[a]Each response could be placed in more than one category. Categories were derived from individuals' open-ended responses.

Symptom and Well-being Outcomes

From baseline to 4 weeks, there was a significant reduction in anxiety symptoms for both per-protocol samples (Table 5; t_{112}=10.92, *P*<.001, *d*=1.03) and intention-to-treat samples (t_{184}=9.48, *P*<.001, *d*=0.70) with large and medium effect sizes, respectively. There was also a significant improvement in perceived stress (per-protocol sample: t_{112}=7.69, *P*<.001, *d*=0.72; intention-to-treat sample: t_{184}=7.09, *P*<.001, *d*=0.52) and depressive feelings (per-protocol sample: t_{110}=7.88, *P*<.001, *d*=0.75; intention-to-treat sample: t_{181}=7.40, *P*<.001, *d*=0.55) with medium effect sizes. Finally, there were significant improvements in emotion regulation (per-protocol sample: t_{105}=5.93, *P*<.001, *d*=0.58; intention-to-treat sample: t_{178}=5.79, *P*<.001, *d*=0.43) and optimism (per-protocol sample: t_{104}=–5.04, *P*<.001, *d*=–0.49; intention-to-treat sample: t_{175}=–5.15, *P*<.001, *d*=–0.39) with small to medium effect sizes.

Table 5. Symptom and well-being outcomes from baseline to 4 weeks.

Outcome	Per-protocol sample (n=113)[a]					Intention-to-treat sample (N=185)[b]				
	Baseline, mean (SD)	4 weeks, mean (SD)	ΔMean (% change)[c]	*P* value	Effect size[d]	Baseline, mean (SD)	4 weeks, mean (SD)	ΔMean (% change)[c]	*P* value	Effect size[d]
Anxiety symptoms (GAD-7[e])	13.30 (4.31)	8.54 (4.61)	–4.76 (–35.81)	<.001	1.03	13.28 (4.39)	10.18 (5.14)	–3.10 (–23.32)	<.001	0.70
Perceived stress (PSS-4[f])	8.96 (2.39)	7.08 (2.29)	–1.88 (–21.03)	<.001	0.72	8.89 (2.41)	7.73 (2.48)	–1.16 (–13.07)	<.001	0.52
Depressive feelings (PHQ-8[g])	11.67 (5.47)	7.77 (4.98)	–3.90 (–33.39)	<.001	0.75	11.99 (5.55)	9.40 (5.66)	–2.59 (–21.61)	<.001	0.55
Emotion regulation (DERS-SF[h])	45.97 (11.86)	39.39 (11.30)	–6.57 (–14.30)	<.001	0.58	47.01 (13.09)	42.95 (13.49)	–4.05 (–8.63)	<.001	0.43
Optimism (LOT-R[i])	7.05 (3.49)	8.16 (3.15)	1.11 (15.75)	<.001	0.49	7.33 (3.57)	8.09 (3.39)	0.75 (10.30)	<.001	0.39

[a]Per-protocol analyses only included participants who completed both survey assessments.

[b]For intention-to-treat analyses, baseline responses were carried forward for nonresponders.

[c]Negative values indicate decreases compared to baseline.

[d]Effect sizes constitute Cohen *d*.

[e]GAD-7: 7-item Generalized Anxiety Disorder scale.

[f]PSS-4: 4-item Perceived Stress Scale.

[g]PHQ-8: 8-item Patient Health Questionnaire depression scale.

[h]DERS-SF: Difficulties in Emotion Regulation Scale–Short Form; negative values on the DERS-SF indicate better emotional regulation (ie, fewer difficulties with emotional regulation).

[i]LOT-R: Life Orientation Test–Revised; positive values on the LOT-R indicate more optimism.

Discussion

Principal Findings

In reviews of mental health programs, researchers have voiced concerns about limited published research on commercial programs, and that programs either have limited public engagement or are not based on evidence-based theory [18,25-27,31,32]. Given the identified need for evidence from this type of commercial program [25,31], this pilot study evaluated the feasibility, acceptability, and preliminary outcomes of Noom Mood, which is widely publicly available, based on CBT and MBSR techniques, designed to encourage engagement among the general public, and includes personal coaching. Our results suggest that the program was usable, feasible, and acceptable to participants. In addition, self-reported anxiety symptoms, stress, depressive feelings, emotion regulation, and optimism improved from baseline to 4 weeks.

Feasibility and Acceptability

Feasibility

Overall, participants rated the program as feasible. The average system usability score was 77.4, which surpasses the threshold for good usability [69], and more than 75% of participants reported that the program was easy to use. These scores are in line with feasibility and usability scores from other mobile programs [70-73]. Similar to levels of engagement reported in studies of comparable mobile mental health programs [46,70,74], participants in this study engaged with Noom Mood regularly, opening the program approximately two times per week and performing an action within the app once every 2 to 3 days (11 of 28 days). Participants engaged most with the articles and least with activities. Of note, it is possible that participants completed activities offline throughout the week, which is how they were designed, but did not mark them as complete in the app. As such, it is likely that the data collected on activities underestimate participant engagement in this aspect

of Noom Mood, given that many activities focus on offline experiences (eg, practicing breathing exercises or grounding techniques). Future studies will aim to assess actions completed offline in relationship to symptom outcomes.

Acceptability

The vast majority of participants found the program to be logical (92%) and effective at reducing stress and anxiety (76%). Importantly, 81% of participants felt confident in recommending the program to a friend. These findings are similar to other studies of mobile mental health programs and suggest that the program was perceived to be acceptable to users [35,70,73]. Additionally, at the follow-up assessment, more than half of the participants reported that they expected that the program would eventually reduce their stress or anxiety by an additional 50% or more. Future work should investigate long-term outcomes and whether these participant expectations are borne out.

Participants reported benefiting most from skills training; program features such as articles, activities, and coaching; learning to better manage their emotions; and reflective processes such as learning, reflecting, and increasing their awareness. Participants reported benefiting from taking the time to reflect on how they were feeling and increasingly becoming aware of their emotions and thought patterns. Many participants also mentioned benefiting from the structure and accountability of a designated program. Participants appreciated the overall tenor of the program; one participant reflected that "the attitude it strikes is a great balance of cheeky humor but realistic so it's not overly strict nor overly cheesy. Makes me connect with it well and stick with it." Other participants, however, reported that they hoped for a more serious tone to the articles. At the time of the study, the program incorporated jokes and hashtags for the sake of relatability, and has since been modified in response to participant feedback.

Participants also indicated that the program could be improved to better help individuals progress in a way that best suits an individual's idiosyncratic wants or needs. For example, some participants wanted a slower pace, whereas others requested more daily reminders. Additionally, some participants provided feedback that they wanted more specialized interactions with coaches. While individuals were informed that Noom Mood is not a replacement for therapy and does not provide clinical assessment or treatment, it is possible that participants were expecting the coaching feature to function more similarly to therapy. However, some participants provided feedback stating that responses given by coaches did not feel personalized and felt too generic. It is also possible that some participants may not have been good candidates for a self-help approach. As mentioned previously, in the literature, there is limited understanding of how participants would experience a commercial mobile mental health program with personal coaching, rather than therapy. This study contributes initial understanding that, in this context, coaching can be helpful, but it can also raise confusion about the role of a coach when providing guidance and support rather than therapy. Future iterations of the program should, thus, be sure to set expectations for this feature clearly.

Participants also relayed some suggestions for program improvements that would provide support in varying environments or situations, such as support for moms with young children, skills to reduce procrastination, video and audio recordings, and easily accessible summaries of activities or articles, all of which should be considered in future programs. Since the time of the study, audio recordings have been added to the program. Some participants reported that they would prefer that the program be offered at a lower cost, and some mentioned they would like the program to be covered by health insurance plans. In order to increase accessibility, future initiatives and programs should consider efforts to provide reimbursable experiences (eg, through employee wellness initiatives).

Preliminary Outcomes

Anxiety Symptoms, Perceived Stress, and Depressive Feelings

From baseline to 4 weeks, anxiety symptoms improved by 36% (d=1.03) in per-protocol analyses and 23% (d=0.70) in intention-to-treat analyses. In addition, stress reductions were 21% (d=0.72, per-protocol analysis) and 13% (d=0.52, intention-to-treat analysis), and depressive feelings decreased by 33% (d=0.75, per-protocol analysis) and 22% (d=0.55, intention-to-treat analysis). These effect sizes are comparable to those reported in studies of other mobile mental health programs with the same study length and outcome measures [44,75-80]. Specifically, anxiety and stress decreased in ways that were comparable to or greater than anxiety reductions shown in previous studies, whereas depression showed comparable, though smaller, effect sizes [44,75,78,79]. Of course, this may reflect the fact that the program focuses more on stress and anxiety management than on depression. Of all our outcome measures, anxiety showed the biggest effect sizes, which contrasts with some studies that have found that anxiety scores did not improve as much as other symptom measures, such as depression [75,80].

Emotion Regulation and Optimism

In this study, we found that emotion regulation improved by 14% (d=0.58, per-protocol analysis) and 8.6% (d=0.43, intention-to-treat analysis). Emotion dysregulation is hypothesized to underpin a wide range of psychological difficulties [81]; in fact, transdiagnostic interventions, such as DBT or the Unified Protocol [82], focus on emotion dysregulation as the primary treatment target. Notably, however, emotion regulation is rarely included as an outcome variable in mobile mental health programs, despite its empirical and theoretical relevance to mental health and well-being [19]. In two studies of mHealth programs conducted with young adults [83] and homeless youth [84] that measured emotion regulation as an outcome variable, results showed no significant improvements in emotion regulation capacity.

We found significantly higher optimism at 4 weeks compared to baseline (15.7% or d=0.49, per-protocol analysis; 10% or d=0.39, intention-to-treat analysis). To our knowledge, this is the first mobile mental health study to measure changes in optimism, though some studies of mobile mental health

programs have found improvements in other positive psychological constructs, such as life satisfaction, general mental well-being, or quality of life [46,85-88]. A robust literature base demonstrates that optimism is inversely correlated with depression and anxiety and positively correlated with measures of life satisfaction and self-reported health variables [89,90]. Importantly, optimism may influence physical and mental health by encouraging adaptive coping [85]. Consistent with previous findings, both baseline and 4-week optimism scores were significantly negatively correlated with time-matched anxiety symptoms, stress, and depressive feelings, and optimism scores were positively correlated with emotion regulation (ie, higher optimism is correlated with greater capacity to regulate one's emotions). Future studies should evaluate optimism and its associations with other mental health outcomes.

Limitations

This pilot study had several limitations. First, without a control group, it was not possible to separate the effects of the program itself from improvement over time (ie, regression to the mean and maturation). In addition, other interventions were uncontrolled; that is, program participants may have been participating in active therapy or may have been taking psychotropic medications while they were participating in this study. Nevertheless, it is unlikely that these findings are purely spurious, as the effect sizes are similar to those found in active treatment groups in RCTs, and they are much larger than those found in control groups (eg, see Bakker et al [75]). Now that preliminary feasibility and acceptability have been established, future studies should use randomized designs to confirm that these results were due to the program itself. Also, the study was conducted over 4 weeks, and it is unclear whether results would change over longer periods of time. Further, the study examined the program as a whole, making it difficult to isolate which specific program components led to changes in outcomes. Future studies should use causal methods to explore this further. In addition, the sample was primarily female, White, and highly educated, which is typical of studies of mobile mental health programs [19]. Future research should evaluate to what extent these results would generalize to other populations and actively recruit from hard-to-reach populations. Lastly, this study did not assess other variables that may have caused improvement in symptoms, such as psychiatric services, individual or group therapy, and participants' use of other self-help materials.

Conclusions

In this study, we explored the usability, feasibility, acceptability, and preliminary effectiveness of Noom Mood, a publicly available, mobile mental well-being program based on CBT and MBSR with personal coaching. The program follows 11 of Bakker et al's [5] evidence-based recommendations for mobile mental health programs: it is based on CBT; addresses both anxiety and low mood; is designed for use by nonclinical populations; includes reporting of thoughts, feelings, and behaviors; recommends activities; provides mental health information; encourages non–technology-based activities; includes gamification or intrinsic motivation to engage; shows logs of past app use (eg, patterns of logged mood); uses reminders to engage (eg, messages from the coach); and provides a simple and intuitive interface and interactions. Our results suggest that Noom Mood was usable, feasible, and acceptable to participants, with promising preliminary improvements in anxiety symptoms, stress, depressive feelings, emotion regulation, and optimism. Future directions should include (1) the incorporation of changes suggested by participants in this study and (2) more rigorous testing of outcome variables, such as through randomized designs.

Conflicts of Interest

Authors MM, ASH, ESM, CNM, HB, and AM are employees at Noom, Inc, and have received salary and stock options for their employment. LR received payment from Noom, Inc, for their role as a consultant on this project and for their contribution as an author on this paper. LR is also a co-owner of the Triangle Area Psychology Clinic; a consultant to, and a DBT trainer for, Behavioral Tech, LLC; and an employee of University of North Carolina School of Medicine. There are no specific conflicts to report with those entities, and none of those entities were involved in their contribution to this project.

Abstract

Background: Health care access issues have long plagued rural Americans. One approach to alleviating the challenges and poor health outcomes for rural individuals is through the use of telemedicine, sometimes called telehealth. It is important to understand factors that may be related to telemedicine adoption or nonadoption, particularly in underserved rural settings.

Objective: This pilot study examines telemedicine perceptions among rural, underserved populations using the Technology Acceptance Model, which serves as a framework to explore the adoption of telemedicine services by those who have used it. This study also explores the differences between user and nonuser perceptions of telemedicine.

Methods: Paper surveys and phone interviews were conducted in rural Northern Lower Michigan.

Results: Perceived usefulness and perceived ease of use explained 91% of the variability in attitude toward telemedicine (R^2=0.91; $F_{1,15}$=73.406; P<.001). Ease of use was a significant predictor (mean 2.36, SD 1.20; P<.001), but usefulness (mean 3.16, SD 0.81; P=.20) was not. Furthermore, there were significant differences in individual perception of telemedicine between users and nonusers. For example, nonusers believed they would receive better care in person (users: mean 3.30, SD 1.22; nonusers: mean 1.91, SD 1.14; $F_{1,32}$=10.126; P=.003). The quantitative findings were reinforced by the qualitative results from the phone interviews.

Conclusions: Overall, the Technology Acceptance Model is an appropriate model to understand the attitudes toward telemedicine that may lead to its adoption by rural Americans.

Introduction

Americans living in rural areas are more likely to have lower levels of education and live below the average income of the country when compared to their urban counterparts. They are more likely to die from all the leading causes of death in the United States and are more likely to have a disability that leaves them unable to work [1]. Additionally, health care access issues have long plagued the 14.5 million rural Americans [2] who face a severe shortage of health care workers and fewer hospital beds per capita than their urban counterparts [3]. These health care access challenges have been exacerbated during the COVID-19 pandemic. One approach to alleviating these challenges and the related poor health outcomes in rural areas is telemedicine, also often referred to as telehealth. Telemedicine can deliver health care through technologies such as mobile phones or computers. Telemedicine programs can address transportation barriers in geographically dispersed rural regions by allowing patients to remotely connect with their providers and enabling access to specialty providers for consultation from afar [4].

