depression and anxiety at intake reported lower levels of resilience at baseline. Notably, members with no or mild depression or anxiety still had low resilience scores on average, demonstrating the need for mental health support among individuals without clinical symptoms. Future research will examine changes in resilience over time in addition to factors associated with those changes.

Abstract

Background: Wearable tracking devices and mobile health technology are increasingly used in an effort to enhance clinical care and the delivery of personalized medical treatment. Postpartum depression is the most frequently diagnosed complication of childbirth; however, significant gaps in screening and treatment remain.

Objective: This study aims to investigate the clinical utility, predictive ability, and acceptability of using ecological momentary assessment to collect daily mood, sleep, and activity data through the use of an Apple Watch and mobile app among women with postpartum depression.

Methods: This was a pilot study consisting of 3 in-person research visits over the course of a 6-week enrollment period. Questionnaires to assess depression, anxiety, and maternal functioning were periodically collected, along with daily self-reported symptoms and passively collected physiological data via an Apple Watch. Feedback was collected from study participants and the study clinician to determine the utility and acceptability of daily tracking. Logistic regression was used to determine whether mood scores in the 2 weeks before a visit predicted scores at follow-up. Compliance with daily assessments was also measured.

Results: Of the 26 women enrolled, 23 (88%) completed the 6-week study period. On average, the participants completed 67% (34.4/51.5 days) of all active daily assessments and 74% (38/51.5 days) of all passive measures. Furthermore, all 23 participants completed the 3 required visits with the research team. Predictive correlations were found between self-reported mood and Edinburgh Postnatal Depression Scale score at follow-up, self-reported anxiety and EDPS, and sleep quality and Edinburgh Postnatal Depression Scale.

Conclusions: Using ecological momentary assessment to track daily symptoms of postpartum depression using a wearable device was largely endorsed as acceptable and clinically useful by participants and the study clinician and could be an innovative solution to increase care access during the COVID-19 pandemic.

Introduction

Background

Postpartum depression (PPD) is a common yet serious disorder of the perinatal period. Despite being the most frequently diagnosed complication of childbirth, there are pervasive gaps in the screening, detection, and treatment of women with this debilitating condition [1]. Lifetime positive screening prevalence estimates for PPD range from 10% to 15% [2-4]. If inadequately treated, the condition can lead to devastating consequences for

families; PPD is considered the greatest risk factor for maternal suicide and infanticide [5]. Research has shown a multitude of harmful effects to the mother-baby dyad, including higher medical costs [6], earlier discontinuation of breastfeeding [7], negative impact on the baby's brain development [8,9], and an increased risk for long-term mental health problems in children of women with PPD [9].

Complex psychiatric disorders, such as PPD, require thoughtful clinical tools for decision support, which are an increasingly important component of providing high-quality health care. Vital information pertaining to a patient's condition can be derived from ecological momentary assessment (EMA) data. EMA includes various methods for data collection, traditionally via paper-and-pencil questionnaires or diaries and more recently via mobile phone or device reporting at certain designated time points throughout the day [10]. This method of *real-world* data collection has been shown to reduce recall bias in reporting mood and to highlight dynamic changes a patient may experience day to day and can be easily integrated with physiological data for a broader picture of a patient's experience outside of the clinical setting [11,12]. EMA ratings can be *prompted* or passively collected, especially in the context of smartphones and smart technology with integrated passive data collection such as heart rate and activity that are constantly sampled throughout the day. In recent years, EMA data have been shown to have the potential to predict oncoming mood and anxiety episodes [12-16]. A review of the literature did not identify any other studies examining mood tracking using EMA in a population with PPD, although recent studies have examined substance use disorder, posttraumatic stress disorder, racial disparities, and postpartum health in perinatal populations using EMA [17,18]. EMA has been used to understand the course of affective experience during pregnancy but not postpartum [19]. Given the significant health burden associated with PPD, there is a need for innovative technology that can enhance and personalize the clinical care of perinatal women at risk for mood disorders. The COVID-19 pandemic has led to devastating consequences for perinatal women, making innovative care solutions all the more relevant [20]. With the closing of medical offices and schools and the decrease in social and community support, accessible and telemedicine-based care options are critical to ensure patient safety and well-being [21]. To address this problem, our team developed and pilot-tested an app-based EMA module within an existing research app for women with PPD to measure mood, anxiety, sleep, and activity in women experiencing PPD.

The existing research app, *PPD ACT* (now *Mom Genes Fight PPD*), was released in 2016 to rapidly and efficiently recruit, consent, screen and enable DNA collection from women with a lifetime history of PPD [22]. Interested participants downloaded the app, consented to the study, completed a series of PPD screening questionnaires, and submitted a saliva sample if eligible. In an effort to increase engagement with the PPD ACT app, the *PPD ACT Apple Watch Module* was created to allow for daily tracking of mood, anxiety, sleep quality, and exercise (via heart rate and step tracking) for participants to better understand how each activity can affect symptoms of

depression and anxiety and to be able to easily share these data with a clinician.

Objectives

It has been well documented that women experiencing PPD face a number of barriers to obtaining appropriate medical care. Prominent barriers include stigma-related reasons such as a hesitancy to admit to experiencing depression and a tendency to minimize symptoms [23]. Engaging patients in care through the use of device-based apps and EMA is a potentially powerful tool to minimize treatment barriers while providing a rich set of data for clinician use to inform more personalized patient care. The primary goal of this pilot study is to determine the clinical utility and predictive ability of using an app-based daily tracking tool to enhance PPD treatment. We also assessed patient compliance with the protocol and feedback on the experience and usefulness of the EMA data by both participants and the study clinician.

Methods

Participants

Recruitment of English-speaking women aged >18 years and currently experiencing PPD occurred from February 2017 to March 2018 in specialized perinatal psychiatry clinics at UNC Hospitals in Chapel Hill, North Carolina, and the surrounding community. Participants were screened for PPD using the Edinburgh Postnatal Depression Scale (EPDS) [24] or identified through medical records. Those who were <7 months postpartum, with an EPDS score of ≥13 or a positive current PPD diagnosis in the medical record were approached to participate in the study. Case status was confirmed within *PPD ACT* using the EPDS lifetime version [25]. The study was additionally advertised in the community via flyers and targeted Facebook advertising. Enrollment was also limited to women who owned an Apple iPhone 5 or a newer model to pair with the Apple Watch.

Ethics Approval

This study was approved by the University of North Carolina Institutional Review Board Office of Human Research Ethics (number 15-2165). All participants provided written informed consent and signed the Health Insurance Portability and Accountability Act.

PPD ACT Apple Watch Module

To collect EMA data via the *PPD ACT* app, we created the *PPD ACT Apple Watch Module* with the support of app development firm Little Green Software using Apple's CareKit framework, a tool allowing for app-based data collection aimed at understanding and management of health conditions. The Apple Watch Module allows women to log their self-reported mood, anxiety, sleep quality, and medication use (if applicable) daily, while using an Apple Watch to passively collect physiological data on their daily activity (steps taken), heart rate (periodic beats per minute), and sleep. The Sleep++ app, a third-party app, was downloaded on the Apple Watch and used to passively log nightly sleep duration. Integrated sleep tracking was not yet available on the Apple Watch, and a third-party app was used

instead. Although categorized as passive, the Sleep++ app did require participant input to log when they went to sleep and woke up each day. Mood, sleep, and physiological data were shared with the study clinician via the participant's PPD ACT app at research visits to provide critical information about the daily experience of PPD outside of the clinical evaluation.

Equipment

A total of 24 Series 2 Apple Watches (42 mm) were donated for study use by Apple, Inc. The Apple Watches were then loaned to participants for the 6-week duration of the study to be used for data collection. Participants signed an Apple Watch Loan Agreement to outline return of the Apple Watch at the end of study participation. Participants were required to own an Apple iPhone 5 or a newer model to pair with the Apple Watch for functionality. The phone was also needed to download the *PPD ACT* app, which participants concurrently enrolled in. The specialized Apple Watch Module was available on the *PPD ACT* app via an enrollment code provided by the research team.

Assessment Measures

Overview

Participants were instructed to wear the Apple Watch continuously for the 6-week enrollment period. Each day, participants were asked to open the *PPD ACT* app Apple Watch Module and fill out a 10-point Likert scale pertaining to their daily mood, anxiety, sleep quality (1 being the worst ever experienced and 10 being the best ever experienced), and medication use (if applicable). A full list of assessments is provided in Multimedia Appendix 1. Participants were asked to rate their sleep quality in the app daily upon waking and to complete the mood and anxiety assessments at the end of each day. Figure 1 shows examples of in-app questionnaires. In addition, the Apple Watch passively collected daily activity and heart rate. Sleep was *semipassively* tracked using the Sleep++ app, which required the participant to open the app before going to bed to indicate the start of the sleep period and upon waking to indicate the stop of the sleep period. Participants were able to track their data over the course of the study via summary charts provided in the Apple Watch Module.

Participants were asked to attend 3 research visits at the UNC Hospitals Perinatal Psychiatry clinic over the course of 6 weeks. At these visits, they met with research coordinators (HK and JS) and the research clinician and completed self-reported questionnaires including the Patient Health Questionnaire-9 (PHQ-9), the Generalized Anxiety Disorder 7-item scale (GAD-7), the EPDS, and the Barkin Index of Maternal Functioning (BIMF). The PHQ-9 and EPDS are commonly administered together in research studies of PPD and have been shown to be reliable and valid measures for identifying major depressive episodes in the general population (and in populations with PPD for the EPDS) [26,27]. As the scales measure slightly different constructs, it is beneficial to administer both. Studies have found discordance to occur between PHQ-9 and EPDS scores [28], and we also had 5 instances where the EPDS and PHQ-9 were discordant over the 3 visits. However, as the scores were not being used diagnostically, we did not find this to be an issue. Participants also completed a feedback survey at their second and third visits about their experience using the Apple Watch. After visit 3, the research clinician completed a feedback questionnaire for each participant on the clinical utility of the EMA measures.

Figure 1. Apple Watch Module questionnaire screens.
Instruments

PHQ-9 Assessment

The PHQ-9 is a validated [29], self-administered questionnaire commonly used in clinical settings to guide screening or measure recovery and treatment response. This 9-item questionnaire was originally designed to measure the presence or severity of depressive symptoms. Patients are asked to rate items based on their experience over the past 2 weeks. Each item is rated on a Likert scale ranging from 0 to 3 and scored based on the frequency of symptoms and functional impairment. Four anchors are included (0=not at all, 1=several days, 2=more than half the days, and 3=nearly every day). Ratings produce a summary score between 0 and 27. A score ≤4 indicates no depressive symptoms, 5 to 9 mild depression, 10 to 14 moderate depression, 15 to 19 moderately severe depression, and ≥20 severe depression [30].

GAD-7 Assessment

The GAD-7 is a well-validated [31] clinical tool for measuring generalized anxiety disorder and the three most common anxiety disorders (panic disorder, posttraumatic stress disorder, and social anxiety disorder) [30]. The GAD-7 assesses the frequency and severity of anxiety symptoms in the past 2 weeks using the same Likert scale and anchors as those used in the PHQ-9. Scores of 5, 10, and 15 are taken as the cut-off points for mild, moderate, and severe anxiety, respectively. Using the threshold score of 10, the GAD-7 has a sensitivity of 89% and a specificity of 82% for generalized anxiety disorder [32].

EPDS Assessment

The EPDS is a 10-item self-reported questionnaire that has been well validated [33] and shown to be reliable and sensitive in identifying women at risk for PPD [24]. Women are asked to report on symptoms over the previous 7 days. Response categories are scored on a 4-point scale from 0 to 3 according to the increased severity of the symptom. A total score of ≥13 indicates the likelihood of depression and suggests the need for follow-up care [24].

BIMF Assessment

The BIMF was developed to measure the maternal functional status of women in the 12 months following childbirth [34]. The BIMF is a self-reported, 20-item questionnaire designed to address seven domains of maternal functioning, namely, (1) self-care, (2) infant care, (3) mother and child interaction, (4) social support, (5) psychological well-being, (6) management, and (7) adjustment [35]. The range of scores are from 0 to 120, with a total score of 120 indicating optimal maternal functioning. The BIMF has been validated in populations with PPD [34].

Data Analysis

Qualitative analyses were conducted using R (version 3.6.3; R Foundation for Statistical Computing). Descriptive statistics are reported using percentages for categorical variables and means (SDs) for continuous variables. To examine the predictive ability of self-report ratings for mood, anxiety, and sleep on outcomes at clinical follow-up visits, linear regression models were created for each participant and each self-report rating. Using self-report data for the 2 weeks before a follow-up visit, linear models were constructed as rating ~ day + visit, where rating is the daily rating, day is the numerical day before the follow-up visit (range 1-14), and visit indicates which visit the self-report data precedes (visit 2 or visit 3). From these models, we predicted the given self-report measure on the given follow-up visit. We measured the predictive ability of these models using root-mean-square error (RMSE). Pearson correlations were performed to measure the strength of the association between predicted self-report values and EPDS scores and actual self-report values on the follow-up visit days. *P* values reported are those from Pearson correlation tests.

Patient and Provider Feedback

Feedback surveys were developed specifically for this study to assess the individual tracking components of the module and the comfort and ease of wearing the Apple Watch. The participants' surveys incorporated free-text questions to assess technical issues, ease, and value of the intervention. The provider survey incorporated free-text questions to evaluate clinical utility and perceived participant value provided to users at home and in a clinical setting. Please see Multimedia Appendix 2 to view the feedback surveys. Feedback responses were evaluated as qualitative data [36]. We utilized a thematic analysis approach [37], and a single coder (HR) tracked developing codes and emerging preliminary themes during analysis and organized these codes into final themes. The selection of codes and original responses were reviewed by a second team member (JS) to establish consensus and increase validity and reliability.

Results

Participants

A total of 26 women were enrolled in the study, but only 23 completed the study. The 3 women who withdrew initially enrolled but did not initiate study procedures before withdrawal, citing lack of time to complete the study as the reason for leaving. Descriptive statistics are presented in Table 1.

Data were tracked across four domains in the study: (1) participant compliance with EMA and study measures (ie, how often did participants complete the required daily activities and how often did participants wear the Apple Watch); (2) assessments measuring depression, anxiety, and maternal functioning (PHQ-9, GAD-7, EPDS, and BIMF) across study enrollment; (3) participant feedback on utility and experience of wearing the Apple Watch and completing tracking measures; and (4) clinician feedback on the utility of tracked data. Of the 23 participants who completed the study, only 21 (91%) completed all data points for each of the 3 visits, whereas 2 (9%) participants did not enter data for all of the assessment measures at visits 2 and 3; those missing data were not included in the results of Table 2.

[b]GAD-7: Generalized Anxiety Disorder-7.

[c]EPDS: Edinburgh Postnatal Depression Scale.

[d]BIMF: Barkin Index of Maternal Functioning.

EMA and Compliance

The mean number of days the participants were enrolled was 52 (SD 12) days. The mean number of days enrolled was greater than the anticipated 6 weeks of enrollment (approximately 42 days), which can be accounted for by patients often being unable to come exactly 3 weeks apart, or piggybacking research appointments on regularly scheduled appointments in clinics, which are often 4 weeks apart. The compliance of measures being reported varied across the self-report and passive measure domains, with steps (activity) having the highest number of days reported (mean 45.2) and the highest percentage of total participation at nearly 90%, as illustrated in Table 3. We did find low compliance for sleep tracking, as participants indicated many technical issues with the Sleep++ app, including it not tracking sleep accurately after following app directions and discomfort wearing the watch overnight.

Depression, Anxiety, and Maternal Functioning Measures and Predictive Value

Assessment measures for depression, anxiety, and maternal functioning were tracked across three research visits using the PHQ-9, GAD-7, EPDS, and BIMF. There was an overall improvement in scores between baseline and end of study assessment scores. However, all but 1 participant was in concurrent treatment for PPD, so these improvements may be accounted for by treatment attendance.

Using the collected prospective data, we attempted to predict outcomes observed at the second and third clinical visits. Data from the 2 weeks before the follow-up visit were used to train a simple regression model to predict various outcomes at follow-up. Self-reported mood on the day of follow-up was negatively associated with EPDS score at follow-up ($r=-0.49$; $P=.02$). We also found that self-reported mood in the 2 weeks before the follow-up visit predicts the self-reported mood rating on the day of follow-up (RMSE=1.21; $r=0.64$; $P<.001$). Furthermore, participants with PPD at follow-up (EPDS>12) had a higher predicted mood rating compared with those without PPD (6.4 vs 6.0; $P=.38$). In addition, self-reported anxiety was positively associated with EPDS score at follow-up ($r=0.56$; $P=.004$). Self-reported anxiety in the 2 weeks before the follow-up visit predicts the self-reported anxiety rating on the day of follow-up (RMSE=1.37; $r=0.75$; $P<.001$). Participants with PPD at follow-up (EPDS>12) had a lower predicted anxiety rating compared with those without PPD (5.2 vs 5.9; $P=.25$). In addition, self-reported sleep quality was negatively associated with EPDS score at follow-up ($r=-0.10$; $P=.66$). Self-reported sleep quality in the 2 weeks before the follow-up visit predicts the self-reported sleep quality rating on the day of follow-up (RMSE=2.2; $r=0.22$; $P=.33$), although not as strongly as predictors for mood and anxiety. Interestingly, participants with PPD at follow-up (EPDS>12) had a higher predicted sleep quality rating compared with those without PPD (5.9 vs 5.2; $P=.35$).

Clinician Feedback

Overview

Three primary themes emerged from clinician feedback regarding the utility of the data collected: (1) increased insight of participants into mental health status, (2) enhancement of patient engagement and discussion of treatment, and (3) improved monitoring of treatment effectiveness.

Increased Insight Into Mental Health Status

The watch's ability to track data including sleep patterns, heart rate, and steps along with daily logs of mood, anxiety, sleep quality, and medication increased the participants' abilities to connect patterns in these factors to their mood and anxiety symptoms. For some women, they had not understood the severity of the symptoms they were experiencing. These data gave participants and providers a tangible picture of symptoms that increased insight into mental health status. For other participants, these data provided insight into how mental health affected other behaviors. There was 1 participant who connected her activity levels with the severity of her symptoms. This participant then made efforts to reach out for more social support to increase feelings of security when leaving home with the baby.

Enhancement of Patient Engagement

The most commonly identified theme among clinician response was that the app data provided a basis for discussion and increased engagement with the participant. In addition to providing a platform for engagement in psychiatric treatment, data from the Apple Watch also prompted participants to reach out to their primary care providers regarding health concerns.

Improved Monitoring of Treatment Effectiveness

The watch data enriched observations around the effects of treatment. For those who were being treated with medication, changes in medication could be monitored using the daily logs.

Participant Feedback

Overview

Participants were amenable to use of this technology with 61% (14/23) endorsing that they would use this technology to inform personal habits, 43% (10/23) endorsing that they would continue to use this technology in medical care, and 57% (13/23) recommending this technology to others. Open-ended feedback was solicited from participants surrounding challenges and benefits to wearing the watch and tracking. These are discussed in the following sections.

Challenges of Use

The primary challenge cited was technical difficulties with the Sleep++ app (9/23, 39% participants). Participants indicated that the app did not always technically perform (would not track sleep when used as directed). These difficulties made some women doubt the accuracy of sleep measures. The second challenge noted was difficulty wearing the watch overnight (8/23, 35% participants). Specifically, the watch lighting up at night was reported as problematic, sound alert notifications at night were disturbing, and there was general discomfort associated with wearing the watch overnight due to bulk and sensitivity with wearing any jewelry or watches while sleeping. Finally, of the 23 women, 2 (9%) reported feeling more stressed and an increase in anxiety from the tracking and extra activities required each day, and 2 (9%) also reported the watchband causing a rash and being generally uncomfortable.

Benefits of Use

The primary benefit of use cited was increased insight into sleep patterns, even despite the technical difficulties with the Sleep++ app (9/23, 39% participants). Primarily, women did not realize how little sleep or how disrupted the sleep they were getting was. These data were then shared with their work, partner, or others to help improve sleep quality or length. There was 1 participant who was able to correlate her daily mood with sleep quality. Second, women reported benefit to seeing their daily or weekly activity, mostly seeing the days they did not get many steps in and a desire to increase activity on those days. Participants also enjoyed the Apple Watch itself, and 3 people subsequently purchased their own.

Discussion

Principal Findings

As a pilot trial, the primary motivation for this study was to determine if EMA has utility in the clinical care of patients with PPD by assessing both provider and patient perspectives. Overall, most study participants and the study clinician endorsed a clinical benefit from using this intervention. We were also able to demonstrate that daily self-reported mood and anxiety scores correlated with EPDS scores at study visits, which is a common and standard screening tool for PPD [3,38,39]. This knowledge could be very useful for predicting when a patient is experiencing an upswing or downswing in symptoms and for prompt early intervention. Participant compliance to both active and passive measures was encouraging, with average compliance rates of 67% for all active daily assessments and 74% of all passive measures. Study participants also identified areas for improvement, specifically about the sleep tracking app Sleep++, which was inconsistent in performance.

A review of the literature did not identify any other studies examining mood tracking using EMA in a population with PPD, although recent studies have examined substance use disorder, posttraumatic stress disorder, racial disparities, and postpartum health in perinatal populations using EMA [17,18]. However, several studies have examined compliance with tracking measures in other psychiatric domains. In a compliance study of computerized ambulatory monitoring in psychiatry, a sample of 45 participants with an anxiety disorder were found to have a 73% compliance rate with assessments over a 1-week period [40]. In a pilot study of mood ratings captured via mobile phones among participants with bipolar disorder, average compliance was 42% over a 12-week period [41], albeit with an SD of 26.6% and a range of 45.8% to 93%. Another mobile health study of EMA and mood symptoms in participants with traumatic brain injury found that the average compliance was 73.4% over an 8-week period [42]. Given these examples, the average compliance for daily mood, anxiety, and sleep quality are encouraging in a population of postpartum women juggling the daily care of an infant (many with multiple children) while experiencing depression.

For the passively collected data measures, we found even higher participation rates, particularly for heart rate and activity (steps), with compliance rates of 76% (SD 27%) and 90% (SD 20%), respectively. Sleep tracking had much lower compliance rates, with an average of 47% (SD 37%) compliance. One would expect the passively collected measures to have the highest compliance, which was true in our study, except for assessment of sleep. Sleep was measured via the free Sleep++ app that was downloaded onto the participants' Apple Watches. The largest number of complaints were about the Sleep++ app, which participants found to be difficult to operate, would not track sleep accurately, or would not initiate sleep tracking despite starting the tracking process. Our feedback questionnaire also asked explicitly about overnight comfort of wearing the watch ("Was it comfortable to wear the Apple Watch while sleeping?") and received feedback from 8 participants that it was not because of the bulk of the watch, alerts or lighting up at night, or general discomfort while wearing jewelry or watches overnight. We believe that this contributed to the reduction in compliance for sleep tracking.

As part of assessing the clinical utility of the data collected, the predictive value of these data were examined. The preliminary data on prediction are interesting and possibly of clinical value. These small-scale associations show that EMA ratings of mood and anxiety in between clinical appointments are correlated with validated scales for mood and anxiety, which could be highly useful in assessing the trajectory of a patient's condition in the periods between clinical contacts. This could be especially useful for postpartum patients who have many barriers to treatment and remission for PPD [1,23]. This type of EMA tracking could be used to signal both patients and clinicians that mood or anxiety is worsening, prompting initiation or changes in the treatment plan. With the decrease in clinical care appointments due to COVID-19, this type of monitoring could be used to determine when appointments are needed and be an additional safety check for postpartum women in between scheduled check-ins. These associations will need further investigation, as significance levels may be driven by the small sample size; however, the trends are encouraging.

Barriers to Adoption and Continued Use

Two of the major issues related to acceptance were the size of the Apple Watch and use of the Sleep++ app. The Apple Watches used for the study were the larger of the Series 2, with a 42-mm face (vs 38 mm). This larger face watch size likely

could have contributed to the discomfort experienced by some participants. In addition, participants reported many technical issues with the Sleep++ app, which was chosen because there was no extra cost to build sleep monitoring functionality into *PPD ACT* and the data were easily integrated using Apple CareKit. At the time the module was developed, integrated sleep tracking was not available with the Apple Watch or Health Kit. Sleep tracking has advanced rapidly since the completion of the pilot study, and integrated sleep tracking is available on many wearable devices, including the Apple Watch. Most sleep trackers now intuitively track the wearer's sleep, as long as the device is worn to bed. The other noted acceptance issue is regarding the process of tracking itself and the possibility that for some, tracking may exacerbate existing anxieties. To mitigate these concerns, clinicians should regularly check in with patients to determine whether their symptoms are directly affected, either positively or negatively, by the use of this tracking modality.

Limitations and Future Directions

Despite promising initial data on the feasibility of using EMA to enhance clinical insight among women experiencing PPD, there are limitations to this pilot study. First, all but 1 participant who enrolled were already in treatment for PPD, so no insight can be gained as to the efficacy of this technology in helping initiate PPD treatment. Furthermore, as the study clinician was not the participants' usual care provider, the study clinician was not able to draw conclusions about the impact of EMA across the course of treatment. Although the use of EMA proved feasible over the course of the 6-week study, we do not know the long-term effect or acceptability of this technology beyond the study period. A larger study of this technology, incorporating the lessons learned from this pilot study, would provide additional information about the long-term use of tracking among women in treatment for PPD and the predictive value of daily mood and anxiety assessments. This information may benefit women in areas of the country where dedicated perinatal psychiatry programs do not exist and assist in determining appropriate treatment modalities and intervals of treatment.

Despite these limitations, valuable information was gained from this pilot study, including a clear demonstration of the acceptability, feasibility, and clinical utility of EMA tracking among women experiencing PPD. These lessons are even more valuable in the context of the pandemic.

Conclusions

EMA has not been studied to date as a method for the enhancement of clinical care in postpartum women. This study found EMA tracking to be acceptable among participants and was endorsed as clinically useful by the study psychiatrist. Given the barriers to care faced by many women with PPD, this largely home-based technology could help both women and their providers better understand the trajectory of their symptoms and identify areas where improvements could be made in the management of their mental health needs. This need is all the greater with the crisis COVID-19 has caused in perinatal mental health.

Abstract

Background: Home-measured blood pressure (HMBP) in combination with comprehensive medication support and lifestyle change are the mainstays of evidence-based hypertension (HTN) management. To date, the precise components needed for effective HTN self-management programs have yet to be defined, and access to multicomponent targeted support for HTN management that include telemonitoring remain inaccessible and costly.

Objective: The aim of this pilot study was to evaluate the impact of a digital HTN self-management program on blood pressure (BP) control among adults with excess body weight.

Methods: A single-arm, nonrandomized trial was performed to evaluate a digital HTN self-management program that combines comprehensive lifestyle counseling with HTN education, guided HMBP, support for taking medications, and led by either a registered nurse or certified diabetes care and education specialist. A sample of 151 participants were recruited using a web-based research platform (Achievement Studies, Evidation Health Inc). The primary outcome was change in systolic BP from baseline to 3 months, and secondary outcomes included change in diastolic BP and medication adherence.

Results: Participants' mean age was 44.0 (SD 9.3) years and mean BP was 139/85 mm Hg. At follow-up, systolic and diastolic BP decreased by 7 mm Hg ($P<.001$, 95% CI –9.3 to –4.7) and 4.7 mm Hg ($P<.001$, 95% CI –6.3 to –3.2), respectively. Participants who started with baseline BP at goal remained at goal. For participants with stage 1 HTN, systolic and diastolic BP decreased by 3.6 mm Hg ($P=.09$, 95% CI –7.8 to 0.6) and 2.5 mm Hg ($P=.03$, 95% CI –4.9 to –0.3). Systolic and diastolic BP decreased by 10.3 mm Hg ($P<.001$, 95% CI –13.4 to –7.1) and 6.5 mm Hg ($P<.001$, 95% CI –8.6 to –4.4), respectively, for participants with stage 2 HTN. Medication adherence significantly improved ($P=.02$).

Conclusions: This pilot study provides initial evidence that a digital HTN self-management program improves BP and medication adherence.

Introduction

Background

Hypertension (HTN) impacts an estimated 116.4 million or 46% of adults in the United States [1]. Annual health care costs associated with HTN are approximately US $131 billion or 3% of the US $3 trillion national health care expenditure [2]. The proportion of adults with controlled blood pressure (BP), has declined in recent years, with <44% of adults achieving this goal [3]. Poor BP control continues to be a persistent public

health challenge because of the high prevalence of obesity, insufficient access to lifestyle counseling, difficulty adopting lifestyle change, medication adherence, therapeutic inertia owing to clinical uncertainty about BP data accuracy, and lack of provider access to adjust medications when needed [4-7].

Home-measured blood pressure (HMBP), when combined with more intensive human-led interventions, such as lifestyle counseling or medication titration, has shown promise in improving BP control [8]. In particular, HMBP data may be superior to in-office measurement to inform treatment decisions. The most effective interventions seem to be those that combine HMBP with medication counseling to address medication-taking beliefs and barriers and facilitate rapid medication titration [9,10]. These programs are typically staffed by pharmacists and embedded within clinics, making them difficult to scale efficiently. Clinics struggle with maximizing pharmacist time and dispensing or triaging devices.

Mobile health (mHealth) interventions can facilitate scalable, accessible, and effective management of HTN. HMBP is a core component with additional features such as automated medication reminders [11] or artificial intelligence (AI) software to provide real-time feedback on monitored BP values [12]. The bulk of innovation in this area has focused on fully automated solutions, but these interventions have had marginal clinical efficacy and have not been shown to be more clinically effective than HMBP alone. Few programs combine HMBP with access to what is known to work—human-led support that interprets BP data, supports lifestyle change, and titrates medication.

Self-management is a daily process where individuals actively engage in the management of a chronic illness, and structured programs such as Diabetes Self-Management Education and Support have demonstrated broad clinical efficacy [13]. Similarly, for HTN, supported self-management interventions, which are complex and employ a broad range of support strategies, have been found to improve BP control [14]. While robust evidence is still lacking, early evidence suggests that mHealth interventions with more comprehensive features are likely to be more effective [15,16]. The self-management approach places focus on the individual to play a critical role in their care in collaboration with health care providers [17].

Objective

The goal of this pilot study was to evaluate the impact on BP control of a registered nurse (RN) or certified diabetes care and education specialist (CDCES)-led mHealth HTN self-management program that combines comprehensive lifestyle counseling (for dietary changes, weight loss, physical activity, and stress management) with HTN education, guided HMBP, support for taking medications, and social support, among individuals with uncontrolled HTN.

Methods

Participants

Members of a web-based health community (Achievement, Evidation Health Inc) were invited to participate in this study. Achievement is a web- and mobile-based community in the United States where members can connect their activity trackers

and fitness and health apps to the platform and, by logging activities, accumulate points that are redeemable for monetary rewards. Additionally, members self-report on various health conditions and are invited to participate in remote research opportunities as relevant studies come available. In this study, recruitment was targeted to members who had self-reported an HTN diagnosis. Invited members were linked to a web-based research study platform (Achievement Studies, Evidation Health Inc) where study eligibility was assessed using automated screener questions. Eligibility criteria for the pilot study included the following: being a US resident, being at least 18 years of age, self-reported HTN diagnosis, self-reported recent systolic BP (SBP) measurement of ≥130 mm Hg or diastolic BP (DBP) of ≥80 mm Hg within 1 month prior to screening, a BMI of ≥25 kg/m^2 (≥23 kg/m^2 if they self-identified as Asian), and access to a computer or smartphone to participate in the virtual HTN program.

Procedures

If eligible after completing the web-based screener, potential participants were asked to sign an electronic informed consent form and complete a web-based baseline survey, consisting of questions about their demographics, health and HTN history, HTN medication usage, and patient-reported outcomes (as described in *Measurements*). After completion of the baseline survey, potential participants were instructed to set up a HTN program account. After completion of both the baseline survey and program account setup, participants were considered to have been enrolled in the study. In the first week of the program, participants were instructed to take BP readings and were asked to take multiple readings throughout the week. The average across all readings in the first 30 days was used as the baseline measurement for the pilot study.

Throughout the study period, participants were encouraged to engage with the supported mHealth HTN self-management program at the time and frequency of their choosing. After 3 months of study enrollment, participants were asked to complete a final web-based survey and submit BP measurements throughout the last week of the program. Study participation was completely remotely, and participants received a small electronic gift card compensation for completion of all data collection.

Ethical Considerations

This study was exempted from ethics approval by the Western International Review Board (WIRB Work Order #1-1249356-1). All participants in this study provided informed consent.

Measurements

All study measures were collected at baseline and at 3 months. BP was collected using a cellular-connected BP monitor (BodyTrace Inc) that was provided to every participant as a core component of the program. Participants were provided with instructions on how to take accurate resting BP readings [18]. Participants were asked to submit a BP measurement at baseline and at 3 months. Baseline BP was defined as the average of at least 3 BP readings taken across 2 days in a 30-day measurement window closest to the baseline time point. Similarly, final BP was defined as the average of at least 3 BP readings taken across

2 days in a 30-day measurement window closest to the 3-month time point. Throughout the study, participants were encouraged to submit additional BP measurements in accordance with the schedule recommended by their health care professional. Program participants were also provided with a cellular-connected weight scale (BodyTrace Inc) and were asked to weigh in daily throughout the program. The median weight collected during weeks 1 and 12 of the program was used as weight outcomes for the pilot study.

The following patient-reported outcomes were assessed through a web-based survey administered at baseline and during week 12 of the program: the Consumer Health Activation Index (CHAI), a 10-item scale measuring health-related activation and engagement [19], with scores between 0 and 79 reflect low activation, scores between 80 and 94 reflecting moderate activation, and 95 and 100 reflecting high activation [19]; the Self-Efficacy for Managing Chronic Disease scale, 6 items on a scale of 1 (not at all confident) to 10 (totally confident) measuring one's confidence in doing certain activities that are common across many chronic conditions, with higher scores indicating higher self-efficacy [20]; HTN medication usage (ie, a self-report of medications, dosage, and timing of administration); and the Simplified Medication Adherence Questionnaire (SMAQ), a 6-item scale that categorizes respondents as adherent or nonadherent on the basis of recent patterns of medication-taking behaviors [21].

Intervention

The Omada for Hypertension Program is a supported digital HTN self-management program that is commercially available through business-to-business relationships with organizations that pay to make the service available to their members (typically employees or health plan members). The program can be accessed through mobile devices (ie, smartphones or tablet devices) or PCs. The program offers a HTN education curriculum along with comprehensive lifestyle self-management support, including support for weight loss, dietary changes (aligning with the Dietary Approaches to Stop Hypertension and Mediterranean Diets), increased physical activity, support for medication adherence, social support, and a cellularly connected BP monitor and body weight scale. Participants are assigned to a HTN specialist coach (either a RN or CDCES), who supports their progress longitudinally through the program, addressing specific questions, providing feedback on HMBP data, supporting medication-taking, and helping prepare participants for primary care physician and specialist visits. Data from the BP monitor and weight scale are provided back to the participant in their program account; the data are also used by the HTN specialist coach to provide counseling on dietary changes, changes in physical activity, and to encourage communication with their health care providers when timely medication adjustments may be needed. Participants are also placed in a virtual peer group and can communicate with other program users through a secure group discussion board.

Statistical Analysis

The study was powered to detect a clinically meaningful 4 mm Hg reduction in the primary outcome of resting SBP. With an estimated SD of 12 mm Hg and power set to 90%, the minimum sample size needed was 113. To allow for a potential 10% loss to follow-up of study participants at 3 months, and an estimate of 30% of participants' resting SBP being <130 mm Hg at baseline, a total of 150 participants were planned for study enrollment.

Descriptive statistics (eg, means and frequencies) were performed to describe the demographic and baseline clinical characteristics of the enrolled study population. Correlations (Pearson correlation for continuous variables and Spearman correlation for categorical variables) were run to detect potential baseline confounders (age, gender, and BMI) of resting SBP and DBP; no significant correlations were found. Two-tailed paired t tests were used to assess significant changes in BP measurements, weight, and patient-reported outcomes from baseline to follow-up. The definitions of stage 1 and stage 2 HTN differ in accordance with BP measurement methodology, with the HMBP threshold for stage 2 HTN (135/85 mm Hg) being lower than the office-based threshold (140/90 mm Hg) [22]. While the HMBP threshold is the most pertinent for this study given the BP measurement methodology, the majority of trials have traditionally used office-based thresholds. Hence, for BP post hoc analyses, participants were stratified by HTN stage using both home-based and in-office cutoffs for stage 1 and stage 2 HTN, and paired t tests were performed within these groups to examine changes in BP on the basis of the baseline BP stage.

The McNemar nonparametric test was used to examine the change in the proportion of the study population that was adherent to their medication regimen from baseline to follow-up and 2-tailed paired t tests were used to assess change in the number of HTN medications used by participants.

Outcomes were analyzed using both intention-to-treat analysis (with baseline carry forward of missing data) and complete case analysis (among those with complete baseline and follow-up data). The outcomes were similar in magnitude and statistical significance using both analytic methods, and thus we present the results on the sample of study participants with complete data from both timepoints.

Results

Study Recruitment

The final enrolled sample comprised 153 participants. Three participants were withdrawn from the study: one developed a medical condition that precluded participation and 2 requested to voluntarily withdraw from the study. At follow-up, 80% (n=121) of participants had a complete follow-up BP measurement, and 81% completed the web-based questionnaire; 29 (19%) participants were lost to follow-up. Figure 1 outlines the flow of participants through each stage of the study. The analyzed sample (n=121) and those lost to follow-up (n=30) were compared for differences in baseline characteristics, which might impact the BP outcomes. There were no significant differences in baseline SBP, weight, medication adherence, gender, age, or race and ethnicity. However, baseline DBP was slightly higher in the group lost to follow-up than in those who stayed in the study (88 vs 84 mm Hg).