Although telemedicine has been around for decades, the COVID-19 pandemic and the resulting reimbursement policy changes accelerated the service's growth and awareness among the public [5-7]. In fact, telemedicine has become a viable way—and for some the only way—to see a health care provider. The adoption of telemedicine services during the pandemic has grown exponentially. The Centers for Disease Control and Prevention reported that 43% of health centers could provide telemedicine services in 2019, and 95% of health care centers reported using telemedicine services by April 2020 [8]. Despite expanded reimbursement, the rapid implementation of telemedicine for health care delivery during the pandemic has excluded approximately one-third of rural Americans, who may lack access to the necessary broadband internet needed for telemedicine [9,10]. Other telemedicine barriers affecting rural populations include limited access to technology at home, low digital literacy, and apprehension regarding telemedicine as a viable health service [11].

Therefore, it is important to understand factors related to telemedicine adoption and nonadoption, particularly by individuals in underserved rural settings. For this study, we examined the adoption of telemedicine through the lens of the Technology Acceptance Model (TAM) [12]. This model posits that perceived usefulness and perceived ease of use predict an individual's attitude toward using the technology. Perceived usefulness has been defined as "the degree to which an individual believes that using a particular system would enhance his or her job performance." Perceived ease of use is generally defined as how easy a system is to use. Greater perceived usefulness and perceived ease of use for a particular system should be predictive of more favorable attitudes toward the technology or the system itself. Together, these factors determine an individual's behavioral intentions to use the technology. Several studies have demonstrated that this model has predictive value in the context of health and technology [13-15].

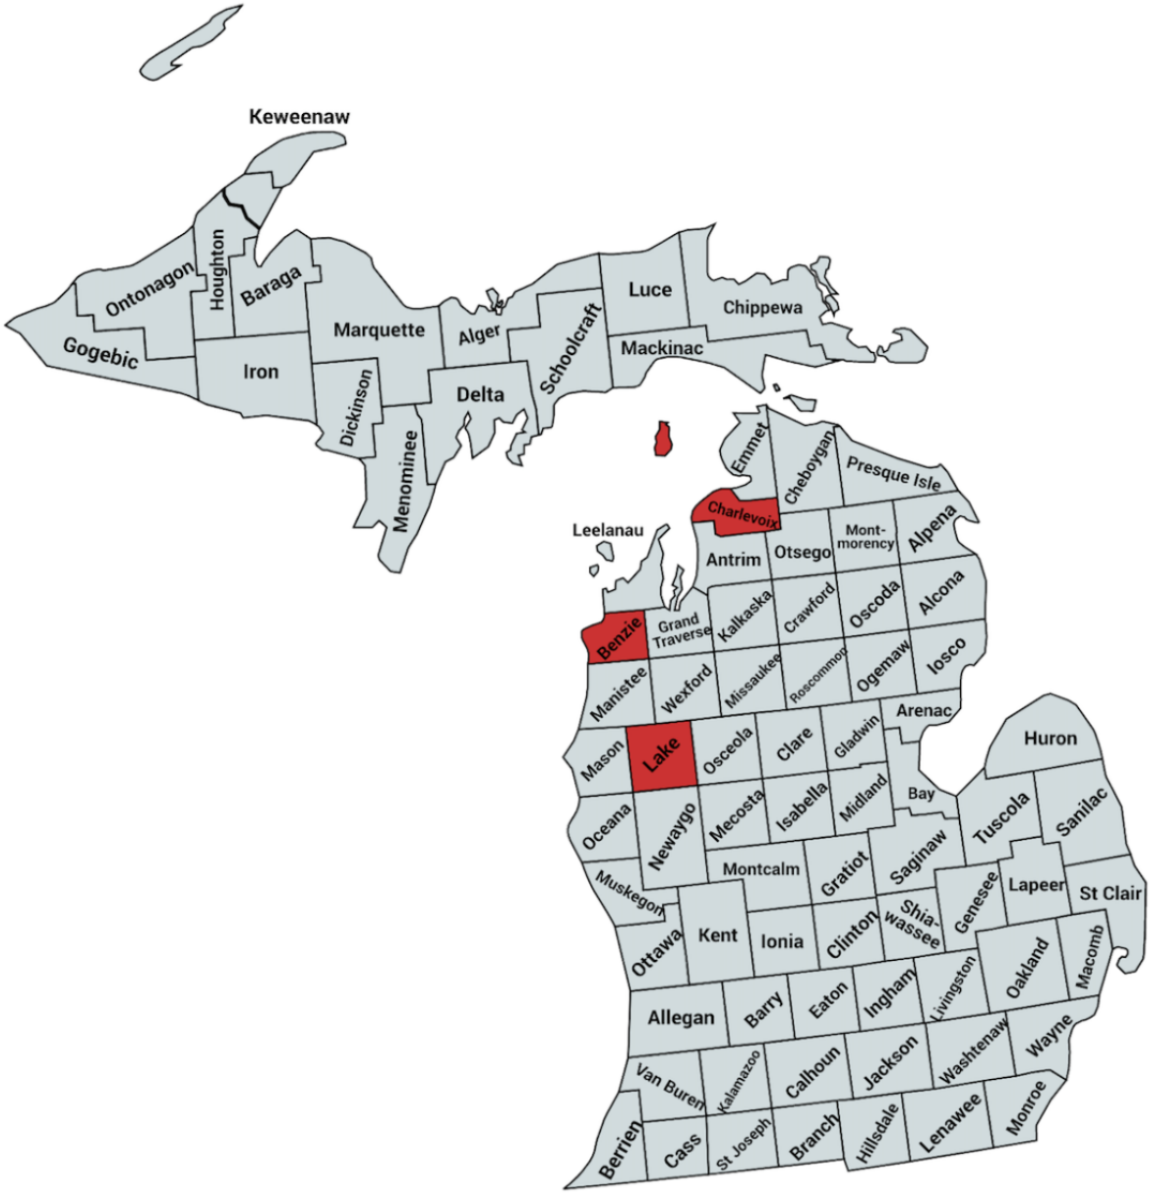
The purpose of this study is to examine telemedicine perceptions among rural, underserved populations (specifically patients) in Northern Lower Michigan using the TAM, which serves as a framework to explore the adoption of telemedicine services by those who have used it. Additionally, the study explores how users and nonusers differ in their perceptions and barriers to using telemedicine, which would provide essential information for the implementation of these services.

Methods

Location and Recruitment

In this cross-sectional study, study locations in rural Northern Lower Michigan were selected in collaboration with our community partners and represented rural regions with health care access barriers. Benzie County was selected because it is the smallest county in the state of Michigan and represents a remote rural county with a Rural-Urban Continuum Code (RUCC) of 9 (codes 1-3 denote metropolitan areas, 4-6 suburban, and 7-9 rural) [16]. Its ratio of population to primary care physicians is higher than the state average (1610:1 vs 1030:1) [17]. Lake County (RUCC of 9) was selected because it is the poorest county in Michigan and has the highest ratio of population to primary care physicians in the state of Michigan (11,880:1). Beaver Island, part of Charlevoix County, was selected as it is rural and only accessible by plane or ferry (in warmer weather) and has a RUCC of 7. See Figure 1 for a map of the surveyed areas.

Figure 1. Map of the surveyed areas in red. In Charlevoix County, only Beaver Island was surveyed (map created with MapChart).



From March to September 2020, researchers provided survey packets to 2 food pantries and an island-based health center in these 3 counties. The food pantry and health center staff handed out the packets to their clients, while keeping a record to ensure only one packet was provided per household. Participants had to be at least 18 years of age and consented to the survey by mailing it back to the researchers. The survey packet included a welcome letter, the paper survey, a self-addressed stamped return envelope, an invitation to participate in a voluntary follow-up phone interview, and a US $2 bill. Paper surveys were used to reach this remote population, comply with COVID-19 research restrictions, and account for uneven technology access among the population.

Respondents were asked if they would be willing to participate in a phone interview to better to understand some of their perceptions regarding telemedicine services. To indicate interest, they completed a contact form to send back with the survey. Interview participants were given a US $20 gift card to a store of their choosing. The phone interviews were conducted by 3 researchers using a semistructured interview guide based on survey responses. All interviews were audio-recorded and transcribed verbatim. The 3 researchers reviewed the recordings and highlighted any commonalities between the respondents.

Ethics Approval

Michigan State University and Munson Healthcare Institutional Review Boards approved this study (STUDY00004682) and all data collection materials.

Data Collection

The paper survey in this study was modified based on a survey used in previous studies regarding use, perceptions, and technology access [18]. The survey asked respondents their previous experience using telemedicine services, perceptions of telemedicine (using a Likert-type response scale, from 1=strongly agree to 5=strongly disagree), insurance and employment status, overall health status, technology access, and primary care provider status. Perceived usefulness was measured using 5 statements (eg, “I generally use telemedicine

when my provider isn't open," "I have used telemedicine because I didn't want to get infected in the waiting room by other people"). Perceived ease of use was measured using 4 statements (eg, "It was convenient to receive care through telemedicine," "It was easy to arrange an appointment"). Attitude toward telemedicine was measured using 5 statements (eg, "The quality of care through telemedicine is excellent," "If I had the opportunity, I would use telemedicine again"). The complete survey can be found in Multimedia Appendix 1.

The semistructured interview guide was developed through a review of the responses to the survey, the TAM constructs, and general use and perceptions of telemedicine.

Statistical Analysis

Descriptive statistics were used to characterize the study population. The reliabilities of survey questions were reported using Cronbach alpha. In addition, frequencies and percentages were evaluated for variables describing barriers to telemedicine use from nonusers and intentions to use telemedicine from previous users. We conducted a factor analysis using principal component analysis with a varimax rotation. The analysis was able to cluster the TAM variables into the constructs of interest. A multivariate linear regression model was conducted to evaluate the relationship between the continuous TAM variables (ease of use and usefulness) and the outcome of attitude toward telemedicine; assumptions of the linear model were specifically tested. Finally, ANOVA was conducted to compare group differences between users and nonusers on multiple outcomes of interest, including perceptions of in-person care and telemedicine care, the ease of seeing their primary care provider, concerns about insurance, continuity of care, and communication. Statistical significance for all analyses was set as $P<.05$. Data screening was performed for missing data and outliers and the assumptions of multiple regression analysis methods were considered.

Results

Respondent Demographics

Characteristics of the 59 survey respondents are shown in Table 1. The majority of respondents lived in Benzie County, Michigan (n=30, 51%), followed by Beaver Island, Michigan (n=16, 27%) and Lake County, Michigan (n=13, 22%). Most respondents identified as female (n=41, 69%) and White (n=41, 69%). A large proportion of respondents indicated having an annual income less than US $20,000 (n=29, 49%) and that they were retired (n=20, 34%) or unable to work (n=10, 17%). In addition, nearly half did not attend college (n=25, 42%). There were 11 (19%) respondents who indicated that they do not have access to the internet in their homes. Overall, 25 (42%) respondents reported having used telemedicine in the past.

Table 1. Paper survey respondent demographics.

Variable	All respondents (N=59), n (%)	Users (n=25), n (%)	Nonusers (n=16), n (%)
Location			
Beaver Island, Michigan	16 (27)	7 (28)	5 (31)

Quantitative Results

Reliability

The reliabilities of survey statements on 3 variables were reported: perceived usefulness (Cronbach α=.73), perceived ease of use (Cronbach α=.87), and attitude toward telemedicine (Cronbach α=.93).

TAM Results

Perceived usefulness and perceived ease of use explained 91% of the variability in attitude toward telemedicine (R^2=0.91; $F_{1,15}$=73.406; P<.001). Ease of use was a significant predictor of attitude toward telemedicine (mean 2.36, SD 1.20; P<.001), but usefulness (mean 3.16, SD 0.81; P=.20) was not. See Table 2 for the full regression analysis.

Table 2. Regression analysis: usefulness and ease of use as a predictor of attitude toward telemedicine.

Effect	Unstandardized B	SE	Standardized β	*t* value (*df*)	*P* value
Usefulness	–0.174	0.128	–.119	–1.357 (17)	.20
Ease of use	0.997	0.087	.999	11.404 (17)	<.001

User and Nonuser Perceptions

Significant differences were observed between users and nonusers on their perceptions of in-person care compared to telemedicine. When comparing previous users of telemedicine to nonusers, the nonusers believed they would receive better care in person compared to telemedicine (users: mean 3.30, SD 1.22; nonusers: mean 1.91, SD 1.14; $F_{1,32}$=10.126; P=.003). Nonusers also believed that health care providers would not be as caring via telemedicine (users: mean 4.09, SD 1.15; nonusers: mean 2.91, SD 1.04; $F_{1,31}$=8.199; P=.007). Finally, the results demonstrated significant differences between users and nonusers on worries about continuity of care (users: mean 4.05, SD 0.95; nonusers: mean 3.00, SD 0.78; $F_{1,31}$=9.957; P=.004), with nonusers having more worries regarding the continuity of care than past users of telemedicine. There were no significant differences between users and nonusers on the ease of seeing their primary care provider (P=.26), concerns about insurance (P=.31), concerns about experiencing worse communication (P=.74), or worries about their primary care provider receiving their information (P=.18). See Table 3 for the full results and statistics.

Table 3. Means, standard deviations, and 1-way ANOVA in outcomes of users compared to nonusers of telemedicine.

Outcome	Users, mean (SD)	Nonusers, mean (SD)	*F* test (*df*)	*P* value
Easy to see provider	2.78 (1.30)	2.27 (1.01)	1.343 (1,32)	.26
Better care in person	3.30 (1.22)	1.91 (1.14)	10.126 (1,32)	.003
Insurance concerns	3.45 (1.41)	2.91 (1.51)	1.051 (1,31)	.31
Worse communication	3.32 (1.46)	3.50 (1.35)	0.111 (1,30)	.74
Provider not caring	4.09 (1.15)	2.91 (1.04)	8.199 (1,31)	.007
Continuity of care concerns	4.05 (0.95)	3.00 (0.78)	9.957 (1,31)	.004
Concerns about provider not receiving information from visit	3.95 (1.09)	3.45 (0.69)	1.915 (1,31)	.18

Qualitative Results

Of the survey respondents, 8 individuals indicated interest in participating in the phone interviews and all completed the interviews. The participants were made up of 1 (12%) man and 7 (88%) women, with 5 (62%) participants from Beaver Island, 3 (38%) from Benzie County, and none from Lake County. There were 5 (62%) participants who had used telemedicine in the past. Examples of interview questions are shown in Textbox 1.

Ease of use was reinforced as a key driver of using telemedicine, with the participants indicating that it was often easier to see a provider through telemedicine when compared to the travel time and costs associated with in-person care. Among telemedicine users, positive perceptions of their experiences were expressed in interviews; they would continue to use it and recommend it to others who might be hesitant. Mirroring our quantitative results, trust in their primary care provider was a key theme. It was important for those who have used telemedicine and a reason why some have not. Another barrier mentioned for using telemedicine was the individuals' access to internet. Many stated that rural internet access was not always stable. There was sometimes only 1 internet provider that was slow, unreliable, or not responsive to their needs. Examples of participant responses are shown in Table 4.

Textbox 1. Sample qualitative interview questions.

- How does your technology access or connectivity impact your willingness to use telemedicine services?
- Why did you use telemedicine? / Why haven't you used telemedicine?
- Were you able to have your visit from your home or did you have to go someplace else?
- Describe the process of setting up a telemedicine appointment, from scheduling to the visit.
- How would you describe the communication between you and your provider during the telemedicine visit?
- What are things you liked about your telemedicine visit(s)?
- What are things that you didn't like about your visit?
- How (if at all) have your past experiences with telemedicine impacted your future use of telemedicine?
- Would you recommend telemedicine to a relative or friend? Why or why not?

Table 4. Sample participant responses.

Theme/category	Illustrative quote
Ease of use	• I didn't have to go through all the trouble of traveling, taking a whole day to go for a doctor's office visit and then sitting in a waiting room.
Positive perception of telemedicine experience	• And I think it's very effective in what it's trying to accomplish. For example, I'm on Beaver Island and I have a teleconference with a doctor off island, the doctor I have on island could be there with me. In other words, we're sharing information. I think it's effective and incredibly beneficial for anybody that has issues that need to be dealt with that way. • I like this wonderful service, especially because I live in a remote area of Michigan, and it is a little bit complicated to get to a doctor. For me, telemedicine is really a wonderful service.
Access to internet as a barrier to telemedicine	• They're [internet providers] utterly unresponsive. They couldn't care less about the people on the island because they don't have to.
Trust	• Probably the connections that they are *[sic]* have with the doctor. If they feel comfortable with their doctor, whether they talking to them over the phone or seeing them face-to-face.

Discussion

Principal Findings

This study sought to understand the adoption of telemedicine among people in very rural communities who were accessing food pantries and a community health center amid the COVID-19 pandemic through the lens of the TAM. The results suggested that the TAM is an appropriate model to view the attitudes toward telemedicine that may lead to its adoption by rural Americans. For this population, perceived ease of use was a stronger predictor of telemedicine use than perceived usefulness. Furthermore, there were significant differences in individual perceptions of telemedicine between users and nonusers.

Although perceived usefulness was not significant on its own, it still represents a concept that should be further explored with this population. There are several possible explanations for this finding. For example, a recent study found that some individuals had concerns regarding the privacy and security of telemedicine visits [19]. Perhaps these concerns impacted perceptions of usefulness in this study. Additionally, perceptions of usefulness may be impacted by limited availability and quality of internet-enabled devices, lack of access to high-speed broadband, or health and technology literacy limitations, as participants mentioned these factors in their statements. Another issue noted in other studies is that people like to see their primary care physician in person [18]; more work should be done to explore if this applies for all types of visits.

Practical Implications

A positive finding from this data was that, once patients have used telemedicine, they generally become more receptive toward it. This mirrors past data regarding users and nonusers of telemedicine during the COVID-19 pandemic [18]. Although this does not suggest that all medical or health visits should be conducted via technology, patients could try telemedicine for simple, quick visits (eg, medication follow-ups, refills) to become more comfortable with technology for future visits. Additionally, these results should have implications on policy changes [20]. For example, in the United States, the Biden infrastructure plan intends to increase access to quality and affordable high-speed internet [21]. Medical schools should offer medical students and residents more opportunities to learn about telemedicine, not just what it is and how it is used, but also how to integrate it into clinical practice, train staff, and prepare patients for their visit. This is especially true for clinics serving primarily older and rural patient populations.

There are limitations of this study that should be mentioned. First, this study examined a specific demographic cohort of mostly low-income, White, older, retired, or disabled participants in Northern Lower Michigan who are traditionally difficult to reach for research, especially during the COVID-19 pandemic. However, it should be noted that gaining insight from this population is important for researchers and policy makers. Although this demographic may not be representative of all rural populations, access issues transcend locations. Further research should be conducted to learn how telemedicine is perceived in various rural populations and locales. Future studies are needed to understand rural individuals' acceptance of and attitudes toward telemedicine with continued testing and exploration of the TAM within these difficult-to-reach populations. These preliminary data can help other researchers determine if the same constructs remain significant for targeting tailored interventions for their community. This study found that by working with the community and distributing paper surveys through food banks, we were able to access difficult-to-reach populations who provided valuable insights about telemedicine. These findings are useful for future research on this population. Based on these data, we have begun implementing interventions to help increase the use of telemedicine and improve access to health care in these rural areas and throughout other rural regions of Michigan.

Conclusion

During the COVID-19 pandemic, telemedicine has allowed for continued health care while adhering to strict social distancing policies. This unforeseen experiment has proven that telemedicine has "come of age" after decades of underutilization. This study offers a deeper understanding of attitudes toward and acceptance of telemedicine by vulnerable rural populations in the United States. If telemedicine is used proficiently and consistently, rural populations can gain improved health benefits, which would promote health equity and improve health outcomes.

Abstract

Background: The rising prevalence of gestational diabetes mellitus (GDM) calls for the use of innovative methods to inform and empower these pregnant women. An information chatbot, Dina, was developed for women with GDM and is Norway's first health chatbot, integrated into the national digital health platform.

Objective: The aim of this study is to investigate what kind of information users seek in a health chatbot providing support on GDM. Furthermore, we sought to explore when and how the chatbot is used by time of day and the number of questions in each dialogue and to categorize the questions the chatbot was unable to answer (fallback). The overall goal is to explore quantitative user data in the chatbot's log, thereby contributing to further development of the chatbot.

Methods: An observational study was designed. We used quantitative anonymous data (dialogues) from the chatbot's log and platform during an 8-week period in 2018 and a 12-week period in 2019 and 2020. Dialogues between the user and the chatbot were the unit of analysis. Questions from the users were categorized by theme. The time of day the dialogue occurred and the number of questions in each dialogue were registered, and questions resulting in a fallback message were identified. Results are presented using descriptive statistics.

Results: We identified 610 dialogues with a total of 2838 questions during the 20 weeks of data collection. Questions regarding blood glucose, GDM, diet, and physical activity represented 58.81% (1669/2838) of all questions. In total, 58.0% (354/610) of dialogues occurred during daytime (8 AM to 3:59 PM), Monday through Friday. Most dialogues were short, containing 1-3 questions (340/610, 55.7%), and there was a decrease in dialogues containing 4-6 questions in the second period (P=.013). The chatbot was able to answer 88.51% (2512/2838) of all posed questions. The mean number of dialogues per week was 36 in the first period and 26.83 in the second period.

Conclusions: Frequently asked questions seem to mirror the cornerstones of GDM treatment and may indicate that the chatbot is used to quickly access information already provided for them by the health care service but providing a low-threshold way to access that information. Our results underline the need to actively promote and integrate the chatbot into antenatal care as well as the importance of continuous content improvement in order to provide relevant information.

Introduction

Gestational diabetes mellitus (GDM) is defined as glucose intolerance that arises and is discovered during the second or third trimester of pregnancy [1]. Globally, it affects 1 in 7 pregnant women [2]. In 2019, 5.09% (2769 of 54,407) of pregnant women were diagnosed with GDM in Norway [3], but the condition is assumed to occur in up to 10% of all Norwegian pregnancies, varying by ethnic origin [4,5]. GDM is associated with numerous pregnancy complications affecting both the mother and the fetus [2,6-8], and women with GDM have an increased risk of later developing type 2 diabetes [9,10]. To ensure good health for both the mother and the fetus, a thorough follow-up of women with GDM is required. In reducing the consequences of GDM [7,8,11-13], antenatal training in self-managing blood glucose measurements and nutritional and physical activity education are cornerstones in current clinical care [8,14,15]. Follow-up is provided both by the primary and specialist health care based on blood glucose values [15]. Information provided should aim to strengthen the women's autonomy to cope with the diagnosis, enabling them to make the best decisions for their own health [8,16]. Traditionally, information is provided in person by medical professionals in addition to written information and referral to official websites. Studies indicate that women with GDM experience a lack of personally adapted information, which may contribute to a sense of insecurity [17,18]. This calls for new ways of complementing the established care. Furthermore, the rising prevalence of GDM will likely increase the need for antenatal care consultations [15], and the use of new technologies like chatbots could be a valuable asset in future health care [19].

Use of information and communications technology has the potential to improve public health by increasing efficiency, lowering costs, and improving quality of care [20]. Different health technology solutions may have positive effects on the self-management of diabetes [19], an asset especially important for women with GDM. Chatbots are conversational agents based on artificial intelligence that interact with users in a natural language, either text-based or voice driven, independent of time and location [21,22]. There is a growing number of health chatbots developed for different purposes [23]. Developed by health care personnel and users, Dina, Norway's first health chatbot, was launched in 2018 and made freely available for women with GDM [24]. Dina provides information on GDM and relevant topics related to the condition in accordance with national recommendations. Chatbots providing health information and support regarding other specific conditions have been developed elsewhere [25-27].

Health technology solutions such as chatbots are rarely implemented in health care after the initial pilot study phase [19]. Previous studies evaluating health chatbots have mostly used interviews or questionnaires and have not been based on quantitative analysis of chatbot logs [28]. Exploring chatbot dialogues may provide valuable information needed for further improvement [29]. In 2019, Dina the chatbot was integrated into the Norwegian official digital health platform and is thus an example of implementation of health technology solutions in clinical care.

Our study aim is to provide a basis for improvement and further development of Dina the chatbot by exploring log data on what type of information the users' seek, with the research question being as follows: What type of information do users seek in a health chatbot providing support on GDM? Further specific aims are to explore how many questions each dialogue contains and the time of day the chatbot is used. We subcategorized questions that led to a fallback message from the chatbot to obtain a deeper understanding of which type of questions the chatbot was unable to answer. This knowledge may provide insight into the use of health chatbots and potentially establish more general theoretical knowledge on this type of chatbot.

Methods

Background and Settings for Developing the Chatbot

In 2016, a pilot study for the project revealed an incoherent follow-up and lack of personally adapted information provided to women with GDM. Contrary to current practice when promoting health technology solutions [30], Dina the chatbot was developed after an observed and expressed need from both women with GDM and involved clinicians. Dina the chatbot was developed at Haukeland University Hospital in cooperation with Bergen municipality and Western Norway University of Applied Sciences. User involvement throughout development and evaluation of health technology is important [19], and a user-centered design [31] was applied throughout the development process. User representatives were involved from idea conception to evaluation [32,33] as was an interdisciplinary team of gynecologists, midwives, psychologists, nutritionists, endocrinologists, and information technology developers [34]. Initially, the chatbot was launched at its own website and was made available to all pregnant women in the country, but promotion was limited to Haukeland University Hospital and surrounding municipalities. In 2019, Dina the chatbot was implemented in the official Norwegian digital health platform, presented with an improved user interface (Dina 2.0), and hence made more available to all pregnant women in Norway. Of the 54,407 women who gave birth in Norway in 2019, the target population represented 2769 pregnant women diagnosed with GDM although a portion of these women might have had difficulty using the chatbot due to language barriers. The chatbot offers low-threshold access to quality-checked information, as login or a registered user account is not required. The overall goal for developing the chatbot was to provide reliable information to women with GDM, strengthen women's knowledge about their own health, and improve their daily coping with the condition. Dina is intended as an addition to established care and was developed as an informational chatbot. Pregnant women frequently seek information online and from apps [35] and expect modern health service to provide integrated digital solutions in treatment and follow-up [36]. This chatbot could be an important supplement for pregnant women with GDM [35]. However, evaluation of its use based on objective data from the chatbot's log is needed for further development. The results may also be beneficial in future development of similar informational chatbots created for other specific medical conditions. An observational study analyzing user data from Dina the chatbot was designed. Dialogues were collected from

the chatbot's log and platform over 20 weeks (from week 41 to 48 in 2018 and from week 47 in 2019 to week 6 in 2020). The management team of Dina added "test dialogues" to the chatbot for training and further development. However, these test dialogues were excluded from the collected data because they were not raised by the target population of Dina the chatbot and would have biased the results. A manual log review of the collected dialogues was performed. All data were anonymous, and the identification of users was not permitted. Thus, it was impossible to identify unique users or to determine if they visited the chatbot once or several times. Each dialogue served as the unit of analysis, and we prefer using the term "users of the chatbot" rather than "women with GDM."

Variables

Questions from users to the chatbot were categorized (see Figure 1), and all categories were mutually exclusive [37].

We identified the time of day that dialogues took place and the number of questions in each dialogue.

Table 1 presents the variables in Dina the chatbot with explanations and categories.

The time of day the dialogue took place was grouped into day (8 AM-3:59 PM), afternoon (4 PM-11:59 PM), and night (midnight-7:59AM), while the number of questions in each dialogue was categorized into 1-3, 4-6, 7-9, and ≥10 questions. We registered the frequency of questions the chatbot was unable to answer that resulted in a fallback message from the chatbot (eg, "I´m sorry, I cannot answer that at this point, could you rephrase the question?"). Questions resulting in a fallback message were subcategorized and counted numerically (see Figure 1) to explore which categories of questions the chatbot was unable to answer.

Figure 1. Categorization of questions for Dina the chatbot. HbA_{1c}: hemoglobin A_{1c}.

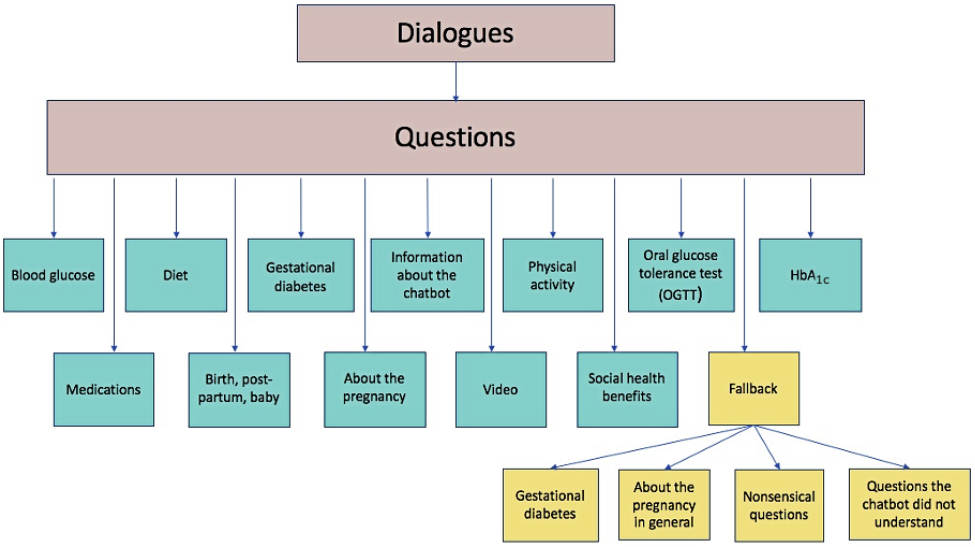

Table 1. Variables with explanations for Dina the chatbot.