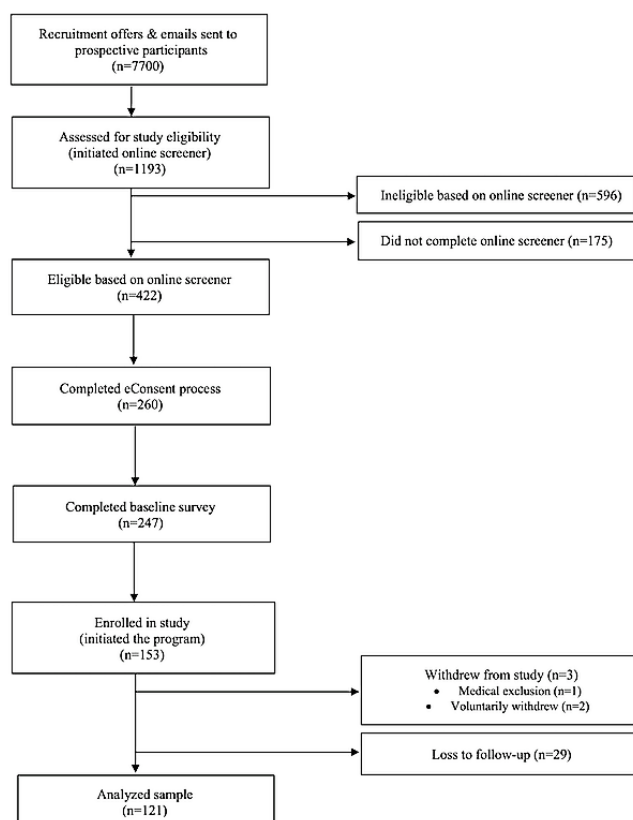
Figure 1. Flow diagram of study participants through each stage of the study.


Participant Characteristics at Baseline

Table 1 shows the baseline characteristics of the study participants, including missing data for participants who did not complete various metrics at baseline. The sample was 56% female, 72% White, and 11% of participants self-identifying as African American. The baseline mean SBP for the sample was 139 mm Hg and mean DBP 85 was mm Hg. In total, 76% of participants reported taking medication for HTN medication at the start of the program and 27% self-reported being adherent to their medication regimen (SMAQ).

The average weight of the sample at program start was 224 lbs. The mean CHAI health activation score at baseline was 71.9 (SD 14.2). The mean self-efficacy score at baseline was 44.3 (SD 11.7) out of a possible 60.

Table 1. Baseline participant characteristics (N=151).

Baseline characteristics[a]	Values
Age (years), mean (SD)	44.0 (9.3)
Females, n (%)	85 (56.3)
White participants, n (%)	109 (72.2)
Black or African American participants, n (%)	17 (11.3)
Systolic blood pressure (mm Hg; n=148), mean (SD)	138.5 (13.1)
Diastolic blood pressure (mm Hg; n=148), mean (SD)	84.6 (8.9)
Weight (lbs; n=149), mean (SD)	223.7 (52.0)
Patient activation (n=144), mean (SD)	71.9 (14.2)
Self-efficacy (n=144), mean (SD)	44.3 (11.7)
Taking hypertension medication, n (%)	114 (75.5)
Adherent to current medications, n (%)	41 (27.2)

[a]The table includes missing data from participants who did not complete baseline data collection.

Program Engagement

Participants used their BP cuff an average of 7.2 times per week across the 12 weeks of the program. Participants weighed in an average of 4.7 times per week, interacted with their coaches an average of 1.2 times per week, completed an average of 0.75 lessons per week, interacted with their peer groups an average of 0.6 times per week, tracked their physical activity 5.4 times per week, and tracked meals an average of 9.0 times per week.

BP Outcomes

In Table 2, the baseline and follow-up changes in mean BP are listed for the analyzed sample (n=121). Baseline SBP significantly decreased by an average of 7 mm Hg (t_{120}=–6.0; P<.001; 95% CI –9.3 to –4.7). DBP significantly declined by 4.7 mm Hg (t_{120}=–6.1; P<.001; 95% CI –6.3 to –3.2). Weight also decreased by an average of –2.4 lbs (t_{119}=–3.5; P<.001; 95% CI –3.7 to –1.0), with 14% of the sample losing 5% of their initial body weight. Table 3 presents changes in BP by baseline BP clinical category based on home-based versus

in-office thresholds for stage 2 HTN [22]. All study participants who started with BP at goal remained at goal (26/121, 21.5%). For participants with stage 1 HTN at baseline (SBP 130-134 mm Hg, DBP 80-84 mm Hg), there was a trend toward significant reduction in SBP by 3.6 mm Hg (t_{18}=–1.8; P=.09; 95% CI –7.8 to 0.6), and DBP significantly decreased by 2.6 mm Hg (t_{18}=–2.4; P=.03; 95% CI –4.9 to –0.3). BP reduction was greater for those with stage 2 HTN at baseline (SBP≥135 mm Hg or DBP≥85 mm Hg), with a 10.3 mm Hg reduction in SBP (t_{75}=–6.5; P<.001; 95% CI –13.4 to –7.1) and a 6.5 mm Hg reduction in DBP (t_{75}=–6.1; P<.001; 95% CI –8.6 to –4.4). Using in-office range thresholds, those with stage 1 HTN (SBP 130-139 mm Hg, DBP 80-89 mm Hg) had a significantly decreased DBP by 2.9 mm Hg (t_{38}=–3.1; P<.004; 95% CI –4.8 to –0.98). For stage 2 HTN defined using office ranges (SBP≥140 mm Hg or DBP≥90 mm Hg), SBP reduction was 13.4 mm Hg (t_{55}=–7.3; P<.001; 95% CI –17.1 to –9.7) and a 7.7 mm Hg reduction in DBP (t_{55}=–5.8; P<.001; 95% CI –10.4 to –5.1).

Table 2. Baseline to follow-up changes in outcomes in participants with complete data.

Parameters	Participants, n	Baseline value	Follow-up value	Difference	t test (df)	95% CI	P value
Systolic blood pressure (mm Hg)	121	137.7	130.7	–7.0	–6.0 (120)	–9.3 to –4.7	<.001
Diastolic blood pressure (mm Hg)	121	83.9	79.1	–4.7	–6.1 (120)	–6.3 to –3.2	<.001
Weight (lbs)	120	221.8	219.4	–2.4	–3.5 (119)	–3.7 to –1.0	.001
Patient activation	115	70.9	74.0	3.1	2.4 (114)	0.6 to 5.6	.02
Self-efficacy	115	43.9	44.4	0.4	0.5 (114)	–1.5 to 2.3	.65

Table 3. Baseline to follow-up changes in blood pressure by the baseline blood pressure category from among participants with complete data.

Parameters	Participants, n	Baseline value, mm Hg	Follow-up value, mm Hg	Difference, mm Hg	t test (df)	95% CI	P value
Home range							
Systolic blood pressure							
Blood pressure at goal	26	122.0	122.0	0.0	0.0 (25)	–3.4 to 3.4	1.00
Stage 1 hypertension	19	130.0	126.0	–3.6	–1.8 (18)	–7.8 to 0.6	.09
Stage 2 hypertension	76	145.0	135.0	–10.3	–6.5 (75)	–13.4 to –7.1	<.001
Diastolic blood pressure							
Blood pressure at goal	26	74.0	73.0	–1.1	–0.9 (25)	–3.7 to 1.5	.40
Stage 1 hypertension	19	79.0	76.4	–2.6	–2.4 (18)	–4.9 to –0.3	.03
Stage 2 hypertension	76	88.4	81.9	–6.5	–6.1 (75)	–8.6 to –4.4	<.001
Office range							
Systolic blood pressure							
Blood pressure at goal	26	122.0	122.0	0.0	0.0 (25)	–3.4 to 3.4	1.00
Stage 1 hypertension	39	133.0	130.0	–2.5	–1.7 (38)	–5.4 to 0.5	.10
Stage 2 hypertension	56	148.0	135.0	–13.4	–7.3 (55)	–17.1 to –9.7	<.001
Diastolic blood pressure							
Blood pressure at goal	26	74.0	73.0	–1.1	–0.9 (25)	–3.7 to 1.5	.40
Stage 1 hypertension	39	81.4	78.5	–2.9	–3.1 (38)	–4.8 to –0.98	.004
Stage 2 hypertension	56	90.1	82.4	–7.7	–5.8 (55)	–10.4 to –5.1	<.001

Medication Outcomes

Table 4 presents changes in medication status and medication adherence from baseline to follow-up. Medication adherence, as measured by the SMAQ, improved for the total sample by 14.4% from 36.7% to 51.1% (McNemar $\chi^2_{1,90}$=5.8, P=.02).

When we conducted post hoc analyses by HTN stage, there were no significant changes in the number of medications among those who began the program at goal or with stage 1 HTN. However, the number of HTN medications increased from 1.0 to 1.2 (t_{76}=2.2; P=.03; 95% CI 0.01-0.30) among those with baseline stage 2 HTN based on the home-based thresholds.

Table 4. Baseline to follow-up changes in medication status.

Parameters	Participants, n	Baseline value	Follow-up value	Difference	t test (df)	McNemar χ^2 (df)	95% CI	P value
Total sample								
Average number of hypertension medications	117	1.1	1.2	0.1	1.1 (116)	N/A[a]	–0.05 to 0.17	.28
Adherent to medications (Simplified Medication Adherence Questionnaire), %	90[b]	36.7	51.1	14.4	N/A	5.8 (90)	N/A	.02
Stage 2 subsample								
Average number of hypertension medications	77	1.0	1.2	0.2	2.2 (76)	N/A	0.01 to 0.30	.03
Adherent to medications (Simplified Medication Adherence Questionnaire), %	54[b]	35.2	46.3	11.1	N/A	2.0 (54)	N/A	.16

[a]N/A: not applicable.

[b]Among participants taking ≥1 hypertension medications at baseline.

Patient-Reported Outcomes

Patient activation on the CHAI significantly increased by an average of 3.1 points (t_{114}=2.4; P=.02; 95% CI 0.6-5.6) but self-efficacy did not improve significantly (P=.65).

Discussion

Principal Findings

The results of this pilot study provide initial evidence that a comprehensive, human-led digital HTN self-management program that includes lifestyle support, medication adherence, and guided HMBP is associated with improved BP control, weight, and medication adherence in a sample of individuals with uncontrolled HTN. Furthermore, those who started the program with stage 2 HTN achieved the greatest improvement in BP control with an average change of 10.3 mm Hg and 6.5 mm Hg in SBP and DBP, respectively. Those who started the program with their BP at goal remained at goal at the end of the study. This pilot study was successful in detecting significant weight loss and improvement in medication adherence. Program engagement was strong, as shown by the high frequency of use across the various features of the digital platform.

The findings from this pilot study are consistent with those of prior studies on digital HTN programs that showed improvements in BP control, weight, and medication adherence [11,16,23,24]. While most participants saw significant improvements in their BP, those with stage 2 HTN at baseline saw the greatest improvement, with a magnitude of decrease similar to those seen with interventions that are led by pharmacists or nurse practitioners [9]. Additionally, the

magnitude of BP reduction observed in this program is comparable to that of previous studies [25,26].

There were no significant changes seen in self-efficacy; this may be in part owing to participants reporting relatively high self-efficacy at baseline. There were significant improvements in patient activation, which is arguably more comprehensive and encompassing than self-efficacy for managing HTN [27].

Limitations

The single-arm, nonrandomized design of this pilot study harbors the challenge of unknown causal inference; thus, future studies with a comparison or control group are needed to confirm the results. Second, all measurements were collected at home using cellularly connected devices. While there is a risk of small intradevice measurement variability, participants did use the same device for their measurements across the study, so any measurement error is likely to be systematic within individuals. Third, participants self-selected from the web-based health community into the research opportunity; therefore, it is possible that the study population recruited for the pilot study is not fully representative or generalizable of the population of individuals living with HTN in the United States. The pilot study was conducted from February to July 2020 during the first wave of COVID-19 exposure. This may have influenced participants' ability to fully engage in the program in the midst of unprecedented stressors and disruptions in health care. However, the observation of significant clinical benefits during this time is an encouraging and suggests that the results might have been stronger if the study were conducted under nonpandemic conditions.

XSL•FO
RenderX

Finally, the pilot study length was brief (3 months); while this is sufficient time to detect meaningful BP changes, it is a short time frame in which to produce clinically meaningful weight loss, which may explain the modest weight loss achieved by study participants. Finally, the size of the study sample limited the ability to conduct meaningful subgroup analyses and limited the statistical power for analyses of secondary and tertiary outcomes.

Conclusions

The COVID-19 pandemic has created unexpected opportunities for digital health, with more routine care, including care for chronic conditions, transitioning to remote delivery, greater demand emerging for remotely delivered solutions, and reconsideration of regulations that previously slowed growth and scalability [28]. HTN self-management is an obvious fit for digital health solutions, and the results of this pilot study add to the growing body of evidence that human-supported digital self-management programs can improve outcomes for those with chronic conditions [29]. With proper design, the essential features of supported HTN self-management, including comprehensive counseling for lifestyle changes, HMBP with actionable feedback, and medication taking support, can be effectively translated to a digital format and result in strong program engagement, improved activation, and desirable clinical outcomes for people with HTN. Future research on this program will focus on the sustainability of the clinical outcomes, the robustness of the clinical benefit under increasingly rigorous testing conditions, and research among more diverse populations to promote health equity from new digital health solutions.

Abstract

Background: The COVID-19 pandemic has transformed how people seeking to reduce opioid use access treatment services and navigate efforts to abstain from using opioids. Social distancing policies have drastically reduced access to many forms of social support, but they may have also upended some perceived barriers to reducing or abstaining from opioid use.

Objective: This qualitative study aims to identify informal coping strategies for reducing and abstaining from opioid use among Reddit users who have posted in opioid-related subreddits at the beginning of the COVID-19 pandemic.

Methods: We extracted data from 2 major opioid-related subreddits. Thematic data analysis was used to evaluate subreddit posts dated from March 5 to May 13, 2020, that referenced COVID-19 and opioid use, resulting in a final sample of 300 posts that were coded and analyzed.

Results: Of the 300 subreddit posts, 100 (33.3%) discussed at least 1 type of informal coping strategy. Those strategies included psychological and behavioral coping skills, adoption of healthy habits, and use of substances to manage withdrawal symptoms. In addition, 12 (4%) subreddit posts explicitly mentioned using social distancing as an opportunity for cessation of or reduction in opioid use.

Conclusions: Reddit discussion forums have provided a community for people to share strategies for reducing opioid use and support others during the COVID-19 pandemic. Future research needs to assess the impact of COVID-19 on opioid use behaviors, especially during periods of limited treatment access and isolation, as these can inform future efforts in curbing the opioid epidemic and other substance-related harms.

Introduction

In 2020, with the arrival and devastation of the COVID-19 pandemic, many of the efforts in fighting the preexisting opioid epidemic in the United States were interrupted and the number of opioid-related deaths have since accelerated. Reports from national, state, and local agencies have shown an alarming increase in opioid-and other drug-related mortality—especially from illicitly manufactured fentanyl [1]. In 2021, overdose deaths soared to a record estimate of 93,331, including 69,710 (74.69%) involving opioids [2]. The overall estimate of overdose

deaths in 2020 far eclipsed the 72,000 deaths recorded the previous year, amounting to a 29.4% increase.

COVID-19 has affected nearly every facet of society, and it has seriously burdened people who use opioids (PWUO) and people who use drugs (PWUD) in general. Health experts are concerned how the public health measures responding to the pandemic—particularly quarantine and social distancing rules—may have exacerbated active drug use and drastically changed remission statuses on the population level [3,4]. PWUD are at an increased risk of COVID-19 transmission and infection and are more likely to be hospitalized for severe symptoms [5,6]. Given the severity of this ongoing public health crisis and the likelihood that further pandemics will take place in coming decades [7-13], it is imperative to understand how PWUO have dealt with the physical and psychological changes brought on by the COVID-19 pandemic, particularly in response to stay-at-home orders that limit in-person interactions.

Only a small percentage of PWUO seek formal treatment options, with less than 25% of PWUO estimated to use treatments with evidence-based medications for opioid use disorder (MOUD) [14]. Others may turn to strategies such as social media for health-related information and community support [15]. Online social media platforms enable PWUD to freely share their experiences, give advice, and comment on others' experiences. Studies have shown that for PWUD, online peer support groups provide an open forum for discussion, while minimizing perceived barriers and stigma [16]. In the context of the COVID-19 pandemic, it may serve as a vital source of personal narratives of opioid use and a means to cope with opioid use without formal assistance (ie, informal coping) or seek formal assistance through treatment (ie, formal coping).

Many barriers exist that may prevent PWUO from seeking formal treatment. Social networks, for example, are powerful influences among PWUD that can encourage continued use or serve as a catalyst for return to use [17,18]. Stigma from both health care workers [19] and family members and friends [20,21] may discourage PWUD from disclosing their substance use disorder and receiving treatment. Access to evidence-based MOUD treatments, such as buprenorphine and methadone, are limited by regulations that require in-person examinations, and physician waivers for buprenorphine prescriptions [22] and take-home allowance limits for methadone result in daily in-person visits to clinics [23]. Finally, PWUO may want to discontinue use, but fear the resulting withdrawal symptoms, which can be painful and distressing [24]. The potential length of withdrawal may inhibit PWUO from cessation if they cannot risk losing work or have other obligations that they must fulfill [24].

Although the COVID-19 pandemic has exposed PWUO to new risks (eg, possible triggers due to loneliness, boredom, and isolation, as well as forcing people into withdrawal due to lack of access), behaviors that prevent the spread of COVID-19 may help mitigate barriers to cessation or entry to treatment. The change in environment spurred by social distancing measures may make it easier for some PWUO to avoid influences in their social circle that might encourage them to continue using drugs. Avoiding these influences might ease unwanted pressures while

they make decisions regarding cessation or treatment [17,18]. Still, a large portion of PWUO do not seek formal treatment, making it critical for the clinical and public health field to understand how people outside of the clinical setting cope with opioid use, especially now within the context of the COVID-19 pandemic.

Using data collected from Reddit, this exploratory and descriptive study aims to characterize the types of informal coping strategies people used to reduce or abstain from opioid use during the first wave of the COVID-19 pandemic in 2020.

Methods

Study Design

This study is part of a larger project that sought to understand the experiences of PWUO during the first wave of the COVID-19 pandemic [25,26]. We extracted publicly available content from Reddit, an anonymous and community-based online platform dedicated to public discussions. Anonymous registered members—also called *Redditors*—submit content to the site, including text, images, or links, which are then filtered by popularity as they are voted up or down by other members. Reddit posts are organized by subject and grouped into user-generated forums called *subreddits*. Posts with more up-votes appear toward the top of their subreddit.

Reddit has over 430 million monthly active users, and in 2020, it was ranked the seventh-most popular social media app in the United States [27]. Because of its anonymity, Reddit provides a virtual space to exchange information about stigmatized topics, such as drug use and mental health [28,29]. This, in turn, provides researchers with a unique opportunity to gain, in real time, insights into behaviors and perceptions that can inform health and drug policy. The anonymity of Reddit, however, hinders our ability to retrieve demographic information of Redditors' whose posts we have included in our analysis. However, in many of our sampled subreddit threads, Redditors disclosed their personal history of opioid use and whether, at the moment of posting, they were abstaining from use. So, despite the lack of demographic information on Redditors, the analyses presented in this exploratory study can still inform efforts to advance health and drug policy—albeit to a certain extent—during the COVID-19 pandemic.

As researchers of drug use and social media, we were interested in characterizing the informal ways in which PWUO navigated the disruptions caused by the first wave of COVID-19 in 2020. Though none of the authors subscribe to the subreddits analyzed in this study, 3 of us have used Reddit in the past and are familiar with the platform and communities it coalesces. At each stage of the study, we discussed our methods, findings, and interpretations with individuals who have lived experiences with the subject matter. The New York University School of Medicine Institutional Review Board exempted our study from review. To protect the anonymity of Redditors, quotes were altered slightly to reduce the risk of immediate identification [30,31].

Collecting Reddit Data

In this study, we analyzed posts from the 3 most popular subreddits about opioids: *r/Opiates* and *r/OpiatesRecovery*. We determined their popularity by the number of Redditors subscribed to each subreddit. At the start of data collection, in March 2020, *r/OpiatesRecovery* had more than 20,000 subscribers; *r/Opiates* had over 90,000.

To pull content from each subreddit, we used Python 3.7.4 run on Jupyter Notebook 6.0 using packages *PRAW, pandas*, and *datetime*. On May 13, 2020, we extracted the 1000 most recent posts—including their subsequent comments—from each subreddit. This amounted to a total of 2000 unique subreddit posts with comments, all of which Redditors posted from March 5 to May 13, 2020. After pulling the posts, we stored them in an online, password-protected database.

Reddit and Qualitative Coding Training

We first trained 9 research assistants on how to conduct qualitative coding using Atlas.ti software (ATLAS.ti Scientific Software Development GmbH). Those 9 coders then underwent 4 one-hour training sessions—developed by our team—on medical terms and slang related to opioid use and Reddit culture.

Thematic Analysis

The 9 trained coders then reviewed all 2000 subreddit posts to determine whether they were relevant to COVID-19. To determine relevance, we used the following list of key terms: *coronavirus*, *COVID-19*, *quarantine*, *social distancing*, *shutdown*, *pandemic*, and other related terms referring to the pandemic. To initially identify COVID-related content, coders reviewed only the original subreddit posts and not their subsequent comments. We wanted to avoid situations in which coders reviewed threads of 50 or more comments, only to discover that 1 comment related to COVID-19. Coders identified 300 (15%) original subreddit posts related to COVID-19; we discarded the remaining 1700 (85%) posts because none of them explicitly included our keywords or hinted at any aspect of the pandemic and its effects.

Using a hybrid inductive-deductive approach through Atlas.ti, the 9 research assistants then coded the 300 COVID-19-relevant subreddit posts and comments using a codebook we created prior to data collection [25,26]. The codebook spanned study themes of interest related to the intersection of opioid use, treatment, and COVID-19. Research assistants coded an initial 30 (10%) of the 300 posts. Afterward, we met with them to assess coding discrepancies and add any new or common topics identified from the subreddit posts to our codebook. We used the methodological approach described by McDonald et al [32]. They specify that for research focused on discovering new concepts, codebook development meetings do not aim to achieve a certain threshold of agreement or interrater reliability. Instead, the goal of the codebook development discussions is to generate concepts and themes that enable discovery of novel content for an exploratory study. During the training process, we asked coders to identify any terms that were unfamiliar to them. Then, during group meetings, we defined these terms—which were often slang terms. The final codebook had 44 codes (see Table S1 in Multimedia Appendix 1), and research assistants coded the remaining sample of COVID-19-related posts.

Using solely an inductive approach, the first author analyzed the 300 COVID-19-related posts previously coded by research assistants to identify and characterize Redditors' informal coping strategies during the early weeks of the COVID-19 pandemic in 2020. Based on previous addiction and recovery literature [33], *informal coping strategies* were defined as those that did not involve professionally assisted support services, such as outpatient/inpatient treatment, antirelapse/anticraving medications (eg, naltrexone or buprenorphine/naloxone), mutual help groups (eg, Alcoholics Anonymous [AA], Narcotics Anonymous [NA], Self-Management and Recovery Training [SMART]), and other community-based support where trained staff typically provide services [33]. Of the 44 codes, 16 (36%) were used to filter out posts relevant to informal coping strategies (see Table S2 in Multimedia Appendix 1). The first author discarded subreddit posts that were specific to other research questions (eg, formal treatment services, such as medication-assisted treatment) or if the content did not include or was entirely unrelated to informal coping strategies to maintain remission or begin/continue cessation from opioid use.

After meeting with coauthors and agreeing on the major themes characterizing the informal coping strategies described in posts, the first author scanned nonexamined Reddit content to identify those same strategies and skills. Using the search function feature, he searched through previously unexamined posts for the exact terms or phrases listed in Table 1. After examining the content's relevance to our research aims, the first author either added it to our preexisting sample of content or discarded it. This process resulted in an increase of 12 subreddit posts, making the total sample amount to 100 posts.

Table 1. Frequency of informal coping strategies described by Redditors during the first wave of the COVID-19 pandemic in 2020 (N=100).

Themes	Posts, n (%)
Psychological/behavioral coping skills (eg, psychological and emotional challenges, triggers)	
Mindfulness (eg, reframing personal problems, identifying discontentment)	20 (20)
Meditation	5 (5)
Prayer	2 (2)
Gaming (eg, video games, board games, internet-based games)	12 (12)
Reading books	4 (4)
Listening or making music	4 (4)
Household chores	1 (1)
Watching movies, television, or videos on social media	6 (6)
Calling friends and family	6 (6)
Posting in subreddit or other online forums (eg, encouraging others to post online, disclosing struggle)	5 (5)
Taking up hobbies or learning new skills	9 (9)
Total	74 (74)
Adopting healthy habits	
Exercise	26 (26)
Drinking water	2 (2)
Eating healthy	6 (6)
Sleep hygiene	4 (4)
Total	38 (38)
Using other substances to manage withdrawal symptoms	
Marijuana	9 (9)
Transcutaneous electrical nerve stimulation (TENS) device (ie, device used to stimulate stiff muscles)	1 (1)
Liposomal vitamin C	1 (1)
Kratom	6 (6)
NyQuil	1 (1)
Total	18 (18)

Results

Informal Coping Strategies

Of the 300 subreddit posts included in our sample, 100 (33.3) posts mentioned at least 1 type of informal coping strategy. Table 1 shows the frequency of Redditors' posts that described at least 1 type of informal coping strategy during the pandemic. Examining these messages revealed a myriad of strategies people used for remission and recovery from opioids. In total, there were 4 types of informal coping strategies that Redditors used themselves or suggested to others. The most frequent were psychological and behavioral skills (74/100, 74%), followed by adopting healthy habits (38/100, 38%) and using other substances to manage withdrawal symptoms (18/100, 18%).

Psychological and Behavioral Coping Skills (n=74, 74%)

The first wave of the COVID-19 pandemic upended the ways people worked and lived. Many employers abruptly required employees to work remotely, and others were forced to lay off large numbers of staff. Quite suddenly and unexpectedly, many

Redditors found themselves mostly restricted to their homes—forcing some to reevaluate their work-life balance and forcing others to navigate social distancing and stay-at-home orders without active incomes. Compounding these difficulties was effectively managing reduction in, or cessation of, opioid use while stuck at home.

To confront these particular challenges, Redditors described a variety of psychological and behavioral coping strategies. Although never explicitly stated, practicing mindfulness was a common psychological skill described in our sample of Reddit posts. According to previous work, mindfulness is generally described as a practice to bring awareness of and attention to the present moment without judgement [34]. To be mindful means to observe what is happening—both inside and outside yourself—in the here and now, without evaluating your observations [35]. Redditors described their mindfulness practices in some of the following ways:

> *I try to look for the good things when I'm sober, the chirps of birds, the sound of trees in the wind, and*

the warmth from the sun on my skin always comes back. It's great to finally be able to listen to the world when I'm sober.

Sobriety can be boring but learning to cope with your baseline emotions feels so much better than dealing with the intense highs and lows of opiates. It's not natural and not worth it.

I make videos every day and write down just how fucking awful I feel to go back and really remind myself how bad it is and why I don't ever want to do it again once I'm done.

The subreddits themselves served as a psychological coping strategy in that they provided Redditors with an easily accessible space for communal support. Redditors shared their experiences and strategies—both successful and unsuccessful—with others to encourage their cessation of or reduction in opioid use, supporting and empowering them to push forward and continue making progress:

I made a plan that was damn near [foolproof] where no matter what happened or how bad it got I had a contingency in place to keep me from getting in my car and going and copping. I used that plan more than I thought I would and I'm glad I had it. It included things like calling my brother or sober friends or when I knew I was going to have a tough day I'd just go spend it with my dad or at the animal shelter . . .

In some instances, Redditors posed thoughtful questions to those who disclosed their personal struggles:

You're also doing something important in reaching out and venting on here, those connections are so important, it certainly doesn't sound like dumb bullshit. Sounds like you've got a lot of inner strength from previous experiences, and you can acknowledge what you've learned from them. Maybe part of coping with this is asking what you can learn from this new thing (in a way you are already asking that!), but I know it's really hard.

Redditors exchanged many behavioral strategies to combat boredom and distract themselves to reduce or abstain from opioid use amid sudden COVID-19 circumstances. The most frequently discussed behavioral strategy was gaming via PlayStation and other consoles, as well as via board games and different websites.

Other Redditors distracted themselves at home by picking back up old hobbies and activities or learning new ones:

I'm not working right now so I'm at home by myself for most of the day, until my husband gets home from work. I'm taking advantage of it though. I'm working on a master list of activities around the house I can do that will help me distract from any paranoid thoughts. Right now my list is made up of music-related things (singing, playing ukulele) and learning-related things (continuing an online class I started a month or so ago) and craft-related things

(working on a diamond painting, picking up knitting again).

In some posts, Redditors mentioned watching movies and amusing videos on social media to fight boredom. For 1 Redditor, an effective strategy to redirect their negative thinking of their personal hardship was to watch documentaries that reframe such hardship through context and comparison:

. . . I'm super weird in that when I'm kicking sometimes I like to watch documentaries about really fucked up shit to remind me that like my situation isn't that bad I guess? Lol kinda crazy but it does work for me in terms of just getting my mind out of that horribly dark place . . .

For 1 self-disclosed "sober" Redditor, using marijuana became another important and much-needed tool to combat boredom and maintain remission from opioid use after withdrawal symptoms dissipate:

Pot is a lifesaver for me in sobriety and I'm not even a pot guy really, it helps me with relative boredom that comes with not chasing pills and just sort of allows me to focus on other things. Doesn't do a damn thing for me in active [withdrawals] but post [withdrawals] it's a solid maintenance tool.

Adopting Healthy Habits (n=38, 38%)

On both subreddits, during the early days and weeks of the COVID-19 pandemic in 2020, Redditors also emphasized the crucial role of developing healthier habits—such as exercising, staying hydrated, and eating healthy—to help improve mood and overall well-being. Some Redditors shared their healthy practices for getting more energy throughout the day or for clearing brain fog:

Stay at home but go for a walk or run, drinks and drinks and drinks to stay hydrated, consume funny media, take a nice shower, clean your tub . . . I need to. But get enough sleep exercise and try to eat okay and you'll start thinking clearer and things will get better.

I've been focusing on getting more energy every day. It's been pouring rain where I am for the last few days which sucks [because] I was getting back into jogging and it feels so good!! And I've been doing yoga pretty regularly, too!!

In some instances, Redditors not only described their routines but also disclosed their gradual health effects in real time. For example, 1 Redditor tracked their progress of adopting healthy habits and the impact it had on their sleep:

Wanted to die in week [1], started eating clean in week 2, started exercising/lifting/getting hobbies back in week 3, and sleep started returning to (almost) baseline in week 4. Things are starting to look up again and I can't wait [till] quarantine is over.

Using Other Substances and Devices to Manage Withdrawal Symptoms (n=18, 18%)

Redditors shared information about managing withdrawal symptoms. In some cases, they used definitions of "sobriety" that allowed for certain kinds of substance use (eg, marijuana) but not others:

> I stay clean by hitting my THC vape, and by playing video games or making music. I'm not doing hard drugs because my fiancé is stuck at home with me. She would be very upset if I did.

For clinicians and public health experts, this serves as a valuable reminder that definitions of "sobriety" and acceptable substances may differ across patients.

One Redditor discussed using transcutaneous electrical nerve stimulation (TENS) to help with restless legs and muscle pain during withdrawal. These posts referred to COVID-19 allowing the use of alternative substances and devices to help manage opioid use.

> So I decided to make my first post here, [m]aybe it will help someone! There is this device for muscle problems: Transcutaneous electrical nerve stimulation (TENS) is a method of pain relief involving the use of a mild electrical current. Some people use it to train their muscles without actually training but I don't know if it really works. I personally got it prescribed because of a muscle problem on my neck! It basically gives you a massage and for that purpose its ideal! But I was also able to use a TENS device successfully against my restless legs while withdrawing! If you want to know how it looks just google: Tens/EMS device/unit.

Using Quarantine as an Opportunity for Opioid Cessation or Reduction (n=12, 4%)

Of the 300 subreddit posts included in our sample, 12 (4%) posts mentioned using quarantine as an opportunity for cessation of or reduction in opioid use. Redditors acknowledged that despite the stress caused by COVID-19, the pandemic represented an ideal opportunity to work toward cessation or reduction. The 12 posts referred to quarantine, remote work, and reduction in responsibility as valuable circumstances for their recovery efforts.

> Anyway, as insensitive as it sounds, corona plopped in my lap at a perfect time. It gave me the perfect opportunity to detox and start recovering without any real responsibility.

> You still have options, and the [COVID] shutdown is a great excuse to be able to take a few weeks away from the world and ride out the withdrawals.

> Thankfully, this pandemic has given me an opportunity to begin recovery. But I know I'm one of the lucky ones, as boredom doesn't get to me.

Discussion

Principal Findings

This exploratory study sought to characterize some of the informal coping strategies used by people who were abstaining from use—or simply managing their opioid use as best as they could—while adjusting to the COVID-19 pandemic and remaining at home during the first wave in 2020. To do this, we thematically analyzed a sample of subreddit threads posted on Reddit sometime between March and May 2020. In 12 (4%) of 300 posts, Redditors remarked that the pandemic provided them with an unparalleled opportunity to reduce opioid use. Our analyses revealed 3 overarching themes of informal coping strategies: psychological and behavioral coping skills (74/100, 74%), adopting healthy habits (38/100, 38%), and using substances to manage withdrawal symptoms (18/100, 18%). To help distract themselves from "negative" thinking and the desire to use opioids, Redditors used a variety of strategies. These included activities such as playing video games, taking up old hobbies again, or learning new ones. Redditors also described their adoption of healthy eating habits and exercise and mindfulness practice. In some instances, Redditors disclosed using substances such as marijuana to sway boredom or manage withdrawal symptoms. These exploratory findings may help further our understanding of how the first wave of COVID-19 uniquely affected PWUO, especially people seeking to reduce their opioid use. Ultimately, contributing to this knowledge base will help inform future drug policy and harm reduction efforts responding to future disruptive public health emergencies.

Limitations

Our study, however, is not without limitations. First, the majority of Redditors are younger men living in the United States [36], so the strategies of coping reflected in the subreddit threads may not represent strategies used by the larger community of PWUO. Second, because of the anonymity of Reddit, we had no demographic information or history of drug use for people who posted on both subreddits, so we could not examine the extent to which suggested coping strategies were effective in recovery. Another limitation of our study is that we were not able to verify demographic characteristics and the exact location of the Redditors. It is possible that some of the posts were written by PWUD or their friends or family members. To address this limitation in future studies, researchers could survey patients who are in treatment for OUD and ask them if they have ever used Reddit to discuss opioid use. Third, we did not evaluate the intercoder reliability of our coding frames. We fully believe in the practice and acknowledge its many benefits for qualitative analysis. These benefits include improving the systematicity, communicability, and transparency of the coding process; promoting reflexivity and dialogue among researchers; and helping convince diverse audiences of the trustworthiness of the analysis [37]. With this research, however, we followed the guidelines set by McDonald et al [32]. We did not aim for a certain threshold of agreement. Rather, we sought to generate concepts and themes so that novel content could be discovered and tested in future exploratory studies. Fourth, future studies should return to subreddit threads to examine data during a longer time frame. Our aim with this study, however, was to

understand Redditors' conversations during the first moments of the pandemic. Analyzing their dialogue during the acute time frame enabled us to examine their coping skills during a crisis. Finally, it is unclear whether these Redditors were a highly motivated group that would have succeeded without support from a social media site; it is possible that other social media sites facilitate forums that exacerbate risk factors for opioid use.

Future Implications

These data have several implications for treatment providers, specifically. First, in times of crisis when social interaction is limited, providers can encourage patients to use online forums as a coping strategy and source of communal support. Second, health care workers can listen nonjudgmentally to patients who may describe Reddit as a valuable recovery tool, and be mindful that it represents a safe space for patients who value to anonymity of the forum. Social media and other forums are popular resources for health information, even though some forums may spread misinformation [38]. Studies have shown that people may seek forums and self-help groups to provide emotional support [39-42], particularly given online forums may allow anonymous disclosure without feelings of shame or guilt [43]. Finding emotional support without being stigmatized is especially relevant for PWUD [44] and is an urgent matter, given opioid overdose–related use of health care has increased throughout the pandemic. Future research should examine subgroups of PWUO who may be at heightened risk for reduced access to care during the pandemic [44].

Conclusion

Our current analysis of subreddits supports our previous research suggesting that Reddit facilitates social support that may aid people in their efforts to reduce or abstain from opioid use and improve their physical and mental health [25]. In other research using the same original sample of Reddit content, we found that Redditors sought support and advice from each other on ways to access formal treatment for opioid use during the pandemic [26], whereas a different set of qualitative analyses of these data revealed that some Redditors reported increases or changes in active drug use (D. Frank, PhD, unpublished data, July 2021). Taken together, these findings demonstrate that Reddit is a valuable data source for rapid public health surveillance, especially for emerging public health crises, such as COVID-19.

Abstract

With the relaxing of telehealth regulations through the Health Insurance Portability and Accountability Act (HIPAA) waiver notification for Telehealth Remote Communications during the COVID-19 Nationwide Public Health Emergency, our organization had the opportunity to pilot an innovative virtual care solution using a modified consumer-grade voice-activated video communication system (Amazon Echo Show 8) within one inpatient COVID-19 unit. In this brief report, we describe our experiences with implementing the system and general feedback from clinicians, and discuss areas for future development required to enable future scaling of this solution. Our pilot demonstrates the feasibility of deploying a consumer-grade voice assistant device in COVID-19 patient rooms. We found the devices engaging due to the voice technologies and Alexa functionalities for both clinician and patient entertainment. To enable future deployment at scale, enhancements to the Echo Show and data analytics will need to be further explored.

Introduction

The COVID-19 pandemic has resulted in the unprecedented adoption of virtual care tools [1-3]. Ideally, virtualizing patient encounters in the inpatient setting can preserve the sense of human contact and increase capacity for human connection with patients while making interactions feel less rushed [4]. Additionally, inpatient virtual care tools were needed to both reduce use of personal protective equipment (PPE), especially when supplies were constrained, and reduce in-person contact and risk of transmission. Despite the numerous barriers to telemedicine, such as educating staff, cost, reimbursement, access to broadband, and patient digital literacy, telemedicine has flourished during the pandemic, accelerating implementation timelines that may have been much longer without such a catalyst [5].