Variable	Explanation	Categorization
Dialogue (the unit of analysis)	Question sequence between the user and the chatbot	N/A[a]
Period	Data collection period	Period 1: week 41 to 48 in 2018 Period 2: week 47 in 2019 to week 6 in 2020
Week number	Week the dialogue took place	Weeks 41 to 48 in 2018 Week 47 in 2019 to week 6 in 2020
Day of the week	Day of the week the dialogue took place	Monday, Tuesday, Wednesday, Thursday, Friday, Saturday, Sunday
Date	Date the dialogue took place	Day, month, year
Time of day	Time of day the dialogue took place	8 AM-3:59 PM 4 PM-11:59 PM Midnight-7:59AM
Total number of questions in each dialogue	Number of questions from the user to the chatbot in each dialogue	1-3, 4-6, 7-9, ≥10
Blood glucose	Number of questions from the user regarding blood glucose	Numerical
Diet	Number of questions from the user regarding diet and nutrition	Numerical
GDM[b]	Number of questions from the user regarding the GDM diagnosis	Numerical
Information about the chatbot	Number of maneuvers to "navigate" in the chatbot (theme button, general information about the chatbot, privacy in use, greetings)	Numerical
Physical activity	Number of questions from the user regarding physical activity	Numerical
HbA_{1c}[c] (average blood glucose levels)	Number of questions from the user regarding HbA_{1c} (specific test used to diagnose pre-existing diabetes before the 16th week of pregnancy)	Numerical
OGTT[d]	Number of questions from the user regarding OGTT	Numerical
Medications	Number of questions from the user regarding medications used in the treatment of GDM	Numerical
Birth/postpartum/baby	Number of questions from the user regarding birth, postpartum period, and/or the baby	Numerical
About the pregnancy	Number of questions from the user regarding the pregnancy in general	Numerical
Video	Link to informational videos	Numerical
Social health benefits	Number of questions from the user regarding sick leave and appointments with midwife or doctor	Numerical
Fallback	Number of questions in free text from the user the chatbot failed to answer that resulted in a fallback message from the chatbot (eg, "I'm sorry, I cannot answer that at the time, please contact your physician or midwife for further information.")	Numerical 1. Questions about GDM 2. Questions about the pregnancy in general 3. Questions the chatbot did not understand (eg, questions with several spelling errors, questions asked in a foreign language) 4. Nonsensical questions (eg, "Who is the king of Denmark?", "When does my bus leave?")

[a]N/A: not applicable.

[b]GDM: gestational diabetes mellitus.

[c]HbA_{1c}: hemoglobin A_{1c}.

[d]OGTT: oral glucose tolerance test.

Data Analyses

The unit of analysis was the individual dialogue. Dialogues were manually registered and thoroughly read by the first author (MHS). In dialogues, users could either type their questions in free text or click theme buttons. Dialogues could therefore consist of free-text questions, theme button questions, or a mix of the 2. All dialogues are displayed the same way in the chatbots log, making it impossible to distinguish between the predefined questions and free-text questions. Therefore, it was not possible to determine if a user chose to spell "blood sugar" in free text or if they pressed the theme button "blood sugar." Both free-text questions and predefined questions were counted as a whole, but questions that led to fallback would naturally be free-text questions, as the chatbot offers answers to the questions that are predefined. Differentiation between free-text and theme button questions will be considered in the future development of the chatbot. Variables were coded as nominal or interval. We used descriptive statistics: frequencies, proportions, and percentages. For continuous variables, we have reported mean as the central tendency with SD. Normal distribution was tested by Q-Q plot. Chi-square tests were performed to explore associations between variables, and independent *t* tests were used for comparisons of means. Results are presented visually in charts [37]. IBM SPSS Statistics (version 26) was used for all analyses. The significance level was set at 5%.

Ethical Considerations

This study was conducted as a collaboration between Haukeland University Hospital, Western Norway University of Applied Sciences, and Bergen municipality. The chatbot's platform and technological design have been validated in a risk and vulnerability analysis by the technical department at Haukeland University Hospital, and users' data are protected according to the General Data Protection Regulation [38]. Data are stored at a secure server, and access to data are limited to authorized personnel only. Users were informed by the chatbot about anonymity, asked not to leave any personal information, and told about potential future use of data for scientific purposes. This study was presented to the regional ethics committee of Western Norway (approval #167012, 12.08.2020) and found exempt from extended application, as all data are completely anonymous. The data protection officer of Haukeland University Hospital approved the study on August 25, 2020 (ID 1555).

Results

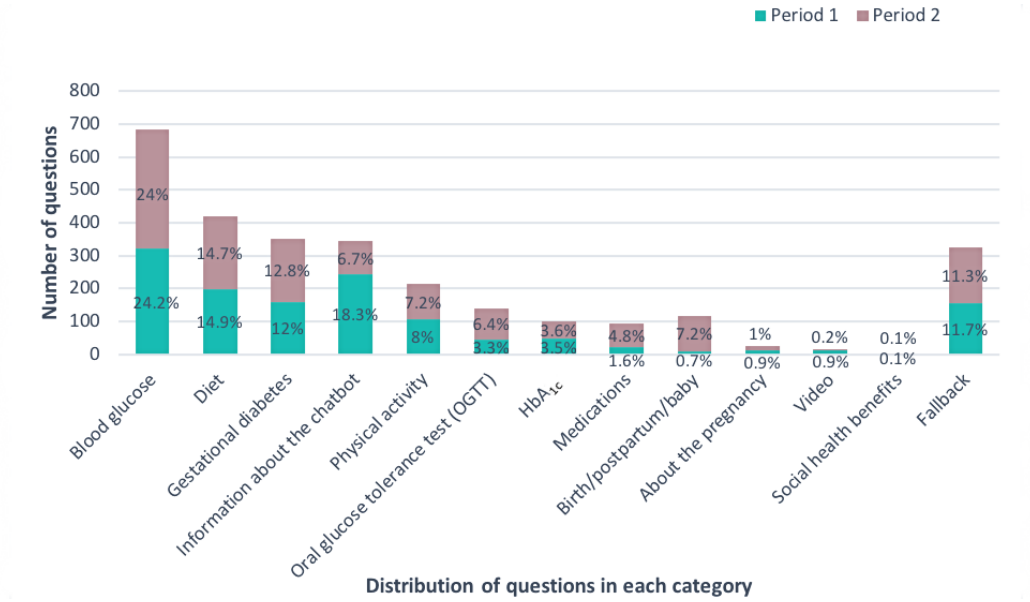
A total of 610 dialogues containing 2838 questions were registered during data collection. In the first period, 288 dialogues were registered, containing 1329 questions, while in the in the second period, 322 dialogues were registered, containing 1509 questions.

The Users' Informational Needs

Questions by category and period are presented in Figure 2.

Questions on blood glucose, diet, the GDM diagnosis, and physical activity accounted for 58.81% (1669/2838) of all questions, with little variation by period. The most frequent single category was questions on blood glucose levels, accounting for 24.07% (683/2838) of all questions. Questions on maneuvering and orienting in the chatbot (information about the chatbot) decreased from 18.28% (243/1329) in the first period, to 6.69% (101/1509) in the second period (P<.001). The remaining categories involving screening for GDM (oral glucose tolerance test and hemoglobin A_{1c}), birth and postpartum period, treatment (medications), general information concerning the pregnancy, informational videos, and questions on social health benefits represented 17.58% (499/2838) of questions.

Figure 2. Number of questions by category and period (period 1: weeks 41 to 48 in 2018 with 1329 questions; period 2: week 47 in 2019 to week 6 in 2020 with 1509 questions) for Dina the chatbot.



When and How the Chatbot Was Used

The number of dialogues per week ranged from 5 to 92 across the 20 weeks of registration, with a mean value of 36 (SD 19.26) and 26.8 (SD 24.34) for the first and second period, respectively. The dialogues by day of the week and time of day for the 2 periods combined are presented in Figure 3.

In total, 90.7% (553/610) of all dialogues took place Monday through Friday, and 58% (354/610) took place during the daytime (8 AM-3:59 PM). The dialogues registered during the afternoon accounted for 28.2% (172/610) of dialogues Monday through Friday. There was little registered activity during weekends.

The number of questions in each dialogue ranged from 1 to 38, with a mean value of 4.65 for the 20 weeks of registration. Short dialogues (1-3 questions) were most frequent, both in the first (153/288, 53.1%) and second period (187/322, 58.1%; see Figure 4).

There was a decrease in number of dialogues containing 4-6 questions from the first period (75/288, 26.0%) to the second period (57/322, 17.7%; *P*=.013). Long dialogues of >7 questions were stable across the 2 periods.

Figure 3. Number and percentage of dialogues in Dina the chatbot (n=610) by weekday and time of day for period 1 and period 2 combined.

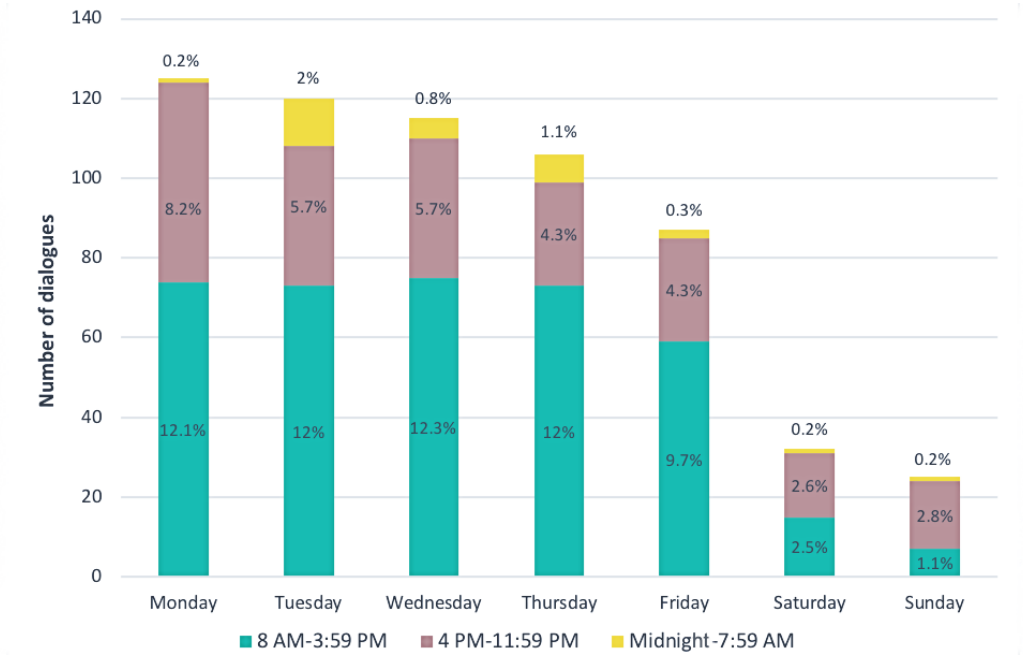


Figure 4. Dialogues by number of questions and period (period 1: weeks 41 to 48 in 2018, 288 dialogues; period 2: week 47 in 2019 to week 6 in 2020, 322 dialogues) for Dina the chatbot.

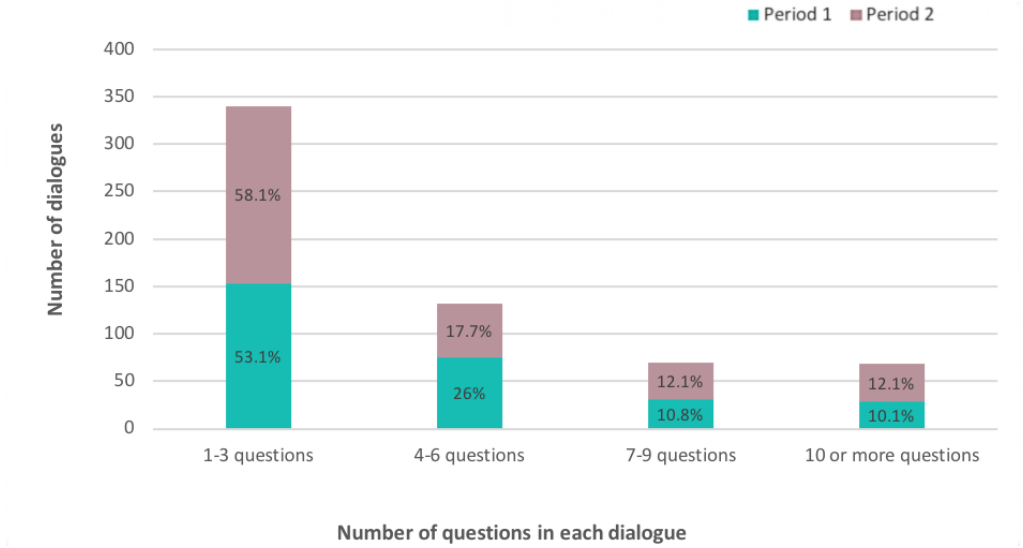
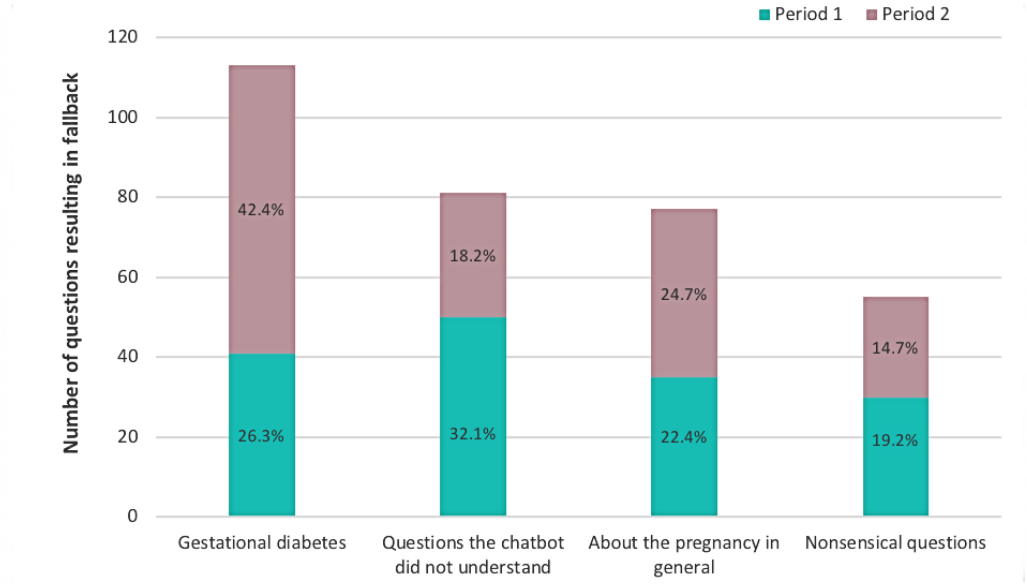


Ability To Answer Questions and Fallback by the Chatbot

Overall, Dina the chatbot was able to answer 88.15% (2512/2838) of all questions asked by users. Figure 5 shows the types of fallback questions by period.

Fallback questions on GDM increased from 26.3% (41/156) to 42.4% (72/170) from the first to the second period (P=.002), while the fallback questions the chatbot did not understand decreased from 32.1% (50/156) to 18.2% (31/170; P=.004). Fallback questions about pregnancy in general and nonsensical questions showed small variations between the 2 periods.

Figure 5. Types of fallback question by period (period 1: weeks 41 to 48 in 2018, n=156; period 2: week 47 in 2019 to week 6 in 2020, n=170) for Dina the chatbot.



Discussion

Principal Findings

Nearly 60% (1669/2838) of all questions from users were on blood glucose, diet, GDM, and physical activity, and the chatbot was able to answer 88.51% (2512/2838) of all posed questions. The chatbot was most frequently used during the daytime, Monday through Friday, and most dialogues were short, containing 1-3 questions. However, the mean number of dialogues per week was 36 in the first period and 26.83 in the second period.

Most Frequently Asked Questions to Dina the Chatbot

Few prior studies have evaluated health chatbots based on log reviews [28]. Inkster et al [27] explored log data on self-reported symptoms of depression, using questionnaires integrated in their chatbot, Wysa, but with a different focus than ours. To the extent of our knowledge, our study is the first study aiming to explore what users ask a health chatbot integrated into a national health service platform by categorizing incoming questions. Dina the chatbot provides the opportunity to click on related themes and questions, “guiding” the user through the conversation. This might have increased conversation efficiency and influenced findings in this study by making some information more available for the users than other topics. Our results indicate that users mainly seek information with high relevance for their currently experienced issues related to GDM (questions regarding blood glucose levels and diet) as opposed to relevant information on future events like the postpartum period or contextual factors such as social health benefits. The information sought also seems to overlap with information available through the established antenatal health care program in Norway, as distribution of the most frequent questions mirrors the cornerstones in the treatment of GDM [14,15]. This indicates that the chatbot could serve as a low-threshold addition to the already-established health care service. The chatbot may enhance the treatment of GDM, promote stable blood glucose, and thereby prevent the development of adverse outcomes for the mother and the fetus. Qualitative studies have shown that women diagnosed with GDM may perceive a lack of personally adapted information, contributing to a feeling of insecurity [17,33] in which managing blood glucose measurements and changing diets are the main challenges [18]. Information provided from a chatbot can thus serve as a reminder or a confirmation for the user on already-received information from medical professionals [33] and not as a substitute for the traditional face-to-face consultation [39]. For users, adding technology like informational chatbots to the standard patient care may reduce insecurities [33,40] and potentially contribute to increased self-efficacy [19].

What Can User Behavior in the Chatbot Tell Us?

Despite some unanswered questions, we found that exploring user behavior in the chatbot will provide useful information for planning and organizing future antenatal care. A previous study on a comparable supportive chatbot developed for patients with breast cancer explored user behavior by asking a weekly question and by observing the retention rate among users [25]. As all data in our study were anonymous, we were unable to explore retention rate, and we treated each dialogue as the unit of analysis. We anticipated a higher frequency of use out of office hours, when medical professionals are less available. Surprisingly, the chatbot was most frequently used during the

daytime, Monday through Friday. Even though a great advantage of chatbots is their 24-7 availability, frequent daytime use provides valuable insight for planning future antenatal care. To our knowledge, prior studies on health chatbots have not explored this issue before. The frequent use during the daytime may be a result of the users needing to quickly access information already provided for them by the health care service. With the timeframe of consultations often being limited [41], questions may arise before or after consultations [33]. The chatbot may provide reassurance for managing the condition of variable validity as an alternative to Google or other internet sources [33]. A chatbot may also provide answers to questions that appear too insignificant or embarrassing to ask health personnel directly [33], potentially reducing the barriers for contacting the health care service [33,42,43].

As there is currently a lack of a standardized methods for evaluating health chatbots, a comparison of chatbots performances may be challenging [25,28]. In general, metrics used to measure chatbot performance depend on which purpose the chatbot is designed to serve; still, most developers aim to keep the conversations short and effective [44]. Keeping this in mind, our results may prove an effective change in user interface in Dina version 2.0, as findings indicate that this version requires fewer conversational steps from the user, evidenced by both fewer questions from users on maneuvering in the chatbot and a decrease in dialogues containing 4-6 questions. This is supported by findings from a previous qualitative study, in which participants stated that they perceived Dina version 2.0 to be effective in providing answers [33]. However, short dialogues could also be an indication of users "giving up" and leaving the conservation; nonetheless, efficiency and the ability to provide a fast answer are important for the intention to use a chatbot [33].

Despite the fact that Dina the chatbot was integrated into the Norwegian digital health platform and made available for all pregnant Norwegian women between the 2 periods of registration, we found that the weekly mean number of dialogues was 36 in the first period and 26.83 in the second period. Although this change was not significant, it could be explained by a possible insufficient promotion of the chatbot among both pregnant women and health care personnel [33]. Previous studies have described several obstacles like organizational, economic, and knowledge barriers when implementing new technology in the health care service [45]. It is our view that the promotion of the chatbot should be a priority going forward to increase the chance of implementation of the chatbot in Norwegian antenatal care.

The Chatbot´s Ability To Answer and Need for Further Development

As the chatbot currently does not provide users with the opportunity to express if they are satisfied with the answer, we used the percentage of questions that the chatbot was unable to answer (fallback) as a measure of how well it operates. Our findings showed that a fallback message was given in 11.49% (326/2838) of all questions asked to Dina the chatbot. The goal is to keep the percentage of fallback as low as possible in order to meet user satisfaction [46]. In a previous study on conversational repair in a chatbot developed for customer service, the fallback percentage was reported to be 15% [47]. However, we did not consider "false positive" responses, where the chatbot seemingly provided an answer but not the answer the user sought. This would have provided more insight into the chatbots ability to answer and will be important to consider in future analyses. We categorized questions resulting in a fallback message to discover problem areas that need further development [48] and to satisfy our specific aim of determining what type of questions the chatbot is unable to answer. Our results (Figure 5) suggested an increase in the fallback category "GDM" between the 2 periods of registration. These are questions the chatbot should be able to answer, and calls for further training and development of content regarding information on GDM are warranted. Notably, we found that that number of questions that the chatbot did not understand decreased in the second period, which may be an indication of increased functionality in Dina version 2.0, as the chatbot may provide more options to click on related themes, thereby guiding the user in a more efficient way. Nearly 1 in 4 questions resulting in a fallback message were related to pregnancy in general, and this may be viewed as an expression of an interest from users and possibly serve as an idea for future development. Nonsensical questions represented 16.9% (55/326) of the overall questions resulting in a fallback message from the chatbot, and one could therefore consider the real fallback rate for the chatbot to be lower than 11.5% if one disregarded these questions.

There are several challenges when it comes to integrating this type of new technology into the established health care [39]. Studies outline several reasons as to why users of health technology tools such as chatbots can lose interest, among them being frustrations with the technology and losing the in-person contact with the caregiver [49,50]. A chatbot is not a finished product once it is deployed, and it is important to continuously monitor and add information to improve the chatbot's ability to function optimally [51]. By highlighting areas in Dina the chatbot that need improvement, we hope this study may serve as a contribution for further improvement and implementation.

Strength and Limitations

The strengths of this study are its use of the chatbot log data from 2 different periods during the course of continuous development and maintenance of the chatbot [52]. Utilization of user data is a cost-effective approach, providing important insight needed for further development. This study also has some limitations. We were unable to assess if users were women with GDM; however, the chatbot could also be a resource for health personnel or partners or next of kin. As all questions to the chatbot are displayed as dialogues in the chatbot's log, we were not able to stratify our analysis according to which method the user decide upon (ie, free text, theme buttons, or a mix of the 2). A registration of users' preferred way of asking questions should be considered in the future development of the chatbot. Furthermore, we could not identify if the user visited the chatbot once or several times. There is currently no way for the users to express whether they received the answer to their question in the dialogue, and obtaining this information would have been a useful addition to the fallback percentage acquired in analyses. Moreover, it would be useful to explore "false positive"

responses by the chatbot (the chatbot provides an answer but not the answer the user is seeking). This would have provided more insight into the functionality of the chatbot and will be considered in future studies. The chatbot is currently only available in Norwegian language, limiting the external validity of the knowledge. In addition, not all women may feel comfortable trusting a chatbot on health issues, which might have potentially excluded some women and introduced selection bias into our study.

Implications

Our findings indicate that users seek information on topics relevant to them at the time, such as blood glucose, diet, and physical activity, and that the most frequently asked questions mirror the cornerstones of GDM treatment. This may indicate that the chatbot is used to quickly access information already provided to users by the health care service, but the chatbot offers a low-threshold way to access that information.

Furthermore, results indicate that Dina version 2.0 guides the user in a more efficient way. However, the low mean number of dialogues per week in the second period (26.83) suggests further efforts should be put into promoting and integrating the chatbot into Norwegian antenatal care. We view our findings as potentially relevant to future development of informational and supportive health chatbots. The authors finds a low-threshold design is an advantage, as this will provide easy access to information the user is also provided through other channels in the health service to further support self-efficacy. As our society quickly becomes more digital, there is a call for the health care service to keep up with the rapid development [36]. We see the need for an informational tool like Dina the chatbot to contribute to increased self-efficacy and coping with GDM, considering the rising prevalence of the condition [2,4,5]. The next step for us with Dina the chatbot would be to continue the ongoing work of further development and to improve promotion to increase its use. We believe that when chatbots are a more integrated part of the health care service, they may serve as a positive contribution to antenatal care.

Conclusions

The majority of posed questions pertained to blood glucose, diet, the GDM diagnosis, and physical activity, and the chatbot was able to answer about 9 out of 10 of all questions from the users. The most frequent use was during the daytime, Monday through Friday, and the majority of dialogues were short, containing 1-3 questions. However, the mean number of dialogues per week was 36 in the first period and 26.83 in the second period.

Acknowledgments

The authors would like to thank Asbjørn Følstad at SINTEF for valuable input and contribution to the paper. Furthermore, we would like to thank the managing team of Dina the chatbot and Western Norway University of Applied Sciences for valuable cooperation in the process. The Research and Development department at Haukeland University Hospital founded this study through a short-term scholarship.

Authors' Contributions

The study was designed by MHS, NHM, AL, LJD, ABVN, and LMS. AL further obtained access to the data. MHS and LJD performed the data collection, and LJD especially contributed to the background material for this manuscript. MHS and LJD performed the statistical analysis with support from LMS and ABVN, and MHS drafted the first version of this manuscript. LMS contributed to project administration, and NHM provided important insight regarding the methodology and statistical analysis. MHS, NHM, AL, LJD, ABVN, and LMS all contributed to the interpretation of the data and the visualization of tables and figures and have critically revised the manuscript throughout the process and approved the final manuscript. The first author, MHS confirms that all listed authors meet authorship criteria.

Conflicts of Interest

Contributing author AL is the founder and concept developer of Dina the chatbot. The other authors have no conflicts of interest to declare.

Abstract

Background: Geographical, financial and travel-related barriers may impact access to necessary health care for people in need of long-term follow-up.

Objective: The goal of the research was to perform a nonblinded, randomized, controlled trial on health-related quality of life (HRQoL), healing, interaction, and satisfaction of patients with spinal cord injury (SCI) and PI receiving multidisciplinary videoconference consultations from a wound clinic to the participant's home versus regular outpatient care. The multidisciplinary team consisted of a medical doctor, a wound nurse, and an occupational therapist. In both groups, district nurses attended the consultations at the participant's home.

Methods: A total of 56 participants, 28 in each group, were randomized to a videoconference group (VCG) or a regular care group (RCG). Validated questionnaires were used to measure and compare the follow-up effect on HRQoL. Percentage reduction of wound volume was measured at end of the follow-up. A Likert scale was used to measure the satisfaction of the patients and district nurses regarding the interaction between different modalities of care in the 2 groups.

Results: The HRQoL did not show significant differences between the 2 groups (P values ranging from .09 to .88) or the rate of PI healing, experienced interaction, and satisfaction in the groups. A total of 67% (37/55) of all PIs healed, 64% (18/28) in the VCG and 70% (19/27) in the RCG. Mean reduction in ulcer volume was 79% in the VCG and 85% in the RCG (P=.32). A Kaplan-Meier plot with a logrank test regarding time to healing did not show any significant difference between the 2 groups.

Conclusions: Videoconference-based care seems to be a safe and efficient way to manage PIs in terms of HRQoL, healing, interaction, and satisfaction compared to conventional care for people with SCI. This should be considered when planning for future care. SCI has a huge impact on the individual, the family, and the health care system. There is an urgent need to improve systems of care so that individuals who live far from specialists and require long-term follow-up for conditions such as PI can get optimal treatment.

KEYWORDS

telemedicine; telecommunication; videoconference; outpatient follow-up; spinal cord injury; pressure injury; healing; participant satisfaction; participant interaction; health-related quality of life

Introduction

Background

For people living in rural or medically underserved areas, treatment access may be limited or even nonexistent [1]. Financial situation, travel and treatment costs, ability to take paid time off from work to visit a clinic or hospital, health insurance issues, pandemics, climate change, and unpredictable weather conditions may all impact access to necessary health care [1,2]. Transportation to hospitals and outpatient clinics may be a barrier because of length and duration of the transportation, discomfort, stress, and risks related to the transport [3]. People with spinal cord injury (SCI) are at particular risk of developing pressure injury (PI) due to paralysis, reduced skin sensitivity, and skin exposure to moisture for extended periods of time [4]. They are often hospitalized for long periods of time and need frequent outpatient care for treatment and to monitor the treatment [5]. However, long transport can cause new wounds to develop [6]. This may cause people not to attend to needed appointments [7]. Telecommunication could help to overcome such limitations [2,8]. Telecommunication between hospital and home is a potential way to offer effective health services, regardless of the geographical location of the patient and health care professional [9,10]. Telecommunication in health care covers a broad range of digital remote care services, all with the aim to provide investigation, monitoring, and management of patients and education for patients and staff using technology, allowing access to expert advice and patient information, no matter where the patient or relevant information is located [11]. Different solutions are in use, depending on the health service offered, technology needed, and performance of the service. There are real-time services like videoconferencing, videophone solutions and phone calls, store-and-forward services like text messages and electronic data collection and transmission, and web-based interactive platforms [7,12]. Services can be used to deliver education, consultation, therapy, social support, data collection and monitoring, and clinical care delivery [7,12]. Real-time video consultations allow health care professionals to perform remote visits to the patients' homes with the possibility to communicate and interact directly with each other [10,11]. Moreover, local care providers, like district nurses, can be included in the consultation. Thus, this system of care delivery increases the possibility of interaction between members at different health care levels and the patient.