In April 2020, Mass General Brigham Health System deployed video intercom communication system (VICS) developed in-house that allowed clinical staff to connect over video to a securely configured tablet inside a patient room [4]. This telehealth solution was implemented to reduce PPE usage and maintain human connection at the bedside. Although quite

XSL·FO
RenderX

successful, there were some limitations to VICS—for example, clinical staff required training to use the technology and it was not a hands-free solution, which was an infection control barrier. Solutions in the consumer space, such as Amazon Echo Show (Amazon.com Inc) devices, addressed the hands-free issue and were familiar to staff already but were historically unable to be used in the health care space.

With the relaxing of telehealth regulations through the Health Insurance Portability and Accountability Act (HIPAA) waiver notification for Telehealth Remote Communications during the COVID-19 Nationwide Public Health Emergency [3], the opportunity to explore additional innovative virtual care solutions emerged, including solutions leveraging consumer-grade systems in the clinical setting. One health system found that "the use of consumer products sourced from local vendors is a viable solution for telemedicine systems focusing on speed, reducing costs, and ease of deployment" [6]. In this brief report, we describe our experiences implementing a voice-activated video communication system for clinicians to communicate with inpatients with COVID-19 using consumer-grade hardware (Amazon Echo Shows).

Methods

Overview

This pilot project was conducted at Brigham and Women's Hospital (BWH), a 736-bed, urban academic quaternary care hospital that is a founding member of the Mass General Brigham health care system in Boston, Massachusetts. For the duration of the pilot from September 21, 2020, to November 9, 2020, BWH had a daily average COVID-19 census of 15 patients. In conjunction with nursing leadership, we selected one unit with primarily inpatients with COVID-19 (COVID-19 Special Pathogens Unit) to conduct the pilot project. Selection criteria included a unit that would consistently treat patients with COVID-19 and one that would be adequately equipped to house the pilot devices.

BWH had previously deployed the VICS platform using tablets to improve communication between staff and patients while reducing use of PPE and physical contact time for health care providers treating patients with COVID-19. The configuration of the VICS tablet is locked and has an auto-answer feature enabled so nurses can monitor patients without disturbing them and engage in high-quality 2-way conversations whenever needed without the patient having to take any action.

We used a modified 2-way video communication device (Amazon Echo Show 8) configured to allow drop-in video calls to the patient room to help the nurse conserve PPE by communicating with the patient without having to enter the room numerous times per day. In partnership with a third-party vendor (Aiva Health), a fleet management software system was implemented to enable drop-ins, manage accounts, and provide additional security measures across multiple Echo Show devices. In a similar manner, the Echo Show devices were programmed to allow drop-ins only from the nurse to the patient room. This drop-in function is an instant live connection from a staff device to a patient device, allowing the clinician to see and speak with

the patient and the patient to see and speak with the clinician. Patients are unable to initiate an outbound audio or video call; to contact nurses, they would still need to use the nurse call button in their room.

Amazon Echo Show Device Deployment

A total of 6 patient rooms were included in the pilot. We matched each patient room Echo Show device with a nurse station Echo Show device for a total of 12 devices in the pilot. The Echo Show devices replaced the VICS devices in the 6 patient rooms. The nurse devices were set up at the nurse stations outside each of the rooms (Multimedia Appendix 1). The patient devices were placed on a shelf attached to an intravenous (IV) stand in the patient room (Multimedia Appendix 2). All Echo Show devices were named based on the building name ("Shapiro") and the assigned number of the device. A new Wi-Fi network was used specifically for the Echo Show devices during this pilot to not interfere with clinical care and as a security measure.

We conducted a live training of the Echo Show device with unit staff prior to the go-live date. Along with the live training, tip sheets were provided for both the nurses and the patients. The tip sheet created for the nurses provided an overview, how-to instructions, important notes, and support guidance (Multimedia Appendix 3). Nurses could drop in to a patient room using voice activation by saying, "Alexa, drop in to Shapiro Echo 2" or by selecting "Shapiro Echo Show" on the touch screen of the Echo Show device.

Patients in the pilot rooms were made aware of the pilot via a patient notification sheet affixed to the Echo Show device in the room (Multimedia Appendix 4). A user guide was also created to explain to patients how to operate the Echo Show device in their room (Multimedia Appendix 5).

We did not encourage patients to touch the Echo Show device. Patients were welcome to explore Alexa functionalities—such as asking everyday questions (eg, weather, news, sports) and listening to music—that did not require any personal account information, although we did not market this feature for the pilot.

Periodic retraining occurred during onboarding of new staff and throughout the duration of the pilot. We collected nurse feedback through regular rounding on the units. The nursing team and technology team feedback was then synthesized and collated into this report.

Technical Infrastructure and Security

Amazon has a proprietary infrastructure for IP-based audio and video calls that uses the Session Initiation Protocol. The session is initiated and established entirely on Amazon's network and the 2-way audio/video communication is peer-to-peer between Echo Show devices on the same network, which is end-to-end encrypted and does not go through Amazon's cloud.

Additional security measures were put in place to ensure Echo Show devices met the security standards of our institution including (1) implementing a fleet management system that automatically deleted all data that originated from the Echo Show devices and (2) configuring the Echo Show devices to

connect to a separate Wi-Fi network specifically set up for this pilot to avoid using clinical networks.

Results

Through rounding on the pilot inpatient unit and compiling comments and emails, we gained valuable feedback on the voice-activated video communication system. The nurses found the Echo Show devices easy to use and the privacy controls were well received. They also enjoyed the additional available features on the Echo Show devices that the VICS system did not have.

Discussion

Overview

In addition to the ease of use for video communications using the Alexa drop-in feature, the most positive feedback received was regarding the voice assistant (Alexa) functionality, which was not a feature we advertised. One nurse described how her patient listened to the radio and programming on the Echo using the Alexa functionality and, being from a different country, loved it as it had content she knew and enjoyed. Likewise, nurses enjoyed using the Echo Show at their workstation to listen to the radio using the Alexa functionality, increasing their satisfaction with the system.

Challenges and Opportunities to Improve Future Voice-Activated Video Communication System Enterprise Deployment

During the pilot, there was interest from nursing leadership to deploy these devices in another building following a COVID-19 outbreak. However, this was not feasible due to several challenges with the current consumer version of the Echo Show device (Table 1).

The Echo Show devices support Wi-Fi Protected Access 2 (WPA2) encryption, which only requires a single preshared key to connect to a network. Learning this single preshared key could lead to a system compromise. Future versions of the Echo Show device can address this by enabling access to WPA2 Enterprise, which requires a unique username and password

and a preinstall unique encryption key, thereby providing additional security and enhancing ease of scalability [7].

One of the barriers to implementation was the lack of an official enterprise fleet management solution for the Echo Show devices. A third-party vendor, Aiva Health, created a custom fleet management solution that provided limited enterprise support that was not native to the device. This resulted in the setup of each device becoming a time-consuming activity, taking 1-2 days, as each Echo Show device needed to be configured and tested individually and then brought online by the Amazon and Aiva Health teams with the drop-in feature turned on. If this pilot were to be expanded, additional dedicated team members would be required to manage the implementation.

Due to the HIPAA waiver for telehealth remote communications, this Echo Show device could only be used in COVID-19 patient rooms and had to be removed from the room and unplugged when a patient with COVID-19 was discharged. This made it very difficult for staff to track the devices. No Echo Show devices were lost during the pilot program, but a fleet management solution that included some type of asset tracking system would have improved the experience.

Echo Show device mounting and placement in the rooms and the fixed camera on the device led to additional challenges. The nurses felt that the placement of the Echo Show device on the IV pole was not secure and, depending on the placement of the IV pole, the camera viewing angle from the device could be suboptimal. This led to situations where the Echo Show device was not always facing the patient when the nurse dropped in.

Lastly, there were no built-in data analytics in the Echo Show devices (eg, number of drop-ins, length of drop-in, and number of times voice activation was used), so there was no official way to track device usage. This would have been helpful in understanding the function and usage of the Echo Show device from a quantitative perspective and for measuring the efficacy of this device and comparing it more effectively with usage of the VICS system.

The barriers that previously limited enterprise scaling of voice assistant systems like Amazon Echo Shows are beginning to soften. Third-party vendors, such as Aiva, provide health care–specific fleet management solutions for Alexa devices.

Table 1. Summary of challenges in implementing a voice-activated video communication system and potential solutions.

Challenge	Potential solution
The devices only support Wi-Fi Protected Access 2 (WPA2) networks	Updating future devices to support Extensible Authentication Protocol-Transport Layer Security (EAP-TLS) authentication
Many nurses were accustomed to using the existing VICS[a] solution so they were less interested in adopting the Echo Show device	Provide more live trainings of Echo Show device or completely replace VICS solution with Echo Show device
Device placement on IV[b] pole was suboptimal as it was not sturdy and was not always facing the patient	Creation of custom mounts for the Echo Show device that can affix to the IV pole and pivot
Lack of data analytics made it difficult to understand usage or efficacy of pilot	Ability to extract and summarize key metrics by device, unit, and user, such as number of drop-ins, length of drop-in, and number of times the voice activation was used

[a]VICS: video intercom communication system.

[b]IV: intravenous.

XSL•FO
RenderX

Further work needs to be done on future devices to support wireless network configurations such as WPA2 Enterprise before these devices can truly be considered for "out of the box" enterprise scaling. Currently, without WPA2 Enterprise support, deploying these devices requires close consideration of how to create a safe and secure connectivity plan. For this pilot, we addressed this through the creation of a stand-alone Wi-Fi network specifically for the Echo Shows. We are hopeful that support for these standards will be adopted in future iterations of the Echo Show hardware.

One of the limitations of this paper is that this is a feasibility pilot in a single unit; more formal research needs to be conducted to help understand and inform further implementation and use of voice-activated video communication systems. Further, we did not formally solicit direct patient feedback on the use of the device. Patient experience is an important area to explore in subsequent research. Finally, this implementation was possible under the HIPAA waiver for telehealth remote communications—additional privacy and security review may be necessary for broader health care use in the future [8].

Conclusion

Overall, this pilot demonstrates the feasibility of deploying a consumer-grade voice assistant device in COVID-19 patient rooms. Although there are a variety of technologies that can be used to deliver similar 2-way video communication, we found the Echo Show device engaging; it differentiates itself due to the voice technologies and Alexa functionalities for both clinician and patient entertainment [9]. To enable future deployments at scale, security and privacy enhancements to the Echo Show and data analytics will need to be further explored.

Abstract

Background: The COVID-19 pandemic has been suspected to increase gambling problems in the population. Several governments introduced COVID-19–specific interventions early with the aim to prevent gambling problems, but their effects have not been evaluated.

Objective: This study aimed to evaluate a Swedish COVID-19–related temporary legislation imposing an automated weekly deposit limit for online casino gambling.

Methods: The study was an anonymous survey sent by a state-owned gambling operator to online gamblers (N=619), among whom 54.0% (n=334) were moderate-risk/problem gamblers who reached the weekly limit on online gambling during the summer of 2020.

Results: Overall, 60.1% (372/619) were aware of having been limited by the COVID-19–related deposit limit, and a minority (145/619, 23.4%) perceived the intervention as fairly bad or very bad. Among those aware of the intervention, 38.7% (144/372) believed the intervention decreased their overall gambling, whereas 7.8% (29/372) believed it rather increased it. However, 82.5% (307/372) reported having gambled at more than one operator after the limit, and the most common gambling type reported to have increased at another operator was online casino (42% among moderate-risk/problem gamblers and 19% among others; *P*<.001). An increase in gambling following the intervention was associated with being a moderate-risk/problem gambler and having negative attitudes toward the intervention.

Conclusions: The weekly deposit limit had relatively high acceptability, but the study highlights the limitations of a single-operator deposit limit, given the high number of gamblers also reporting gambling at other operators and the lower effect in clients with gambling problems.

Introduction

The global spread of SARS-CoV-2, causing the COVID-19 pandemic, is resulting in a number of mental health consequences in the population [1] caused by either the direct effects of the disease or the restrictions imposed on society and the following behavioral changes. One of the public health hazards suggested to be caused by the pandemic is gambling. Increased gambling behavior, at least in subgroups in the population, was feared in the early phases of the pandemic [2]. A priori, problem gambling, including in the group of

XSL•FO
RenderX

individuals who meet the criteria of having a gambling disorder, constitutes a well-known hazard to health and a risk of psychosocial problems [3]. An overview of the research hitherto conducted in the area of gambling behaviors during COVID-19 recently demonstrated the different findings of the studies conducted so far, with several studies demonstrating that gambling practices rather decreased or did not increase, but some reporting an increase among subgroups, including individuals with a higher degree of gambling problems [4].

Thus, altogether, there are hitherto no convincing findings of generally increased gambling due to COVID-19, but there are indications that the potential effects are very unevenly distributed in the population. Sweden in one of the settings where a number of studies have assessed objective gambling activity measures, or self-reported survey data, during COVID-19. Objective measures of gambling activity have shown that gambling at online commercial gambling operators did not increase during the very first phase of the pandemic, when sports events generally were cancelled [5,6]. However, the financial activity of gambling operators demonstrated some likely migration of gambling behavior away from traditional sports betting during the early period of the sports lockdown [7]. In line with the overall picture of a potential gambling increase in subgroups of the population, an early survey study [8] and its similar follow-up [9] demonstrated that 4% and 6%, respectively, stated a self-reported increase in gambling after the onset of the pandemic, with a considerable overrepresentation of individuals with moderate-risk or problem gambling in this group. As an additional data source in this context, treatment uptake at a regional health care facility for gambling disorder patients was not statistically changed by the COVID-19 pandemic [10].

A number of countries took early action with legislation aiming to prevent problem gambling in response to the pandemic. This included gambling bans, bans against gambling advertising, or limits on gambling deposits, for example, in the United Kingdom, Spain, and Latvia [11-13]. A COVID-19–related legislation, effective from July 2, 2020, was also introduced in Sweden, as a response to the debate during the first phase of the COVID-19 pandemic in Sweden, where problem gambling was suggested to be one of the health hazards potentially associated with the societal changes of the pandemic. This legislation was decided by the Swedish parliament after a proposal made by the government, and it included a maximum limit of weekly deposits made to each single operator (at a level of 5000 SEK [around 560 USD] per week) for the following 2 gambling types: (1) online casino services, which are commercialized and offered by a large number of licensed operators within Sweden, and (2) land-based electronic gambling machines, which all belong to a monopoly of a Swedish state-owned gambling operator. An additional feature of the special COVID-19–related legislation was the introduction of a 100 SEK (around 9 USD) limit to the bonuses offered to first-time clients of a gambling operator, which is typically offered by commercial online casino and sports betting services in the country [14], although not by the state-owned operator at the time of this study.

The effect of government policies on problem gambling during the COVID-19 pandemic is largely unknown. A survey study in the general population in Sweden (ie, both gamblers and nongamblers among web panel respondents) examined awareness of the COVID-19–related gambling regulation and the subjective effects of the regulation. A minority of respondents (30%) were aware of the legislation, which was however markedly more well-known among people with at least moderate-risk gambling (56% were aware of the legislation) and in the subgroup of individuals who had ever self-excluded from gambling (78% were aware of the legislation). A very low proportion of respondents reported being influenced by the regulation, with the group split between those reporting an increase or a decrease in their gambling [9]. No study has been able to examine the effects of the legislation in the specific subgroup targeted, that is, people who reach the weekly deposit limit of the legislation. In addition, it is unknown to which extent at-risk gamblers perceive such a limiting regulation as acceptable. For example, it has been suggested that deposit-limiting interventions in high-risk gambling may potentially be perceived as annoying and potentially even stimulate migration to other gambling types with a higher degree of severity [15]. Thus, there is reason to address targeted gamblers' attitudes to this type of COVID-19–specific limit setting and determine whether such attitudes are associated with an increase or decrease in gambling.

This study was carried out by the communication and sustainability division of the state-owned Swedish gambling operator AB Svenska Spel, as a web survey targeting the group affected by the legally imposed limit on deposits. The aim of the study was to assess, in an anonymous sample of online gamblers, who reached the 5000 SEK deposit limit at the Swedish state-owned gambling operator; determine the self-reported effect of the intervention on subsequent gambling behaviors; and evaluate the knowledge about, attitudes to, and experiences of the effects of this intervention.

Methods

Setting

The Swedish gambling market is based on a license system, where gambling operators involved in a number of gambling types can receive a license to operate within Sweden. Operators need to follow Swedish responsible gambling legislation, including an 18-year minimum gambling age and adherence to a national government-based self-exclusion service. The self-exclusion service, administered by the Swedish Gambling Authority, allows for any individual to self-exclude from all licensed gambling (ie, with the exception of physical lotteries, including charity-based lotteries, minor gambling in funfairs, and limit-deposit "restaurant casinos" offering table games in restaurants, which constitute a very minor proportion of the Swedish gambling market). This service, described in previous publications, is a rare example of a nationwide self-exclusion service [16,17]. In Sweden, individuals with online gambling practices constitute the overwhelming majority of patients who seek treatment for a gambling disorder [18]. The prevalence of moderate-risk or problem gambling in the country has been

estimated to be around 1.5%, and among these individuals, around one-third may likely meet the criteria of a disorder [19].

The state-owned operator AB Svenska Spel was traditionally a gambling monopoly and was effective in that role as long as gambling was primarily land-based. Since January 2019, the license-based system allowed for a large number of licensed operators on the Swedish market. AB Svenska Spel has one subdivision that operates in the areas of sports betting, online poker gambling, and online casino gambling, in competition with a large number of commercial operators in these areas. Another subdivision of AB Svenska Spel is a state monopoly responsible for land-based electronic gambling machines and for land-based casinos. The land-based casinos (consisting of 3 state-owned casinos in the 3 major cities of Sweden) were temporarily closed due to the COVID-19 situation from April 2020 to July 2021.

Study Procedure

This is a self-report, electronic, anonymous survey study carried out by AB Svenska Spel. A web link was sent by email to a sample of clients who reached a 5000 SEK gambling limit (at online casino, online bingo, online sports betting, and online poker) after the introduction of the COVID-19–related gambling legislation. The survey was introduced as being sent from the gambling operator AB Svenska Spel to customers who reached this 5000 SEK deposit limit. Invited subjects were informed that the survey was confidential and that its aim was for Svenska Spel to learn more about how to improve its work against problem gambling. An incentive (a 100 SEK gift card of a type that cannot be used for gambling, alcohol, or tobacco products) was offered to respondents.

Individuals who reported being unaware of having been subject to the deposit limit were excluded from the remaining survey. The study was anonymous. Clients reaching the 5000 SEK limit were identified in the client database, where the operator has information about each client's gambling data, but the data collection was carried out by an external consultant (the market survey company Norstat). Thus, the operator and authors were unaware which individuals responded to the survey. Age data were reported on a group level, and given the confidentiality measures, information about gender or geographical location was not collected.

As the study does not involve data that can be directly or indirectly referred to identified individuals, the project does not require ethical permission according to the Swedish ethics in research legislation. Parts of mainly descriptive data from the survey have previously been posted online in Swedish on the operator's home page.

Study Participants

Individuals were selected based on their gambling statistics during weeks 27 to 40 (July 2 to October 4, 2020). Individuals were addressed if they (1) had received at least one automated notification from Svenska Spel because of having deposited 5000 SEK or more during the same week in their joint gambling account involving either online casino, online bingo, online sports betting, or online poker, after the introduction of the COVID-19–related gambling legislation and (2) had lost at least

1000 SEK on online casino, online bingo, or online poker during that week. The latter was specified in order to exclude sports-only bettors who were not affected by the legislation but who may have reached the 5000 SEK limit on their joint sports and casino account of Svenska Spel. This approach identified 4782 individuals, and among them, we selected those who had not actively refused to receive client surveys and who had an email address available. This resulted in a total of 3442 potential participants. According to the funding of the study, recruitment was aimed to stop after reaching around 600 collected responses, and when recruitment was finally halted, a total of 619 responses had been received. The mean age of the participants was 45.0 years (SD 12.3 years), with a median of 45 years (IQR 35-54 years).

Study Variables

The following study variables were collected in the study:

1. Dichotomous question about awareness of the COVID-19 legislation imposing the 5000 SEK deposit limit.
2. Likert-scale response questions about subjective self-reported effects on one's gambling, and opinions about such an intervention and about subjective changes in a number of gambling types following the 5000 SEK limit for online casino gambling and electronic machine gambling.
3. Likert-scale response questions about the acceptability of the intervention; whether the gamblers perceived the government's decision to introduce this intervention as "very bad," "fairly bad," "neither good nor bad," "fairly good," "very good," or "don't know." These responses were dichotomized into "fairly good" or "very good" vs others and "fairly bad" or "very bad" vs others in the statistical analyses.
4. Multiple-choice questions about whether the gambler had gambled more or less on any of the following gambling types: sports betting, horse race betting, land-based restaurant casino, online poker gambling, lotteries/number games, land-based machine gambling with Svenska Spel, land-based machine gambling with other operators, and online casino with other operators; whether no other gambling type involved gambling more/less; or whether the gambler did not know.
5. Dichotomous question about whether one had gambled more or less (or did not know) after the deposit limit at Svenska Spel Sports & Casino, Svenska Spel in general, or other operators.
6. The Problem Gambling Severity Index (PGSI) [20], a validated 9-item survey tool measuring the level of risky and problematic gambling practices. The same assessment instrument has been used in general population surveys on gambling practices in Sweden [19], as well as in the COVID-19–related surveys in Sweden [8,9,21].
7. Age (in years, here reported only on a group level).

Statistical Methods

Data were reported descriptively, and comparisons were made using the chi-square test for categorical data and Student *t* test for continuous data (and Fisher's exact test for cross-tabulation comparisons where one or more of the squares contained less

than five individuals). Finally, for the measure of whether gambling after the intervention had increased or decreased, these 2 measures were studied as outcome measures in 2 separate logistic regression analyses, where age, attitudes toward the intervention, and moderate-risk/problem gambling status were included as independent variables. Here, results were reported using odds ratios with 95% CIs. By default, associations were considered statistically significant at P values below .05.

Results

Levels of Hazardous and Problem Gambling

Full PGSI data were available from a total of 467 individuals, and of these, 25.1% (117/467) were no-risk gamblers, 20.3% (95/467) were low-risk gamblers, 31.3% (146/467) were moderate-risk gamblers, and 23.3% (109/467) were problem gamblers. In addition, another 79 individuals with partly missing answers could be identified as being at least moderate-risk gamblers, based on a PGSI score of 3 or above from available items, resulting in adequate PGSI data from 546 individuals. Thus, in the full sample of 619 individuals, 54% (n=334) were at least moderate-risk gamblers and 34% (n=212) were no-risk or low-risk gamblers, with missing data in the remaining 73 individuals for whom the total score from available PGSI items was 0 to 2. Moderate-risk/problem gamblers were significantly younger than others (43.5 vs 48.3 years, $P<.001$).

Awareness and Acceptability of the Government Regulation

Overall, 60.1% (372/619) were aware of the limit for their deposits by the government's COVID-19–specific gambling regulation. Awareness of the regulation was higher among individuals with moderate-risk/problem gambling than among others (68% vs 48%; $P<.001$), but was unrelated to age (44.5 vs 45.6 years; $P=.29$). In the entire sample, 34.6% (214/619) believed that the regulation was very good, 19.2% (119/619) believed that it was fairly good, and 21.0% (130/619) believed that it was neither good nor bad. Moreover, 9.5% (59/619) stated that it was fairly bad and 13.9% (86/619) stated that it was very bad. Furthermore, 1.8% (11/619) reported that they did not know.

Gambling After the COVID-19 Regulation in Individuals With Awareness of the Regulation

After reaching the 5000 SEK limit, among those reporting being aware of the regulation (n=372), 38.7% (144/372) stated that this had decreased their total gambling, 47.3% (176/372) stated that their gambling remained approximately the same as before, 7.8% (29/372) believed it increased their gambling, and 6.2% (23/372) did not know.

Gambling types perceived to have increased (in other operators) after the intervention were horse race betting (29/372, 7.8%), sports betting (52/372, 14.0%), lotteries and "number games" (18/372, 4.8%), online casino (123/372, 33.1%), online bingo (12/372, 3.2%), online poker (12/372, 3.2%), "restaurant casinos" (7/372, 1.9%), land-based electronic gambling

machines of Svenska Spel (29/372, 7.8%), and other land-based electronic gambling machines (13/372, 3.5%). Additionally, 37.4% (139/372) did not perceive themselves to have increased any gambling type and 9.7% (36/372) did not know.

Moreover, 37.6% (140/372) reported that they decreased their gambling on the Svenska Spel Sports & Casino subdivision, 19.4% (72/372) reported that they decreased their gambling on Svenska Spel overall, 19.4% (72/372) reported that they decreased their gambling at other operators, and 30.6% (114/372) did not know.

We found that 13.4% (50/372) had gambled on casino, poker, or bingo games at only 1 operator since July 1 (since the introduction of the intervention), 55.6% (207/372) had gambled on these games at 2 to 4 operators, 21.2% (79/372) had gambled at 5 to 10 operators, 3.0% (11/372) had gambled at 11 to 15 operators, 2.7% (10/372) had gambled at more than 15 operators, and 4.0% (15/372) did not know. Thus, altogether, 83% had gambled on casino, poker, or bingo games on more than one gambling operator after the deposit limit. Moreover, 40.6% (151/372) reported being limited, following the COVID-19 regulation, from another operator than Svenska Spel during the observation period, 53.2% (198/372) reported not being limited, and 6.2% (23/372) did not know.

Comparison of Moderate-Risk/Problem Gamblers and Others

Among individuals reporting being aware of the COVID-19 regulation, 284 had full data for the PGSI and 327 had full data in the dichotomy of moderate-risk/problem gambling vs no-risk/low-risk gambling. The number of gambling operators reported was strongly associated with moderate-risk/problem gambling ($P<.001$, chi-square linear-by-linear). Among those reporting two or more other gambling operators after reaching the weekly limit at Svenska Spel, moderate-risk/problem gambling was detected in 74% compared with 39% among those reporting 1 operator ($P<.001$).

Differences between moderate-risk/problem gamblers and other gamblers are demonstrated in Table 1. Altogether, moderate-risk/problem gamblers were significantly more likely to report an increase (following the intervention) in Svenska Spel machine gambling, online casino at other operators, and lotteries and number games, and they were markedly less likely to report that they had not increased gambling at other operators, whereas no differences were seen for other gambling types. Moderate-risk/problem gambling was not significantly associated with having decreased Svenska Spel gambling or Svenska Spel Sports & Casino gambling.

Altogether, moderate-risk/problem gamblers were significantly more likely than others to report having increased overall gambling after the introduction of the regulation, and were not more likely to report overall decreased gambling due to the present regulation. They were significantly more likely to perceive the regulation as very good or fairly good, and less likely to perceive it as very bad or fairly bad.

Table 1. Statistical comparisons between moderate-risk/problem gamblers and other gamblers (N=327).

Variable	Moderate-risk/problem gamblers (n=226), n (%)	Other gamblers (n=101), n (%)	*P* value
Postintervention increase			
Svenska Spel machine gambling	22 (9.7)	3 (3.0)	.04
Online casinos, other operators	95 (42.0)	19 (18.8)	<.001
Lotteries and number games	15 (6.6)	0 (0.0)	<.007
Non-Svenska Spel land-based machine gambling	7 (3.1)	4 (4.0)	.74
Restaurant casino gambling	4 (1.8)	1 (1.0)	>.99
Online poker, other operators	8 (3.5)	2 (2.0)	.73
Online bingo, other operators	8 (3.5)	1 (1.0)	.28
Sports betting	36 (15.9)	10 (9.9)	.15
Horse race betting	17 (7.5)	10 (9.9)	.47
Postintervention increase in gambling overall	24 (10.6)	2 (2.0)	.007
No postintervention increase in gambling on other operators	66 (29.2)	59 (58.4)	<.001
Postintervention decrease			
Svenska Spel gambling overall	47 (20.8)	19 (18.8)	.68
Svenska Spel Sports & Casino gambling overall	85 (37.6)	39 (38.6)	.86
Postintervention decrease in gambling overall	88 (38.9)	37 (36.6)	.69
Perceived intervention as very good or fairly good	126 (55.8)	42 (41.6)	.02
Perceived intervention as very bad or fairly bad	53 (23.5)	40 (39.6)	.003

Correlates of Reporting Increased or Decreased Gambling Following the Intervention

Age was unrelated to the reporting of decreased gambling after the regulation (45.9 vs 43.7 years, *P*=.09), but the group reporting increased gambling after the regulation was significantly younger (38.1 vs 45.1 years, *P*<.01). Age was unrelated to the perception of the regulation as very good/fairly good (*P*=.86) or very bad/fairly bad (*P*=.82). Age was also unrelated to a decrease in gambling on Svenska Spel Sports & Casino (*P*=.68), Svenska Spel overall (*P*=.52), and other operators (*P*=.78).

The reporting of increased or decreased gambling following the intervention was associated with attitudes toward the regulation. Among those who perceived the regulation as very good or fairly good, 53.1% (102/192) reported decreased gambling (compared to 23.3% [42/180] among others; *P*<.001) and 4.7% (9/192) reported increased gambling (compared to 11.1% [20/180] among others; *P*=.02). Among those who perceived the regulation as very bad or fairly bad, 18.1% (19/105) reported decreased gambling (compared to 46.8% [125/267] among others; *P*<.001) and 15.2% (16/105) reported increased gambling (compared to 4.9% [13/267] among others; *P*<.001).

In logistic regression analysis (Table 2), a reported increase in gambling following the intervention (n=26) was significantly associated with the opinion that the regulation was very bad or fairly bad and with being a moderate-risk/problem gambler, and was nearly significantly associated with younger age. A reported decrease in gambling following the intervention (n=125) was associated with the opinion that the regulation was very good or fairly good, but not with being a moderate-risk/problem gambler or with age (Table 2).

Discussion

Principal Findings

This study examined self-report of gambling among individuals after online gambling was limited due to a special COVID-19–related gambling regulation imposing a weekly deposit limit on online casino and electronic gambling. The study demonstrated that acceptability of the intervention was generally fair. Although only 6 out of every 10 gamblers reported being aware of the limit introduced by the regulation, a majority perceived the intervention as generally positive. In those who were aware of this, it was considerably more common to perceive that the intervention had decreased their overall gambling than to perceive that it increased their gambling. However, limitations and challenges of the intervention were demonstrated. A large majority gambled at other operators, where 4 out of every 10 gamblers reached the regulated weekly deposit limit. This challenge was more pronounced for online casino, which was by far the gambling type most commonly reported to have increased at other gambling sites after being limited by the present operator. This sample of online gamblers who reached the weekly limit had very high rates of gambling problems, and those who scored positive for at least moderate-risk gambling were considerably more common to report online casino gambling at other sites after being limited, to gamble at more operators, and to perceive themselves to have increased gambling after the introduction of the weekly limit. A self-reported negative effect from the intervention was associated with negative attitudes toward it and with higher gambling problems.

Awareness of the fact that one had reached the deposit limit imposed by the government regulation may seem surprisingly low; only 6 out of every 10 gamblers reported that they were aware. However, consistent with previous general population data assessing knowledge about government policies related to gambling and COVID-19 [9], this awareness was markedly higher in the subgroup with manifest gambling problems. Thereby, it can be assumed that people with highly hazardous gambling patterns constitute a group with particularly high gambling involvement and therefore a higher likelihood of recognizing and understanding the nature of the present intervention. Likewise, it can be argued that the intervention

imposed by the government aims particularly at this group, although it also indicates that awareness, and therefore efficacy, of the intervention may have the potential to increase in gamblers without detected gambling problems.

A subgroup of respondents here reported an increase in gambling subsequent to the intervention (ie, intuitively a negative and unintended effect of the intervention). The reporting of an overall increase in gambling as a consequence of the intervention was rare, but was several times more common in moderate-risk or problem gamblers than in others. Thus, although only a minority reported a markedly deteriorating effect from this intervention, it is clear that individuals with a likely addictive behavior were at higher risk of having experienced such a negative effect in contrast to the intentions of the intervention. It cannot be concluded that an actual increase in gambling was indeed a consequence of the temporary COVID-19 legislation, but again, individuals with higher levels of gambling problems may be at a particular risk of having an unfavorable course in gambling as a reaction to the crisis. In previous research involving prevention or harm reduction methods in problem gambling, it had been stated that subgroups of gamblers may perceive preventive interventions as annoying in a way that would, theoretically, even worsen their gambling practices. While this has been described as unlikely, it has been stated that problem gamblers may be at higher risk of such reactions than other gamblers [15]. Given the very high levels of gambling and detected gambling problems in this study, it cannot be excluded that such negative reactions to an intervention are responsible for one part of the perceived negative effect in some gamblers. Here, it should be kept in mind that a significant proportion of the study sample expressed negative feelings related to this type of intervention, but somewhat contrary to what could be expected, moderate-risk/problem gamblers had somewhat more favorable attitudes toward it.

The present findings may be considered to corroborate previous findings that individuals who report an increase in gambling during these times of COVID-19 have a markedly higher probability of being problem gamblers [8,21]. While the gambling increase was not measured in relation to the pandemic itself, but in relation to a specific regulation in affected gamblers, it further demonstrates that people with hazardous gambling practices are more likely than others to demonstrate

a negative development during the COVID-19 crisis. Likewise, in a survey study among gamblers in the population, those who gambled even in highly restricted gambling types during the lockdown period when sports were generally cancelled, were a group with markedly higher gambling problems [21]. Among US casino gamblers, when casinos closed, a minority migrated to new types of gambling, but this group demonstrated more problematic levels of gambling [22]. Thus, as a general rule from these studies conducted during COVID-19, including the present setting, high levels of gambling during these times of crisis are more likely to be associated with problematic gambling behaviors.

Meanwhile, it should be kept in mind that all studies in the area have not demonstrated an increasing trend in gambling during the pandemic. In Australia, for example, an increase was not seen [23], and in a Canadian study of land-based casino gamblers, during casino closure, a migration toward online gambling was seen primarily among those who had engaged in online casino gambling before, rather than in the full population [24]. Likewise, early observations from the very first phase of the pandemic did not display obvious increases in online gambling activity [5,6]. In line with this, subgroups of gamblers with manifest gambling problems have even reported the COVID-19 period as relieving, due to a decrease in gambling opportunities during some phases [25]. Thus, it is unclear whether the increase in gambling in a subgroup of respondents here and in response to the imposed deposit limit, may be due to pandemic-related effects or the intervention itself, or simply because of a generally increasing course in the gambling practices of these specific individuals.

It can be debated whether the present data support an effect from the type of intervention imposed or whether the nature of the intervention only may invite gamblers to migrate to other gambling types. Again, it is clear from the present data that at least for some gambling types, individuals with risky gambling habits are more likely than others to transfer their gambling to other modalities or gambling types. This corroborates the findings of survey studies in the population, where individuals who increase another gambling type in response to a limit to one gambling type (in this case, the limitation of sports betting during the lockdown period) are more likely to have gambling problems [8,21]. The present type of intervention appears to have at least a relatively high level of acceptability in affected individuals. A majority had a favorable attitude toward it, and a minority claimed to be against it. However, although acceptability was relatively high, only around 1 in 5 respondents believed they had decreased their gambling with other operators due to the intervention. Thus, while the intervention does not technically prevent an individual from continuing to a different gambling operator after reaching the COVID-19–related limit at the first one, the signaling value of the intervention might decrease gambling at other gambling sites. Here, it should again be remembered that the study sample generally involved a very high level of gambling problems, and it can be suspected that the enforcement of a deposit limit may not necessarily invite reflection and a motivational process of change in the individual in the short term.

Three gambling types stood out as being more commonly reported in problem gamblers owing to an increase in gambling practiced in response to the imposed deposit limit. This included machine gambling and lotteries/number games, as well as online casinos at other operators. Online casino was the most commonly cited. The large role of online casinos in problem gamblers in the present setting has been documented previously; for example, it is by far the most common gambling type reported in clients seeking treatment at a regional gambling unit in Sweden [18]. Thus, it is of great interest to conclude that when gamblers are temporarily banned from one online operator service due to the weekly deposit limit, they most commonly turn to this gambling type but at other operator sites. Moreover, again, it confirms the addictive potential of online casino gambling, which is a highly accessible, rapid, and repetitive type of gambling, as the proportion reporting an increase in that gambling type at other operators was markedly more common among individuals with gambling problems.

Our study sample had very high rates of gambling problems. More than half of the full sample represented at least moderate-risk gamblers, and for the further items studied in the subgroup with awareness of the intervention, moderate-risk gamblers made up a large majority. This is further supported by the fact that a majority reported gambling at more operators, even to the extent that 2 of every 5 respondents had experience of reaching the imposed limit at a different operator. It can be argued that the intervention therefore specifically addressed the targeted group, and therefore, from this study, less is known about whether the intervention plays any role in the remaining population (ie, among people with low nonhazardous gambling practices). Over and above the actual effect of the intervention in those facing the limit, it can be argued that an intervention of this nature may have a didactic effect in individuals without current gambling problems, but who may potentially benefit from advice or from the political signal that gambling is a product with addictive potential and has the risk of severe harm during COVID-19.

Limitations

Owing to the confidentiality protocol applied in this survey study, more detailed data, such as gender, geographical location, and previous gambling habits, were not collected. Thus, individual responses could not be linked to any identifying information or to any prior gambling statistics in the databases of Svenska Spel, for whom the identity of respondents remained unknown. While this successfully maintained confidentiality of the respondents, more in-depth data on risk factors could not be detected, and response data clearly rely on the self-report of participants. As in all self-report surveys, the risk of recall bias or other misinformation cannot be disregarded. Moreover, the limited number of participants, which included the first individuals who responded to the invitation to participate, may constitute a risk of bias, as individuals responding first may potentially have a different degree of involvement in these issues and therefore potentially have a different gambling pattern or different opinions than others. Moreover, it should be kept in mind that the population assessed here was recruited from a single gambling operator, and although it operates in diverse areas, such as sports betting, poker gambling, and chance-based

rapid online games (eg, casino slots and bingo), its profile as a state-owned gambling operator may potentially attract a somewhat different group of gamblers than certain other operators in the market.