Prior Work

Today there are telecommunication services available for many different health care issues. Teleradiology, telepathology, teledermatology, and telepsychiatry are popular and established areas all with the purpose of transmitting images, test results and medical information, as well as performing evaluations and consultations. The transmitting is via digitalized solutions, video and telephony [7,12-18]. Some services, like cardiology, electrocardiography, ultrasonography and mammography, are available at several hospitals and in different countries, while some services, like emergency medicine, immunology, hematology and speech therapy, are only performed in individual countries or individuals hospitals [7,16,18,19]. As in rehabilitation, research into long-term follow-up has shown mixed evidence of feasibility and efficacy regarding use of telecommunication solutions [15-18,20,21].

The Sunnaas model of telerehabilitation [22] has been used to provide videoconferencing as part of inpatient and outpatient rehabilitation services at a Norwegian rehabilitation hospital. A feasibility study evaluated videoconference as a possible alternative method for outpatient follow-up for patients with SCI and PI [4].

Goal of the Study

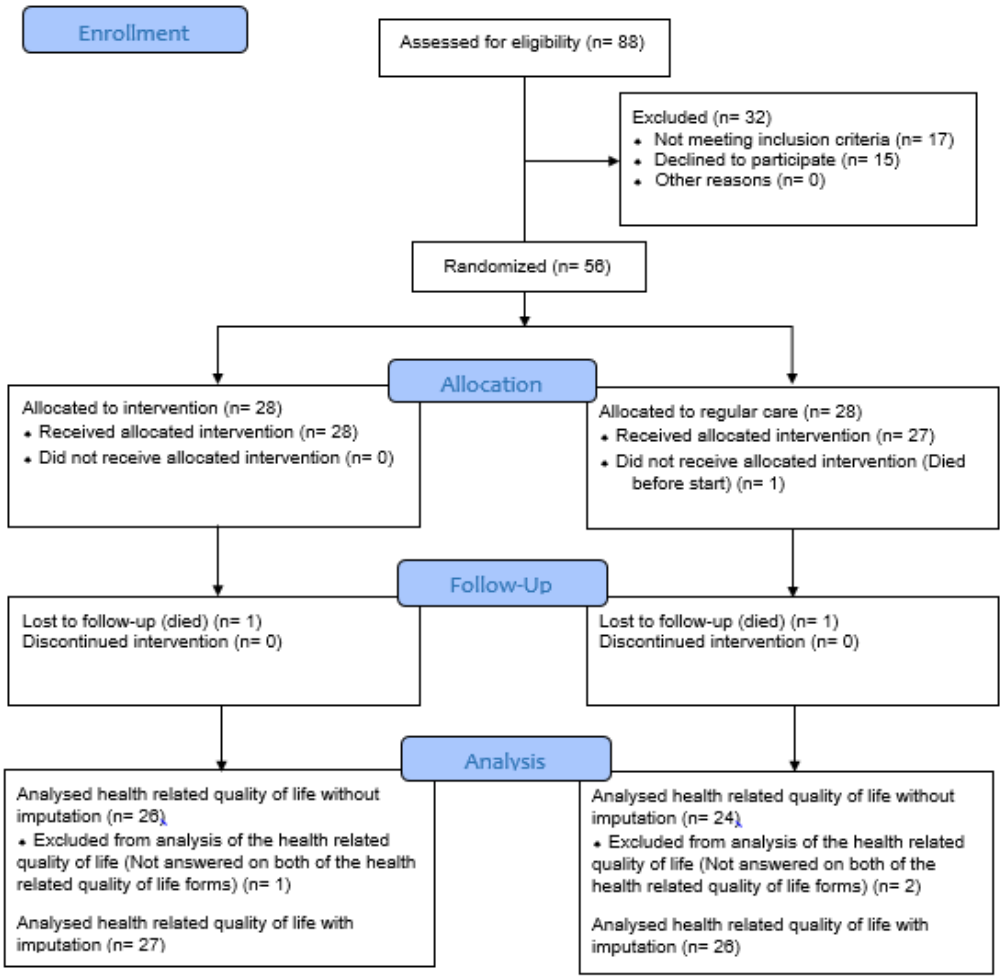
The primary aim of this study was to investigate if videoconference consultations could increase health-related quality of life (HRQoL) in people with SCI and PI. Secondarily, we wanted to determine whether PI healing, perceived interaction, and satisfaction could be considered as good and efficient as conventional follow-up [11].

Methods

Recruitment

People with SCI and ongoing PI were invited to participate in a nonblinded, national, randomized controlled study at 2 spinal cord units in Norway, located at Haukeland University Hospital in western Norway and Sunnaas Rehabilitation Hospital in southeastern Norway. Participants were invited based on response to a questionnaire [11] and from referrals to the outpatient wound clinic at the units. Inclusion criteria were traumatic or nontraumatic SCI, ongoing PI, aged over 18 years, and consent to participate. Individuals were included regardless of concomitant medical concerns. Exclusion criteria were not living in Norway and unable to give their consent due to cognitive impairments. Eligible participants were provided with written and oral information and signed a written consent before inclusion. The study took place between March 6, 2016, and October 19, 2019. The study flowchart is shown in Figure 1.

Figure 1. CONSORT 2010 (Consolidated Standards of Reporting Trials 2010) flow diagram of the trial.

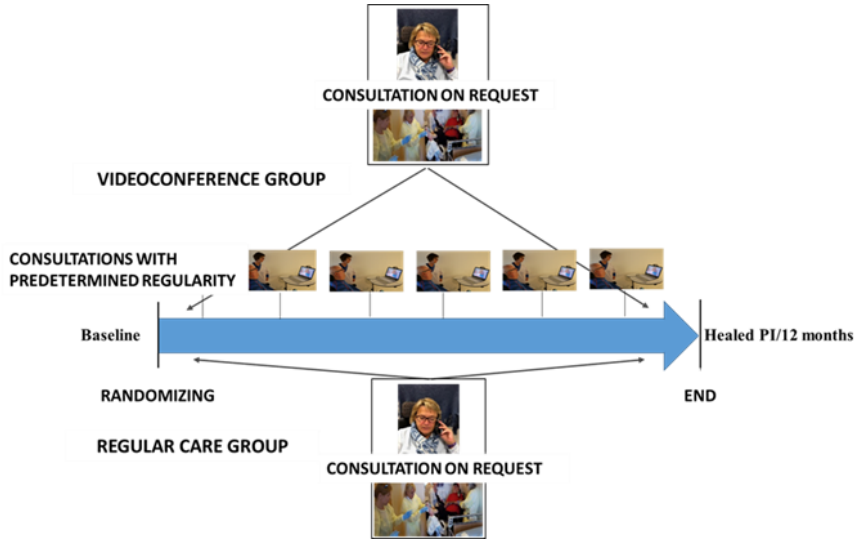


Study Design

Once the written consent was given, baseline data were collected and participants were randomized to a videoconference group (VCG) and a regular care group (RCG) by use of the random number generator in the statistical software SPSS (version 25, IBM Corp). The group allocations were then told to the participants. For both groups, a multidisciplinary wound team conducted the follow-up from the outpatient clinic. The team consisted of a medical doctor with several years of experience in PI treatment, a certified wound care nurse, and an occupational therapist with specialized skills regarding pressure measurements and PI follow-up. For both groups, district nurses were present with the participant at the participant's home during the consultations. The district nurses performed the wound treatment supported by remote guidance from the multidisciplinary wound team at the outpatient clinic. The participants in the RCG received treatment and guidance based on existing routines (ie, by telephone or outpatient consultations at the hospital, if requested). The participants in the VCG were offered treatment and guidance via predetermined videoconference consultations and regular care similar to the RCG. Both groups were followed until healing of the PI or for a maximum of 52 weeks. Figure 2 shows the organization of the follow-up in the 2 groups.

The timeline for study enrollment, intervention, and assessment is described in the Standard Protocol Items: Recommendations for Interventional Trials (SPIRIT) [23]. The Template for Intervention Description and Replication (TIDieR) [24] checklist and guide were used to record and describe the intervention. The study conforms to the Consolidated Standards of Reporting Trials (CONSORT) guidelines extension for randomized pilot and feasibility trials [25].

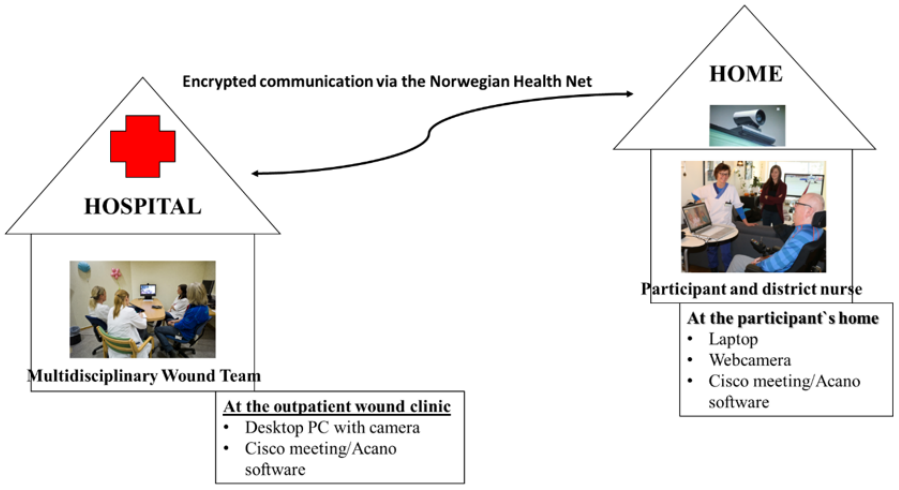
Figure 2. Organization of follow-up for the videoconference and regular care groups.



Technical Logistics

In both groups, the district nurses used their work phone or the participant's cell phones for telephone consultations. For participants in the VCG, arrangements for installation of encrypted software and rehearsal in the use of the program and equipment were addressed immediately after randomization. All participants in the VCG had available broadband or mobile broadband connection. Most of them used their private laptops in the consultations or they borrowed laptops from the hospital's storage. All of them borrowed mobile webcams from the hospital's storage. The consultations were performed as synchronous live, videoconferencing in real time, using a Cisco TelePresence System EX90 PC with camera at the wound clinic and a laptop with a mobile webcam at the participant's location. Encrypted communication channels via the Norwegian Health Net were used to protect privacy of the participants [26]. The wound care nurse at the outpatient wound clinic tested the equipment with the participant and the district nurses before start of the follow-up. Each participant was given a unique subscription number. The wound care nurse at the outpatient wound clinic addressed the participant at each session, and the participant had to accept the call before the consultation could start. Figure 3 shows the organization of the videoconference consultations.

Figure 3. Organization of the videoconference consultations.



Information and Guidance

For both groups, the participants gave their consent to send medical records to the general practitioner and their district nurses after each consultation, no matter the kind of consultation. For both groups, all treatment and guiding were conducted in accordance with evidence-based wound therapy guidelines [27] and individualized in accordance with each participant's needs. The district nurses in both groups were guided in treatment principles according to their knowledge needs. Clinical guidelines, online education programs, and e-learning programs were accessible for the district nurses in both groups.

Study Variables

Demographic information included gender, date of birth, age at SCI, time since SCI, etiology (traumatic, nontraumatic), level and grade of the SCI, and SCI associated problems. SCI was described according to the International Standards for Neurological Classification of SCI recommendations including clinical findings standardized by the American Spinal Injury

Association (ASIA) Impairment Scale (AIS) [28]. Any use of alcohol or tobacco or abuse of drugs was recorded. In addition, information regarding any previous PIs and PI recurrence was recorded, together with the number of present PIs, as well as the category and volume of the present PIs. All PIs were categorized and numbered according to the joint 2019 guideline prepared by the 3 collaborating PI organizations: National Pressure Injury Advisory Panel, European Pressure Ulcer Advisory Panel, and Pan Pacific Pressure Injury Alliance [27]. According to this guideline, the categorization of PIs varies with size and severity of the tissue affected, ranging from reddening of the skin (category 1) to damage to muscle and underlying bone (category 4). In category 1 and 2, the injury is partially going through the skin, while in category 3 and 4, there is a full thickness skin wound. In a suspected deep tissue injury, the depth and severity of the wound is unknown. In an unstageable PI, the wound cannot be categorized due to sloughing/scarring [27]. The PI categorization and volume, (length × width × depth) was measured at baseline by the medical doctor and wound care nurse and at the end of the follow-up by either the medical doctor and wound care nurse at the outpatient wound clinic or by the district nurses guided by the wound team. A ruler adapted for PI measurement was used. The district nurses gained access to the rulers via the multidisciplinary wound team. Difference in volume was calculated as percentage change. Time to healing was measured as days from baseline to healing. Changes in HRQoL in the 2 groups were compared using the Norwegian versions of the 36-item Short Form Health Survey (SF-36) [29] and the Five-Dimension European Quality of Life (EQ-5D) scale [30]. In case of lack of an available Norwegian index version of the EQ-5D scale, the validated UK index is recommended to be used in analyses regarding Norwegian subpopulations [30]. We also used the International Spinal Cord Injury Quality of Life Basic Data Set (ISCI-QoL-BDS) questionnaire [31] to measure the HRQoL among the participants. The form used is similar to the version used by the Norwegian Spinal Cord Injury Registry [32].

The participants reported subjective ratings regarding satisfaction, safety, and level of interaction during the follow-up using a Likert scale with 1 being completely dissatisfied and 5 being totally satisfied. Moreover, as an ad hoc analysis, we wanted to gain knowledge about the district nurses' experience, and thus we invited them to report their ratings as well.

Ethics

The research project was carried out in accordance with ethical guidelines and privacy rights for health services in Norway [26] based on the code of ethics of the World Medical Association (Declaration of Helsinki) for experiments involving humans. Established routines to secure confidentiality and ethical guidelines for conducting consultations involving examinations related to intimate body areas, which may be visible on the screen, were established before the study was initiated [22]. Knowledge and expertise achieved through a previous feasibility study [4] was applied in this study. Communication occurred through the Norwegian Health Network's encrypted video channels. The study was performed in compliance with Norwegian data security and privacy standards [26]. The study was approved by the regional committees for medical and health research (2014/684/REK-Nord) [33] and registered with ClinicalTrials.gov (NCT02800915). All participants were insured through the Norwegian health care system and the hospitals' insurance programs for adverse effects.

Statistical Analyses

Demographic variables were descriptively analyzed. Continuous variables are presented as mean with standard deviation whereas categorical variables are presented as counts and percentages. For the HRQoL scores, missing data were handled by multiple imputation. Each missing data point was replaced by m=20 imputed values based on the predictive mean matching technique before analysis. The imputation models include age, gender, AIS grade, and HRQoL scores.

Mean HRQoL scores with corresponding 95% confidence interval are presented for each of the 2 treatment groups at baseline and end of follow-up, and the groups were compared using linear regression analysis with adjustment for baseline. This analysis was repeated without imputation for missing values as well, for comparison. The mean percentage reduction in PI size was calculated with corresponding 95% confidence interval for each of the 2 groups and compared using a Mann-Whitney test. Time to healing was analyzed by the logrank test and is presented by a Kaplan-Meier plot.