A strength of the study is that it, quite uniquely, had the ability of addressing one operator's clients with respect to their gambling at other operators, a type of data that cannot easily be obtained from other sources. The present group is also less likely to be examined in detail in larger population surveys, where the group makes up a small minority with extreme gambling patterns, but it could be assessed here. Moreover, the study had the advantage of being able to address a new COVID-19–specific intervention in relatively temporal proximity to the introduction of the intervention.

Conclusions

In a high-level gambling sample exposed to a government-imposed weekly deposit limit aiming to prevent potential COVID-19–related gambling issues, the acceptability of the intervention was relatively high and somewhat higher in problem gamblers, although many exposed individuals were not apparently aware of having been subject to the intervention. The challenges of a single-operator weekly deposit limit were obvious; many of these exposed individuals subsequently gambled at other operators, and in many cases, they gambled at many operators. Self-reported improvement from the intervention was common and self-reported negative effects were rare, but risk gamblers demonstrated a much higher rate of negative effects and, in particular, a high prevalence of online casino gambling at other operators after being limited by the imposed intervention at the operator studied here. Promising attitudes toward this kind of deposit-limit intervention were seen, but the study identified some difficulties, and it may inspire future development of further types of interventions addressing the overall problem of high-risk gamblers. High-level online gamblers constitute a group with great needs, and the gambling operator's own monitoring may identify this group with potential for receiving harm-reducing and therapeutic interventions.

Abstract

Background: During the COVID-19 pandemic, threats to mental health, psychological safety, and well-being are evident, particularly among the first responders and the health care staff.

Objective: This study aims to examine the prevalence and potential predictors of the likely stress, generalized anxiety disorder, and major depressive disorder among health care workers (HCWs).

Methods: A cross-sectional survey was used through a survey link sent to gather demographic information and responses on several self-report scales, including the Perceived Stress Scale, the Generalized Anxiety Disorder 7-item scale, and the Patient Health Questionnaire-9 among HCWs enrolled in the Text4Hope program.

Results: The result from this study suggests that during the COVID-19 pandemic, HCWs reported a high likelihood of moderate-to-high perceived stress (n=840, 81.2%), moderate-to-severe anxiety (n=369, 38.6%), and depression (n=317, 32.7%) symptoms. Nurses and other HCWs were significantly more likely to report depressive symptoms compared to physicians (F(2, 159.47)=15.89, 95% CI –5.05 to –2.04). Younger age groups of HCWs (≤30 years) were more prone to report likely stress, anxiety, and depressive symptoms compared to HCWs 41-50 and >50 years old (odds ratio [OR] 1.82-3.03). Similarly, females and those who reported a lack of social support (separated/divorced and single) among HCWs had a higher likelihood to report likely stress and depressive symptoms, respectively (OR 1.8 and 1.6, respectively).

Conclusions: This cross-sectional study explored a high level of mental health burdens during the COVID-19 pandemic among HCWs in Alberta. Levels of psychological symptoms were more noticeable in the female gender and the nursing profession.

Introduction

Background

During pandemics, an exponential increase in the demand for health care services takes place. Several factors contribute to increased physical and mental health strain for health care workers (HCWs). This can include long work shifts, a lack of personal protective equipment, and limited resources to care for patients [1,2]. With a lack of PPE, HCWs can feel unprepared to deal with unknown viruses and bacteria. In addition, with pandemic demand–induced limits on resources, such as ventilators or general medical supplies, it can be difficult to care for patients.

In November 2019, a novel coronavirus disease caused by SARS-CoV-2, called COVID-19, was first reported in Wuhan, China. The disease rapidly spread throughout China and prevailed worldwide, resulting in a global health emergency [1]. On March 11, 2020, the World Health Organization declared the COVID-19 outbreak as a global pandemic [2].

Alberta Health Services (AHS) defines health care professionals/providers as "individuals that work in the health field and can include doctors, nurses (RNs, LPNs), dentists, psychologists, physiotherapists, pharmacists, and dieticians, etc" [3]. The nursing staff constitutes the largest health profession in Canada, followed by physicians and other regulated HCWs [4]. As of July 2020, the Canadian Institute for Health Information (CIHI) reported that 19.4% of all confirmed infections of COVID-19 cases were among HCWs in Canada, and in the province of Alberta, it was 8.8% [5]. HCWs are exposed to mental health stresses due to the nature of their work that usually involves trauma and vulnerability [6].

During the 2003 SARS outbreak, HCWs expressed immediate psychological distress manifested as fear and anxiety that exhibited a relative decrease during the early phases of the epidemic [1]. However, depression and posttraumatic stress symptoms emerged later during the epidemic and lasted for longer periods, affecting the long-term mental well-being of HCWs [1]. A greater psychological impact was coupled with the higher risk of exposure to the virus, especially among frontliners, who usually face both heavy workloads and a higher risk of infection [7,8]. One year after the SARS outbreak, HCWs who were in close contact with infected patients or virus material had elevated levels of stress, depression, and anxiety [9].

One study examining the psychological effects of COVID-19 on HCWs in Italy found that depression and posttraumatic stress symptoms are higher in HCWs caring for patients in COVID-19 wards compared to other HCWs caring for patients in other units [10].

Additionally, emotional impacts in terms of contagion fear and infecting loved ones, uncertainty, and stigma were documented among health care staff [11], leading to isolation from their families, changing routines, and a narrowing down of their social support network [12]. During the pandemic of COVID-19, health care professionals declared 5 main requests from their institutions [10]: "hear me, protect me, prepare me, support me, and care for me" [7]. Burnout is also an ongoing problem among physicians and other HCWs during the COVID-19 pandemic. It is characterized by "emotional exhaustion, depersonalization, and a feeling of low personal accomplishment" and attributed to many factors, including heavy workloads, that may exacerbate burnout and negatively impact the overall productivity of the health care system [13,14]. HCWs are predisposed to "moral injury" during the current pandemic, a term that can be defined as *the psychological distress that results from actions, or the lack of them, which violate someone's moral or ethical code*. Although it is not a mental health condition, people with moral injury are more likely to experience negative thoughts about themselves or others, together with intense feelings of shame, guilt, or disgust [15].

During the COVID-19 pandemic, several studies have examined the impacts of the pandemic upon the psychological health and mental well-being of the general population. A number of studies have examined such impacts among HCWs, with many interesting findings; for example, the frontliners and those who have experienced physical symptoms, such as headache, throat pain, and lethargy are at more risk of developing stress, anxiety, and depressive symptoms during the pandemic compared to the other comparative groups [16,17].

In a systematic review assessing the impact of COVID-19 on HCWs' mental health, the authors found that the prevalence of anxiety was estimated between 9 and 90% (median 24%) and depression between 5 and 51% (median 21%) [18]. In another systematic review and meta-analysis, Pappa et al [19] examined 13 research studies to compute the prevalence of anxiety, depression, and insomnia during the current pandemic. The authors reported 23.2% for anxiety and 22.8% for depression. Additionally, discrepancies of the prevalence or severity of such symptoms were reported among different demographic and occupational groups, such as in nurses, women, and frontliners who were usually reported to have more severe symptoms compared to other HCWs [19,20].

Aim and Objectives

This study aims to examine the psychological impacts of the COVID-19 pandemic among different groups of HCWs who were enrolled in the Text4Hope program.

The primary objectives are:

- Studying the demographic characteristics and the prevalence and mean scores of perceived stress, likely major depressive disorder (MDD), and likely generalized anxiety disorder (GAD) among HCWs.
- Studying the predictors of developing likely stress, MDD, and GAD among HCWs.

Methods

Study Design

A cross-sectional survey was used to explore mean differences in perceived stress, anxiety, and depression symptom scores of HCWs enrolled in Text4Hope.

Ethics

The authors assert that all procedures contributing to this work comply with the ethical standards of the relevant national and institutional committee on human experimentation and with the Declaration of Helsinki of 1975, as revised in 2008. Participant consent was implied by submission of the subscribers' survey responses. The University of Alberta Health Research Ethics Board provided ethics approval for this research (Pro00086163).

Recruitment

The study recruitment procedures and sample size estimations are described in a published study protocol [21]. The study participants are subscribers to the Text4Hope program, a daily supportive text message service, launched by the AHS on March 23, 2020, to help Albertans cope with the mental health effects of the COVID-19 pandemic. An online survey link was sent to subscribers who were enrolled during March 23 to May 2, 2020. Subscribers receive free daily supportive text messages, which are cognitive behavioral therapy–based messages created by a team of mental health professionals [22]. In addition to demographic information, clinical characteristics were assessed using self-report scales, including the Perceived Stress Scale (PSS-10; for moderate-to-high stress, PSS≥14) [23], the Generalized Anxiety Disorder 7-item (GAD-7) scale (for likely GAD, GAD-7≥10) [24], and the Patient Health Questionnaire-9 (PHQ-9; for likely MDD, PHQ-9≥10) [25]. The PSS-10 is a validated 10-item questionnaire used to assess the self-reported level of stress in the previous 1 month by assessing thoughts and feelings. Each item on the scale is scored from 0 (never) to 5 (very often). Higher scores on the scale denote higher levels of stress. The GAD-7 is a validated 7-item questionnaire used to assess the self-reported levels of anxiety in respondents in the 2 weeks prior to assessment. It is based on the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* (DSM-IV-TR) symptoms of anxiety. Each item on the scale is scored from 0 (not at all) to 4 (nearly every day). The PHQ-9 is a 9-item validated instrument used to diagnose and measure the severity of depression in general medical and mental health settings; it is the major depression module of the full Patient Health Questionnaire (PHQ). Each of the 9 items on the questionnaire is scored from 0 (not at all) to 3 (nearly every day). It may be used to plan and monitor treatment of depression. Participant consent was implied by submission of the subscribers' survey responses.

Data Analysis

Data analysis was undertaken using the IBM Statistical Package for Social Sciences (SPSS) Statistics for Windows, version 25 [26]. Descriptive analysis illustrated the differences between the 3 categories of HCWs (physicians, nurses, and other) by their sociodemographic characteristics (ie, gender, age, ethnicity, education, relationship status, housing status, and self-isolation/quarantine status) and examined the prevalence of clinical characteristics (ie, moderate/high stress, likely GAD, likely MDD) among the 3 HCW groups.

One-way ANOVA with 2-tailed significance ($P<.05$) was performed to assess the statistical differences of mean scores on the PSS-10, GAD-7, and PHQ-9 among HCW groups. For variables that did not violate the assumptions of homogeneity of variance in the mean scores on the ANOVA test, we performed a Tukey posthoc test. For variables that violated the homogeneity of variance assumption, we used the nonparametric Welch F test and Games-Howell posthoc tests.

To examine potential predictors of the self-reported clinically meaningful symptoms of moderate-to-high perceived stress, likely GAD, and likely MDD, we entered all demographic predictors and self-isolation, along with HCW type, into a multivariate logistic regression model. Correlation analysis was performed before logistic regression analysis to rule out strong correlations among predictor variables. Odds ratios (ORs) from the binary logistic regression analysis were examined to determine the association between HCW type and the likelihood of respondents self-reporting symptoms of moderate-to-high stress, likely GAD, and likely MDD, controlling for the other variables in the model.

Results

Participant Characteristics

Of the 8267 subscribers who responded to the Text4Hope online survey in the first 6 weeks, 1414 (17.1%) self-identified as HCWs, while 1096 (13.3%) provided their specific occupation type. Of these 1096, 63 (5.7%) were physicians, 355 (32.4%) nurses, and 678 (61.9%) other HCWs (eg, occupational therapist, psychologist, dietitian, pharmacist, and first responder). The demographic and clinical characteristics of the respondents are shown in Table 1.

As presented in Table 1, most of the 1096 respondents were female (n=1006, 91.8%), aged 31-40 years (n=330, 30.1%), and Caucasian (n=919, 83.9%); had postsecondary education (n=1066, 97.3%); were married, cohabiting, or partnered (n=852, 77.7%); and owned their own home (n=836, 76.3%). Except for a few variables, nurses represented the highest percentage of these responses.

Table 1. Distribution of the demographic and clinical characteristics by HCW[a] type.

Variables	Physicians (N=63)	Nurses (N=355)	Other (N=678)	Total (N=1096)[b]
Gender, n (%)				
Male	17 (27.0)	10 (2.8)	55 (8.1)	82 (7.5)
Female	46 (73.0)	343 (96.9)	617 (91.1)	1006 (92.0)
Other	0	1 (0.3)	5 (0.7)	6 (0.5)
Age (years), n (%)

[a]HCW: health care worker.

[b]Data were reported according to the provided responses. The total percentages may not add up to 100%.

[c]Multiple responses were possible.

[d]Moderate-to-high stress was defined as PSS-10 score of ≥14.

[e]Likely GAD was defined as a GAD-7 score of ≥10.

[f]Likely MDD was defined as a PHQ-9 score of ≥10.

[g]PSS-10: Perceived Stress Scale.

[h]GAD-7: Generalized Anxiety Disorder 7-item.

[i]PHQ-9: Patient Health Questionnaire-9.

Among the 1096 respondents, 237 (21.7%) reported having self-isolated/quarantined during the pandemic time. Among those who reported their clinical symptoms, most respondents who self-reported moderate-to-high perceived stress were nurses (279/338, 82.5%), while those who self-reported likely GAD and likely MDD were other HCWs (233/591, 39.4%) and (209/596, 35.1%), respectively.

The mean scores for all HCWs were 19.25 (SD 6.34, n=1035) on the PSS-10 scale, 8.32 (SD 5.48, n=956) on the GAD-7 scale, and 7.61 (SD 5.53, n=968) on the PHQ-9 scale.

One-way ANOVA revealed a significant difference among the 3 groups of HCWs only in terms of their PHQ-9 mean scores. The Welch test and Games-Howell posthoc tests showed that physicians (mean=4.46, SD 4.36) scored significantly lower on the PHQ-9 scale compared to nurses (mean=7.42, SD 5.17, 95% CI –4.51 to –1.4, P<.01) and to other HCWs (mean=8.01, SD 5.72, 95% CI –5.05 to –2.04, P<.001).

Logistic Regression

Spearman correlation analysis revealed no high collinearity among the suggested variables (r_s<0.4), so all the variables were entered into the multivariate regression model.

Table 2 presents data indicating that for moderate-to-high likely stress, the model containing the 8 predictors was statistically significant (χ^2_{21}=68.76, P<.001). The model explained between 6.6% (Cox and Snell R^2) and 10.6% (Nagelkerke R^2) of the variance and correctly classified 80.8% of all cases. The type of HCWs did not significantly contribute to the likely stress model among all the HCWs. Controlling for all other factors in the model, age categories made a unique statistical contribution (Wald=34.24, P<.001) to the likelihood that a respondent presented with moderate-to-high stress.

Table 2. Logistic regression predicting likelihood for the respondents among HCWs[a] to present with moderate-to-high stress.

HCWs who were >50 years old were less likely to report moderate-to-high stress during the COVID-19 pandemic compared to respondents who were ≤30 years old, when all other variables in the model were controlled (OR 0.43, 95% CI 0.23-0.79). Although the gender variable did not significantly contribute to the model, females were almost 2 times more likely to report moderate-to-high stress during the COVID-19 pandemic compared to males, when controlling for other variables (OR 2.0, 95% CI 1.12-3.52).

The data in Table 3 indicate that for likely GAD, the 8-predictor model was statistically significant (χ^2_{21}=70.82, P<.001),

explaining between 7.3% (Cox and Snell R^2) and 9.9% (Nagelkerke R^2) of the variance and correctly classified 64.9% of all cases. The type of HCWs did not significantly contribute to likely GAD among all the HCWs. Likewise, age categories made a unique statistical contribution (Wald=41.85, P<.001) to the probability that a respondent presented with likely GAD, after controlling for all other factors in this model. HCWs who were 41-50 years old and those who were >50 years old had a lower probability of reporting likely GAD symptoms during the COVID-19 pandemic compared to those who were ≤30 years old (OR 0.41, 95% CI 0.26-0.66 vs OR 0.33, 95% CI 0.2-0.53).

[e]—: Not applicable.

The data displayed in Table 4 indicate that for likely MDD, the model containing the 8 predictors was statistically significant (χ^2_{21}=69.14, P<.001). The model explained between 7.0% (Cox and Snell R^2) and 9.8% (Nagelkerke R^2) of the variance and correctly classified 68% of all cases. After controlling for all other factors in the model, the type of HCWs made a unique statistical contribution (Wald=6.1, P=.05) to the likelihood that a respondent presented with moderate-to-high MDD. Nurses and other HCWs exhibited a 2 times greater probability of presenting with likely MDD during the pandemic compared to physicians (OR 2.32, 95% CI 1.06-5.10 vs OR 2.60, 95% CI 1.20-5.58). The variable of age categories made a unique statistical contribution (Wald=24.54, P<.001) to the probability that a respondent presented with likely MDD. Like the previous (GAD) model, HCWs who were 41-50 and >50 years old had a lower OR to report likely GAD symptoms during the COVID-19 pandemic compared to those ≤30 years old (OR 0.55, 95% CI 0.34-0.90 vs OR 0.39, 95% CI 0.24-0.65). Although the relationship status variable did not contribute significantly to the model, separated/divorced and single respondents reported a higher likelihood of MDD compared to married/cohabiting/partnered respondents when controlling for other variables (OR 1.80, 95% CI 1.04-3.02 vs OR 1.60, 95% CI 1.07-2.52).

From the 3 models collectively, there was a trend for age, whereby HCWs who were below 40 years old appeared more likely to exhibit psychological clinical symptoms compared to older participants.

Discussion

Principal Findings

Using self-reported data from the Text4Hope service, this study illustrates the different mental health impacts of the COVID-19 pandemic on HCWs, including physicians, nurses, and other HCWs. The study suggests that more than 4 in 5 HCWs expressed a likelihood of reporting moderate-to-high perceived stress rates, while around a third expressed a likelihood of reporting moderate-to-severe anxiety and depressive symptoms during the COVID-19 pandemic. In Muller et al's [18] systematic review, it was determined that the prevalence of mental health distress ranged from 7% to 97%, with a median of 37%. In our study, the prevalence of GAD and depression in HCWs was 38.6% and 32.7%, respectively, which was comparable to the medians reported in the aforementioned 2 systematic reviews [18,19].

In a survey of health care providers in Wuhan, the number of frontline health care providers with depressive symptoms was estimated to be 50.4%, with correlates of nursing profession and female gender [20]. This higher figure compared with the prevalence of depression in our study may be explained by the demographics of the population that study focused on, as most participants were female, nurses, of lower ages, and with a junior technical title that could be considered as elevating COVID-19 exposure risk factors for the development of depressive symptoms [20,27].

Physicians had the lowest prevalence of GAD and depression in this study (20/63 [36.4%] and 9/63 [16.1%], respectively), followed by nurses (116/355 [37.4%] and 99/355 [31.3%], respectively) and was highest in other HCW groups (233/678 [39.4%] and 209/678 [35.1%], respectively). Pappa et al [19] noted similar trends in the prevalence of depression and anxiety between physicians and nurses in their systematic review. Physicians had a lower prevalence of depression (25.4%) when compared with nurses (30.3%), and this was the case for GAD that was found in 21.7% of physicians, while 25.8% of nurses were affected [19].

Compared to the frontline physicians, first responder nurses are more likely to develop behavioral disengagement during similar epidemics, a result highly associated with aggravating levels of depression [28,29]. This may be due to stress and the fear of contracting the infection or spreading it to their families, along with the perceived stigma and sense of uncertainty [20]. Consistent with our research, where nurses were found to be more likely to report moderate-to-severe likely stress symptoms compared to the physicians, in a study carried out in Wuhan, China, nurses were also reported to experience higher levels of different psychological impacts, such as distress, anxiety, depression, and insomnia, when compared to their physician counterparts during the COVID-19 pandemic [20].

Females comprised most of our survey respondents (1006/1096, 92%) and showed a higher likelihood to report stress, GAD, and depressive symptoms compared to their male counterparts. However, this was statistically significant only for likely stress symptoms. This was consistent with other studies. For example, after pooling the prevalence from 6 studies that reported complete data for anxiety symptoms based on gender during the COVID-19 pandemic, Pappa et al [19] reported a lower prevalence of anxiety in males (20.9%) compared to females (29.1%). Conversely, they noted that the prevalence of depression was higher in males (26.9%) than in females (20.3%) [19]. Several studies have demonstrated that being a woman, getting exposed to patients with SARS-CoV-2 infection, and worrying about being infected are the most common risk factors associated with increased mental health problems in HCWs during the pandemic [18].

Younger HCWs were generally at a higher risk of developing likely stress, anxiety, and depression compared to other groups. This finding is aligned with other previous findings that consistently report a higher risk among younger ages during the pandemic [27,30,31]. This may be attributed to the longer duration the younger generation usually spends focusing upon the data of the pandemic or to the lack of experiencing similar stressful situations in their few years of experience compared to older groups, who possibly have passed by similar experiences [27,30].

In our study, the lack of a confiding relationship (separated/divorced and single) appeared to be a risk factor for HCWs to self-report likely depression. It is likely that HCWs who are in confiding relationships have better social supports that those who are single, divorced, or widowed. This finding appears clearly in the literature, where social, family, and friend support is found to be the most commonly reported protective factor associated with a reduction in mental health problems among HCWs [18,32].

Not surprisingly, the younger age group of HCWs expressed a higher likelihood to show likely stress, GAD, and MDD symptoms compared to the other older groups. Additionally, the likelihood to report the 3 clinical conditions of focus in our study seemed to decrease with age, where HCWs who were ≤30 years old were at a higher risk of developing likely stress, GAD, and MDD during the pandemic compared to those who were 41-50 and >50 years old (OR 1.82-3.03). This aligns with previous research that reported the same finding among all subscribers of Text4Hope [27,33]. Relatively little experience and the lack of exposure to similar epidemics in the younger age group could predispose younger people to a greater likelihood of developing maladjustment and mental distress in this context [27,34].

Other researchers are examining COVID-19-related measurements among HCWs across Canada, including exposure to the virus and other mental health parameters [13]. Preliminary results from the other study suggests that there are high COVID-19 infection rates among HCWs and that physicians are more likely than other HCWs to develop mental health symptoms. These results differ from the findings of our study, which suggest that physicians are less likely to develop mental health symptoms during the COVID-19 pandemic compared to nurses and other HCWs. Observed differences between each

study's results could be attributed to differences in data collection periods (eg, early pandemic, during a wave), differences in COVID-19 positivity rates and R values, or even differences in the level of resource strain (eg, bed capacity, worker shortages) on the health care system. Although our data were collected during the early phase of the pandemic, when the health system was not strained, data from an ongoing Canadian study were collected at a later stage of the pandemic, when infection rates were higher and health care systems across Canada were under greater strain.

During the COVID-19 pandemic, some digital initiatives took place to mitigate psychological distress among health care professionals; these included a digital support package on psychological well-being provided for HCWs in the United Kingdom. The package was easily delivered and reached the target group, with a high rate of usage and accepted cost [7]. In a recent review of the literature demonstrating the mental health problems that HCWs are facing during the COVID-19 pandemic, the authors concluded that health authorities need to build multidisciplinary mental health teams in order to mitigate mental health and psychological consequences of the pandemic on both patients and HCWs. It was suggested that electronic media through web apps could be used for this purpose [6]. In Alberta, Canada, the AHS launched a supportive text message program (Text4Hope). The service aims to support the mental health of Albertans during the COVID-19 pandemic and is presented as a feasible and reliable medium for wide-scale data collection for epidemiological research, as illustrated by this report.

Limitations

This study had several limitations. The data were obtained via an online request sent to all subscribers of the Text4Hope service, and there was a risk of selection bias, where the HCWs who responded may have been more interested in the service and not necessarily representative of all HCWs in Alberta. Females also showed overrepresentation in our cohort, which may limit the generalization of the provided results. Additionally, as self-report scales were used in this study and participants were not clinically assessed or confirmed, the results need to be interpreted carefully.

Finally, this was a cross-sectional study with no established baseline prevalence or a control group to compare with. It cannot draw any inferences about the impact of the pandemic on HCWs' mental health; thus, the presented findings may need further similar studies across different timepoints into the pandemic to validate our results.

Conclusion

This cross-sectional study explored the impact of the COVID-19 pandemic on the mental health and well-being of HCWs in Alberta. Overall, we highlighted the prevalence of the psychological distress symptoms in the early phase of the COVID-19 pandemic. Nurses were observed to be at high risk for developing stress, depression, and anxiety during the pandemic. Tracking such symptoms through digitally supported means is highly emphasized, particularly during pandemics where physical contact is not a viable option. Usually, digitally provided programs may yield high fidelity in relation to their acceptability and engagement [35]. Such services are impactful and cost-effective and fulfil essential social distancing requirements with remote delivery.

In the light of time progression and the development of the knowledge around the pandemic and the available vaccination, we aim to examine the changes in these symptoms and their timely progress among the health care providers after 1 year of the initiation of the Text4Hope service. From the literature, positive impacts of similar interventions were reported, in terms of reducing depressive symptoms and increasing the abstinence duration in alcohol use disorder, after 3 months of receiving daily supportive text messages in the community settings [36,37]. The availability of the texting service on most cell phones, and the lack of required software or app downloads to function, rendered text messaging services significantly advantageous over similar technologies (eg, email or messaging apps) [36].

Abstract

Background: The COVID-19 pandemic prompted safety-net health care systems to rapidly implement telemedicine services with little prior experience, causing disparities in access to virtual visits. While much attention has been given to patient barriers, less is known regarding system-level factors influencing telephone versus video-visit adoption. As telemedicine remains a preferred service for patients and providers, and reimbursement parity will not continue for audio visits, health systems must evaluate how to support higher-quality video visit access.

Objective: This study aimed to assess health system–level factors and their impact on telephone and video visit adoption to inform sustainability of telemedicine for ambulatory safety-net sites.

Methods: We conducted a cross-sectional survey among ambulatory care clinicians at a hospital-linked ambulatory clinic network serving a diverse, publicly insured patient population between May 28 and July 14, 2020. We conducted bivariate analyses assessing health care system–level factors associated with (1) high telephone adoption (4 or more visits on average per session); and (2) video visit adoption (at least 1 video visit on average per session).

Results: We collected 311 responses from 643 eligible clinicians, yielding a response rate of 48.4%. Clinician respondents (N=311) included 34.7% (n=108) primary or urgent care, 35.1% (n=109) medical, and 7.4% (n=23) surgical specialties. Our sample included 178 (57.2%) high telephone adopters and 81 (26.05%) video adopters. Among high telephone adopters, 72.2% utilized personal devices for telemedicine (vs 59.0% of low telephone adopters, *P*=.04). Video nonadopters requested more training in technical aspects than adopters (49.6% vs 27.2%, *P*<.001). Primary or urgent care had the highest proportion of high telephone adoption (84.3%, compared to 50.4% of medical and 37.5% of surgical specialties, *P*<.001). Medical specialties had the highest proportion of video adoption (39.1%, compared to 14.8% of primary care and 12.5% of surgical specialties, *P*<.001).

Conclusions: Personal device access and department specialty were major factors associated with high telephone and video visit adoption among safety-net clinicians. Desire for training was associated with lower video visit use. Secure device access, clinician technical trainings, and department-wide assessments are priorities for safety-net systems implementing telemedicine.

Introduction

The COVID-19 pandemic catalyzed a dramatic increase in telemedicine care, prompted by the need for physical distancing and Medicare and Medicaid reimbursement changes enabling parity in coverage for telemedicine [1-3]. Many safety-net and public health systems serving primarily publicly insured, low-income populations [4,5], implemented ambulatory telemedicine with little prior preparation or experience [6,7]. Most safety-net sites provided mainly audio-only telephone visits, in contrast to non–safety-net sites that had prior video visit infrastructure [8]. Video visits have higher patient satisfaction than telephone consultations [9], and policy briefs [10] predict that telephone-only visits will not be reimbursed at parity with video after the pandemic abates [11,12]. As telemedicine becomes integrated into ambulatory care, safety-net health networks must explore factors affecting audio versus video telemedicine visits to maintain reimbursement parity with in-person visits.

Prior studies have found older adults, those insured by Medicaid, or low-income [13] and racial and ethnic minorities receive fewer video visits [14-16]. This has been hypothesized to be due to patient-facing barriers, such a lower digital literacy and lack of patient access to video-enabled smartphone and internet [17,18] and, to some degree, clinician-specific factors. However, a recent analysis of telephone and video visit variation found that practices (38%) and clinicians (26%) drove more of the variation in video visit use than patient-level factors (9%) [18]. System workflows are emphasized as influential for telemedicine implementation in rural sites [19]. Since much of the current literature has focused on patient-level telemedicine barriers to explain differences in telephone versus video visit uptake in the safety-net [9,18,20], we sought to assess other system-level factors influencing telephone and video visit implementation at a large urban public hospital during the first 6 months of the COVID-19 pandemic. Examination of system-level implementation factors during the early transitional phase of telemedicine can inform the adoption and sustainability of video visit use at safety-net sites [13].

Methods

Study Setting

Our study setting was a large, hospital-linked ambulatory clinic network serving an ethnically diverse, publicly insured patient population. This network had limited telemedicine visit capacity prior to the COVID-19 pandemic and began providing telemedicine care on March 3, 2020, with support and infrastructure primarily for telephone visits. Departments and clinicians could provide video visits on an ad hoc basis. All clinic and charting rooms had landlines and access to local area network–connected client computers without webcams. The network developed a standardized electronic health record (EHR) visit type and video visit workflow on June 15, 2020. Details of EHR implementation for telemedicine during the COVID-19 pandemic in this network are published elsewhere [21].

Ethical Considerations

This quality improvement study was exempt from institutional review board review.

Study Participants

We invited all 643 clinicians providing ambulatory telemedicine care to participate via email, with prompts from specialty-specific study champions. We aimed for a response rate greater than 40% given the challenges of surveying clinicians during the COVID-19 pandemic.

Study Instrument

We conducted a cross-sectional anonymous survey via the cloud-based platform Qualtrics. We developed our survey on the basis of key constructs from validated implementation science and telemedicine surveys such as the Telehealth Usability Questionnaire [22-25] and discussions with clinical leaders in the network. The full survey is provided in Multimedia Appendix 1. We conducted pretesting of the instrument at 2 clinical sites from April 20 to May 18, 2020. We distributed the finalized survey from May 28 to July 14, 2020. Reminders were sent by department-specific champions during June 2020.

Primary Outcome Variables: Phone and Video Visit Adoption

To assess telemedicine adoption, we asked respondents, "On average, how many telemedicine visits do you complete per half-day session? Think back to the last month of ambulatory care." Answer options were 0, 1-3, 4-6, 7-9, or ≥10. We dichotomized responses for our two distinct outcomes of interest: (1) high telephone visit adoption (defined as 4 visits per half day or more on average in the last month) and (2) video visit adoption (defined as at least 1 video visit on average per half day in the last month at the telemedicine clinic). We defined "high telephone adopter" as 4 visits or more because telemedicine was still a novel innovation for the delivery system at this time, with almost none prior to March 2020. In June 2020, ambulatory providers had 2-12 visits total per day across specialties (mean 5 visits per day); 4 visits comprise a majority of a day's visits and therefore fits our definition of substantial use. The half day distinction is because of the high proportion of part-time clinicians in this network. For video visits, there was extremely low uptake (<1%) of video visit use across the network [26]; therefore, even experience with 1 video visit per half day on average would signify adopters of video visits. We excluded residents and trainees as they rotated through multiple sites and had inconsistent experiences with telemedicine during this period.

Individual-Level Clinician Characteristics

We assessed demographic characteristics including age, gender, and clinical specialty. Respondents reported their age range (<30 years, 30-49 years, etc.), which we collapsed to a binary variable of <50 versus >50. We categorized gender as male and nonmale (combining female, nonbinary or nonconforming, and transgender entries to minimize identifiability without excluding sexual or gender minorities [27]). We grouped clinical specialty as "primary/urgent care," "medical specialty," or "surgical specialty" (see Table 1 and Multimedia Appendix 2 for all specialty categories included in this survey).

Table 1. Clinician characteristics and self-reported telemedicine use (N=311).

[a]See Multimedia Appendix 2 for all specialty categories included in this survey.

System-Level Variables

System-level factors included the following: perceived workload of telemedicine compared to in-person consultations (more, same, or less), estimated time spent helping patients navigating their telemedicine visit (dichotomized to <5 or ≥5 minutes), ease of interpreter use during telemedicine (Likert scale of 1-4 points, dichotomized to more or less difficult than in-person consultations), desire for additional telemedicine training (with respect to conducting technical aspects of visits, supporting patients with low digital literacy, gathering clinical information, developing an assessment or plan, or teaching trainees), and adequacy of audio or video quality of telemedicine encounters (yes or no). We asked what devices were used for telemedicine encounters; respondents could select smartphone, landline phone, desktop, laptop, or tablet device and specify if these were personal devices or institutional (work-provided) devices; we dichotomized this to "any personal device use" versus "only institutional device use."

Statistical Analysis

We conducted bivariate chi-square tests to assess if individual-level characteristics and system-level variables were associated with high telephone adoption, and, separately, video visit adoption. We conducted a sensitivity analysis including only respondents who had completed ≥50% of the survey for a "complete case" analysis. There were no major differences in including all responses versus "complete case" analysis; therefore, we report all responses available.

Statistical analysis was conducted in SAS software (version 9.4). This was a voluntary study encompassing the entire source population; no power calculation was attempted given the lack of prior reference data on telemedicine during a pandemic to extrapolate to the analysis.

Results

We collected 311 responses from 643 eligible clinicians, which resulted in a response rate of 48.4%. Full demographic characteristics of respondents are listed in Table 1. Primary and urgent care clinicians comprised 34.7%, medical specialists comprised 37.0%, and surgical specialists comprised 7.7% of the participant pool. Of clinicians, 57.2% (178/311) reported ≥4 telephone visits per half day on average. There were 81 of 311 (26.1%) clinicians who reported at least 1 video visit per half day on average. Most respondents (163, 52.4%) used ≥1 personal device (either smartphone, landline phone, laptop, desktop, or tablet device) for telemedicine encounters; 77 (24.8%) physicians used exclusively work-provided, institutional devices.

On bivariate analysis, we found that personal device use was associated with high telephone adoption (Figure 1A; Table 2). Among high telephone adopters, 72.2% (117/163) utilized at least one personal device for telemedicine encounters (P=.04). Personal device use was higher among video visit nonadopters than among video visit adopters, but this was not significant (71.2%, 126/177 vs 58.7%, 37/63, P=.07).

Many video adopters as well as nonadopters expressed interest in many training domains, especially supporting patients with low technical literacy, technical aspects of the visit, and teaching trainees telemedicine (Figure 2). Desire for training in conducting technical aspects of a telemedicine visit was statistically significantly higher for video nonadopters (49.6%) than for video adopters (27.2%, P<.001).

We found that clinical specialty was significantly associated with high telephone adoption and video adoption (Figure 1B). Primary or urgent care clinicians had the highest proportion of high telephone adoption (84.3%, 91/108), compared to 50.4% (58/115) of medical and 37.5% (9/24) of surgical specialties (P<.001). Medical specialties had the highest proportion of video adoption (39.1%, 45/115), compared to 14.8% (16/108) of primary care and 12.5% (3/24) of surgical physicians (P<.001).

We did not find associations between telemedicine adoption and workflow-specific challenges (Table 2). The perceived workload of telemedicine relative to in-person visits, the

estimated average time spent helping set up a patient for a telemedicine visit, and the perceived difficulty of working with an interpreter in a telemedicine encounter were not significantly different between telephone high-adopters or video adopters versus low or nonadopters. Few clinicians reported inadequate audio quality during telephone visits (16/166, 9.9% for high-adopters and 9/91, 12.0% for low adopters). Of video visit adopters, 8 of 70 (13.6%) found audiovisual quality inadequate.

Figure 1. Association between clinician and system-level factors with self-reported high telephone use and any video use, comparing adopters to nonregular/nonadopters. Experience with 4 completed telephone visits in a half day session implies a high telephone adopter, and <4 implies a low telephone visit adopter. 1 video visit per half day on average signifies a video visit adopter. (A) Using at least one personal device is associated with being a high telephone adopter (72.2%, 117/162), compared to 59.0% (46/78) among low telephone adopters (χ^2_1= 4.24, P=.04). Personal device use was higher among video nonadopters than for video visit adopters, but this was not significant (58.7%, 37/63 vs 71.2%, 126/177; χ^2_1=3.31; P=.07). (B) Primary or urgent care specialty had the greatest high telephone adoption (84.3%, 91/108) compared to medical (50.4%, 58/115) and surgical (37.5%, 9/24) specialties (χ^2_1=35.7, P<.001). Medical specialties had the highest proportion of video adoption (39.1%, 45/115) compared to primary care (14.8%, 16/108) and surgical (12.5%, 3/24) (χ^2_1=19.64, P<.001).
Table 2. Association of system-level factors with self-reported high telephone use and any video use, the latter 2 being independent outcomes and calculated separately.

System-level factors (N=311)	Telephone visits per half day				Video visits per half day			
	≥4 visits (n=178), n/n (%)	≤3 visits (n=133), n/n (%)	Chi-square (df)	P value[a]	≥1 video visit (n=81), n/n (%)	No video visit (n=230), n/n (%)	Chi-square (df)	P value[a]
Perceived workload (compared to in-person visits)			2.78 (1)	.10			1.32 (1)	.25
Less or same workload	143/166 (86.1)	71/91 (78.0)			42/70 (60.0)	20/41 (48.8)		
More workload	23/166 (13.9)	20/91 (22.0)			28/70 (40.0)	21/41 (51.2)		
Time helping patients navigate (minutes)			0.0006[a] (1)	.98			0.51 (1)	.47
≤4	131/154 (85.1)	69/81 (85.2)			30/62 (49.4)	13/31 (40.6)		
≥5	23/154 (14.9)	12/81 (14.8)			32/62 (51.6)	19/31 (59.4)		
Ease of interpreter services (compared to in-person visits)			0.02 (1)	.90			1.16 (1)	.28
Somewhat or much more difficult	88/134 (65.7)	34/51 (66.7)			24/31 (77.4)	17/19 (89.5)		
Somewhat or much easier	46/134 (34.3)	17/51 (33.3)			7/31 (22.6)	2/19 (10.5)		
Audio and video quality			1.41 (1)	.24		N/A[b]	N/A	N/A
Not adequate	17/161 (10.6)	12/75 (16.0)			8/59 (13.6)	N/A	N/A	N/A
Adequate	144/161 89.4)	63/75 (84.0)			51/59 (86.4)	N/A	N/A	N/A
Device			4.24 (1)	.04[a]			3.31 (1)	.07
Only institution-provided devices	45/162 (27.8)	32/78 (41.0)			26/63 (41.3)	51/177 (28.8)		
At least one personal device used	117/162 (72.2)[a]	46/78 (59.0)			37/63 (58.7)	126/177 (71.2)		

[a]Significant at P<.05.

[b]N/A: not applicable.

Figure 2. Clinician-identified training needs for conduct of telemedicine, comparing adopters to low/nonadopters. Experience with 4 completed telephone visits in a half day session implies a high telephone adopter, and <4 visits implies a low telephone adopter. Experience with 1 video visit per half day on average implies a video visit adopter. *A higher proportion of video nonadopters stated a desire for training on the technical aspects of a telemedicine visit, compared to video adopters (49.6%, 57/115 vs 27.2%, 28/103; *P*<.001).
Discussion

Principal Findings

Our investigation is one of the few studies assessing system-level factors that might influence multispecialty clinicians' telephone and video visit adoption at a safety-net site in the early phase of the COVID-19 pandemic. Like many safety-net clinics, our telemedicine services were largely telephone-based [8].

We found that many clinicians utilize their personal devices to provide both telephone and video visits. A study of family planning clinicians found high personal smartphone use for telemedicine care during the COVID-19 pandemic, despite respondents' preference for work-issued devices [28]. This raises equity concerns, as not all clinicians will have the same access to high-quality video and audio via their smartphone, tablet device, or computer. In our network, departments variably distributed laptops with video capacity. Privacy and security are concerns if personal devices are used for encounters without appropriate encryption, 2-factor authentication, or HIPAA (Health Insurance Portability and Accountability Act)–approved software [29]. Our system supports a server-based thin client computing environment where most computers are run from a central server. Widespread use of hardware peripherals such as webcams for video visits on such devices increases risk for network instability. This will limit safety-net clinicians who practice on site to reliably use video visits without using or compromising the security of their personal devices [30,31].

We also observed higher personal device use among video nonadopters than video adopters, although this was not significant. This may be due to clinician reluctance to access clinical or HIPAA-relevant video through their personal device, which may be an additional barrier to video visit adoption that warrants further investigation.

Desire for more training in telemedicine was high for video visits, with almost half of video nonadopters requesting training in the conduct of the technical aspects of the visit. The extent and capacity to which clinicians have been trained in telemedicine modalities have been variable throughout the COVID-19 pandemic, and standardized trainings may influence adoption [32].

Although we could not statistically compare telephone adopters against video adopters, we see that barriers such as increased workload, greater time spent supporting the patient, difficulty with the interpreter, and poor audiovisual quality were more common for video adopters than high telephone adopters. In this network, clinicians must provide their own time and support necessary to allow patients to engage in video visits. Direct patient supports, through patient orientations or external services assisting patients in logging into video visits and contacting an interpreter, would drastically reduce these barriers.

Neither perceived workload of telemedicine (compared to in-person care), nor length of time spent supporting a patient to enter a telemedicine visit were associated with telemedicine adoption. Interpreter challenges were not associated with adoption, although this has been endorsed as a barrier by

clinicians [33]. Although safety-net patients may experience access barriers to bandwidth or adequate audio, audio quality was not associated with telemedicine adoption. Our sample size may have been too small to detect a relationship with these factors. Another interpretation is that clinicians using telemedicine during the COVID-19 pandemic were willing to surmount significant patient-level barriers to provide care. As telemedicine continues, it will be important to assess if later adopters will have different responses to these workload-related challenges.

Within this network, there was wide variation in infrastructural support for video visits by department. Some surgical specialties may have needed in-person evaluation rather than virtual visits. These factors likely explain specialty-specific differences in our findings.

Since our survey, telemedicine has become integrated into ambulatory care and is likely "here to stay," both owing to ongoing pandemic surges because of new variants, as well as patient and provider preference for the convenience and access enabled by virtual visits. For example, in this network, telemedicine volume appears to be approaching a plateau of 20%-30% of primary and specialty care, although video visit uptake remains low (internal data). Learning health systems serving vulnerable populations must assess the first years of implementation to optimize video visit delivery for the long term. Without system-level investments, disparities in video visit access may worsen disparities in the safety-net [34]. First, safety-net leaders should assess telemedicine utilization patterns by department to perceive variation in audio-only versus video visits. Reliance on personal device use should be surveyed; future research should query what devices are key for high-quality telemedicine interactions [35,36]. Third, further research should explore facilitators and barriers to video visits in safety-net settings, and identify what skills and trainings are most helpful to support telemedicine practice. Clinician ability to provide video visits will remain a priority in a shifting reimbursement policy landscape.

Limitations

We almost reached a 50% response rate for this voluntary survey among diverse clinicians. Although this was greater than our prespecified target, participants may have differed in their experience of telemedicine compared to nonparticipants. There was high variation in the completeness of survey responses; this was likely owing to the survey burden early during the pandemic. However, we observed no differences in results when comparing all participants to complete case analysis. Owing to survey missingness, we could not generate a multivariable model nor assess for variable interactions. As findings are based on bivariate analysis, they are exploratory and hypothesis-generating for system-level factors that may be related to safety-net telemedicine implementation. As telemedicine workflows were evolving during the survey period, some telemedicine practices may have changed during our assessment; this may have confounded some of our findings regarding specialty-specific differences. However, although a specific workflow was disseminated in June 2020, the same video visit software was available to clinicians over the entire survey period. While our definitions of "high telephone adoption" and "video adoption" were appropriate when we conducted the survey, telemedicine volume will continue to shift and evolve. Comparing the proportion of telemedicine visits to that of in-person visits may be an alternative definition for future studies; qualitative work should also assess how varying specialties choose to optimize their ambulatory schedules between virtual and in-person visits.

Conclusions

Clinical specialty type, personal device use, and desire for technical training were major factors associated with telephone and video visit adoption among safety-net clinicians. Department-level support, assessment of use of personal devices, and clinician training are priorities for safety-net systems.

Abstract

Background: Since the pandemic, more Canadians have reported poorer mental health. A vital group experiencing a high level of stressors consists of health care providers (HCPs) caring for COVID-19 patients, carrying out public health responses, or working with vulnerable populations. The mental health of HCPs is negatively affected by the pandemic, not only at work but also at home and in the community. Intersecting stressors at multiple levels contribute to HCPs' experiences of fatigue, insomnia, anxiety, depression, and posttraumatic stress symptoms.

Objective: The aim of this qualitative study was to explore the pandemic stressors experienced by HCPs at work, at home, and in the community before participating in the Pandemic Acceptance and Commitment to Empowerment Response (PACER) online intervention.

Methods: Informed by a social ecological approach, we used a qualitative reflective approach to engage 74 HCPs in diverse roles. Data were collected during the first 2 waves of the COVID-19 pandemic (June 2020 to February 2021) in Canada.

Results: Informed by a social ecological framework, 5 overarching themes were identified in our thematic analysis: (1) personal level stressors that highlight HCPs' identities and responsibilities beyond the workplace; (2) interpersonal level stressors from disrupted social relationships; (3) organizational stressors that contributed to unsettled workplaces and moral distress; (4) community and societal stressors attributed to vicarious trauma and emotional labor; and (5) the multilevel and cumulative impacts of COVID-19 stressors on HCPs' health.

Conclusions: COVID-19 is not merely a communicable disease but also a social and political phenomenon that intensifies the effects of social inequities. Current understanding of pandemic stressors affecting HCPs is largely partial in nature. Although workplace stressors of HCPs are real and intense, they need to be explored and understood in the context of stressors that exist in other domains of HCPs' lives such as family and community to ensure these experiences are not being silenced by the "hero" discourses or overshadowed by professional demands.

Introduction

In Canada, the COVID-19 pandemic has claimed over 31,000 lives [1]. It has profoundly affected the lives of Canadians, particularly their mental health and well-being. Although everyone is affected by the pandemic, the degree of COVID-19 impact varies across groups and communities. Since the pandemic, more Canadians have reported poorer mental health, particularly women, individuals with chronic illnesses or disabilities, racialized persons, immigrants, and Indigenous peoples [2,3]. A vital group experiencing a high level of stressors consists of health care providers (HCPs) directly involved in caring for COVID-19 patients, carrying out public health responses, or working with vulnerable populations. Emerging evidence in Canada and elsewhere indicates that the mental health of HCPs is negatively affected by the pandemic. HCPs have reported sleep disturbances, fatigue, and episodes of insomnia [4,5] as well as increased prevalence of anxiety [6,7], depressive symptoms [8,9], suicide ideation [8], and posttraumatic stress symptoms triggered by repeated intense stressful experiences and reduced social life [5,10].

During a pandemic, the popular image of HCPs is often limited to individuals in personal protective equipment (PPE) and saving lives. However, behind the masks and full PPE gear, HCPs are people with many social identities, roles, relationships, responsibilities, emotions, and needs. There is relatively limited qualitative research on the experiences of stress and challenges that negatively affect the mental health of Canadian HCPs, particularly those that extend beyond their professional identities and roles. A study with 20 Canadian nurses identified uncertainty, inadequate access to PPE, repeated witnessing of patient deterioration and death, and experience with social isolation as key sources of stress [11]. Two other studies found that HCPs experience increased stressors related to rapidly changing policy, unclear or lack of leadership communication, anxiety about safety for self and family, and tension between meeting the needs of their patients and pandemic protocols [9,12]. Studies in other countries also revealed similar multilevel stressors that affect HCPs' mental health. Additional stressors include caring for and losing one's own infected colleagues to COVID-19, inconsistent guidelines on COVID-19 testing and treatment, ineffective staff redeployment, and staff shortages [13-15]. All these intersecting challenges also contribute to moral distress, which can be defined as the emotional, psychological, and physical suffering that HCPs experience when they carry out their responsibilities in ways that are inconsistent or contradictory to the ethical values, principles, or commitments that they hold deeply [16].

Current understandings of pandemic stressors affecting HCPs are largely partial in nature. Since the beginning of the COVID-19 pandemic, HCPs (especially nurses) have been hailed as "unsung heroes" by politicians, the mass media, and the general public. In their poststructural analysis of over 70 documents in mass media and social media on "nurses as heroes," Mohammed and colleagues [17] argued that the hero discourse positions nursing as "model citizens" and "a necessary sacrifice," whereby heroism is the reward. When taken together, the hero discourse imposes a new form of subjectivity and normalizes nurses' exposure to workplace risks. We further argue that the hero discourse has created a spotlight that solely focuses on the professional identity and roles of HCPs, negating the multiple identities that constitute their "holistic self" and their everyday lived experiences that are inseparable and indistinguishable in their intertwined home-work-community life. Thus, while workplace stressors of HCPs are real and intense, they need to be explored and understood in the context of stressors that exist in other domains of HCPs' lives. In the context of a pandemic, stressors can be understood as an ever-present condition that threatens the health or well-being of individuals [18].

To date, an overwhelming majority of empirical studies on pandemic-related stressors among HCPs are quantitative in nature and report specific measurable aspects of stressors that are often decontextualized. Qualitative research on this topic is needed to provide insights on the multilevel contexts of how HCPs experience and are impacted by COVID-19 stressors. In this paper, we report on the qualitative data collected from HCPs who self-identified as experiencing a high level of stress and wished to enroll in an online stress-reduction intervention designed for HCPs and affected communities. The results presented contribute to addressing the gaps in our current understanding of pandemic stressors experienced by HCPs in the Canadian context.

Methods

Study Setting: The PACER Intervention

The Pandemic Acceptance and Commitment to Empowerment Response (PACER) intervention [19] is an evidence-informed 6-week online training based on the Acceptance and Commitment to Empowerment (ACE) model. ACE is an innovative integration of the mindfulness-based Acceptance and Commitment Therapy (ACT) [20] and the social justice-based Group Empowerment Psychoeducation (GEP) [21]. It has been applied effectively in previous in-person interventions to reduce stigma and promote resilience. Recognizing the growing mental health needs of frontline HCPs and constrained by pandemic lockdowns, we developed the PACER intervention, which consists of 6 weekly online self-guided learning modules, each lasting 1 hour, accompanied by weekly 90-minute facilitated online group video-conferencing sessions. Prior to engaging in the first online learning module and first group sessions, participants were invited to complete a sociodemographic survey and questionnaires that consisted of both quantitative and qualitative questions (see the Procedure section).

Ethical Review

This study was reviewed and approved by the Research Ethics Boards at Ryerson University (2020-123), University Health Network (20-5210), and York University (2020-096).

Participants

We used convenience and snowball sampling, supported by targeted outreach and recruitment via circulations of e-flyers through our collaborators, nursing professional associations, hospital bulletins, community networks, and social media. The participation criteria were self-identifying as 18 years of age or older, being a service provider in the health care sector, experiencing high levels of stress related to the COVID-19 response, and interested in joining the PACER training. HCP participants in this study included registered nurses (RNs), registered practical nurses (RPNs), personal support workers, physicians, medical residents, social workers, counsellors, therapists, and other clinical or community-based personnel.

A total of 74 HCPs enrolled and took part in PACER between June 2020 and February 2021: 63 (85%) self-identified as female, 10 (14%) self-identified as male, and 1 (1%) self-identified as transgender. Most participants were under 40 years of age: 20-29 years: 10/74, 14%; 30-39 years: 38/74, 51%; 40-49 years: 14/74, 19%; 50-59 years: 9/74, 12%; and 60-69 years: 3/74, 4%. When asked about the ethnocultural communities they identified with, about one-half of the participants (38/74, 51%) indicated that they identified with the Canadian community, while the other one-half (36/74, 49%) identified with multiple communities including African, American, Chinese, Filipino, Haitian, Irish, Hong Kong, Taiwan, Jewish, and Latinx. Participants came from a wide range of health and social care professional backgrounds and roles such as primary care, psychiatry, nursing, social work, public health, community health practitioners, therapists/counsellors, administrative staff, environmental service staff, and volunteers.

Procedure

Before data collection, online informed consent was obtained from all participants. Once enrolled, participants were invited to complete a pre-intervention questionnaire that consisted of sociodemographic questions and measures on general mental health distress, psychological flexibility, and resilience. These measures were repeated immediately post- and 3 months postintervention. In addition, prior to Session One of the intervention, we used qualitative open-ended questions to explore participants' self-identities and experiences with pandemic stressors. Specifically, we invited participants to describe "who you are" and "the impact of COVID-19 on your work and your life—what has been challenging for you."

Analysis

The focus of this paper was on the pandemic-related stressors reported by participants in the qualitative questions before they engaged in the 6-week online intervention and online group sessions. Responses from the online questionnaires were downloaded, and pseudonyms are used in this paper to protect participants' identities. Our thematic analysis was informed by the social ecological framework [22], which allowed us to examine the sources of stressors experienced by HCPs at multiple interconnected levels [23]: personal (identity, social position), interpersonal (family, relationships, social networks), organizational (operational characteristics, formal and informal rules), community contexts (relationships among organizations and institutions), and societal (local, provincial, and national guidelines and policies) [24]. This approach enabled us to make sense of how different synergistic factors and contexts intersect to shape the experiences with pandemic stressors among HCPs.

The first 4 authors, under the guidance of the last author, conducted thematic analysis [25] using both inductive and deductive approaches. First, we engaged in repeated readings of the participant responses to gain a broad understanding of the data. Second, we identified and developed thematic codes inductively based on the ideas and perspectives articulated by the participants (ie, data-based coding). Third, guided by our research purpose and the social ecological framework, we applied deductive analysis that enabled us to connect the data to the sociocultural contexts and structural conditions that shaped the experiences of the participants [26,27]. Fourth, the team engaged in multiple rounds of interpretive discussions to arrive at the agreed themes presented in this paper. In the last round of thematic interpretation, all authors took part to discuss the nuances and contexts of the narratives under each theme to arrive at a holistic interpretation.

Results

Informed by a social ecological framework, 5 overarching themes were identified in our thematic analysis: (1) personal-level stressors that highlight HCPs' identities and responsibilities beyond the workplace, (2) interpersonal-level stressors from disrupted social relationships, (3) organizational stressors that contributed to unsettled workplaces and moral distress, (4) community and societal stressors attributed to vicarious trauma and emotional labor, and (5) the multilevel and cumulative impacts of COVID-19 stressors on HCPs' health.

Personal Stressors: Identities and Responsibilities Beyond the Workplace

Stressors at the personal level emphasize the identities and responsibilities of HCPs above and beyond the workplace that participants encountered in their day-to-day lives. Many participants expressed fear and worries about bringing the SARS-CoV-2 virus home to their elderly family members or loved ones with existing health problems.

> *My husband had been undergoing intensive chemotherapy and radiation treatment at [a cancer care hospital], and was halfway through a year of treatment... I was very scared that I might contract the virus at work and bring it back to our house... and impact his access to his next treatment.* [Sharon, 30-39 years, female, children's rehab coordinator, Canadian]

It is also important to note that HCPs are not only service providers; some relied on accessing services to meet their own health needs or the needs of their family members. Hence, service disruptions are not only felt professionally but also personally at home or in their communities.

As the parent of a child with dual diagnosis I already feel isolated from society. My son is not capable of wearing a mask and as a result we have not been to any activities together since the first lockdown... My son does not understand the restrictions and has been suffering from lack of social interaction and engagement in his community. [Kathy, 30-39 years, female, behavior therapist, Canadian]

To meet the demands of their multiple roles and responsibilities, some participants had to make use of available resources to mitigate some of these struggles. Sun, an RN, had to rely on her elderly in-laws to care for her toddler while she was at work. Meanwhile, she also expressed her concerns:

[We] fear the potential transmission of COVID-19 to my in-laws as they are of higher risk from pre-existing medical conditions and advanced age." [Sun, female, 30-39 years, RN and case manager, Chinese-Canadian, Hong Kong]

Sun's fear was echoed by other HCPs living in multigenerational households comprised of vulnerable elderly adults and young children.

Interpersonal Stressors: Disrupted Social Relationships

Similar to all Canadians, many participants identified disruptions to routines and structures in their personal life as stressors. Social distancing and quarantine measures had heightened participants' sense of isolation and loneliness where social relationships are vital resources in fostering HCPs' resiliency. For participants with many demands and responsibilities, travelling is not merely a leisure activity but a coping strategy to reduce stress. Andrew, who had to manage demands from school, work, and family, indicated that his once-a-year vacation was "a breather" from his stressful life. He further explained:

The vacation time is my only chance to see my family, who lives in the Philippines. As the pandemic unfolds, all my plans are put on hold." [Andrew, male, 30-39 years, RPN in retirement facility, Filipino-Chinese]

For participants with transnational family and social ties, pandemic travel restrictions resulted in prolonged separation and disconnection from their families. Those with elderly or sick family members felt additional challenges.

The biggest issue was, my mother is in advanced Alzheimer's back in India and her health had started to decline. Prior to [the] COVID-19 outbreak, I had booked a flight for India, which of course got cancelled. [Priya, female, 40-49 years, RPN in geriatric care facility and BScN student, South Asian]

Furthermore, while the pandemic had forced many participants to put their plans on hold, it had not stopped other critical events from taking place around the world. Participants with families and loved ones in Iran, India, and the United States expressed a sense of powerlessness and worries due to the pandemic situation worldwide.

I have felt very helpless while watching the effects of COVID tear through the U.S., on top of all the other crises that the country is currently facing. I spend a lot of time worrying about my parents and I have had difficulty focusing on my schoolwork. [Adam, male, 20-29 years, graduate student in clinical psychology, American]

Participants' sharing illustrated that, in addition to their demands as frontline HCPs, they also shouldered many demands similar to the general population, even though these stressors were overshadowed by discourses of their professional demands.

Organizational Stressors: Unsettled Workplace and Moral Distress

Not surprisingly, HCP participants encountered many workplace stressors, ranging from increased health risks related to direct exposure to COVID-19, changes in work routines and workloads, and the need to wear PPE all day. At the beginning of the pandemic, uncertainty about COVID-19 created a lot of fear among HCPs, particularly those with less formal biomedical or health care training. Matthew, an environment service staff member in a hospital, expressed tremendous fear toward COVID-19.

When I was assigned to clean rooms where there were patients with COVID-19... I was too scared to communicate with the patients. I limit our conversation by just answering yes or no. I feel very guilty because of my fear... I am working again tomorrow, I hope I will not encounter a patient with COVID." [Matthew, male, 30-39 years, environmental service staff, Filipino]

For some HCPs, their fear was not limited to personal safety but extended to the uncertainty and demands of keeping their staff and patients or vulnerable service users safe.

At times I feel overwhelmed that my support is not sufficient in supporting a large team. Stressed by the ongoing changes, angry at the impact it's having on the homeless community and the lack of acknowledgement frontline staff in shelters and homelessness services receive. [Tracy, female, 40-49 years, community practitioner, Canadian]

The rapid changes in the workplace routines and structures also led to considerable distress that altered or strained participants' interpersonal relationships with their patients, colleagues, and other staff. For Kathy, a behavior therapist working with children diagnosed with autism spectrum disorder, it was difficult to carry out her work with PPE:

I miss being able to high five my clients and look into their eyes unobstructed by PPE in order to read the small changes in their expressions. [Kathy, female, 30-39 years, behavior therapist, Canadian]

Other HCPs were concerned about access to safe PPE due to previous experience of receiving defective PPE.

Many participants identified deployment as a major source of stress. One RN experienced anger and resentment "when colleagues were redeployed to other areas of the hospital," but her team was "expected to maintain the same caseload with less human resources" [Sun, female, 30-39 years, RN, Chinese-Canadian, Hong Kong].

Marianna, who was deployed to work in nursing homes, recalled the stress and exhaustion:

> It was a bit stressful to learn 3 different positions within 3 months... I often worked overtime and weekends, so it left long stretches of very little time for myself and my family. [Marianna, female, 40-49 years, RN, Portuguese Canadian]

In addition to deployment and increased workload, some HCPs experienced moral distress when their efforts to provide safe and quality care to their vulnerable patients were compromised by the rapidly changing policies at work, as Giselle explained:

> Most of our patients have a history with mental health challenges and trauma. While my workplace is based on a harm reduction philosophy, it felt like we were also re-traumatizing our patients due to the new COVID-related policies. [Giselle, female, 20-29 years, RN, Filipino]

Similarly, Ariana expressed her moral struggles and dilemma in attending to the special needs of families in her clinic.

> Families... having their kids with behavior and mood challenges at home with them, much reduced access to in-person and out-of-home respite and other services... I am the point person for families... Ethical dilemma of having to medicate children to keep everyone sane and safe when we know it's the circumstances brought about by COVID-19 restrictions that is making things worse. [Ariana, female, 50-59 years, clinical nurse, Canadian, Welsh]

Other participants expressed concerns about workplace opacity and suggested that their employers had used pandemic emergency protocols to implement "different priorities" without consulting staff and patients. When participants' concerns about safety and accountability toward patient care were dismissed, they were left feeling undervalued and disempowered.

> When feedback was provided to management in regards to concerns about safe practice and lack of proper transfer of accountability between teams... I was met with ridicule and publicly humiliated, which caused me to feel insignificant, with feelings of powerlessness. [Sun, female, 30-39 years, RN and case manager, Chinese-Canadian, Hong Kong]

As the HCP participants encountered stressors of an unsettled workplace, many also struggled with the moral distress of weighing the quality of care they could realistically provide to patients against the safety of self and others. Other stressors included guilt for minimizing interactions with clients for fear of contracting the virus, the impact of services on staff and clients working with vulnerable populations, or feeling dismissed when concerns about workplace policies and practices are brought to the attention of administrators.

Community and Societal Stressors: Vicarious Trauma and Emotional Labor

Another stressor faced by HCPs during the pandemic is the intensified emotional labor placed on them at work. There seemed to be a collective resonance of vicarious trauma expressed by participants who witnessed the suffering of their patients or service users.

> Witnessing the impact of Covid-19 on seniors and feeling helpless has a negative impact on my own mental health. One lonely senior passed away and one senior's cat was missing, that especially hit hard on mental health. [Margaret, female, 50-59 years, community health promoter, Chinese-Canadian, Mainland China]

Amy, who witnessed and experienced the collective suffering, expressed her feelings of sadness:

> Clients are dying alone or with the touch of a gloved hand; loved ones are not able to say their goodbyes; and questions are not always answered... makes me feel drained emotionally and physically... and it has made me feel guilty. [Amy, female, 30-39 years, RN and NP student, African-Canadian]

As caregivers, HCPs often carried the emotional "burdens" of suppressing their own feelings while supporting and reassuring their loved ones, colleagues, patients, and service users who were in distress. Some of them also experience vicarious trauma as they witnessed the inequities and social oppressions experienced by individuals, families, and communities they worked with.

> It has been devastating to see the inequity and injustice around, who has been most impacted by the pandemic, and this is evident in the families I support. Community resources are stretched and limited so there are less options for support. This has resulted in higher demands on our service. All of this combined has left me feeling more depleted and less hopeful. [Julia, 40-49 years, social worker of children living with disabilities, Canadian]

Peggy, a Chinese-Canadian, described the pain in witnessing the most marginalized in the Asian Canadian community be further marginalized during the pandemic, due to "loss of income, mental health deterioration from social isolation, school closures, and experiences of anti-Asian racism" [female, 30-39 years, youth mental health clinician].

The demands of pandemic challenges were also felt by participants in management positions. Some of them felt inadequate when they were faced with concerns about the psychological and physical safety of both their staff and patients. This emotional labor could be difficult to bear when their efforts were met with abusive behaviors from the service users, as Louisa indicated:

> Over the course of the past several months, I have been subject to ongoing verbal abuse by patients and families, who disagree with the COVID-19 related precautions that have been implemented. [Louisa, female, 30-39 years, hospital clinical manager, Canadian]

Other HCPs reported experiencing overwhelming feelings of anger, frustration, worry, sadness, confusion, loneliness, helplessness, and burnout. Sun, who worked as a case manager, recalled:

...there was a period between April and June where I felt overwhelmed and started experiencing bitterness and resentment toward being a health care provider. [Sun, female, 30-39 years, RN, Chinese-Canadian, Hong Kong]

Despite the overwhelming emotional demands and sense of uncertainty, some participants were also inspired by a sense of collectivism. Many commented on the strength they received from sharing a strong sense of team spirit that brought value and meaning to their work.

The collaboration and teamwork! The all-hands-on-deck approach to my organization's response to the pandemic. It was not as smooth, but the teamwork was visible in ensuring that staff are aware of policy changes or updates. [Julian, male, 30-39 years, RN, Filipino-Canadian]

Other HCPs derived their sense of strength and optimism by focusing on "being part of a team working toward a greater goal, that we are all in this together, and a shared understanding of what it is to be a front-line worker during a pandemic" [Kamal, female, 30-39 years, intensive care unit nurse and critical care research coordinator, Canadian, Indian]. Hence, despite all the challenges encountered by HCPs, there were factors and contexts that promoted a sense of togetherness and connection with others, which can help foster resilience.

The Multilevel and Cumulative Impact of COVID-19 Stressors on Health

As highlighted in the previous themes, participants experienced multiple ongoing and compounding pandemic stressors in the domains of work, home, and society that undoubtedly impacted their physical, psychological, and emotional health and well-being. These impacts can also be considered stressors in and of themselves because dealing with the impact of these challenges simultaneously contributes to secondary stressors.

COVID-19 and the quarantine process has led to a collective trauma, even those whose physical health is functioning, but they are impacted emotionally... I have had moments of wanting to end my life back in April. [Jess, gender-fluid, 30-39 years, health discipline student, Canadian, Hong Kong]

Others described a range of physical problems from feeling drained, tired, burned out, concerns regarding sleep, poor concentration, and feeling tension and pain in their bodies. In some cases, individuals had pre-existing health conditions that worsened during the pandemic.

I am currently undergoing physiotherapy because I suffered a hip injury two years ago. Closure of the facility where I receive physiotherapy services [has] been a significant factor why I experience pain while I work. I only rely on my daily stretches and pain medications to cover-up the anticipated pain that I will experience at work. [Matthew, male, 30-39 years, environmental service staff, Filipino]

For some HCPs, deployment and workplace chaos had taken a toll on their mental health, yet they felt guilty and blamed themselves.

When I was redeployed to an entirely new department my anxiety intensified, to the point that I needed to seek accommodation to work from home. During this time I had negative thoughts about myself, including thoughts that I was weak, that I was letting my colleagues down, or that I should be able to handle this better. [Julia, 40-49 years, female, social worker in field of disabilities, Canadian]

Other HCPs prioritized the needs of others, sometimes to their own detriment because they neglected their own emotional and psychological needs.

I felt like I lived ten years. I felt like I was in a war for a long time. I stayed up till 3:30 in the morning for almost 2 months. I slept about 2 or 3 hours then went to work. I had to do 14 shifts straight without a day off due to staff shortage... I feel powerless to control my own life. [Lynn, 50-59 years, RN in long-term care (LTC) home, Chinese Canadian]

For Grace, the mother of an adult son with developmental disabilities, the pandemic made her feel anxious about the future of her son.

COVID has also highlighted painful thoughts about what would happen to my son if anything should happen to me... COVID has made me think more about my own mortality and how much work is still left to be done to prepare my son [who is an adult with developmental disabilities]. [Grace, female, 60-69 years, parent advisor in developmental disability sector, Canadian]

Participant responses in this section illustrate the multilevel and cumulative impact of pandemic stressors experienced by HCPs that were often intricately connected to pre-existing sociocultural contexts and structural conditions of their lives, as in caring for children with disabilities or managing new and existing psychological distress.

Discussion

Principal Findings

In this paper, we applied a social ecological approach to make visible the complex synergistic stressors experienced by HCPs at home, at work, and in the community. The main findings of the study highlighted 5 key pandemic-related stressors experienced by HCPs that manifested at the personal, interpersonal, organizational, community, and societal levels. Taken together, the findings contribute to a more holistic understanding of the stressors and impacts experienced by HCPs during the first 2 waves of the COVID-19 pandemic in Canada.

Many of these stressors were shaped by pre-existing structural conditions. Although many of the workplace-related stressors for HCPs (eg, fear of getting infected, anxiety related to uncertainty, rapid changes in protocols, deployment, staff shortage) identified in this study are consistent with what has been reported in the emerging literature and news reports [13-15], this study offers insights drawn from participants' qualitative reflections to contextualize and illustrate how workplace stressors interact with other stressors in the everyday

lives of HCPs to negatively affect their physical, emotional, and mental health. We also illustrate how the experiences of individual HCPs are nested in organizational practices, which are shaped by structural influences and power relations in society.

At the personal and interpersonal levels, most of the participants were also caregivers before and after work, as daughters and caregivers of elderly family members, mothers of young children, or caregivers of loved ones living with special needs, disabilities, or serious illnesses. Yet, their personal life was intricately connected to their professional life and shaped by structural conditions. With or without the pandemic, unpaid and unrecognized caregiving in both the public and private realm is well recognized to be "invisible labor" that is also gendered and racialized [28,29]. In 2020, women made up over 80% of all workers in health care and social services in Canada [30]. Racialized immigrants, particularly adults from the Caribbean, Africa, and Southeast Asia, are overrepresented in nursing and health care support occupations, and over 58% of these adult immigrants with international training were overqualified for their employment [30]. Reflective of the statistics on the Canadian health care workforce, 85% of our 74 HCP participants self-identified as female, and about 50% identified as belonging to diverse ethnocultural communities beyond English and French. Most of the participants were nurses, social workers, LTC activity aides, counsellors, and therapists.

At the personal and professional levels, the hero discourse has posed many psychological dilemmas for HCPs. They are expected to be strong, invincible, all-enduring, and willing to sacrifice their personal well-being for the common good. When faced with the challenges of sustained long work hours, workplace chaos, physical and emotional exhaustion, and frequent experiences of vicarious trauma, this glorified expectation of self-sacrifice discourages HCPs from recognizing and embracing their limitations, leading to negative self-judgment, feelings of guilt, and a sense of incompetence that further compromise their mental health. In addition to workplace demands, they also have to attend to the physical, psychosocial, and spiritual needs of their family members and loved ones at home. When the hero discourse creates a spotlight solely on the professional identities and roles of HCPs, little attention is afforded to the multiple interdependent identities, experiences, and mental health needs of HCPs beyond their workplace. The results of this study enable us to highlight the seldom explored research gap of understanding the experiences of HCPs as both service providers and service users.

HCPs living with elderly family members or family members with weakened immune systems often function as protective agents as well as caregivers at home. During pandemic lockdowns, HCPs who are family caregivers of children or adults living with disabilities and special needs have to carry out specialized care, and the boundary between family caregiving and service provision becomes blurred. The required efforts to perform specialized care at home have created a double-bind paradox in which they have become unpaid service providers in their personal lives, while also having to maintain their highly demanding health care provision role at work. The multilevel intersecting stressors had taken a toll on the physical

and mental health of HCPs, resulting in sleep disturbance, bodily pain, anxiety, anger, emotional exhaustion, burnout, and even suicidal ideation. Indeed, the Registered Nurses Association of Ontario (RNAO) Work and Wellness Survey [31] showed that 60% of respondents reported very high to high level of stress.

At the organizational level, the hero discourse has also created additional challenges for HCPs. Expressions of concern about workplace pandemic protocols, staff deployment, and shortage of protective equipment as well as questions about organization transparency may be dismissed as unimportant or a sign of individualistic selfishness. As indicated by some study participants, the hero discourse does not address HCPs' frustration and distrust toward policy makers and institutions. Decades of neoliberal practices of austerity, decentralization, privatization, underfunded regulatory regimes, a culture focused on financial efficiency, and increasing controlled and standardized care work in the health and social care sectors have contributed to this distrust [28,32], which is heightened by the chaos, uncertainty, and unprecedented demands of the pandemic. Furthermore, despite making up over 80% of the health care workforce, there are disproportionately fewer women and racialized HCPs in leadership and decision-making positions within the health care system [33]. These structural inequities may help to explain the distrust and the sense of powerlessness expressed by participants. In addition, although established evidence shows that empowerment work environments and meaningful engagement of staff in decision-making are critical mitigating strategies to reduce burnout among HCPs [34,35], policy makers within the health care system have failed to address the challenge of burnout, leaving HCPs at increased vulnerability to burnout and distress during the pandemic [36]. Indeed, 13% of RNs aged 26 years to 35 years reported in the RNAO Work and Wellness Survey that they were very likely to leave the profession after the pandemic [31].

At the community level, many HCPs also experience moral distress [37] associated with a collective visceral resonance of fear, grief, empathy, stress, and anger as they witnessed the devastating impact of COVID-19 (death, loss, social isolation, xenophobia, and racism) on their patients, service users, co-workers, as well as vulnerable groups in the community. For some HCPs, the experience of moral distress intensified during the pandemic lockdowns when medicating children with behavioral challenges (attention deficit hyperactivity disorder, autism spectrum disorder) seemed to be the only viable option to prevent mental health crises of the affected families. For others, the frequent witnessing of patients "dying alone" and having to comfort them with "the touch of a gloved hand" are poignant reminders that the pandemic is not merely a communicable disease that threatens life and brings death; it is an unprecedented phenomenon that disrupts our taken-for-granted sociocultural values and desired practices of dying with dignity, surrounded by loved ones, and comforted by human connections of touch. The witnessing and partaking in these difficult situations left some participants with a sense of helplessness. The so-called pandemic new normal is anything but normal when services are shaped by the fast-changing protocols across the education, community care, and public health sectors, in which care work is deeply rooted in shared

humanness between the care providers and care recipients [38,39].

At the societal or public policy level, the contributions of HCPs were not valued. During the COVID-19 pandemic, HCPs (especially nurses) have been hailed as "unsung heroes" by politicians, the mass media, and the general public [17]. Although the hero discourse has raised public recognition of the important contributions of HCPs, it has not amounted to anything to improve the well-being and pay equity of HCPs. Since November 2019, HCPs in Ontario had been calling the government to repeal Bill 124 without any success. Bill 124 restricts the wages of HCPs (who are mostly women) to a maximum of 1% even though the inflation rate has been over 2% over a decade, and other frontline professionals such as police and firefighters (who are mostly men) are not subject to this bill [17]. Bill 124 illustrates that the hero discourse is merely an empty rhetoric that does not provide any support needed by HCPs. In the Work and Wellbeing Survey of over 2100 nurses, conducted by the RNAO in early 2021, 81% of the respondents reported receiving very poor to fair support from the government, and 59% reported receiving very poor to fair support from their employers [31].

Amid the challenges and demands at work, some participants expressed their desire and commitment to ensure quality care for their patients and service users. For some, the workplace struggles served as a catalyst in strengthening their interpersonal connections with colleagues. The "we are all in this together" spirit seemed to have provided them with a sense of stability amid all the chaos and struggles. Indeed, many participants expressed a deep sense of altruism or responsibility to provide instrumental, psychological, and emotional support to their peers and those affected by the pandemic. This altruistic desire to help others seemed to help give meaning to their stressful work. Thus, the hero discourse is paradoxical in that it functions both as a stressor and a protective anchor. However, altruistic contributions and sustained stressors are often accompanied by adverse health consequences as indicated in the previous paragraphs.

Implications for Policy and Practice

Consistent with the results of this study, 2 decades of research on large-scale epidemics and pandemics have shown persistent and pervasive negative personal impacts on the mental health of HCPs, including increased anxiety, burnout, and posttraumatic stress symptoms [40-42]. In addition, there is established evidence to show that organizational factors like staffing shortage, high workload demands, high work stress, low teamwork, low supervisor support, and work-life imbalance contribute to burnout and high rates of turnover [43-45]. In the fourth quarter of 2020, the job vacancy rate in health and social care increased to 4.7% [46]. The negative impact of COVID-19 on the mental health of HCPs has likely intensified the job vacancy rate. Thus, during a pandemic, it is imperative for health and social care organizations to attend to the mental health and emotional needs of HCPs.