$P<.05$ is considered significant. Independent *t* tests were used to analyze the mean difference in participant satisfaction scores. Corresponding 95% confidence intervals were calculated. All statistical analyses were performed using SPSS statistical software.

Sample Size

We based our sample size calculation on investigation of HRQoL and the group comparison at the end of follow-up. Our hypothesis was that HRQoL would increase in the VCG as compared to the RCG, and the sample size calculation was based on an expectation of a standardized difference of at least 0.8 (typically considered a large effect). With 80% power, we would need 25 patients in each of the 2 groups.

Results

Demographics

A total of 56 participants were included, with 28 in each group. One participant in the RCG died of acute illness prior to start of the follow-up, and the participant's data were excluded from the analyses. Furthermore, 2 participants, 1 in each group, did not complete any of the HRQoL questionnaires and were removed from the analysis of the primary outcome. Two participants, 1 in each group, died during the follow-up. They are included in the analysis of wound healing as not healed PIs. All deceased participants were male and causes of death were reported to be cardiovascular disease (2) and pneumonia (1). Of the 55 participants included in the analysis, the majority were male, 86% (24/28) in the VCG and 78% (21/27) in the RCG. The mean age was 58 years in both groups. Baseline data of the included participants are shown in Table 1.

Table 1. Baseline data of the participants in the 2 groups.

Characteristics	Videoconference group (n=28)	Regular care group (n=27)
Gender, n (%)		
Male	24 (86)	21 (78)

[a]SCI: spinal cord injury.

[b]TSCI: traumatic spinal cord injury.

[c]NTSCI: nontraumatic spinal cord injury.

[d]Level of injury: location of the injury in the spinal cord (C: cervical, T: thoracic, and S: sacrum).

[e]AIS grade: completeness/severity of the injury.

[f]PI: pressure injury.

[g]DM1: diabetes mellitus type 1.

[h]DM2: diabetes mellitus type 2.

[i]CV disease: cardiovascular disease.

[j]TE disease: thromboembolic disease.

Pressure Injuries at Baseline

In the VCG, 32% (9/28) of the PIs were category 2, 50% (14/28) category 3, 11% (3/28) category 4, and 7% (2/28) could not be categorized at the time of inclusion. The distribution in the RCG was 52% (14/27) were category 2, 22% (6/27) category 3, 19% (5/27) category 4, and 7% (2/27) were unstageable.

Most of the PIs were located at the ischial tuberosities: 50% (14/28) in the VCG and 33% (9/27) in the RCG. At the sacrum-gluteal cleft, PIs occurred in 32% (9/28) of the participants in the VCG and 48% (13/27) in the RCG.

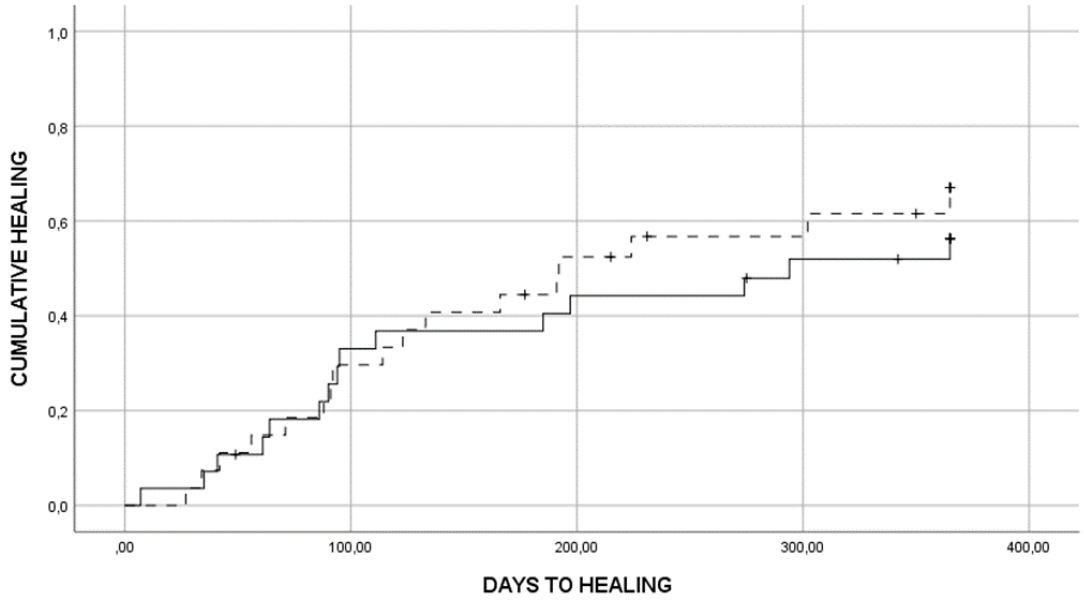
Health-Related Quality of Life

The SF-36 scale, the UK version of the EQ-5D scale, and the ISCI-QoL-BDS basic data set were used to measure and compare changes in HRQoL. Performing a linear regression analysis, comparing the 2 groups with adjustment for baseline, did not yield any significant differences regarding HRQoL, as shown in Multimedia Appendix 1 (imputed data). Multimedia Appendix 2 shows the complete data.

Healing

A total of 67% (37/55) of all PIs healed completely during follow-up: 64% (18/28) in the VCG versus 70% (19/27) in the RCG. Mean reduction in ulcer volume in the VCG was 79% versus 85% in the RCG. No significant difference in the 2 groups were found (P=.32). The median time to healing in the VCG was 275 days (95% CI 111.18-438.83) versus 192 days (95% CI 113.71-270.29) in the RCG. A Kaplan-Meier plot (Figure 4) with a logrank test regarding time to healing did not show any significant difference between the 2 groups (P=.56). Figure 4 displays time to healing in both groups.

Figure 4. Kaplan-Meier plot showing time to healing in the two groups (videoconference: solid line; regular care group: dotted line).



Interaction, Satisfaction, and Safety

A total of 85% (47/55) of the included participants responded to the feedback form, 86% (24/28) in the VCG and 85% (23/27) in the RCG. No significant differences were found in interaction, satisfaction or safety, and the estimated mean differences were minor. Table 2 shows the mean difference between the RCG and VCG, with corresponding confidence intervals and P values. The district nurses were also asked to report their experienced interaction, satisfaction, and safety with the follow-up. A total of 45% (24/55) of the nurses responded, 52% (14/28) in the VCG and 38% (10/27) in the RCG. No significant differences were found in the 2 groups.

Table 2. Comparison of interaction, satisfaction, and safety experienced by participants and district nurses as reported at follow-up.

	Mean difference[a]	95% CI	P value[b]
Participants			
Planning	–0.08	–0.78 to 0.62	0.82
Implementation	–0.04	–0.73 to 0.81	0.91
Interaction	0.14	–0.59 to 0.87	0.70
Participation	–0.13	–0.67 to 0.94	0.74
Safety	–0.01	–0.77 to 0.76	0.99
Usefulness	–0.19	0.97 to 0.60	0.63
Overall satisfaction	0.11	0.66 to 0.88	0.78
District nurses			
Planning	0.21	–0.41 to 0.82	0.49
Implementation	0.04	–0.55 to 0.63	0.88
Interaction	0.33	–0.32 to 0.99	0.30
Participation	0.00	–0.60 to 0.60	1.00
Safety	0.16	0.41 to 0.74	0.56
Usefulness	–0.15	0.87 to 0.56	0.65
Overall satisfaction	–0.16	–0.68 to 0.36	0.52

[a]Mean difference: difference in mean values (regular care group minus videoconference group).

[b]Based on an independent *t* test.

Discussion

Principal Findings

SCI has a huge impact on the individual, the family, and the health care system. Regular contact with specialized health care is required for the condition itself as well as the frequent related complications such as PI. Thus, there is an urgent need to secure availability of high-quality services for patients who live far from specialists and require long-term follow-up [5,34]. Individuals with SCI and PI require frequent outpatient care to monitor their wounds [34]. Long travel distances to receive treatment, resulting in time-consuming transport, can attribute to greater morbidity [6]. To our knowledge, this is the first randomized controlled study using videoconferencing to provide long-term treatment to persons with PI. The results from our study indicate that regular home-based videoconferences are as safe for patients and their district nurses as conventional care with in-person attendance.

According to our study, the HRQoL was not dependent of the type of health service offered. We still find it relevant to mention that the estimated mean difference was in favor of the VCG for 12 out of 13 HRQoL scores. There were no substantial differences between the analyses based on the imputed data (Multimedia Appendix 1) and the complete case analysis (Multimedia Appendix 2).

In this study, the 2 groups were evenly distributed by gender, age, PI occurrence, and PI location. There were no significant differences regarding healing between the 2 groups. Looking at the Kaplan-Meier plot (Figure 4), the 2 curves follow each other very closely, at least for the first 200 days, indicating that the videoconference service was as efficient as the conventional follow-up. All participants and their district nurses were given similar guidance regarding nutrition, skin care, PI prevention, position change, and pressure relieving mattresses and cushions, and an individual treatment plan was established for each participant in both groups [27].

We also investigated the association between potential risk factors and time to healing as a post hoc analysis. Interestingly, overall comorbidities did not show any association regarding time to heal. Due to low number of concomitant diseases among the participants in our study (Table 1), further substudies could not be performed.

Participants in both groups and their district nurses reported acceptable levels of experienced interaction and satisfaction, with no significant differences regarding the follow-up. This indicates videoconference consultations offer satisfactory remote

interaction with the district nurses as compared to regular follow-up. However, we believe a larger study with a noninferiority design would be warranted to establish this.

There is a lack of studies regarding PI and long-term follow-up in the literature. Based on the number of nonhealing PIs in our study, a longer follow-up period may be an interesting topic for future research. We also think that the issue of nonhealing PI should be further explored, no matter the mode of follow-up intervention.

Telemedicine has been widely adapted in many fields of medicine, especially in recent years. We believe that this should also be the case for rehabilitation and that individualized follow-up where a hybrid solution of video communication and conventional consultations is used, may be a promising path for the future.

Limitations

When the present study was designed, we based our sample size calculation on an investigation of HRQoL. However, we do not have sufficient statistical power to provide conclusive evidence regarding the rest of the comparisons we performed in this study.

Comparison With Prior Work

This study is the first randomized, controlled, multidisciplinary long-term study using videoconference as mode of administration of treatment to provide care to persons with SCI and PI [15]. Videoconference consultations seem to be an acceptable solution concerning treatment and follow-up. Our study shows feasibility and efficacy in the examined population. However, the heterogeneity regarding participants, modalities, and the level of mixed evidence in previous research makes it difficult to compare with prior work [15,35]. This is also in line with previous research [13,15,17,20,21,36].

Conclusion

Videoconference in a patient's home ensures safe and efficient quality of care without any reduction in HRQoL, PI healing, or satisfaction as compared to conventional outpatient care at the hospital. Long-term videoconference at home under these circumstances ensures interaction with patients and district nurses and assures they receive relevant information on-site. Further research should assess and compare the value of videoconference for routine long-term care, such as managing spasticity, urinary tract and bowel needs, and chronic pain.

Data Archiving

The dataset is stored in a locked and fireproof research cabinet at the research department, Sunnaas Rehabilitation Hospital, Norway, and can be made available on request according to the Norwegian Data and Telecommunications Authority's requirements for safe information flow [26].

Acknowledgments

The authors wish to thank specialized wound care nurses Hanne Haugland, Tori Lunde, and Irene Nærdal, occupational therapists Unn Svarverud and Gunnbjørg Aune, telemedicine consultant Hilde Sørli, participant in the project reference group Ingar K Bergersen, and participants from the Norwegian SCI Association, LARS, for collaboration in the project. The first author is funded by the DAM Foundation. The trial founder is Linda Åsheim, and she can be reached at linda.aasheim@nhf.no. The DAM Foundation has no influence on the trial protocol or the results.

Authors' Contributions

II and TR designed the protocol of the study. JMH, RJ, MT, and JKS coauthored the protocol, in particular regarding the methodology and design of the custom-made forms and scales. II collected and entered the data. II and MT performed data analysis. II was the main author of the article, and JMH, RJ, MA, JKS, MT, and TR coauthored the manuscript and supervised during the writing. The main author and all coauthors critically read and approved the final manuscript before submission and publishing.

Conflicts of Interest

None declared.

Abstract

Background: Evidence suggests that smartphone apps can be effective in the self-management of weight. Given the low cost, broad reach, and apparent effectiveness of weight loss apps, governments may seek to encourage their uptake as a tool to reduce excess weight in the population. Mass media campaigns are 1 mechanism for promoting app use. However, the cost and potential cost-effectiveness are important considerations.

Objective: The aim of our study was to use modeling to assess the health impacts, health system costs, cost-effectiveness, and health equity of a mass media campaign to promote high-quality smartphone apps for weight loss in New Zealand.

Methods: We used an established proportional multistate life table model that simulates the 2011 New Zealand adult population over the lifetime, subgrouped by age, sex, and ethnicity (Māori [Indigenous] or non-Māori). The risk factor was BMI. The model compared business as usual to a one-off mass media campaign intervention, which included the pooled effect size from a recent meta-analysis of smartphone weight loss apps. The resulting impact on BMI and BMI-related diseases was captured through changes in health gain (quality-adjusted life years) and in health system costs. The difference in total health system costs was the net sum of intervention costs and downstream cost offsets because of altered disease rates. An annual discount rate of 3% was applied to health gains and health system costs. Multiple scenarios and sensitivity analyses were conducted, including an equity adjustment.

Results: Across the remaining lifetime of the modeled 2011 New Zealand population, the mass media campaign to promote weight loss app use had an estimated overall health gain of 181 (95% uncertainty interval 113-270) quality-adjusted life years and health care costs of –NZ $606,000 (–US $408,000; 95% uncertainty interval –NZ $2,540,000 [–US $1,709,000] to NZ $907,000 [US $610,000]). The mean health care costs were negative, representing overall savings to the health system. Across the outcomes examined in this study, the modeled mass media campaign to promote weight loss apps among the general population would be expected to provide higher per capita health gain for Māori and hence reduce health inequities arising from high BMI, assuming that the intervention would be as effective for Māori as it is for non-Māori.

Conclusions: A modeled mass media campaign to encourage the adoption of smartphone apps to promote weight loss among the New Zealand adult population is expected to yield an overall gain in health and to be cost-saving to the health system. Although other interventions in the nutrition and physical activity space are even more beneficial to health and produce larger cost savings (eg, fiscal policies and food reformulation), governments may choose to include strategies to promote health app use as complementary measures.

Introduction

Background

The obesogenic food environment and unhealthy dietary patterns have led to overweight and obesity becoming a critical public health problem [1,2]. These risk factors result in numerous health conditions, including diabetes, cardiovascular disease, and certain forms of cancer [1,2]. Overweight and obesity are the fifth highest risk factor for global mortality, corresponding to at least 2.8 million deaths each year [1]. Elevated BMI levels also pose a substantial economic burden, with obesity alone directly accounting for an estimated 0.7% to 2.8% of national health care expenditures among a wide range of countries [3].