Since the mental health of HCPs during the pandemic was influenced by complex and dynamic interplay of personal, interpersonal, organizational, community, and societal factors,

a multiprong approach is necessary to mitigate these complex stressors. The RNAO Work and Wellness Survey [31] showed that, while 60% of respondents reported very high to a high level of stress, only 8.6% used mental health support through their employers, and only 1.1% used the provincial helpline. Instead, 49.6% sought support from their spouse, family, and friends, and 28.5% sought support from their colleagues. These results suggest that structured peer support programs at work may be an important strategy to maintain mental health of HCPs during a pandemic. Other organizational support such as flexible scheduling, destigmatization of help-seeking, and free programs that support HCPs to develop self-awareness of stress, self-care, and stress reduction are important. Free programs that apply mindfulness, music therapy, relaxation techniques, online workout, peer support, and one-on-one counselling have been found to be effective in stress reduction [47-49].

Additionally, providing timely and effective multiway communication and feedback can enhance social relationships and foster strong social support networks for HCPs within their organizations. Frequent timely communication of accurate, clear, and accessible information about the pandemic with HCPs of all levels is critical. At the same time, mechanisms for HCPs to report concerns, ask questions, and provide feedback to changing protocols are critical. Organizations may benefit from the real-time insights and feedback from the staff to refine their changing protocols. Although it is often impossible for organizations to adopt all suggestions from all staff, thoughtful responses to questions and concerns can be constructive in building and maintaining a collective vision, especially during a period of uncertainty and rapid change. Using peer liaison leaders in every department can enhance effective communication, build trust, and promote a sense of belonging among staff.

Finally, at the societal or public policy level, pandemic preparedness needs to be underpinned by the principles of social justice and equity. Across Canada, over 80% of the COVID-19–related deaths occurred in LTC homes [50]. Low wages, scarce sick benefits, and part-time employment meant that many LTC staff were working in multiple LTC homes, and some might have continued to work while they were ill [50,51]. Thus, existing inequitable distribution of resources within the health care system (eg, hospital vs LTC facilities), inadequate regulation of LTC homes, pay inequity for nursing staff, and the lack of access to full-time employment experienced by racialized staff in the lower ranks of the HCP hierarchy must be addressed.

Limitations

In this study, we engaged participants who are reflective of the HCP workforce in Canada (ie, 85% self-identified as female), as well as ethnoracially diverse participants reflective of the Greater Toronto Area (close to 50% self-identified as belonging to visible minority groups). We have drawn on the qualitative reflection of participants to provide insights on the multilevel, intersecting sources of stressors experienced by HCPs amid a global pandemic. However, there are some study limitations. Since we used convenience and snowball sampling in recruitment, the range of HCP participants we engaged with

might be limited. Furthermore, the self-reflective method did not allow us to engage in more in-depth exploration of specific phenomena that might have emerged from follow-up questions. As this is a qualitative component of the study, we did not generalize our findings. Rather, we have provided important contexts about the sources of stressors in the different domains of the participants' lives, which are useful to guide follow-up research, programs, and policies in the postpandemic period. To reduce possible biases of the researchers toward a particular perspective, we have presented our theoretical framework, engaged team members with different disciplinary perspectives, and kept an audit trail of our analysis process including transcripts of responses, coding, and notes or recordings documenting decisions made in the study.

In addition, this paper reports only on the results of the qualitative component of a broader intervention study. It focuses on the sources and contexts of stressors experienced by HCPs during the first 2 waves of the pandemic. It does not include results on the feasibility and outcomes of PACER, which are beyond the scope of this paper. However, the evaluation protocols of PACER have been published elsewhere [19]. The evaluation of PACER is currently underway to examine the effectiveness of PACER in reducing the psychological impact of stress, improving mental health outcomes, and promoting resilience but is beyond the scope of this paper.

Conclusion

Insights from this study demonstrate that COVID-19 is not merely a communicable disease but is also experienced as a social and political phenomenon. The reflections of HCP participants based on their lived experiences were situated within a social ecological perspective to provide a broader, more holistic understanding that reveals how personal and interpersonal experiences are shaped by power relations at organizational and societal or policy levels. Applying a socioecological lens allows for multilevel analysis that provides a deeper awareness of pre-existing challenges in the health and social care systems that become magnified during the pandemic. From a public health standpoint, it is critical for government and policy makers to engage HCPs in postpandemic discussion and also respond to pre-existing structural issues that contribute to the mental health stressors of HCPs. Finally, interventions from the individual to public policy levels to address the identified stressors must extend beyond the workplace identities and roles of HCP but to also include multidimensional aspects of their lives and consider home, community, and societal contexts. Thus, areas for future research could explore stressors according to the different types of job among HCPs, as well how stressors are experienced by HCPs from different identities, for example, deeper exploration of the stressors on HCPs from racialized or gendered identities and how they are impacted by these stressors.

Authors' Contributions

CS, AA, and JPHW led the data analysis and drafted the manuscript. MKA and PDG conducted the literature review and contributed to data analysis. ATWL, KF, MKLP, and MV provided critical reviews of the thematic analysis and contributed to revision of multiple drafts of the manuscript. All authors have reviewed and agreed that the final version of the manuscript reflects accuracy and integrity of the study.

How Vaccine Ambivalence Can Lead People Who Inject Drugs to Decline COVID-19 Vaccination and Ways This Can Be Addressed: Qualitative Study

Abstract

Background: People who inject drugs are disproportionately impacted by SARS-CoV-2 and COVID-19, yet they do not frequently accept vaccination against SARS-CoV-2 when offered.

Objective: This study aimed to explore why people who inject drugs decline free vaccines against SARS-CoV-2 and how barriers to vaccination can potentially be addressed.

Methods: We conducted semistructured qualitative interviews with 17 unvaccinated adult persons who inject drugs during August and September 2021 at a New York City syringe service program, where approximately three-fourth of participants identified as Latino (55%) or African American (22%). Interviews lasted roughly 20 minutes. The interview guide examined reasons for declining vaccination, participants' understanding of COVID-19 risks, and how messages could be developed to encourage vaccine uptake among people who inject drugs.

Results: Participants acknowledged that they faced increased risk from SARS-CoV-2 owing to their injection drug use but feared that long-term substance use may have weakened their health, making them especially vulnerable to side effects. Fears of possible side effects, compounded by widespread medical mistrust and questions about the overall value of vaccination contributed to marked ambivalence among our sample. The desire to protect children and older family members emerged as key potential facilitators of vaccination.

Conclusions: Community-developed messages are needed in outreach efforts to explain the importance of vaccination, including the far greater dangers of COVID-19 compared to possible unintended side effects. Messages that emphasize vaccines' ability to prevent inadvertently infecting loved ones, may help increase uptake. Community-focused messaging strategies, such as those used to increase HIV and hepatitis C virus testing and overdose prevention among people who inject drugs, may prove similarly effective.

Introduction

People who inject drugs face drastically increased risk of exposure to SARS-CoV-2, the virus that causes COVID-19, and are far more likely to experience severe complications, including death, if they develop COVID-19 [1]. Because COVID-19 principally targets the lungs, it can be especially harmful to individuals who experience respiratory toxicity due to opioids [2,3] (this includes overdose-related respiratory depression) [3] and presents additional risk to polysubstance users who inject opioids and smoke tobacco, cannabis, crack cocaine, or other drugs.

People who inject drugs are frequently homeless [4] or living on streets or in unhygienic settings that severely limit their access to clean water and handwashing [5]. Many also experience crowded, poorly ventilated conditions in shelters and group living settings that make social distancing impossible [5]. The close personal contact required to obtain drugs introduces additional risks of SARS-CoV-2 infection [6], which further increases if people share drugs or equipment. Moreover, to reduce the risk of overdose, People who inject drugs are frequently advised not to inject alone because if something went wrong, no one would be around to help them. Unfortunately, while this prevents overdose deaths, it can cause additional COVID-19 risk.

At the same time, owing to stigma [7,8], lack of access to health care [5], and widespread medical mistrust [9] rooted in a history of discrimination and systemic racism, many people who inject drugs, who are most at risk, are highly unlikely to get vaccinated. Prior research indicates that before the current pandemic, people who inject drugs frequently avoided testing and treatment for hepatitis C virus (HCV) because they feared inappropriate or disrespectful treatment from medical staff [9]. Likewise, although hepatitis B virus (HBV) infections are frequently attributed to injection drug use, people who inject drugs are less likely to vaccinate against HBV compared to those who do not inject drugs [10], and among persons who inject drugs who do vaccinate against HBV, two-thirds of individuals do not complete the 3-dose vaccination series [11]. A recent study shows nearly half of individuals with substance use disorders (SUDs) are unwilling to vaccinate against COVID-19 [12], underscoring the critical need for new messaging and enhanced outreach to this population.

For African American and Latino people who inject drugs, the disproportionate impact of COVID-19 can be especially deadly [1,5]. COVID-19 has been concentrated in African American and Latino communities nationwide [13,14] since the start of the pandemic, and the effects are clearly visible in New York City [15-17], where this study was conducted. In parts of the South Bronx and East Harlem—New York City areas with mostly African American and Latino populations—COVID-19 deaths per 100,000 people reached roughly 10 times those in majority White areas of Manhattan [16]. Nonetheless, in a survey published in late 2020, fewer than half of African American respondents and fewer than two-thirds of Latino respondents indicated that they would receive COVID-19 vaccines if they were available free of charge [18]. In a 2021 study, 60% of White respondents said that they would get vaccinated against COVID-19, but only 36% of African Americans indicated that they would [19]. A 2021 nationwide study of vaccination rates by race, ethnicity, and state found that although numbers are improving among underrepresented groups, relative uptake rates of COVID-19 vaccination among White adults were higher by a median factor of 1.3 times compared to African American adults and by a median of 1.3 times compared to Latino adults as well, highlighting the need to promote vaccine equity [20].

There is a rich history of messaging guided by evidence-based theories of behavior change (eg, Social Cognitive Theory [21] and the Information, Motivation, Behavioral Skills Model [22]). This includes studies examining how messages can be tailored for, and evaluated among, specific groups (eg, underserved populations who attend church [23]; African American and Latino adolescents [24]). In the course of multiple National Institutes of Health–funded studies designed to encourage health behavior change among underserved populations, our team has developed a methodology focused on community members' expertise. We first conduct in-depth qualitative interviews to understand barriers to, and facilitators of, specific health behaviors among members of a selected population, and then iteratively develop technology-based interventions in response. We have used this methodology to increase HIV testing among emergency department patients [25,26], to increase HIV and HCV testing and overdose prevention among people who inject drugs [27], and to encourage people who inject drugs to carry naloxone kits to reverse overdose events [28]. Accordingly, to inform technology-based intervention messaging aimed at encouraging African American and Latino people who inject drugs to vaccinate against SARS-CoV-2, our team conducted qualitative interviews to examine why people who inject drugs in low-income, historically disadvantaged communities in New York City choose not to get vaccinated. This study describes our initial findings.

Methods

Overview

A purposive sample of unvaccinated people who inject drugs (n=17) was recruited in August and September 2021 from individuals receiving services at a community-based syringe service program (SSP) with a participant base of mostly African American and Latino people who inject drugs in New York City. Staff from the SSP recruited participants in a drop-in-center at SSP headquarters. Participants were recruited from the population of people who come to the organization for a host of services on a weekly or daily basis. Eligibility criteria for interviewees included injection drug use within the past 90 days, and not having received a vaccination against COVID-19, both assessed via self-report. Once it was determined they were eligible, they were referred to members of our research team who explained details of the study. To ensure both anonymity and to prevent duplicate responses, we used program participants' existing SSP anonymous identifiers as their study identification. After participants provided verbal informed consent, 1 of 2 project staff members—who are

coauthors of the current paper—conducted interviews on site in private rooms at the SSP. Interviews lasted approximately 15-30 minutes and were audio-recorded and transcribed verbatim by a third-party service. Participants received US $20 cash at the end of the interview as compensation for their time.

Interviews were conducted in English and Spanish by project staff, using an interview guide developed by the principal investigator (PI) with input from the full project team, including members of the partnering organization. Preliminary interview topics were developed from an exhaustive literature review on vaccine hesitancy and COVID-19. Two members of the study team who were experienced qualitative interviewers and researchers conducted semistructured interviews that explored both barriers to and facilitators of COVID-19 vaccination including the following: COVID-19 knowledge, sources of information, perceptions of vaccine risk, vaccine uptake, vaccination settings, stigma, medical mistrust, and policy-related barriers to and facilitators of vaccination. As part of the discussion of potential facilitators, interviewers asked participants to suggest messages our team could share with other people who inject drugs to increase vaccination rates. The study team also collected demographics from study participants, including race and ethnicity, gender, and primary language spoken at home.

Transcripts were analyzed through thematic analysis. Following completion of each audio-recorded interview, the digital file was promptly transcribed by external transcription services: REV.com for English language interviews and Datagain Services for interviews conducted in Spanish. The PI made sure interview files did not contain any identifying data before submitting them for transcription. Coding was conducted using MAXQDA qualitative analysis software.

Our team met weekly to conduct preliminary analysis of the interview transcripts to identify broad thematic categories addressed in each interview and to discuss these identified thematic categories which consisted of both a priori constructs (based on the aims of the study and the interview guide) and emerging themes (that were related to the study aims but not specifically anticipated). An initial code list was developed from the interview guide and project aims. To expand this preliminary code list, a small subset of interviews was jointly analyzed by 3 team members, and codes and coding strategies were then discussed by the larger team.

Three team members, including 2 who also conducted interviews, used an inductive or deductive approach to analyzing the interviews using a combination of a priori and emergent code categories to identify some of the barriers to and facilitators of COVID-19 vaccination [29]. Additional codes were added during discussions with community partners at the SSP. Codes were compared for thematic consistency and discrepancies were processed during regular team meetings to ensure intercoder reliability. Two authors then independently coded the remaining 15 transcripts, frequently meeting with the study team after coding sets of five interviews to discuss and resolve any coding discrepancies by consensus.

To characterize the range of reasons for declining a vaccination and the most salient ones, we calculated the frequency with which themes were endorsed by study participants. This is not to imply that our qualitative data can be generalized to larger populations of people who inject drugs or to vaccine decliners, but to better characterize the range of themes that emerged among a population of people who inject drugs in New York City. As other qualitative studies have suggested, infrequently endorsed themes can be as important for designing public health interventions as frequently endorsed ones [30]. Once we reached a point where no new thematic areas were identified in newly conducted interviews, we determined by consensus that saturation had been reached; at this point, we completed scheduled interviews and stopped recruiting new interviewees. This process resulted in a total of 17 interviews.

Ethical Considerations

All procedures, including the interview guide, were approved by a single governing institutional review board, BRANY (protocol number 21-039-524), and the study participants provided informed consent.

Results

Participant Characteristics

Seventeen people who reported injection drug use in the past 90 days and had not been vaccinated were interviewed for this study. Participants identified as male (n=11, 64.7%) and female (n=6, 35.3%). The majority of participants identified as Hispanic or Latino (n=11, 64.7%), 5 (29.4%) identified as Black non-Hispanic, and 1 (5.9%) identified as White non-Hispanic. A chief goal of our research was to keep interviews brief and focused on why participants declined vaccination and how potential barriers to vaccination could be addressed. An additional important goal was to protect the privacy of respondents. As a result, we did not include questions about participants' backgrounds beyond self-reported race and gender.

Barriers to Vaccination

Participants described multiple reasons for not getting vaccinated, ranging from a fear of side effects (both known and as of yet undiscovered), to misinformation and medical mistrust, as well as questions about whether the vaccines were even needed. Participants also reported understanding they faced increased risk of SARS-CoV-2 exposure because of their injection drug use, but said they feared long-term drug use could have weakened their immunity and overall physical condition, rendering them especially vulnerable to negative vaccine side effects. Details of related findings, accompanied by specific quotes illustrating each emerging theme, appear below.

Side Effects (Endorsed by 17 of 17 Interviewees)

This fear of side effects included not only immediate reactions, but also reports of people who took the vaccine and within days or weeks developed other health problems or died. These fears appear compounded by concerns the vaccine was released only a short time after the first cases of COVID-19 were reported: "six months later, we got a vaccine. How did they do that?" [Interviewee 6, Hispanic man]. Accordingly, a number of participants reported a desire to wait and see if additional negative effects would emerge over time.

I don't want to get it, and then, you know, three months from now, all of a sudden, um, people who are 40 and under are dying because they, they're, something with the vaccine, how it interacts with our, our brain chemicals as we reach the age of 40. … I've been waiting to see. You know? I'd say five years would be a good period of time to get all the ducks in a row, to know if it's worth it or not. [Interviewee 14, non-Hispanic White man]

I'm like wait a minute … there's a chance I'm taking. I know it's a- it's a better thing for me, like just do it and get it out the way and- and hope not to catch the virus. But it's another thing for me to think "Wait a minute, but if I do it what will happen to me?" I'm not sure I might get a side effect, a bad side effect, some- you know, detrimental to my life or whatever. [Interviewee 7, Hispanic man]

I literally seen somebody caught a reaction next to me on the bus, just came off from getting the Johnson & Johnson. They never made it out of the bus without the paramedics. So, um... I don't know. I want to, but I don't want to. I don't know how it's gonna look in the future. I don't know how the future will be. I was gonna... I was just gonna put that to the future, but... I'm pretty sure they're gonna come up with something better, with vaccines. [Interviewee 6, Hispanic man]

As highlighted by the last quote, many participants claimed firsthand knowledge of someone who became ill after vaccination. However, it remains unclear how many of these incidents are attributable to the vaccine, and which might still have happened (eg, a person getting sick on a bus) even if the person had not vaccinated.

Mistrust (Endorsed by 9 of 17 Interviewees)

Interview data indicate that other theories are circulating and spread by social media and television, as well as by close friends and family members, and they have created strong barriers to vaccination.

You see the TV. You have Farrakhan, Minister Farrakhan. "Don't take this vaccination. It killed this one, it killed that one." … "Oh, the government is putting a chip inside you" and so on and so on. [Interviewee 15, Non-Hispanic Black man]

Lotta people don't vaccinate because they say, "Oh," 'scuse my language, "Oh, that's bullshit," you know. 'Scuse me for expression. You know, "That's, that's, it's a lie or it's the fake. It's just the government, you know, trying to, another way of keeping track of you," you know, and stuff like that. [Interviewee 3, Hispanic man]

Barriers Specific to People who Inject Drugs (Endorsed by 5 of 17 Interviewees)

Two additional themes that emerged through our interviews appear specific to people who inject drugs. Some participants indicated that maintaining a relatively healthy lifestyle, combined with steps they take to protect themselves from HIV—such as only using new syringes and not sharing injection equipment—would protect them from COVID-19 just as well as vaccination:

I've been doing good with my own regimen. You know, washing my hands, eating right, so on and so on. I've been doing good so far and I figure I don't need it. [Interviewee 15, Non-Hispanic Black man]

Other participants recognized that the close contact of social interactions related to drug use made them increasingly vulnerable to COVID-19 and therefore required additional safeguards. At the same time, some within our sample questioned whether the toll that years or decades of drug use had taken on their physical health made them even more susceptible to potential vaccine side effects.

Especially as drug users … it attacks us first. Because we come in contact with all different kind of people and they be high and they don't take care they life … They don't take, medicate, nothing … So we are high risk. So therefore as, as us being high risk, we should be at the door, knocking at the door like bang, bang, bang, let me in. [Interviewee 13, Non-Hispanic Black woman]

Well I've been a drug user for a lot of years, number of years, and I don't know if my body will be able to take- I'm not- I'm not sure about catching certain side effects that can be detrimental to my life. You know? … I'm scared of that fact that I don't know what to expect. I mean I know I have a better chance at surviving from getting at if I am vaccinated. However … if I do take the vaccination I'm not sure what might happen to me. You know? I'm not sure if I might get a side effect … or die. Die from it because of my drug use over the years. [Interviewee 7, Hispanic man]

Facilitators

Interviews with our sample of unvaccinated people who inject drugs also established a number of potential vaccination facilitators. Participants spoke of wanting to protect family members from inadvertent exposure, especially children who were too young to receive vaccination and older adults who, in general, faced greater risk from COVID-19. Participants also reported that simply discussing the increased risk of COVID-19 exposure among substance users might facilitate vaccination uptake, if handled correctly. Interview data underscore the value of phrasing intervention messages in positive terms (eg, "getting vaccinated will help you because…"), and the importance of not making intervention recipients felt as though vaccination is being forced upon them.

Protecting Family and Members of One's Social Network (Endorsed by 5 of 17 Interviewees)

Children, mothers, and grandmothers all emerged as potential facilitators of vaccination among our sample. As noted earlier, participants expressed a strong desire to protect their families. In addition, participants noted that mothers could prove to be excellent messengers for and models of vaccination uptake.

I would tell them to do it, that they should think about their children, they wouldn't want that to happen to

their children, or anybody else. [Interviewee 1, Hispanic man]

If my mother tells me. She has told me so many times too. She is vaccinated too. My mom. Thank God. And she is fine. … And my grandma. Thank God, they are already fine, and they are vaccinated. [Interviewee 16, Hispanic man]

Importance of Vaccination for People who Inject Drugs (Endorsed by 9 of 17 Interviewees)

Similar to concerns about vaccination among people who inject drugs, which emerged among our sample, themes about messages that would facilitate vaccination among people who inject drugs emerged as well. These included messaging about the increased dangers of injection drug use during the pandemic, which again underscore the risks stemming from the close personal contact associated with injection drug use:

> *I recommend vaccination to any person using drugs on the streets. They should be vaccinated, because they are on the streets, and they don't know who they may infect if they are infected. You don't know … When you use drugs, you interact with many people, and you may infect many people. So, I would tell them to get vaccinated as soon as possible. That's what I say.* [Interviewee 17 Hispanic man]

Importance of Positive Message Tone (Endorsed by 17 of 17 Interviewees)

Suggested methodologies to increase vaccination among people who inject drugs also included simple reassurance as a facilitator, including telling people that they would not be left alone in their time of need.

> *Something like that, "If you're afraid, I'll go with you." Yeah … just to encourage them by saying that it does- I, I, it doesn't hurt, you know. Only take a couple of seconds, and, and it's over. And you're good.* [Interviewee 9, Hispanic man]

Lastly, although our sample only included people who had not vaccinated against COVID-19, some participants indicated that the process of discussing their resistance to vaccination during study interviews and describing how they might explain the importance of vaccination to someone else left them more likely to accept a vaccination if one were offered.

> *I would say, "Listen … with me, myself, I never got the vaccine." I will try 'cause, you know, really, I, I'm scared, but ... I'm sitting here with you, so that's why I'm try- I would like to get the vaccine.* [Interviewee 11, Hispanic woman]

Discussion

Principal Findings

In many ways, our sample may be described as more "vaccine ambivalent" than "vaccine hesitant" or "vaccine resistant." Interview data show participants are clearly aware of their increased risk of COVID-19 exposure, and that participants understand the importance of vaccination to prevent illness. At the same time, participants expressed concerns about the vaccines' safety, and whether a possible weakening of their bodies owing to injection drug use has intensified the danger of possible vaccine side effects. In addition, participants in our sample, like others in our society, describe a seemingly endless stream of social media misinformation, often repeated by close friends and family members, which actively discourages vaccination. Together, these issues have left our participants unsure what steps they should take to protect themselves and what sources of information they can trust.

This ambivalence becomes more important to address as the danger of COVID-19, specifically among substance users, is increasingly well documented. According to a large, nationwide study conducted by the National Institutes of Health and researchers at Case Western Reserve University [31], risk of hospitalization and death from COVID-19 is strongest among those recently diagnosed with opioid use disorder (OUD), which includes heroin injectors. Further, among individuals recently diagnosed with OUD, risks are significantly stronger among African American people who use opioids than among White people who use opioids (risk among Hispanic or Latino people who use opioids was not specifically analyzed by the study) [31]. Thus, given the composition of our sample in which the majority of participants were by far African American or Latino, it would be logical to expect that an understanding of these risks would in itself encourage vaccination. Nonetheless, interview data indicate that barriers to vaccination described above, and in particular those related to potential side effects, strongly discouraged participants from getting vaccinating even when they clearly understood their increased risk from COVID-19 and expressed a desire to protect themselves and people close to them.

Participants repeatedly mentioned that they feared their history of drug use would exacerbate the dangers of potential side effects, possibly to the point that vaccination might prove deadly. These concerns may be particularly difficult to dispel among people who inject drugs, who are contemplating vaccination and, in fact, appear to have scientific merit. Clinical trials for the approved COVID-19 vaccines did not explicitly include participants with SUD, and there are no current systematic studies examining the real-world effectiveness of COVID-19 vaccines among SUD or populations of people who inject drugs [32]. Additionally, a large nationwide analysis published in October 2021 indicates that fully vaccinated people who were diagnosed with SUD are at significantly higher risk for breakthrough infection than fully vaccinated people who have not been diagnosed with SUD [32]. Thus, although it is completely understandable when an interviewee says they want to wait 5 years to see if vaccination is worthwhile and safe, curtailing the spread of COVID-19 among people who use drugs and others at the highest risk of infection requires far more immediate action.

Some interviews suggest participants became more amenable to vaccination during their discussions with our team. This may indicate that simply allowing interviewees to voice their concerns about vaccination without being judged or silenced encouraged participants to consider the benefits of vaccination and left them feeling empowered to make positive decisions

about protecting themselves. A similarly supportive and noncoercive approach could potentially encourage vaccination—and health care utilization in general—on a wider scale among people who inject drugs and other members of marginalized, high-risk populations, especially if paired with messaging designed to address known barriers to vaccination and emphasize facilitators (eg, "No matter what you do we want you to be safe, and the best way to keep yourself, your kids, and people you care about safe from COVID is to vaccinate"). This type of strategy, rooted in the idea of low-threshold access to health care via harm reduction services [33,34], could prove particularly valuable if vaccine mandates are shown ineffective among our target population. Not all the people who inject drugs in our sample have jobs; hence, employer mandates might not fully increase vaccination rates. Similarly, many people in our sample might not seek to dine at restaurants or visit museums; hence, related vaccination requirements may similarly have little effect.

Next Steps

Building upon our team's participatory methodology, we now plan to create a series of digitally delivered intervention messages based on the aforementioned findings, including short videos and SMS text messages to encourage vaccination among people who inject drugs, who initially decline. All steps of intervention development and evaluation will include continued involvement among people who inject drugs, including ongoing monthly meetings with a community advisory board who we have consulted since August 2021.

Limitations

This study is not without limitations, the first one related to the generalizability of a fairly small sample recruited at a New York City SSP. Owing to the relative saturation of area harm reduction services, participants may feel less stigma and may therefore be more open to discussing substance use and related health issues, including decisions to decline vaccination. This may also be a strength of our study, as interviews conducted in a supportive SSP environment may have resulted in more detailed,

and possibly more honest, participant responses. Additionally, our analyses show the themes discussed in this study emerged among a number of interviews. This suggests current data may represent larger topics of concern among people who inject drugs in the New York City area. Further research is warranted to examine whether similar themes would be present among additional populations of people who inject drugs nationwide.

Conclusions

Effectively encouraging vaccination among people who inject drugs remains a public health priority. If members of populations of people who inject drugs, who are generally already greatly underserved by health care, do not get vaccinated in adequate numbers, SARS-CoV-2 can continue to spread and mutate into potentially more dangerous variants. Appeals to protect the health of loved ones and the safety of the larger community have been successfully employed to encourage important health behaviors among populations of people who inject drugs, such as HIV or HCV testing and prevention along with overdose prevention and reversal. Developing intervention materials that depict trusted community members (eg, recognizable peer educators and individuals with compelling personal stories) delivering clear, nonjudgmental messages may prove especially helpful now. Similarly, organizations that currently offer services to people who inject drugs, including SSPs or other community-based organizations, can facilitate vaccination by offering easy access to vaccines on site (people may be more likely to accept a vaccine offer from someone they already know and trust, especially if they do not have to travel to an additional location).

Importantly, data from this study show that people who inject drugs often remain reluctant to get vaccinated even when they understand the dangers posed by COVID-19, and the increased safety vaccines can offer to them and their families. Given historic vaccine hesitance and medical mistrust among people who inject drugs, combined with pervasive concern about possible side effects, interventions are urgently needed to effectively offer vaccines in ways those most in need will actually accept them.

Abstract

Background: How do health systems in the United States view the concept of merger and acquisition (M&A) in a post-COVID 19 "new normal"? How do new entrants to the market and incumbents influence horizontal and vertical integration of health systems? Traditionally, it has been argued that M&A activity is designed to reduce inequities in the market, shift toward value-based care, or enhance the number and quality of health care offerings in a given market. However, the recent history of M&A activity has yielded fewer noble results. As might be expected, the smaller the geographical region in which M&A activity is pursued, the higher the likelihood that monopolistic tendencies will result.

Objective: We focused on three types of competition perceptions, external environment uncertainty–related competition, technology disruption–driven competition, and customer service–driven competition, and two integration plans, vertical integration and horizontal integration. We examined (1) how health system characteristics help discern competition perceptions and integration decisions, and (2) how environment-, technology-, and service-driven competition aspects influence vertical and horizontal integration among US health systems in the post-COVID-19 new normal.

Methods: We used data for this study collected through a consultant from a robust group of health system chief executive officers (CEOs) across the United States from February to March 2021. Among the 625 CEOs, 135 (21.6%) responded to our survey. We considered competition and integration aspects from the literature and ratified them via expert consensus. We collected secondary data from the Agency for Healthcare Research and Quality (AHRQ) Compendium of the US Health Systems, leading to a matched data set for 124 health systems. We used inferential statistical comparisons to assess differences across health systems regarding competition and integration, and we used ordered logit estimations to relate competition and integration.

Results: Health systems generally have a high level of the four types of competition perceptions, with the greatest concern being technology disruption–driven competition rather than environment uncertainty–related competition and customer service–driven competition. The first set of estimation results showed that size, teaching status, revenue, and uncompensated care burden are the main contingent factors influencing the three competition perceptions. The second set of estimation results revealed the relationships between different competition perceptions and integration plans. For vertical integration, environment uncertainty–related competition had a significant positive influence ($P<.001$), while the influence of technology disruption–driven competition was significant but negative ($P<.001$). The influence of customer service–driven competition on vertical integration was not evident. For horizontal integration, the results were similar for environment uncertainty–related competition and technology disruption–driven competition; however, the significance of technology disruption–driven competition was weak ($P=.05$). The influence of customer service–driven competition in the combined model was significant and negative ($P<.001$).

Conclusions: Competition-driven integration has subtle influences across health systems. Environment uncertainty–related competition is a significant factor, with underlying contingent factors such as revenue concerns and leadership as the leading causes of integration plans. However, technology disruption may hinder integrations. Undoubtedly, small- and low-revenue health systems facing a high level of competition are likely to merge to navigate the health care business successfully. This trend should be a focus of policy to avoid monopolistic markets.

Introduction

Background

The COVID-19 pandemic in 2020 transformed several aspects of the health care industry. Across the United States, health systems had to activate emergency plans, and cancel elective procedures, patient visits, and many nonessential activities, all while adopting remote and virtual communication care delivery models. As a result of the pandemic, providers have faced many new challenges and opportunities. Some of the financial and operational challenges have led to integrations among health systems to survive in the postpandemic "new normal," with several health systems planning mergers and acquisitions (M&A) involving billions of dollars.

The rise in health care M&A is not entirely new; indeed, it has been increasing over the last decade, with total deals amounting to US $200 billion [1,2]. In 2020-2021 alone, several mergers worth billions of dollars have been in the spotlight. Recent announcements of UnitedHealth's US $13 billion acquisition of Change Healthcare, Centene's US $2.2 billion purchase of Magellan Health, Anthem's deal for MMM Holdings in Puerto Rico, and Cigna's acquisition of the urgent care telehealth provider MDLIVE exemplified both horizontal and vertical integration progressions in the US health care industry in 2021.

M&A reflects two underlying phenomena in the health care business: (1) competitive dynamics and struggle for survival, and (2) integration to solve competitive threats. This study focuses on relating competition perceptions and health systems' integration plans, using data reported by chief executive officers (CEOs) in early 2021.

The objective of this study was two-fold. First, we sought to examine how health system characteristics lead to competition perceptions among health systems, as reported by CEOs in 2021. We assessed the differences between environment-, technology-, and service-driven competition perceptions in health systems with different characteristics, including size, region, ownership status, teaching status, revenue, number of physicians, and number of hospitals, among other factors.

The second objective of this study was to examine how these three types of competition perceptions influence vertical and horizontal integrations of US health systems in the post-COVID-19 new normal. Delineating competition perceptions and integration plans will help guide strategies and policies in health care.

Competition Perceptions and Integration Plans

Beyond the recent disruptions due to COVID-19, health systems have been facing at least three types of competitive threats over the last decade, driving integrations more than ever before. First, uncertainties stemming from scientific developments have kept some health systems at the forefront of treatment, while others

follow the developments [3]. For example, Detroit-based Henry Ford Health System and East Lansing–based Michigan State University partnered (as an integration, but not a merger) in 2020 to establish a fully integrated cancer program [4]. Similarly, fueled by expanding scientific horizons to care delivery, Atrium Health and Wake Forest Baptist Health merged to form a next-generation academic health system [5].

Second, technological developments have led to new solutions, which have led to new startups in the health care space, such as recently emerging remote and virtual care delivery firms and technology-enabled homecare delivery models (eg, DispatchHealth). The mergers of GigCapital2, UpHealth, and Cloudbreak Health as a unified telemedicine solution provider, and Teladoc's acquisitions of several other technology-enabled models such as Livongo and InTouch Health, exemplify the competition and subsequent mergers due to technological imperatives [6].

Third, capturing a more significant share of patients' care choices across the disease and life continuum increases revenue prospects. In other words, patient–service scope and scale have emerged to fuel competition among health systems. Salt Lake City–based Cimarron Healthcare's acquisition of Ascent Behavioral Health Services, Monroe Capital, and Veronis Suhler Stevenson to expand into therapy and wellness areas is an example [7]. Similarly, the joint venture between Kindred Healthcare of Kentucky and Landmark Medical Center in Rhode Island (a subsidiary of Prime Healthcare Services from California) to own and operate a rehabilitation hospital showcases service expansion competition and integration imperatives [8].

Thus, attempts to adapt and change with innovation, while resisting specialized new generations of competitors on the one hand and the legacy burden of high-cost conglomerate structures to provide everything from high-level intensive care units to quick clinics colocated in drugstores as patient services on the other hand, have aggravated the competitive landscape for health systems [9]. Several very large health systems can bind or lock patients into their ecosystem, with a goal to emerge as a one-stop shop for the entirety of a patient's health care needs and encounters "from the cradle to the grave," in turn encouraging patients to think of the health system for all their health care needs [10]. Some of the examples we provide also reflect that competition has become more asymmetric and is expanding to organizations that are not in health care, such as technology, supply chain, or logistics firms [11].

Ignoring competition looming on the horizon will perish any health system, although managing the problem is not easy. Structural, operational, and strategic issues have only compounded the concerns. Health systems cannot move away from being all things to consumers. Competing in the health care business while lowering costs and improving efficiency

may be possible, but only if health system leaders are innovative and proactive in integrating both high- and low-acuity care options into an effective strategy that seeks to capture a more significant share of patients' health care service continuums and drive subsequent revenue opportunities. Two broad strategies help facilitate these goals: *vertical and horizontal integrations*.

Vertical integration expands the business by acquiring another company that operates before or after the acquiring company in the value chain. In contrast, horizontal integration is when a business grows by acquiring a similar company in their industry at the same value chain point [12]. Often, vertical integration is also done to increase network size and geographic coverage to mitigate risk in contracting, and to achieve market power over buyers and suppliers [13]. Small health systems or physician groups, which align with nonphysician partners such as hospitals, universities, medical schools, and health plans in health care, are touted as vertical integrations. In contrast, merging large or small health systems with similar expertise is an example of horizontal integration [14].

Horizontal integration might lead to enhanced operating efficiencies and economies of scale, improved coordination and quality of patient care, more in-house all-inclusive services, and higher-revenue services (eg, outpatient surgeries, imaging services) [15]. Through megamergers between large health systems, horizontal integration can thwart leaner niche competitors. Integration is challenging in any form because monitoring, coordination, and creating a cohesive culture across the integrated entities are always tricky. In addition, scope economies either do not exist or worsen the integrated organization's dynamics.

The US health care industry has been characterized by different aspects of horizontal and vertical M&A. Such consolidations have changed the structure of US health care markets over time. Care integration has been an emerging solution to improve health quality and reduce costs, especially for a growing population of chronically ill patients in the United States [16]. More specifically, horizontal consolidation occurs when hospitals or physician groups merge, enabling the combined entity to increase its market share. Mergers reduce competing hospitals in a market, and vertical consolidations through acquisition of physician practices by a hospital reduce competition by reducing physicians vying for patients [17].

More structurally integrated organizations may manage care, coordinate across the care continuum, and exploit economies of scale and scope; such capabilities should, in theory, improve health care quality and lower costs. Practitioners and policymakers have therefore made investments in horizontal and vertical integrations. Vertical integration has been associated with better quality and is often framed as optimal care for specific conditions. Stakeholders perceive the positive impacts of consolidation on the long-term viability of health care facilities and their ability to adopt new care models, enhanced competition in health insurance, the creation of foundations, and pioneering medical research and innovation [18]. Stakeholders also believe that consolidation has changed geographic access to care; how physicians make referrals; and

how educated patients are about care, the advertising environment, and economies in surrounding neighborhoods [19]. Market concentration also provides some benefits such as influencing utilization or readmissions and other potential health benefits [20].

Approaches to improve health system performance have been implemented to address care coordination problems and physician burnout. A widely advocated solution is the development of more integrated health delivery systems. While uncertainty remains about the drivers of organizational changes, these changes have led to health care organizations becoming more extensive and more financially integrated [21]. Horizontal and vertical integrations of hospitals and physicians have occurred rapidly for more than two decades. The COVID-19 pandemic may have exacerbated integration plans. Financial sustainability challenges because of declines in utilization and revenue emerged during COVID-19; the economic incentives for hospitals to merge, acquire physician practices, and employ more physicians are increasing. The financial and operational challenges faced during COVID-19 may incentivize health care organizations to make timely decisions for survival. Health systems might gain more significant market power through integration, resulting in greater competitive advantages [17].

Theoretical Framework on Competition and Integration

Transaction cost economics theory has been applied in the health care context, and can plausibly explain the nuances associated with competition and integration dynamics [22]. Anchoring to the transaction costs perspective, this study proposes hazards exchange, transaction efficiency, and cost leadership as the three mechanisms behind the pathway from competition perceptions to integration plans. First, prior literature reveals that the transaction cost perspectives mostly have a focus on exchange hazards and can be used to explain the contracting between hospital groups [22], which forms the competition perceptions of a health system against another one, especially in uncertain environments. Second, transaction cost perspectives consider the efforts and costs required to complete the exchange and contracting activities [22]. Advanced information technologies such as cloud computing can significantly change the operation efficiency and cost, thus changing the economic paradigm and the relationship between collaborative parties [23]. This leads to the consideration of technology disruption–driven competition. Third, as health care is a service-based industry, the application of transaction cost perspectives in the health care context should consider the factor of customer service when perceiving the relationship with partners [24]. The competitive advantage framework proposed in extant research [25] considers three generic strategies: low-cost leadership, differentiation, and focus. This framework reveals the connection between transaction cost economics principles and competition categories, and highlights the significance of the target market or customer to sustain superior performance. This is consistent with customer service–driven competition. In other words, the needs of exchanging hazard in the external environment uncertainty–relevant competition results in integration, the efforts of improving transaction efficiency in the technology disruption–driven competition lead to integration, and the

strategy of cost leadership in the customer service–driven competition causes integration.

More specifically, from the transaction cost economics perspective, vertical integration is about the economies of scope and horizontal integration is about the economies of scale [15]. In order to respond to the potential competition risks and change the competitive status, health systems are seeking either hospital-hospital mergers or hospital-physician integration [26]. Through the acquisitions of physician groups, health systems can expand the scientific horizons to care delivery [5]. Through the mergers of hospitals with similar focus, physicians in health systems can collaborate with similar expertise on a specific program [4]. Both integrations can reduce the hazards caused by uncertain environment–related competition. With higher perception, health systems will seek more unified solutions through vertical integration [6] and change the care delivery model through horizontal integration (eg, DisPatchHealth). The underlying mechanism for both cases is the improvement of transaction efficiency. However, such an outcome may cause even higher perception of technology-driven competition. Prior research suggests a positive relationship between CEO competition perceptions and integration, which arguably needs to be revisited given the recent post-COVID-19 "normal" contexts addressed in this study [27]. The perceptions of competition by CEOs of hospitals include the external market competition, and the integration considers the cost of information sharing. Strategic priorities in a health care system also propose the integrated framework of competition and collaboration, with discussions on competition around information technology [28]. Furthermore, the influence of customer service–driven competition on horizontal integration through the mechanism of cost leadership is reflected in the service niche [15]. The outcome of vertical integration when facing customer service–driven competition comes through the one-stop shop service to achieve cost leadership [10]. Details of these three mechanisms are summarized in Table 1.

Table 1. Mechanisms from competition perceptions to integration plans.

Transaction cost economics theory		Integration plans	
Competition reasons	Mechanisms	Vertical integration *(economies of scope)*	Horizontal integration *(economies of scale)*
Uncertain environment	Hazards exchange	Expansion	Collaboration
Technology disruption	Transaction efficiency	Unified solutions	Delivery models
Customer service	Cost leadership	One-stop shop	Service niche

Methods

Data Collection

The effort to assess the linkage between competition and integration prospects of health systems is part of a broad project undertaken by the Health Administration Research Consortium at the Business School of the University of Colorado Denver [29]. The project involves an annual and broad study on health systems and collects insights via a survey of health system CEOs. The insights will help policymakers, practitioners, and academic stakeholders as they collaborate to create strategies to help the industry respond to the pandemic and prepare for the next crisis.

A survey questionnaire was developed in December 2020 to collect data from health systems and to study the environment that health systems face scientifically. The survey items came from prior literature, with questions reworded to fit the health systems context. Inputs were taken from researchers, consultants, and executives with appropriate expertise to design the questions. The survey was validated using a scientific process of expert evaluations and was pilot-tested with five top executives from the Health Administration Program Advisory Board. The survey questionnaire was revised and finalized in January 2021.

A contact list of CEOs was compiled from 624 health systems across the United States using data from multiple sources, contacts, professional networks, websites, and annual reports. The survey instrument was implemented in a professional survey platform and was mapped emails to the platform to create unique, trackable links for each health system. Email and phone solicitations were made in multiple rounds between January 25 and March 2, 2021. A total of 148 responses from the 624 CEOs contacted, representing a 23.7% response rate, out of which 13 incomplete responses could not be used, leaving 135 final usable responses.

The 135 health systems represented in this survey varied from 1 to 18 hospitals with 176 to 75,000 employees. The annual revenue in 2020 of the health systems ranged from US $0.7 million to US $14 billion. The health systems aggregately represented US $300 billion in revenues and 1.1 million employees across the United States.

We then matched the survey data set with secondary data collected from the Agency for Healthcare Research and Quality (AHRQ) compendium to glean a complete picture of the health systems. Finally, we had data from 124 health systems located across the United States. We analyzed this combined data set, which yielded several important insights.

Ethics Consideration

An ethics review was not applicable for this study. The data used was received through a leading professional consulting firm that anonymizes and provides secondary firm-level data for research and analysis to draw insights.

Variables and Measures

Table 2 describes the variables used in this study. The main variables in this study are vertical integration (VINT), horizontal integration (HINT), external environment uncertainty–related competition (EEUC), technology disruption–driven competition (TDDC), and customer service–driven competition (CSDC).

These variables were measured using 7-point Likert scales for relevant items. We tested the internal-consistency reliability of these multi-item variables using Cronbach α. The four α values were close to or greater than the recommended acceptable threshold of .70 for exploratory research.

Table 2. Description of variables, including survey questions and coding scheme.

Variable	Description
Integration plans	
VINT[a]	Develop through vertical integration
HINT[b]	Develop through horizontal integration
Competition perceptions	
Main question	What is needed for your health system to compete in today's post-COVID-19 economy?[c]
EEUC[d]	External environment uncertainty–relevant competition (Cronbach α=.84); focus on services in which you excel, reevaluate the business you are in, anticipate policy issues and be ready for that
TDDC[e]	Technology disruption–driven competition (Cronbach α=.73); transform through digital technologies, keeping current with technologies, new entrants disrupting the business model
CSDC[f]	Customer service–driven competition (Cronbach α=.67); loyalty of customers, develop a mix of talent, quality of services, and patient satisfaction
Contingent variables	
SIZE_B-SMALL, SIZE_B-MEDIUM, SIZE_B-LARGE	The three size variables of the health system are measured using the total beds managed by the health system across all hospitals, reported by the AHRQ[g] Hospital Compendium: SIZE_B_SMALL, <100 beds; SIZE_B_MEDIUM, 100-400 beds; SIZE_B_LARGE, >400 beds
REGION-NE, REGION-MW, REGION-SOUTH, REGION-WEST	The four region variables of the health systems are coded based on their primary location in the United States, following the Census Bureau categorization: REGION-NE, Northeast; REGION-MW, Midwest; REGION-SOUTH, South; REGION-WEST, West
TEACHING-NON, TEACHING-MINOR, TEACHING-MAJOR	The three teaching variables are coded based on the teaching status of a health system: TEACHING-NON, nonteaching; TEACHING-MINOR, minor teaching; TEACHING-MAJOR, major teaching
REVENUE-LOW, REVENUE-MEDIUM, REVENUE-HIGH	The three revenue variables of the health systems are measured using the health system's annual revenue across all hospitals: REVENUE-LOW, <US $2 billion; REVENUE-MEDIUM, US $2-5 billion; REVENUE-HIGH, >US $5 billion
HIGH-DSH-HOSP	The health system includes at least one high DSH[h] patient percentage hospital (1=yes, 0=no)
HIGH-BURDEN-SYS	Health system–wide uncompensated care burden flag (1=yes, 0=no)
HIGH-BURDEN-HOSP	The health system includes at least one high uncompensated care burden hospital (1=yes, 0=no)
OWNERSHIP	Predominantly investor-owned hospitals (1=yes, 0=no)
PHYSICIANS	The number of physicians in the health system, measured by the number of physicians reported by the AHRQ Hospital Compendium
HOSPITALS	Number of hospitals the health system has reported by the AHRQ Hospital Compendium

[a]VINT: vertical integration.

[b]HINT: horizontal integration.

[c]All questions are measured using a 7-point Likert scale; 1=strongly disagree to 7=strongly agree.

[d]EEUC: external environment uncertainty–related competition.

[e]TDDC: technology disruption–driven competition.

[f]CSDC: customer service–driven competition.

[g]AHRQ: Agency for Healthcare Research and Quality.

[h]DSH: discharge level.

The influencing factors examined in this study represent several categories: size, region, teaching status, revenue, and several other system characteristics. These variables are coded (see Table 2) to reflect the characteristics of a health system that may influence its competition perception and integration preference. Three size variables measure the number of beds across a health system (SIZE_B-SMALL, SIZE_B-MEDIUM, and SIZE_B-LARGE), four region variables reflect the location of a health system (REGION-NE, REGION-MW, REGION-SOUTH, and REGION-WEST), three teaching status–related variables assess the extent to which a health system is associated with a teaching program (TEACHING-NON, TEACHING-MINOR, and TEACHING-MAJOR). Three revenue variables measure the

annual revenue of a health system (REVENUE-LOW, REVENUE-MEDIUM, REVENUE-HIGH). In addition, we included variables to capture the discharge levels of patients (HIGH-DSH-HOSP), uncompensated care burden (HIGH-BURDEN-SYS and HIGH-BURDEN-HOSP), ownership status (OWNERSHIP), number of physicians (PHYSICIANS), and number of hospitals (HOSPITALS).

Sample Statistics

The descriptive statistics and pairwise correlations among the key variables used in this study appear in Table 3 and Multimedia Appendix 1, respectively. As shown in Table 3, health systems have a relatively high perception of TDDC compared with EEUC and CSDC. Furthermore, horizontal integration seems to be more popular for health systems than vertical integration.

In addition, to check for nonresponse bias, we compared the characteristics of responding and nonresponding health systems. Detailed comparisons are shown in Table 4. The *t* test results for all comparisons indicated no significant difference between respondents and nonrespondents.

Table 3. Summary statistics (N=124).

Variable[a]	Mean (SD)	Range
EEUC	5.10 (1.39)	1.67-7.00
TDDC	5.63 (0.94)	2.67-7.00
CSDC	5.12 (1.21)	2.00-6.67
VINT	4.51 (1.85)	1.00-7.00
HINT	4.97 (1.53)	1.00-7.00
SIZE_B-SMALL	0.09 (0.28)	0.00-1.00
SIZE_B-MEDIUM	0.37 (0.49)	0.00-1.00
SIZE_B-LARGE	0.54 (0.50)	0.00-1.00
REGION-NE	0.22 (0.42)	0.00-1.00
REGION-MW	0.24 (0.43)	0.00-1.00
REGION-SOUTH	0.35 (0.48)	0.00-1.00
REGION-WEST	0.18 (0.38)	0.00-1.00
TEACHING-NON	0.30 (0.46)	0.00-1.00
TEACHING-MINOR	0.48 (0.50)	0.00-1.00
TEACHING-MAJOR	0.22 (0.41)	0.00-1.00
REVENUE-LOW	0.61 (0.49)	0.00-1.00
REVENUE-MEDIUM	0.23 (0.43)	0.00-1.00
REVENUE-HIGH	0.15 (0.35)	0.00-1.00
HIGH-DSH-HOSP	0.33 (0.47)	0.00-1.00
HIGH-BURDEN-SYS	0.20 (0.40)	0.00-1.00
HIGH-BURDEN-HOSP	0.30 (0.46)	0.00-1.00
OWNSHIP	0.02 (0.13)	0.00-1.00
PHYSICIANS	1.84 (0.80)	1.00-3.00
HOSPITALS	1.50 (0.77)	1.00-3.00

[a]See Table 2 for a description of variable codes.

Table 4. Characteristics of responding and nonresponding health systems.

Characteristics[a]	Respondents (n=124), n (%)	Nonrespondents (n=511), n (%)	t test (633)
Size			
Small (6-99 beds)	11 (8.9)	42 (8.2)	–0.19
Medium (100-399 beds)	45 (36.3)	212 (41.3)	–0.56
Large (≥400 beds)	68 (54.8)	257 (50.3)	1.41
Region			
Northeast	27 (21.8)	117 (22.9)	0.07
Midwest	30 (24.2)	133 (26.0)	0.55
South	45 (36.3)	169 (33.1)	–0.48

[a]The number of physicians and hospitals are presented in this table in different categories for easy comparison across respondents and nonrespondents.

Statistical Analysis

To answer the two research questions stated earlier, we performed two sets of analyses. We used ordered logit regressions to estimate (1) the relationship of the three competition perceptions to specific hospital characteristics and (2) the relationship between competition perceptions and integration plans. The integration variables are ordinal (with a sequentially higher value), thus driving the decision for ordered logit regressions. The ordered logit approach does not assume equal intervals between levels in the dependent variable and is thus a preferred estimation than ordinary least square estimation processes that assumes equal linear intervals. The ordered logit model is as follows:

$$Y_i^* = \beta X_i + e_i,$$

where Y_i^* represents respondents' propensity to indicate higher levels of the dependent variables (ie, EEUC, TDDC, CSDC, VINT, and HINT), X_i is a set of explanatory variables, β is a vector of parameters, and e_i are disturbances.

We did not observe Y_i^*. Instead, we observed the ordinal dependent variable Y_i depending on the values of thresholds or cut-off points τ_{m-1} and τ_m. The probability distribution of Y_i is given as follows:

$$Pr(Y_i = m | X_i = F(\tau_m - X\beta) - F(\tau_{m-1} - X\beta)$$

Results

Estimation Outcomes

Table 5 shows the results of the ordered logit model estimation that describe the relationship between contingent factors and each of the three types of competition perceptions.

One teaching variable had a significant, negative association with EEUC. The major teaching health systems variable showed high statistical significance (*P*<.001). This suggests that major teaching health systems tend to have lower perceptions of EEUC. Based on the marginal-effects analysis, we found a 1.1% decrease in the probability of perceiving EEUC among major teaching health systems compared with nonteaching health systems.

There was also a significant negative relationship between high revenue and EEUC ($P<.001$), indicating that high-revenue health systems tend to perceive less EEUC than low-revenue health systems. The marginal-effects analysis suggested a 0.71% decrease in the probability of perceiving EEUC among high-revenue health systems than low-revenue health systems.

A high-burden system had a significant positive impact on EEUC ($P<.001$), while a high-burden hospital had a significant negative impact. These results indicate that (1) a health system with a system-wide high uncompensated care burden tends to perceive EEUC, while (2) a health system with no high uncompensated care burden hospital is less likely to perceive EEUC. We also examined the marginal effects of these two variables. The results indicated a 0.52% increase in the probability of perceiving EEUC by a health system with a system-wide high uncompensated care burden and a 1.32% decrease by a health system with at least one high uncompensated care burden hospital.

For TDDC, there was a significant negative relationship between this perception and both medium size ($P<.001$) and large size ($P=.04$), indicating that smaller-sized health systems are more likely to have a higher level of TDDC. The marginal-effects analysis showed that the probability changes for these two factors are 3.08% and 2.13%, respectively.

Region had significant effects on the perception of TDDC. For example, health systems in the south ($P<.001$) have a higher TDDC perception than those in the northeast. The change in the marginal effects was 0.92%. Similarly, there was a significant positive relationship between high revenue and TDDC ($P<.001$). This result indicates that high-revenue health systems tend to perceive more TDDC than low-revenue health systems. The marginal effect of this change was 0.93%.

The relationship between a high system-wide burden and TDDC and the relationship between total hospitals in a health system and TDDC were both significant and negative ($P<.001$). These results suggest that health systems without a system-wide high uncompensated care burden and those with fewer hospitals are more likely to perceive TDDC. The marginal effects for these two variables were 1.14% and 0.59%, respectively.

For CSDC, compared with small-sized health systems (ie, those with a fewer number of beds), medium- and large-sized health systems ($P<.001$) are less likely to perceive CSDC. These results reveal the strong influence of health systems' size on their competition perceptions regarding customer service provision. More specifically, marginal-effects analysis indicated a 1.11% and 0.49% decrease in the probability of perceiving CSDC for medium- and large-sized health systems, respectively.

There was a significant negative relationship between major teaching health systems and CSDC ($P<.001$), indicating that compared with nonteaching health systems, those with a teaching focus tend to perceive less CSDC. The marginal-effects analysis indicated a 0.78% decrease in the probability of perceiving CSDC among major teaching health systems than among nonteaching health systems.

In addition, there was a significant negative relationship between CSDC and medium revenue ($P<.001$), suggesting that health systems with a midrange revenue may not favor perceived CSDC. The marginal-effects analysis showed a 0.13% impact for this revenue variable.

Table 6 and Table 7 display the estimation results for the second set of models, illustrating the relationship between competition perceptions and vertical and horizontal integration, respectively.

The results in Table 6 show different relationships between the three types of competition perceptions and vertical integration. Models 1-3 demonstrate the direct relationships of EEUC, TDDC, and CSDC with VINT, respectively, while model 4 is the combined model, which includes all three competition perceptions. The results indicated a significant positive relationship ($P<.001$) between EEUC and VINT, and a significant negative relationship ($P<.001$) between TDDC and VINT. The relationship between CSDC and VINT was not significant. More specifically, the results suggest that health systems with higher EEUC perceptions tend to choose vertical integration plans. The marginal-effects analysis showed a value of 4.64% for this variable. However, health systems with a higher level of TDDC are less likely to opt for vertical integration. The probability change, according to the marginal-effects analysis, was 4.11% for TDDC.

Similarly, the results in Table 7 display the different direct (models 1, 2, and 3) and combined (model 4) effects of the three types of competition perceptions on horizontal integration. The most significant relationship was the impact of EEUC on HINT ($P<.001$). This significant and positive relationship is consistent in both the direct and combined models, indicating that health

systems with higher EEUC perceptions have a higher probability of following horizontal integration plans. The negative relationship between TDDC and HINT was significant (*P*=.05) in the combined model. This result suggests a lower probability of adopting horizontal integration for health systems with higher TDDC perceptions. Finally, although the direct relationship between CSDC and HINT was not significant in the direct model, the combined model showed a highly significant negative relationship (*P*<.001) between these variables. This result indicates that health systems that perceive a higher level of CSDC are more likely to pursue a horizontal integration approach.

Discussion

Principal Findings

This study explored the differences of three competition perceptions of health systems in the United States, contingent on their characteristics. The study further examined how competition aspects are related to the different integration plans. The main findings are two-fold. For the first set of explorations on the main factors that influence health systems' competition perceptions, asking about the similarities and differences of such influences and their implications, we found that size, teaching status, revenue, and burden are the four main factors influencing health systems' competition perceptions.

First, the results indicate that small-sized health systems will perceive a higher level of all three types of competition perceptions. Therefore, a driving reason for integration plans among small-sized health systems may be to mitigate competition. The influences of size on all three competition perceptions were consistent.

Second, compared with nonteaching health systems, major teaching health systems perceive less EEUC and CSDC. A potential reason is an emphasis on major teaching health

systems; they are less bothered by the external environment and customer service provision changes.

Third, the results indicate that revenue has opposite influences for TDDC perceptions and EEUC and CSDC perceptions. On the one hand, the results suggest that high-revenue health systems perceive a higher level of TDDC. On the other hand, health systems with more revenue (both medium and high revenue) perceive lower EEUC and CSDC. These results demonstrate the nuanced influences of revenue on competition perceptions, and imply that the role of revenue should be examined more carefully in relevant decision-making.

Fourth, according to prior research (AHRQ), there are two types of uncompensated care burdens: a system-wide burden and hospital-level burden. This study employed two variables, high-burden system and high-burden-hospital, to capture these two types of burdens. The results showed that they have different influences on different competition perceptions. For example, health systems with a system-wide burden are more likely to perceive EEUC, while those with at least one high-burden hospital are less likely to perceive EEUC.

For the second set of examinations, we found a consistent significant positive relationship between EEUC and both vertical and horizontal integration; a consistent negative relationship, with changing significance, between TDDC and the two integration plans; and a negative relationship between CSDC and horizontal integration (see Table 8).

The results suggest the following. First, the strongest motivation for integration or an M&A is EEUC perceptions. When there is external environment uncertainty, organizations tend to pool their efforts to overcome the difficulties. Second, counterintuitively, TDDC perceptions hinder integrations. Data, privacy, and intellectual property issues may be the underlying reasons for such findings. For example, Internet of Things (IoT) technology can bring in a privacy threat in the process of integration. There will be data acquisition, aggregation, and integration in an IoT ecosystem where different systems build the linkage [30]. Third, to provide better customer services, health systems may not pursue a vertical integration strategy (it is unclear in this study), but they will not pursue horizontal integration. Organizations may not think they can gain better customer services by acquiring a similar company.

Table 8. Summary of findings: relationship between competition and integration.

Variable	Vertical integration	Horizontal integration
EEUC[a]	Positive***	Positive***
TDDC[b]	Negative***	Negative*
CSDC[c]	N/A[d]	Negative***

[a]EEUC: environment uncertainty–related competition.

[b]TDDC: technology disruption–driven competition.

[c]CSDC: customer service–driven competition.

*** $P<.001$,* $P<.05$

Implications

The findings of this study have several practical and policy implications. First, this study sheds light on the influence of the characteristics of health systems on competition perceptions. Medium size, major teaching status, high revenue, and having at least one uncompensated care burden hospital lead to lower perceptions of EEUC. Health systems with a high system-wide burden of uncompensated care feel a stronger sense of competition due to external environment uncertainty. Such differences support our definition and understanding of EEUC perceptions. In other words, external environment uncertainty is considered at the health-system level. Furthermore, the system-wide burden has an opposite influence on EEUC and TDDC. Health systems with a system-wide burden tend to perceive a higher level of external environment–driven competition but a lower level of technology-driven competition. This is a meaningful finding. The implication is that a system-wide burden motivates or even forces health systems to worry about external environment uncertainty, including changes in Medicare policy. Health systems with a system-wide uncompensated care burden may not think technological disruption can solve their problems. The main takeaway is that even in the post-COVID-19 era, where technologies such as

telehealth dominate and change the health care industry, other organizational factors are still critical for competition.

Recent research provides a rationale in the technology context. For example, digital orientations of smaller and less complex health systems are not aspirational [31]. This study also implies that medium size, system-wide burden, and more hospitals in a system can have negative influences on TDDC, while health systems in the south and those with high revenue perceive TDDC negatively at an even higher level. In other words, health systems with such characteristics should leverage the technologies for their organizations. Furthermore, revenue from customer services may not be equally important for all health systems when examining the influence of CSDC. This supports the prior literature on competitive markets [32,33]. Thus, policies designed to reform the delivery system must consider the diversity in system characteristics [17].

Second, the critical implication of this study is related to how EEUC, TDDC, and CSDC perceptions influence vertical and horizontal integration plans by the leaders of health systems. We found that the EEUC perception is influential on both vertical and horizontal integration plans. This finding indicates that in unstable markets and situations such as the COVID-19–relevant financial disruptions, there may be more

M&As. As a result, policymakers and practitioners may want to get ready for the changes in the post-COVID-19 new normal.

Regarding the influence of TDCC perceptions on vertical and horizontal integration, we found that technology-based competition drives less vertical integration. Given that health systems have recently aspired to accommodate remote- and virtual-care delivery options using technology, this is surprising. Plausibly, rather than acquiring firms, they may be focusing on developing in-house expertise. Indeed, a few telehealth M&As have been at the technology provider level rather than at the health system level. This may signal that health systems are preparing to develop technological expertise rather than making it an excuse for quick buyouts or mergers.

In addition, customer services should be an essential parameter for all health systems. However, whether it drives integration decisions remains an open question. We found that CSDC perceptions are not a strong driver of integration, although the external environment and technological uncertainties do affect horizontal integration. In other words, in a highly competitive market that includes external-, technological-, and customer service–relevant competitions, health systems will pursue horizontal integration strategies through mergers. This reflects an opportunistic behavior to monopolize markets and lock customers into one system.

There are a few other findings relevant to the contingent factors that influence integrations. For example, we found that health systems in specific regions and those with high revenue and high burden have a higher propensity for vertical integration, with slight variations in these findings for horizontal integration. We do not tease out many implications from these findings, except that they suggest that M&A decisions are influenced by a set of factors other than simply competition aspects.

There are strong indications that external uncertainty is a significant cause for thinking about integration. Perhaps policy interventions for fiscal assurance are a way to help suffering health systems survive the pandemic. The aspirations of some healthy and large health systems to take advantage of this situation to buy out weaker ones and emerge as the key dominant player in a region need to be kept in check.

Limitations and Directions for Further Research

This study has a few limitations that future studies may be able to address. Focusing on internal issues (eg, management and coordination, value-chain dynamics) and demand-driven integration plans may be other perspectives to explore for health systems. Furthermore, opportunities for and barriers to integration may be studied in greater detail. Recent studies have shown that hospital M&As are associated with decreased patient experience measures, along with no evidence of quality improvement with the change in ownership of health entities [20]. Studies on the association between structural changes have yielded mixed results on cost, quality, and patient experience outcomes, indicating that the structural integration of health care organizations is conceptually distinct from integrated care delivery. Structural integration may or may not lead to integrated care, and providers and policymakers should focus on the conditions and strategies that enable structurally integrated

organizations to capitalize on their ability to deliver more integrated care [16].

There are also concerns that integrated systems may increase prices and cost of care without commensurate improvements in quality and outcomes. The vertical integration approach showed no differences or lower efficiencies, as measured by utilization, spending, and prices [34]. Some evidence indicates that higher levels of integration are associated with higher levels of health care spending and increasing prices [35]. Other evidence shows mixed results, suggesting no significant effects or effects dependent on insurance type. While increased efficiencies may be possible, emerging research raises concerns about anticompetitive behavior, spending increases, and uncertain effects on quality. Vertical integration poses a threat to the affordability of health services and merits special attention from policymakers and antitrust authorities [13].

Reviews of hospital markets have found that concentrated markets are associated with higher hospital prices, with price increases often exceeding 20% after mergers. Of even more significant concern, reviews find that these price increases do not improve quality. In some cases, higher hospital concentration is associated with higher mortality rates. The higher concentration is associated with higher physician prices across a range of services. Despite evidence of associated price increases with no significant quality or efficiency improvements, both vertical and horizontal integration approaches have proceeded unchallenged. Health care consolidation concerns policymakers and regulators because market concentration can harm patients by increasing prices and premiums without accompanying improved care quality.

We also recognize that integration is not insufficient by itself, although we acknowledge that our underlying tone in this study has been to avoid overly integrated monopolistic endeavors. Future work might investigate M&As with outcomes, as done in prior work [9,26]. It is also worth noting that increases in the market concentration of health care providers and insurers have been examined nationally, and that increases in market concentration are associated with increases in prices and premiums. However, local markets for health care can differ dramatically. At the state level, laws and regulations, and the mix of providers and insurers, make markets in each state vastly different [36].

Another limitation of this study is that we used the cross-sectional data set to examine the relationships between variables. Future studies are planned to collect and use multiple years of data from health systems to address this limitation and provide causal inferences.

Conclusions

Disruptions in health care are an emerging challenge and stem from a variety of sources. Recently, the COVID-19 pandemic has been a significant factor. In addition, technological disruptions and demands from empowered customers have put enormous pressure on health systems to shape different strategies for survival. Integration is one such strategy. However, understanding why leaders plan for integration is an essential insight for the health care sector. This study unravels

competition-integration dynamics, and relates external environment uncertainty, technological competition, and customer services–driven competition to vertical and horizontal integration plans. Almost all health systems have some plans for integrations [37]; however, we found that environmental uncertainty drives integration more than other competitive factors. In addition, health systems with heavy competition dynamics will opt for mergers to alleviate survival challenges.

Competition-driven integration is unavoidable. However, overly integrated markets may lead to monopolistic entities and behavior, and that potential needs to be carefully managed and avoided with policy-level interventions. While interventions in the US health care sector are achieved through laws and regulations, proactively managing competition is an essential aspect of shaping policy interventions, and requires broader discussion and action.

Abstract

Background: Although telehealth appears to have been accepted among some obstetric populations before the COVID-19 pandemic, patients' receptivity and experience with the rapid conversion of this mode of health care delivery are unknown.

Objective: In this study, we examine patients' prenatal care needs, preferences, and experiences during the COVID-19 pandemic, with the aim of supporting the development of successful models to serve the needs of pregnant patients, obstetric providers, and health care systems during this time.

Methods: This study involved qualitative methods to explore pregnant patients' experiences with prenatal health care delivery at the onset of the COVID-19 pandemic. We conducted in-depth interviews with pregnant patients in the first and second trimester of pregnancy who received prenatal care in Cleveland, Ohio, from May to July 2020. An interview guide was used to probe experiences with health care delivery as it rapidly evolved at the onset of the pandemic.

Results: Although advantages of telehealth were noted, there were several concerns noted with the broad implementation of telehealth for prenatal care during the pandemic. This included concerns about monitoring the pregnancy at home; the need for additional reassurance for the pregnancy, given the uncertainties presented by the pandemic; and the ability to have effective patient-provider discussions via a telehealth visit. The need to tailor telehealth to prenatal health care delivery was noted.

Conclusions: Although previous studies have demonstrated that telehealth is a flexible and convenient alternative for some prenatal appointments, our study suggests that there may be specific needs and concerns among the diverse patient groups using this modality during the pandemic. More research is needed to understand patients' experiences with telehealth during the pandemic and develop approaches that are responsive to the needs and preferences of patients.

Introduction

Telehealth is a rapidly evolving approach to the delivery of health care, and significant strides have been made in its use for the delivery of prenatal care [1-4]. The appeal of telehealth is growing, as it provides not only a convenient and cost-effective way to deliver prenatal care, but also a way to improve patient experience [1,5-7]. Although telehealth was incrementally implemented before the emergence of COVID-19 across different patient populations and specialties of medicine, the pandemic radically altered both the timeline and the trajectory of its use to prevent the spread of the virus among health care providers, patients, and communities.

Preventing the spread of COVID-19 has been a particular priority in delivering prenatal care, because prior infectious disease threats, such as H1N1 and Zika, have had major implications for pregnant patients and infants [8-10]. In addition, as there is limited information about the impact of SARS-CoV-2 on pregnant women and newborns, health care institutions made tremendous efforts to ensure social distancing and infection prevention among this population [11-15]. Consequently, there has been rapid adoption of telehealth across diverse obstetric patient populations and health care systems [3].

As a result of initial efforts to implement telehealth in prenatal care, it was possible to begin to operationalize telehealth strategies that allowed patients to continue accessing health care during the pandemic, while eliminating the exposure risks of presenting to an outpatient center or hospital setting. Yet, this required instituting widespread acceptance of this approach among obstetric patient and provider populations who otherwise might not have embraced this type of visit before. For example, some providers either may not have used or elected to use telehealth prior to the pandemic. In addition, some patients may have had limited access to the equipment, internet services, or other resources needed to use telehealth; such issues have often been observed among patients from minority or low-socioeconomic groups [16,17]. Moreover, some patients may not have had an insurance plan that would cover the cost of a telehealth visit, while others may have elected not to use telehealth services because of a preference for in-person visits.

Consequently, although telehealth appears to have been accepted among some obstetric populations before the pandemic, patients' receptivity and experience with the rapid conversion to telehealth are unknown. Furthermore, it is unknown how patients will respond to telehealth visits for obstetric management amidst all the uncertainties presented by the pandemic. It is critical to understand not only patients' experiences with this mode of prenatal health care delivery during the pandemic but also how those experiences may influence health care delivery in the future. Therefore, we conducted a study to understand patients' prenatal care needs, preferences, and experiences during the COVID-19 pandemic to support the development of successful models to serve the needs of pregnant patients, obstetric providers, and health care systems during this time.

Methods

This study was developed as a qualitative study to explore emerging concepts and themes as they relate to obstetric health care delivery and patient experience during the pandemic.

Ethics Approval

All research procedures were reviewed and approved by the (deidentified) institutional review board (number 20-408; IRB) of the outpatient clinics of the (deidentified) health care system. Eligible participants were contacted using an IRB-approved study recruitment letter with instructions to contact the research team if interested in participation and informed consent obtained from them.

Recruitment

We conducted in-depth telephone interviews with pregnant women to understand their prenatal care needs, preferences, and experiences during the COVID-19 pandemic. Inclusion criteria included women who were 18 years of age or older, were English speaking, were able to provide informed consent for research participation, received obstetric care at 1 of the outpatient clinics of the (deidentified) health care system, had a viable intrauterine pregnancy, and had not experienced pregnancy loss at the time of study participation. Recruitment was structured to seek input from 2 groups of women who represent patients at different significant time points in pregnancy. One group included women in the first trimester of pregnancy to capture prenatal care needs, preferences, and experiences at the onset of the pregnancy and prenatal care delivery. A second group included women in the second trimester, whose prenatal care had been established prior to the declaration of a COVID-19 pandemic in the state of Ohio (March 2020). We conducted interviews from May to July 2020. During this time, telehealth was instituted across the health care system and, while encouraged, not required. After providing informed consent, participants took part in a semistructured telephone interview. The interviews were conducted using an interview guide that contained probes to explore pregnant patients' knowledge and perception of the COVID-19 pandemic and the pandemic's impact on their ability to access different aspects of prenatal care. The interview guide was developed in conjunction with content experts in obstetrics, health care communication, medical decision making, clinical genetics, and maternal-fetal medicine. It was piloted before use; the final version was modified based on initial participant feedback. Interviews were audio-recorded and transcribed for analysis.

Statistical Analysis

Analysis was approached as an iterative and progressive process of data immersion, coding, memoing, and theme identification, an inductive process consistent with grounded theory [18,19]. We identified content domains and categories in transcripts to

create a coding tree used to organize the data. A companion codebook was created to serve as a reference for the analysis. The coding and analysis processes were led by 2 members of the study team (authors RF and MP) using NVivo version 12 (QSR International). The research team held weekly meetings to review data coding and memoing and identify themes. Themes identified were contextualized with information about the trimester of pregnancy, gravity/parity, and previous pregnancies.

Results

Patient Characteristics

We contacted 115 (first trimester) and 139 (second trimester) patients scheduled at various outpatient clinics within this health care system. Of those, we recruited a total of 40 (15.7%)

pregnant women: 20 (50%) in their first trimester and 20 (50%) in their second trimester. The mean patient age was 32.25 (SD 4.54) years, this was the first pregnancy for 15 (37.5%) patients, 3 (7.5%) patients had symptoms of COVID-19 during this pregnancy, 5 (12.5%) were tested for COVID-19, and all results were negative (Table 1). Qualitative analysis identified 4 major themes: (1) perceptions of the benefits of telehealth during the pandemic, (2) the need for reassurance that comes from in-person clinical visits with an obstetric provider, (3) added concerns about being responsible for determining the well-being of the pregnancy at home, and (4) the impact of telehealth on patient experience with pregnancy and prenatal care (see Table 2 for additional qualitative data). No major differences in thematic identification were noted among women in the first trimester of pregnancy (study ID denoted by G1) and women in the second trimester of pregnancy (study ID denoted by G2).

Table 1. Demographics (N=40).

Demographics of participants	Participants, n (%)
Age (years)	
Non-AMA[a] (<35)	27 (67.5)
AMA (≥35)	13 (32.5)
Race	
White	34 (85)
Black	4 (10.0)
Asian	2 (5.0)

Positive	0 (0)
Negative	5 (100)
Use of telehealth (prior to interview)	
In-patient visit only	32 (80.0)
Telehealth visit	8 (20.0)

[a]AMA: advanced maternal age.

Table 2. Supplemental qualitative data.

Theme	Illustrative Quotes
Theme 1: Perceptions of the benefits of telehealth during the pandemic	• "Truthfully, for a lot of the early prenatal visits, you just sat in the waiting room for what felt like 10 hours, you peed in a cup, and you waited in the exam room for 10 hours. Then, it was a quick Doppler belly check, a quick 'How are you doing?', [a] blood pressure check, [and] 'All good. Great. We'll see you in a month.' So that's it. I can do the blood pressure at home. I could do the Doppler, theoretically. I could do weight at home." [G1, patient 13] • "Well, I think it is very cool that they're doing virtual visits. One thing that I thought was really neat is that, at my doctor's appointment, they gave me a Doppler so I can listen to the baby's heartbeat at home . . . I was very pleasantly surprised. I felt like, you know, unless there's something major going on, that a virtual visit every now and then was totally appropriate." [G1, patient 12] • "Virtual visits are a big deal . . . I was comfortable doing one. Of course, if there was something I was concerned about it, I could come in. I think it is just less enjoyable to come in because, you know, in the back of your head, you are worried about the possibility of being exposed to someone, especially if you are in a medical building." [G2, patient 4] • "I feel great about it. They sent me home with a blood pressure cuff and I want to say . . . a Doppler. I think that, with the baby and stuff, it really . . . you minimize your exposure, and you don't have to drive back and forth and sit in a waiting room. So, I feel like as long as you're healthy and everything's good, then these are great options." [G2, patient 10]
Theme 2: Reassurance that comes from in-person clinical visits with an obstetric provider	• "She [her provider] said she'd send us home with Dopplers to listen to the baby's heart at home, which is like, 'Woah. I'm supposed to sit there and try to find it?' I can't even think about that. So, it's definitely weird and different and not what I expected at all. It makes me nervous that the doctor won't be right there to do it for me, like someone who went to school for this and is trained in this." [G1, patient 3] • "I don't necessarily feel a virtual visit with my provider offers the same thing that an in-person appointment would, for example, with measuring your fundal height or making sure the heart rate is good. Unless you have the tools at home or the knowledge, you wouldn't have the ability to make sure you're on track compared to your provider doing that in person." [G1, patient 10] • "I would like more in person visits versus the telehealth, just for my own peace of mind that the pregnancy is progressing as it should." [G2, patient 12] • "I just feel like it would feel safer for me to actually see a doctor and actually have them look at me, instead of having the virtual visit. I was never worried or concerned about going to the doctor to get checked." [G1, patient 8] • "Being the first child, I just think it's nice going into the doctor especially early on when, even though you might have symptoms like you're tired or nauseous, I don't have much of a stomach yet, I don't feel the baby • kicking. So, it's nice to go in and have that reassurance that [the] baby is still growing properly and everything. So, I would prefer going in." [G1, patient 11]
Theme 3: Added concerns about the responsibility of determining the well-being of the pregnancy at home	• "The only thing I would be worried about is if something was wrong. Like, they need to make sure they hear a heartbeat or something like that having more fetal movement when I was further along." [G1, patient 4] • "I went home, and I tried to use it, and it was a couple days later and I couldn't get it to work, and I was worried it was because there was nothing there to listen to." [G1, patient 13]
Theme 4: The impact of telehealth on patient experience with pregnancy and prenatal care	• "But I think it's also important to be able to do the in-person visits, and there's some things I would imagine could get missed just by not having that in-person contact, so I see why that's important as well." [G1, patient 14] • "Right now, my regular physician has been going teledoc, so we've had to do a couple of those. The worst part about it is maybe the connection when you're standing at a laptop and there might be, like, a delay. So, that is just something you gotta take, I guess, if you're doing virtual. I wouldn't not be interested in it." [G2, patient 9] • "I don't necessarily feel a virtual visit with my provider offers the same thing that an in-person appointment would." [G1, patient 10]

Perceptions of the Benefits of Telehealth Visits During the Pandemic

For some participants, their first exposure and opportunity to use telehealth were because of the changes made in response to the pandemic. Some discussed the convenience of this approach. As described by 1 participant who had not elected for telehealth visits before the pandemic,

> I realized that the only things that were different with a virtual visit would be checking the heart rate and checking the blood pressure. Once I realized I wasn't really missing out on much and that I can check the heart rate at home by myself, made me feel better

XSL•FO

RenderX

about them [telehealth visits]. I wasn't missing out on anything. [G2, patient 2]

This finding was noted among participants in the first trimester who were beginning their prenatal care and participants in the second trimester who had already had a series of in-person visits with their provider prior to the pandemic.

Yet, for many, the benefit of telehealth was the ability to reduce the risk of exposure to COVID-19. A recurrent subtheme was concern about the "the possibility of being exposed to someone" [G2, patient 2] while presenting for an in-person prenatal care visit. For some, "virtual visits" (the term used for telehealth in this health care system) felt "safe" and "safer" than going into the office during the pandemic to avoid unnecessary potential exposures during the visit for themselves and their family. Although many participants noted the steps health care clinics and providers had taken to prevent COVID-19 exposure, there was a concern about other patients who presented for care.

> *I think that the home virtual visits are a really great option so I don't have to sit in the waiting room. Even though everyone has a cloth mask on, it's just a nice comfort level to avoid unnecessary exposures to who knows what. [. . .] I really looked forward to my prenatal visits in my other pregnancies. But, sitting in the waiting room with everybody and masks on, and seeing the front door be so busy with people, it just made me more aware of all the people that are touching surfaces and adding to the potential exposure. Because, you can't really, really trust all people.* [G1, patient 13]

For these participants, telehealth visits added a degree of safety and reassurance.

The Need for Reassurance That Comes From In-Person Clinical Visits With an Obstetric Provider

Although some participants spoke of the benefits of telehealth during the pandemic, others discussed reservations with this approach. Several participants discussed how they weighed their needs and preferences for reassurance with an in-person visit against the risk of possible COVID-19 exposure by presenting to an office or health care center.

> *It would feel safer for me to actually see a doctor and actually have them look at me instead of having the virtual visit.* [G1, patient 8]

Participants were aware of the risks of COVID-19 for themselves and their families. Yet, many also felt increased uncertainty from the pandemic and stated a preference for in-person visits to alleviate that uncertainty. As described by this participant who initiated prenatal care during the initial phases of the pandemic,

> *When I first found out I was pregnant, it was scary and stressful. When I found out, that's when the whole pandemic started. So, it was very, very stressful at first. The only thing that we were thinking of was I have a way to protect myself [. . .]. I just feel like it would feel safer for me to actually see a doctor and actually have them look at me instead of having the*

virtual visit. I was never worried or concerned about going to the doctor to get checked. [G1, patient 8]

The preference for an in-person visit was noted among women in the first and second trimester of pregnancy. Some participants in the first trimester of pregnancy preferred in-person visits to reassure them of the status of the pregnancy, particularly before there were visible or tangible changes of pregnancy. This reassurance is something that they did not feel could come from a telehealth visit. As described by this participant in the first trimester,

> *I wanted to make sure I was still pregnant even though I took like ten tests and they all said, "Yes." I just definitely wanted to make sure I still am . . . I want to make sure everything's gonna be okay.* [G1, patient 3]

This was also observed among women in the first trimester who had never been pregnant.

> *My doctor said that, maybe down the line, we could do some virtual visits. I thought, oh, that's interesting. I've never done those. I would save some time and energy on those. But at the same time, I still feel like, with my first pregnancy, I should still get to the office and have [one-on-one], face-to-face.* [G1, patient 7]

This was a theme noted across both trimesters. For example, participants in the second trimester also sought reassurance until they could experience tangible evidence of the pregnancy.

> *I still wanted to go into the doctor at least until I could feel the baby moving because I don't feel many symptoms when I'm pregnant. So, I just wanted confirmation that there was still a baby in there.* [G2, patient 21]

Added Concerns About Responsibility for Determining the Well-being of the Pregnancy

Participants also spoke of their concerns about managing their prenatal care with home monitoring and during their telehealth visit. These concerns augmented existing concerns about their health and the well-being of the pregnancy during the pandemic. One main subtheme was that although participants were provided with the instructions and tools to check the presence and status of the fetal heart tones, they noted some concern over whether they had the skills and competence to use the equipment. This concern stemmed from an underlying concern that "something would be missed" or "overlooked" if a trained health care provider did not perform the evaluation in person.

> *So, they gave me a blood pressure monitor and a Doppler. So, I guess, I am going to be in charge of doing those things, which is making me anxious.* [G1, patient 2]

Participants worried both about missing a potential health problem and about misinterpreting a result so that they would suspect a problem that did not really exist. As described by this patient,

> *So, my OB [sic] also does the virtual visits, and they said, "We'll give you a blood pressure cuff. We'll give you a Doppler. You can check your own baby's heart*

rate." And to me, I mean I know they're taking precautions, everybody . . . all the doctors are trying to see less patients and all that. But I feel like, being pregnant, I feel like that should have to be something an OB [sic] should have to physically evaluate their patient for, not me doing it myself. [. . .] I just feel like it's an important thing that the OB should be the one to physically assess the baby and me. Check my blood pressure for me because I'm not . . . I'm not trained in that. I feel like that's their job and they're the ones that are the trained professionals and they would know how to do that better than I would. [G2, patient 17]

Several participants also had a profound fear of discovering an obstetric complication or pregnancy loss while using the equipment provided for at-home monitoring. As described by this participant who was provided a Doppler to hear the fetal heart tones,

The Doppler . . . I tried using it a couple times, [and] it's still early on in the pregnancy, so it is harder to pick up on. Sometimes I'm like, "Oh gosh. Why don't I see it? Is something wrong?" [G1, patient 11]

This was also a prominent concern among participants who had experienced a pregnancy loss or complication in an earlier pregnancy. As described by this participant,

I know my next appointment will be virtual and I'll need to do my own Doppler, and that's definitely different. So, I'm not sure how I'll feel about it, especially with the scare we had [referring to a threatened miscarriage]. I'm not sure if I can't find it [heartbeat], or with me being early on, if I can't find something. It would be a huge worry on me. [G1, patient 6]

The Impact of Telehealth on Patient Experience

The meaning and significance of the experience of pregnancy were an important topic for participants. Participants sought meaningful and personal experiences with the pregnancy, something many felt that in-person access to a health care provider could offer.

If I don't go [into the office], I don't get to see the progress of my baby, and I want to be able to see that still despite the pandemic. [G1, patient 20]

There was also a sense of confronting and managing a sense of loss in the expected experience and the reality of prenatal care as it was unfolding during the pandemic.

I never imaged my first pregnancy would be like this and that I'd be talking to my doctor about a lot of things over the phone or with a mask on in our visits. [G1, patient 3]

Participants spoke of the desire to have an experience where they could align their care with their personal needs and preferences during pregnancy. Some participants noted that communication during a telehealth visit was different than their expectations for their prenatal care or than their experiences during another kind of telehealth visit. For participants, there seemed to be greater familiarity or effectiveness during an in-person interaction with the health care provider.

I prefer in-person visits because sometimes, I think of more questions to ask or I have certain concerns. So, I feel like I get better answers and support in-person. [G1, patient 5]

Interpretation of nonverbal communication, gestures, body posture, and facial expressions was also a concern for telehealth visits. As this participant explained,

I do wonder if you'll be able to catch everything that you would have [at] an in-person appointment. I know you go through your basics. You go through your basic numbers like the fetal heart rate, blood pressure, and such. [. . .] In person, with facial expressions and such, you can pick up on some subtleties. So, I do wonder if something might get lost. [G2, patient 23]

For some patients, the personal nature of pregnancy, with discussions of reproduction, children, and family, presented a sharp contrast to other types of medical visits. This participant described the uniqueness of obstetric visits and conversations compared to other health care encounters:

But it is a . . . it's a very personal thing, and I think that you kind of need to be with your doctor physically. I think it's just a different kind of care. It's a different kind of appointment, and so, I think it's a mistake to treat OB/GYN care just like any other doctor's appointment, like, 'cause, I just think it's different in so many ways. [G2, patient 18]

Discussion

Principal Findings

Our study provides important insight into the nature and scope of health care delivery challenges caused by the COVID-19 pandemic, specifically those associated with the implementation of telehealth as a formative strategy to control infection spread among health care providers, patients, and communities. Although previous studies demonstrated that telehealth is an acceptable and available way to obtain prenatal care for some pregnant patients [2,6,20], the majority of these studies were conducted prior to the pandemic and with patient populations who may have been more accepting of or able to use this approach. As a result, there is little data on the impact of broad and rapid telehealth use across diverse patient and health care provider populations in response to a pandemic.

Our study sheds light on patients' experiences and attitudes about integrating telehealth in prenatal health care delivery. Many participants in this study supported the use of telehealth in their prenatal care, citing reasons, including a sense of greater convenience, less time commitment, and less frustration from logistic steps of navigating the clinical setting compared to in-person visits; similar reasons had been noted in previous studies on the use of telehealth. In addition, they valued telehealth as a way to avoid possible exposure to COVID-19 and the potential negative consequences of infection for themselves, the pregnancy, and their family. Such factors may

help patients who may be unsure of or inexperienced with using the internet for health care to try telehealth [21-25].

However, there were several concerns about telehealth broadly and its rapid integration during the pandemic, concerns that have not been reported in earlier studies of the use of telehealth in prenatal health care delivery. A leading finding was that many participants sought additional reassurance about their health care during the pandemic, particularly the implications of COVID-19 for the pregnancy and the best approaches to managing key aspects of their pregnancy amidst the pandemic (eg, accessing testing during pregnancy, management of labor and delivery). Several participants felt that they could only achieve the level of reassurance they needed from an in-person visit. This was due, in part, to a concern that health care communication may not be as effective during an internet-based interaction compared to an in-person visit. Participants described how they viewed the use of telehealth for obstetric care compared to its use for general health care concerns. Reasons included the need for additional care and sensitivity needed for personal discussions pertaining to reproductive health, the pregnancy, parenthood, and family. For these participants, different and unfamiliar approaches to patient-provider communication also led to questions about health care quality and patient experience during their pregnancy as it was uniquely affected by the ongoing pandemic. Among this group, there was a call for health care systems to adapt telehealth approaches that would address the nuances of pregnant patients and prenatal care delivery.

Other important concerns were described. As part of telehealth implementation, participants were often provided with home monitoring equipment, such as a fetal Doppler to assess the fetal heartbeat at home. Most felt satisfied with the education provided by their health care provider about how to use this equipment. Yet, several were concerned about using this equipment at home [26,27], specifically whether they had the ability to correctly use the Doppler to hear the heart tones. This is a unique finding that calls for further investigation as other studies show patients' acceptance of using home monitoring tools [28]. Yet, a recent study demonstrated that 68% of participants were comfortable using a fetal Doppler for fetal heart tones [26], raising a question of the perspectives of those participants who did not. Further research is needed to understand how diverse patient populations may be able to implement home monitoring plans as part of telehealth, an issue that may be affected by health literacy and other key patient demographic factors.

Another concern pertained to a fear that they would be the ones to directly identify miscarriage or fetal loss by detecting the lack of a heartbeat using the fetal Doppler. Prior studies demonstrate the fears and experiences of women regarding the experience of miscarriage, particularly among those who experienced loss in a prior pregnancy [29-33]. These are significant considerations that must be addressed in telehealth implementation, both for patients experiencing pregnancy during the pandemic and for those who may use telehealth under different circumstances.

These findings raise questions about how patient experience and health care communication, key metrics to health care quality and safety, may be altered by telehealth, particularly when broadly implemented during a pandemic or other similar public health crises. Obstetric patients may have unique needs with the implementation of telehealth during the pandemic, given the myriad of uncertainties that COVID-19 has introduced to health care deliveries and communities. A model by Peahl et al [6] suggested that a 4-1-4 method may be possible for prenatal care, describing a process that combines in-person with telehealth visits that may balance the preferences and needs of patients, while also maintaining health and safety during an infectious public health threat. Thus, there is a need to develop approaches to telehealth for prenatal care delivery that align with the preferences and needs of diverse pregnant patient populations.

Limitations

Although our study sheds light on the emerging challenges with telehealth implementation, there were some limitations. The study used qualitative methods among a sample of patients at a single health care system. Our sample was limited in size and in racial and ethnic representation among diverse populations. In addition, study participants were from a health care system that could readily deploy telehealth, which may reflect participants' interest and exposure to this approach. Therefore, further research is needed to examine study findings among diverse patient populations and as the course of the pandemic continues.

Conclusion

In conclusion, although previous studies have demonstrated that telehealth is a flexible and convenient alternative for some prenatal appointments, our study suggests that there may be specific needs and concerns among the diverse patient groups using this modality during the pandemic. More research is needed to understand patients' experiences with telehealth during the pandemic and to develop approaches that are responsive to both the needs and preferences of patients and the challenges presented by public health emergencies that call for significant changes in health care delivery. This includes understanding the experiences of not only pregnant patients but also patient populations who may also have experienced the rapid conversion to telehealth in response to the pandemic.

Abstract

Background: Quarantines and nationwide lockdowns implemented for containing the spread of the COVID-19 pandemic may lead to distress and increase the frequency of anxiety and depression symptoms among the general population. During the nationwide lockdown of the first wave of the COVID-19 outbreak in Spain, we developed and launched a web-based app to promote emotional self-care in the general population and facilitate contact with health care professionals.

Objective: This study aimed to describe a web-based app and analyze its utilization pattern throughout 2 successive waves of the COVID-19 outbreak in Spain.

Methods: Our web-based app targeted all individuals aged 18 years or more and was designed by adapting the contents of a mobile app for adjuvant treatment of posttraumatic stress disorder (ie, the PTSD Coach app) to the general population and the pandemic or lockdown scenario. We retrospectively assessed the utilization pattern of the web-based app using data systematically retrieved from Google Analytics. Data were grouped into 3 time periods, defined using Joinpoint regression analysis of COVID-19 incidence in our area: first wave, between-wave period, and second wave.

Results: The resulting web-based app, named gesioemocional.cat, maintains the navigation structure of the PTSD Coach app, with three main modules: tools for emotional self-care, a self-assessment test, and professional resources for on-demand contact. The self-assessment test combines the Patient Health Questionnaire-2 and the 7-item Generalized Anxiety Disorder scale and offers professional contact in the advent of a high level of depression and anxiety; contact is prioritized in accordance with a screening questionnaire administered at the time of obtaining individual consent to be contacted. The tools for emotional self-care can be accessed either on-demand or symptom-driven. The utilization analysis showed a high number of weekly accesses during the first wave. In this period, press releases regarding critical events of the pandemic progression and government decisions on containment measures were followed by a utilization peak, irrespective of the sense (ie, positive or negative) of the information. Positive information pieces (eg, relaxation of containment measures due to a reduction of COVID-19 cases) resulted in a sharp

increase in utilization immediately after information release, followed by a successive decline in utilization. The second wave was characterized by a lower and less responsive utilization of the web-based app.

Conclusions: mHealth tools may help the general population cope with stressful conditions associated with the pandemic scenario. Future studies shall investigate the effectiveness of these tools among the general population—including individuals without diagnosed mental illnesses—and strategies to reach as many people as possible.

Introduction

In the last months, most countries worldwide have experienced uncontrolled outbreaks of the COVID-19 soon after reporting the first case. The rapid spread of its causative agent, SARS-CoV-2, has led to an unprecedented overburdening of health care systems, prompting many governments to dictate strict lockdowns for containing the outbreak.

While such indiscriminate strategies have succeeded in containing SARS-CoV-2 spread and reducing mortality [1], evidence warns on many psychological harms potentially associated with quarantines [2], particularly among older and dependent people and those with previous psychiatric pathologies [3-5]. Alongside the quarantine-specific stressors, the uncertainty associated with the pandemic scenario and impossibility of accompanying loved ones during their hospital stay or end-of-life stage has contributed to psychological overwhelming in many cases [5].

The use of mobile health (mHealth) and web-based technologies for health (eHealth) has been shown to improve access to health care services under confinement situations. In previous years, information and communication technologies (ICT) (including mHealth and eHealth solutions) for people with mental health needs have been gradually incorporated into routine care, as also for social groups not considered regular digital consumers such as older people [6]. A successful example of ICT-based solutions for mental health is the mobile app for managing posttraumatic stress disorder (PTSD; ie, the PTSD Coach app), developed by the Veterans Affairs National Centre for PTSD and the Department of Defence's National Centre for Telehealth & Technology [7]. The PTSD Coach app has been translated to many languages—including Spanish, a translation led by our team [8]—and it is currently used in our psychiatry department as an adjuvant to face-to-face therapy for PTSD.

The Catalan Health Service, which provides universal health care to a population of 7.7 million inhabitants in Northeast Spain, has a long tradition of implementing ICT solutions for promoting integrated care and increasing the efficiency and quality of health care delivery. The overloading of the health care system experienced during the COVID-19 outbreak boosted the implementation of various digital health strategies to counteract the collapse of many health resources [9]. To our knowledge, by the time of the nationwide lockdown in our country, no mHealth solutions had been developed for supporting people with mental health needs in a quarantine or lockdown context. Thus, considering the limited access of people to the health care system and the potential of ICT-based solutions to bridge these gaps, we aimed to develop a web-based app platform for supporting emotional management among the general population during the COVID-19 outbreak in our country. The existence of the PTSD Coach app provided us with an opportunity to develop such a web-based app quickly and offer it to the local population timely.

We present herein the development, main characteristics, and launch of the web-based app, named gestioemocional.cat ("emotionalmanagement" in Catalan), and a retrospective analysis of its use throughout alternate periods of lockdown and ease of social distancing measures.

Methods

Design Objectives

The web-based app was developed in response to a request by the Catalan Health System and Catalan Ministry of Health to provide Catalonia citizens (Northeast Spain) with support for coping with the emotional struggle associated with the COVID-19 pandemic and the nationwide lockdown. The web-based app was designed to assess two main objectives: (1) to provide users with tools and guidance for emotional self-assessment and care, and (2) to establish a communication channel to reach health care professionals in the advent of worsening of mental health symptoms.

The web-based app targeted all individuals aged 18 years or older with the capacity to use a mobile app or website. Spain has a high smartphone penetration rate [10], for which the web-based app had the potential to reach a significant part of the population. Nonetheless, technical requirements of the web-based app were minimized to facilitate access. Furthermore, to achieve high acceptability and on-demand use of the web-based app [11], we decided to store the least information possible and not retain the user's historical records.

Development of the Web-Based App

The government request for developing the web-based app was made on March 26, 2020. A panel of experts consisting of 2 clinical psychologists with expertise in psychological trauma and crisis intervention and 2 psychiatrists of the Catalan Health System coordinated and oversaw the web-based app development and content generation. Considering the limited time for developing the web-based app and the effectiveness of the previously developed PTSD Coach app, we used it as a

starting point to translate its contents and adapt them to a lockdown or pandemic scenario when necessary.

The panel of experts reviewed all items of the PTSD Coach app and grouped them into three categories: (1) items that could be translated into local languages without changes in their content; (2) items that required adaptation owing to cultural differences, need for broadening the clinical scope to cover anxiety and depression symptoms, or adequateness to the quarantine or pandemic scenario; and (3) items to be removed for definite inappropriateness in accordance with the intended use of the App. Owing to the urgency of the development of the web-based app, item review was based on the clinical criteria and the expertise of panel members. Of note, 2 of them had contributed to developing and translating the PTSD Coach App and had, therefore, in-depth knowledge of the rationale behind each item. The resulting contents were used to develop the web-based app using the corporate colors and design of the Catalan Health System. The authors of the PSTD Coach app kindly provided permission to adapt and translate their App.

Time Frame and Launching Strategy of the Web-Based App

The first case of COVID-19 in Spain was officially reported in late January 2020. The Spanish government halted public gatherings on March 9, 2020, and led to a state of alarm and a nationwide lockdown on March 13, 2020. The lockdown started a progressive easing on May 10, 2020, and was definitely lifted on June 20, 2020.

The web-based app gestioemocional.cat was launched by the Catalan Health Department on April 15, 2020. Information regarding the web-based app was disseminated using television and radio advertisements, which were released through the channels of the public corporation.

Utilization Analysis and Statistics

Data for utilization analysis of the web-based app were gathered from Google Analytics. The main objective of the utilization analysis was to describe the number of users throughout the study period. We used a script to systematize queries for retrieving information on daily accesses to the web-based app. For longitudinal analysis of the use of the web-based app, the number of events was transformed into a logarithmic scale and plotted against a timeline covering the period from the web-based app launch on April 15, 2020, to data set closure on December 16, 2020. Key events regarding outbreak progression (ie, relevant press releases on epidemiological information and government decisions) and the time window of each wave of the outbreak were added to the plot. The 2 waves of the COVID-19 outbreak were defined using Joinpoint regression analysis of publicly available data on COVID-19 incidence in our area. A permutation test with 0.05 confidence and 4499 permutations was used as described elsewhere [12]. Differences in the distribution of test scores on each of the priority levels in the 3 study periods (ie, first wave, second wave, and between waves) were assessed using a Pearson chi-square test and setting the significance threshold at a 2-sided α value of .05. The rest of the analyses were descriptive, and no other hypothesis tests were conducted. All analyses and plots were performed using R package [13].

Results

Platform Components

The gestioemocional.cat web-based app has the same navigation structure as the PTSD Coach app. Table 1 summarizes the changes introduced to the PTSD Coach items to adapt them to the intended use of the gestioemocional.cat web-based app; the resulting list of items was translated to the local languages (ie, Spanish and Catalan). Figure 1 outlines the navigation structure of the web-based app. The main menu provides the user with access to three sections: (1) resources for emotional management, (2) tools for self-assessment, and (3) professional resources.

Table 1. Summary of content changes for adaptation of the PTSD Coach app into gestioemociona.cat web-based app[a].

PTSD Coach app contents	Gestioemocional.cat contents	Rationale for change

Figure 1. Navigation structure of the gestioemocional.cat web-based app. CAP: primary care center (for the Catalan acronym "Centre d'Atenció Primària"), GAD-7: 7-item Generalized Anxiety Disorder scale, PHQ-2: Patient Health Questionnaire-2.
Resources for Emotional Management

The section "resources for the emotional management" can be accessed through two pathways: symptom-guided and resource type–guided (Figure 1). Symptoms include painful memories, self-isolation, disconnection from reality, sadness or hopelessness, worries, negative emotion, and sleeping disturbances. All these symptoms have been identified as very common during quarantines and lockdowns in the context of the COVID-19 pandemic [14,15]. Resource types include body scan (ie, audio-guided), change one's perspective (ie, random text messages to rationalize distress thoughts), connect with others (ie, list of ideas or tips for establishing interpersonal relationships under a quarantine context), deep breathing (ie, audio-guided technique for emotional regulation trough breathing), grounding (ie, list of tips for helping to be fully present for whatever is occurring right here and now), inspirational phrases, use of personal leisure time (ie, list of proposed activities to be performed during the lockdown), mindfulness exercises, progressive relaxation, observe thoughts (ie, audio-guided techniques to help coping with distress thoughts), relationships improvements (ie, list of tips to improve peer communication), help falling asleep (ie, list of proposals for sleeping better), calm the senses, relaxing images, thought shifting (ie, list of phrases to be repeated over 5 minutes using a countdown tool), and time-out (ie, list of proposals to change the environment when remaining quarantined).

Irrespective of the pathway chosen to access the section "resources for the emotional management," the web-based app suggests a particular resource based on the user's distress level, assessed using a single-item questionnaire (ie, what is your distress level? [use the arrows to indicate how you feel]) and rated on a 10-point scale with scores ranging 0-10. Users can select the distress level either stepwise—using up and down arrows—or using a distress thermometer with an intensity color code (Figure 1).

Self-assessment

The self-assessment section is based on two questionnaires for a mental health assessment with a Spanish version adapted and validated: the Patient Health Questionnaire-2 (PHQ-2) [16] and the 7-item Generalized Anxiety Disorder scale (GAD-7) [17]. The PHQ-2 is intended as a first-step approach to identify depressive symptoms on the basis of the frequency of depressed mood and anhedonia. While not recommended for depression diagnosis or monitoring, it is considered useful for screening for depression, which is the most common psychological conditions in clinical practice and research; individuals who

screen positive should be further evaluated with the PHQ-9 to determine whether they meet the criteria for a depressive disorder [18]. The Spanish version of the PHQ-2 has shown good reliability and validity in identifying depressive symptoms in the primary care setting [19]. The GAD-7 was developed for its use in primary care, and it has high sensitivity in identifying symptoms of the anxiety spectrum. The Spanish validation of the questionnaire has shown good reliability and validity [20]. To facilitate self-assessment, the 2 questionnaires were merged into a single questionnaire. The combination of the PHQ-2 and GAD-7 for a joint assessment of anxiety and depression has shown high internal reliability and strong convergent and construct validity when assessing its association with other mental health, quality of life, and disability measures [21]. All items of the combined questionnaire refer to the frequency of symptoms within the past 2 weeks and are rated on a 4-point scale where 0="never," 1="less than seven days," 2="more than seven days," and 3="almost every day."

The results of the 2 questionnaires are combined to provide 4 priority levels of care needs (Figure 2). Users with low scores in the PHQ-2 and GAD-7 (ie, suggestive of mild symptoms of anxiety and depression) are encouraged to the routine use of self-management and self-assessment tools to either maintain (level 4) or improve (level 3) their emotional health status. Conversely, users with high scores on the PHQ-2 and GAD-7 (ie, suggestive of severe anxiety and depressive symptoms) are offered telephone contact with professionals of the emergency medical service. Users who agree to be contacted by a health care professional are redirected to a consent form, which collects minimum personal data. Contacts are prioritized on the basis of the combined result of the self-assessment questionnaire (ie, 1 or 2) and a screening form asking about 6 extreme mental health conditions: suicidal ideation, loss of a loved one due to COVID-19, family member admitted to hospital owing to COVID-19, living with someone at high risk of severe illness or with COVID-19 symptoms, current psychiatric treatment, and previous psychiatric treatment. Affirmative responses to these questions were assigned the highest priority, irrespective of the self-assessment questionnaire results (Figure 2).

Scheduled telephone calls are performed by the same professionals attending calls from people who reach the emergency medical service seeking mental health support. Once the phone contact has been established, health care professionals perform an independent assessment, irrespective of the contact source (ie, direct call to emergency medical services or scheduled call through the web-based app).

Figure 2. Prioritization algorithm for proactive contact with health care professionals on the basis of the assessment of mental health status. GAD-7: 7-item Generalized Anxiety Disorder scale, PHQ-2: Patient Health Questionnaire-2.

Healthcare Resources

The section "healthcare resources" allows the user to proactively contact community resources, including general health information, emergency medical services, general government information office, the user's primary care center, and the office for women under gender violence. Additional resources include the Galatea Foundation, aimed at providing support to health care professionals, the Official College of Psychologists, which can respond to population demands and transfer cases to public health care professionals, and the Vall d'Hebron Coronavirus Section, a web-based platform available 24 hours a day, 7 days a week for attending concerns related to emotional and social impact of the COVID-19 pandemic.

Utilization

Between April 15, 2020 (ie, the launch date), and December 16, 2020, the web-based app reported 582,826 accesses. Figure 3 shows the longitudinal analysis of the number of users and critical events of pandemic progress. During the final period of the nationwide lockdown, the daily number of users peaked concomitantly with key news or government actions released by the press. Most of the press releases announcing changes on containment measures were immediately followed by a utilization peak, irrespective of the sense of these changes (ie, increasing or easing restrictions). Immediately after announcing the easing of restrictions (eg, the start of the de-escalation plan), the daily number of users remarkably decreased. The decrease was particularly abrupt when Barcelona, the most populated area, entered the first phase of the de-escalation plan.

Figure 3. Longitudinal analysis of the number of accesses to the web-based app (logarithmic scale). Each time point shows the cumulative number of users in the 5 previous days. Red dotted lines show press releases of key events and government decisions regarding the COVID-19 outbreak. A: April 17, 2020—the Catalan Ministry of Health reports and posts the highest RT-PCR–positive and hospitalization rates. B: April 28, 2020—the Spanish government announces a de-escalation plan, to be deployed in 4 phases. Catalonia exceeds 10,000 deaths due to COVID-19. C: May 5, 2020—the government announces an upcoming partial lockdown. D: May 25, 2020, Barcelona—the greatest area in Catalonia, enters de-escalation phase 1. E: June 21, 2020—the whole country officially starts the "new normal" state. F: October 16, 2020—the government dictates a temporal lockdown of bars and restaurants. G: October 25, 2020—the government dictates nationwide curfew from 10 PM to 6 AM. H: October 30, 2020—the government dictates a permanent closure of area boundaries and weekend closure of city boundaries. The time window of each period (ie, first wave, between waves, and second wave) was defined using a Joinpoint regression analysis. RT-PCR: reverse transcription–polymerase chain reaction.
The number of users during the second wave of the outbreak was persistently lower than that in the first wave. During this period, use of the web-based app was less sensitive to the announcement of government measures.

Progression of Self-assessment

During the study period, the web-based app recorded 142,337 self-assessment tests: 124,087 (87.2%) during the first wave, 8510 (6.0%) during the period between waves, and 9740 (6.8%) during the second wave. The chi-square test revealed significant differences in the distribution of percentages across the priority levels (obtained from the self-assessment module) between the analysis periods (Figure 4). The percentage of tests scoring for priority levels 1 or 2 (associated with more severe symptoms of anxiety and depression) was higher in the second wave and between-wave periods. Overall, the offer of professional help was accepted in 8588 cases (11.4% of all cases with priority levels 1 or 2 and, therefore, triggering the message for an offer of professional help).

Figure 4. Distribution of the results of the self-assessment test across priority levels (ie, risk group) in each of the analysis periods: first wave (n=124,087), between waves (n=8510), and second wave (n=9740). The 3 periods were defined using a Joinpoint regression analysis. The Pearson chi-square test for percentage distribution was significant at $P<.001$ ($\chi^2_6=1349.1$).
Discussion

Principal Findings

In this study, we describe a web-based app aimed at providing the general population with self-care and self-assessment tools for emotional health during the lockdown associated with the COVID-19 pandemic and establishing a new communication channel between the population and health care professionals. In addition, to reporting the characteristics of the web-based app, we analyzed the utilization pattern of the web-based app during the first 10 months of the COVID-19 outbreak in Spain. The frequency of use of the web-based app was particularly high during the first wave of the outbreak in Spain and progressively declined until reaching a baseline activity below 1000 weekly accesses after halting the national lockdown. During the first wave, the number of accesses peaked after press releases associated with the pandemic progression or changes in the containment measures dictated by the government. Interestingly, positive news (eg, relaxation of social distancing measures) were immediately followed by a sharp increase in utilization and a successive decline. The between-wave and second wave periods were characterized by a less responsive pattern of web-based app users.

The self-assessment module of the web-based app, designed to work as a sentinel for detecting severe mental health symptoms and proactively offer direct contact with health care professionals, was mostly used during the first wave. However, the scores of the self-assessment questionnaire were higher after the first wave, suggesting a higher proportion of people with

mental health care during the second wave and between-wave periods.

Limitations

Development and launching of the web-based app were strongly influenced by the urgency and overloading of the health care system, which challenged the design of an adequate assessment strategy of the platform. We chose the PTSD Coach app because of the symptom overlapping between PTSD and those reported elsewhere for lockdown situations, particularly regarding anxiety and depression. One of the advantages of the PTSD Coach app was the body of evidence on its effectiveness for self-management of mental health needs. However, owing to the shift in the target population (ie, from people diagnosed with PTSD to the general population), effectiveness of our web-based app cannot be assumed and should be confirmed in future studies. Of note, the complicated scenario in which the web-based app should be assessed will strongly challenge the trial conduct.

Another important limitation of our retrospective analysis was the limited data stored, which precluded more exhaustive assessments of behavior patterns among users (eg, to discriminate between entries of new users and regular access of the same user). However, because of the negative correlation that often exists between App use or demand and permissions for accessing private data [11], we were concerned that collecting too much data from users might be a barrier to web-based app utilization. Of note, the government announcement of launching a COVID-19 tracer app raised many privacy concerns among the population and was strongly

criticized. In light of this general perception, we prioritized the acceptability of the web-based app over the capacity of collecting personal information. As a result, our database for the retrospective analysis lacked important information that might have helped to understand behavior patterns among users. One of the most remarkable consequences of this limitation is the lack of data at a user level, which precludes discriminating between entries of new users and regular access of the same user. More importantly, the lack of historical records of users prevents us from analyzing improvement or worsening of mental health state. Finally, we could not analyze the usage of the web-based app in accordance with socioeconomic status, which has been highlighted as a source of inequality in other aspects associated with access to COVID-19 resources [22,23]. Nevertheless, while all these limitations compromise analytical approaches of the web-based app, the absence of personal questions and no need for signing in are likely to promote the platform use, in line with the overarching goal of the project, which was to help the population during the stressful circumstances of the lockdown.

Comparison With Prior Work

To our knowledge, by the time of developing the web-based app, no other mHealth solutions for promoting emotional self-care in the general population during a lockdown or quarantine situation had been launched or published. The closest example of an mHealth tool that matched our aim was the PTSD Coach app, which was innovative in the sense that users can access tools through two alternative pathways: on-demand and symptom-driven [7]. Although the PTSD Coach app was designed as adjuvant to face-to-face therapy for PTSD, its authors suggested that it could also help people not receiving psychological treatment [24,25]. Further experiences also showed good usability and ease of cultural adaptation of the App [8], encouraging us to adapt its contents to a lockdown and pandemic scenario in our country.

Although we cannot directly compare the utilization patterns of our web-based app with other mHealth or eHealth solutions for lockdown contexts, the trends observed in our analysis are consistent with information reported elsewhere. For instance, the increased consumption of alcohol and drug abuse reported during this period in our area [15] could likely be attributed to increased anxiety symptoms, grief processes, and difficulties associated with intensive cohabitation [26,27]. Similarly, other countries have reported increased demand for attention from people with mental health needs during nationwide lockdowns associated with the COVID-19 pandemic [28,29].

The design of our retrospective analysis precludes drawing strong conclusions regarding the reasons underlying the observed trend toward a less responsive usage of the web-based app during the second wave of the outbreak. However, this finding is consistent with the "pandemic fatigue" phenomenon highlighted by the World Health Organization and defined as an expected and natural response to a prolonged public health crisis [30]. This type of reaction might correspond to M Seligman's Paradigm on learned helplessness, which describes a passive behavior exhibited by a subject after enduring repeated aversive stimuli beyond their control. It is worth noticing, however, our finding that self-assessment tests more often scored priority levels 1 or 2 during the between-wave and second wave periods suggests that people with higher mental health needs were more likely to retain the usage of the web-based app after the first wave.

Finally, the fact that 8588 self-assessment tests ended up with a scheduled telephone call with health care professionals for mental health support indicates that the web-based app has emerged as an additional communication channel for seeking professional help. The number of telephone contacts represents a low percentage (11.4%) of the total situations in which professional support was offered. However, this finding is consistent with current evidence, which suggests that most people with common mental health problems do not seek professional help [31,32].

Conclusions

In the first year of the COVID-19 pandemic, various authors have emphasized the need to promote original and creative ways to help people cope with the new and stressful conditions during the pandemic [33,34]. We did not want to miss the opportunity to adapt mHealth tools with proven efficacy in self-management of stressful situations to the pandemic scenario. Future studies shall investigate the extent to which this tool helps people cope with the pandemic scenario and address strategies for making as many people as possible aware of this resource.

Conflicts of Interest

JB was on the speakers' bureau and/or acted as consultant for Janssen-Cilag, GILEAD, MSD, ViiV, Menarini in the last 3 years. He also received travel awards (transport + hotel) from Lundbeck, Janssen-Cilag, GILEAD, MSD, and Menarini for taking part in psychiatric meetings. All the other authors confirm that they have no conflicts of interests related to the manuscript.

Correction of: https://formative.jmir.org/2022/3/e31972

In "Ascertaining Medication Use and Patient-Reported Outcomes via an App and Exploring Gamification in Patients With Multiple Sclerosis Treated With Interferon β-1b: Observational Study" (JMIR Form Res 2022;6(3):e31972) the authors noted one error.

In the originally published article, Figure 2 appeared incorrectly (as shown in the Multimedia Appendix 1).

The correct Figure 2 is provided below.

The correction will appear in the online version of the paper on the JMIR Publications website on March 17, 2022, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Figure 2. (A) Compliance overall and by gender and age group, (B) patients categorized by percentage of interferon β-1b injections missed (based on an expected frequency of 1 injection every other day), and (C) adherence overall and by gender and age group, analyzed (i) prospectively and (ii) retrospectively. Compliance at 6 and 12 months was assessed in patients with ≥6 and ≥12 months of injection-related data, respectively. In the box and whisker plots, the colored bars indicate median and IQR, the whiskers indicate minimum and maximum values, and the white circles indicate the mean.