Although modifying the food and physical activity environment is critical, addressing unhealthy dietary patterns and insufficient physical activity (and therefore overweight and obesity [4]) in individuals is also important. Even modest weight loss can yield substantial health benefits [5,6], especially when distributed across the population level. There has been an increase in the use of mobile health (mHealth) tools for addressing weight loss goals [7,8]. The widespread use of mobile phones makes mHealth interventions easily scalable to a broader population [9,10], and as a result, mHealth interventions are increasingly considered tools for weight loss in individuals. Although there are numerous types of mHealth tools (eg, PDAs, iPods, and MP3 players) and services (eg, health call centers, appointment reminders, health surveys and data collection, and mobile patient records [11]), smartphone apps have been identified as particularly popular among the general population and potentially effective at supporting weight management [7,9,12].

The use of health apps is increasing, with a reported 50% of smartphone users having ever downloaded a health app [13,14]. The most popular health apps are typically for diet and physical activity tracking, weight management, and adherence to medication [13,15]. Weight loss apps may be especially useful for circumstances where face-to-face weight loss treatments are not possible or not preferred [16]. Smartphone apps are generally considered easy to use and to be helpful in pursuing weight loss goals by many patients [7], even for older participants [12].

Reviews have found that mHealth interventions can be more effective than non-mHealth interventions at inducing weight loss and improving diet and physical activity [17]; mHealth interventions also promote adherence to weight loss behaviors [9]. Even when mHealth apps produce outcomes equivalent to those of traditional interventions, their broad accessibility makes them a valuable tool [7]. However, there are limitations to the effectiveness of app use. For instance, engagement with apps declines over time [7,18], especially for dietary tracking [19,20]. Researchers estimate that a quarter of mHealth apps are only used once after download, and most individuals stop using mHealth tools before the fifth interaction [21,22]. However, other evidence suggests that apps are most effective for weight loss management when certain characteristics are incorporated [7], such as self-monitoring of physical activity and diet, reminders for app use, and social interaction with peers [7,23,24]. Generally, higher adherence to self-monitoring is associated with improved weight loss outcomes [10,25].

Given the low cost, broad reach, and apparent effectiveness of apps at promoting weight loss, governments may seek to encourage the uptake of such apps as an opportunity for reducing excess weight among the population. For example, in the United Kingdom, the National Health Service has developed a free 12-week diet and exercise plan that is available as an app [26] that incorporates a mass media campaign to promote use [27]. Such campaigns may be an important intervention component to increase the use of effective weight loss apps among the population and stimulate reductions in BMI. Evidence indicates that health mass media interventions can effectively encourage the use of health support resources [28,29] and influence public dietary behaviors [30-35].

The cost and potential cost-effectiveness are important considerations when governments are selecting among obesity reduction interventions, including the use of mass media campaigns. Research by Cleghorn et al [36] used health economic simulation modeling to assess the cost-effectiveness of a hypothetical mass media campaign in New Zealand that promotes the uptake of weight loss mHealth technologies. Along with numerous other parameters, the authors used the results of a 2014 meta-analysis of mobile device interventions to quantify how much weight loss could occur [17]. The authors found that such a campaign was not cost-effective in the base case analysis [36]. Another study using similar methods assessed the potential of a mass media campaign to promote smartphone apps for physical activity and found that it was unlikely to be cost-effective at the population level, although the health impact and cost-effectiveness estimates were highly sensitive to assumptions around long-term adherence [37]. The evidence on the cost-effectiveness of mass media campaigns is primarily from tobacco control [29], and previous research indicates that a mass media campaign for promoting smoking cessation apps is likely to be cost saving [38].

Updated Estimates

Since the modeling conducted by Cleghorn et al [36] on the weight loss mHealth mass media campaign, there has been rapid growth in the literature on the effectiveness of weight loss apps, as well as changes in app technology and a higher uptake of smartphones. In this study, we use updated parameters that reflect these developments and recent data on app use over time, thereby providing updated estimates that reflect the current context. The setting for this study is New Zealand, a typical high-income country with high rates of overweight and obesity [39]. Our study uses a multistate life table modeling approach to assess the health impacts, health system costs, cost-effectiveness, and health equity of a mass media campaign to promote high-quality smartphone apps for weight loss in New Zealand.

Methods

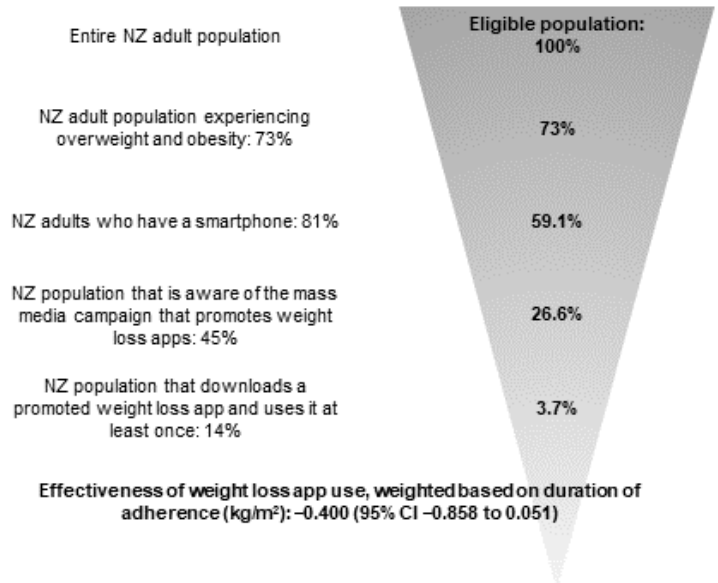
Overview

We used an established proportional multistate life table model [40] that was parameterized with health data for the 2011 New Zealand adult population and simulates this population until death. The risk factor of interest was BMI; the simulation model designates the proportion of New Zealand adults with overweight or obesity (overweight: BMI 25 kg/m^2 to <30 kg/m^2; obesity: BMI ≥30 kg/m^2). We compared a business-as-usual baseline analysis to an intervention base case analysis. The resulting impact on BMI and BMI-related diseases was captured through changes in health gain (as measured by quality-adjusted life years [QALYs]) and in health system costs (net sum of intervention costs and downstream cost offsets because of altered disease rates). The study used a health system perspective that focused on costs and benefits within the health system [41]. An annual discount rate of 3% was applied to health gains and health system costs, consistent with established New Zealand modeling protocols [41] and health economic expert recommendations [42]. Discounting is a standard practice in economic evaluation to account for preferences toward present benefits over future benefits [41]. Full details on the model are documented elsewhere [40].

Intervention Pathway

The modeled intervention was a one-off mass media campaign among the New Zealand population stimulating the uptake and use of a smartphone app for weight loss that effectively promotes weight loss. The pathway from the intervention's implementation to impact is detailed in Figure 1. The proportion of the New Zealand population that would experience weight loss was calculated as follows: out of the New Zealand adult population, the intervention was applicable to only New Zealand adults aged >18 years with overweight or obesity (73% of the total adult population). Using recent metrics on New Zealand smartphone ownership, 81% of New Zealand adults own a smartphone [43] (eligible population reduced to 59.1%). To model the reach of the mass media campaign, we used the results reported by Kite et al [44] of an obesity-prevention mass media campaign called Make Healthy Normal that was run over 1 year by the New South Wales (NSW) government in Australia. Recognition of the campaign was 45% among sampled adults aged ≥18 years after completion of the campaign, which consisted of television commercials, community events, press, out-of-home (eg, billboards) and web-based advertising, public relations, a website, and social media [44]. We identified other studies that evaluated recognition of mass media campaigns [30,32]. However, the NSW study by Kite et al [44] was preferred because it evaluated a health campaign that we could verify was resourced similarly to the high level of costs associated with our modeled mass media campaign: Make Healthy Normal campaign NZ $0.37 (US $0.25) per capita of the NSW population [44] and modeled campaign NZ $0.66 (US $0.44) per capita of the New Zealand population. As the New Zealand modeled campaign involved a higher cost per capita than the NSW campaign, in sensitivity analysis we modeled a scenario where this greater resourcing produced an enhanced mass media campaign that achieved wider recognition than the NSW campaign. On the basis of the rate of campaign recognition, the eligible population reduced to 26.6% of the total adult population. We found limited published research on the degree to which government-led mass media campaigns can stimulate health app use. After a search of academic and gray literature, we identified only 1 study that quantified a relationship between a mass media campaign to promote health app use and subsequent health app use [45]. In the study, the authors found that 14% of the surveyed respondents reported *taking an action* after a UK-based mass media campaign to promote an uptake of a health app [45]. Assuming that this *action* was to download and use the app at least once, we modeled app downloads and use as 14% of the New Zealand adult population. The final eligible population that would use the app and experience weight loss was 3.7% of the New Zealand adult population.

Figure 1. Flowchart of intervention conceptualization. NZ: New Zealand.



Weight Loss App Effectiveness

We quantified the effectiveness of weight loss apps using the results of a recent meta-analysis by Islam et al [46]. The review's authors examined randomized controlled trials and case-control studies published from 2000 to mid-2019 on mobile phone app interventions for reducing body weight (including BMI) and increasing physical activity among children and adults. We preferentially selected this meta-analysis for modeling over other reviews [9,47-53] because of the focus on mobile apps (over other mHealth or mobile phone–based interventions), selection of studies with control groups that received minimal or no interventions, preferred outcome (ie, BMI), meta-analyzed results, and recent publication date with latest available studies. In the 10 included studies that examined BMI, the proportion of male participants ranged from 0% to 15%. The mean age of the participants ranged from 12.7 years to 44.9 years. For the outcome of weight, Islam et al [46] reported finding that longer trials (>3 months) were associated with significantly greater weight loss than shorter trials (≤3 months), suggesting that greater app adherence (ie, longer use) is associated with greater weight loss than shorter app adherence. For the outcome of BMI, Islam et al [46] conducted an analysis of all included trials (pooled effect size –0.454, 95% CI –0.787 to –0.121) and did not conduct meta-analyses by trial duration subgroup (ie, ≤3 months vs >3 months). We calculated these pooled effect sizes using the study's reported data (≤3 months –0.219, 95% CI –0.672 to 0.223; >3 months –0.609, 95% CI –1.072 to –0.146) [46]. In the >3-month subgroup, the maximum trial length was 9 months. We consulted evidence on weight loss app adherence from the UK study by Carter et al [54], which measured the proportion of users who adhered to app use for ≤3 months (53% of the users) and >3 months (47% of the users). We multiplied each pooled effect size by the proportion of users and summed to produce a weighted effect size of app effectiveness that accounted for variations in duration of app use:

$$E_{weighted} = (E_{\leq 3\ months} \times >P_{\leq 3\ months}) + (E_{>3\ months} \times P_{>3\ months})$$

where E is the effect size and P is the proportion of users. The resulting weighted estimate of weight loss app effectiveness was –0.400 kg/m^2 (95% CI –0.858 to 0.051 kg/m^2). Additional details on these decisions and steps are reported in Multimedia Appendix 1 [19,46,54].

Intervention Modeling Approach

In our modeling, the business-as-usual baseline encapsulated the existing levels of dietary health promotion in New Zealand, including current promotion of weight loss apps, and the continuation of the current low or no app promotion environment. The costs of implementing the intervention are reported in Table 1, with further details regarding the methods used to scope these costs reported by Cleghorn et al [36].

Table 1 provides further detail on the inputs used to conceptualize the intervention pathway, along with the type of distribution modeled for each of these inputs. For the effectiveness of the weight loss app, CIs quantified the range of plausible values. As no measures of variance were available for the remaining inputs, we applied our established protocol and estimated an SD of either 5%, 10%, or 20% of the central value [56]. A value of 20% was used when there was deemed to be a high degree of uncertainty that could influence effectiveness and cost-effectiveness outcomes from the modeled intervention.

Table 1. Intervention parameters and uncertainty distributions.

Parameter	Value	Distribution	Source
Adult New Zealand population who own a smartphone, % (SD)	81 (5)	Beta	As reported by DataReportal based on Google Consumer Barometer data [43]
Adult New Zealand population who are assumed to be aware of a relevant mass media campaign, % (SD)	45 (20)	Beta	On the basis of an evaluation of an Australian obesity-prevention mass media campaign that measured the proportion of survey respondents who recognized the campaign [44]
Adult New Zealand population who were assumed to download and use a promoted weight loss app, % (SD)	14 (20)	Beta	On the basis of the proportion of survey respondents who reported *taking an action* after a UK-based mass media campaign to promote use of a health app [45]
Intervention BMI reduction for those who used the app (kg/m^2; 95% CI)	–0.400 (–0.858 to 0.051)	Normal	The weighted results of studies included in the Islam et al [46] meta-analysis of smartphone app weight loss trials whereby the pooled effect sizes for interventions ≤3 months and interventions >3 months were weighted based on adherence rates at 3 months, obtained from Carter et al [54]
Assumed weight regain after delivery of the intervention (kg/m^2 per month; SD %)	0.03 (20)	Log-normal	Meta-analysis of weight loss decay evidence from Dansinger et al [55], as used in the previous published work by Cleghorn et al [36]
Estimated cost of one-off 1-year national-level mass media campaign, NZ $ (US $; SD %)	2,883,000 (1,940,000; 20)	Gamma	As used in the previous published work by Cleghorn et al [36]. New Zealand data on the costs consist of identifying high-quality apps and a national mass media campaign across multiple media

Multistate Life Table Model Overview

The multistate life table model consists of a main life table organized by age, sex (male or female), and ethnicity (Māori or non-Māori) and populated with all-cause mortality and morbidity rates for the 2011 New Zealand adult population. Parallel to this are life tables for each BMI-related disease where proportions of the simulated population are also modeled. Although the model includes a wide array of diet-related diseases [40], our intervention focused on weight loss and used only the disease tables for 14 BMI-related diseases: coronary heart disease, stroke, type 2 diabetes, osteoarthritis, and cancers (endometrial, kidney, liver, esophageal, pancreatic, thyroid, colorectal, breast, ovarian, and gallbladder).

Mortality and Morbidity Modeling

Within the model, the proportions of the population in each disease table are a function of past and current rates of disease incidence, case fatality, and, for cancers only, remission, which are calculated at each annual time step. The model is populated with mean BMI values according to age, sex, and self-identified ethnicity measured in person during New Zealand's most recent available national nutrition survey (New Zealand Adult Nutrition Survey 2008-2009) [57]. The mass media campaign intervention induces changes in BMI for a proportion of the New Zealand population. The effect of these BMI changes is combined with relative risks that capture the association between BMI and BMI-related disease outcomes to produce modified population impact fractions [40]. As the risk of BMI-related diseases decreases after implementation of the intervention, the population impact fractions modify disease incidence rates, resulting in changes to all-cause mortality and morbidity rates. Time lags to simulate the delay between when BMI change occurs and when changes in disease incidence across the population-risk distribution occur were built in for all conditions. Specifically, the change on disease rates was distributed over 0 to 5 years for cardiovascular diseases, diabetes, and osteoarthritis and over 10 to 30 years for cancers, with probabilistic uncertainty added in around these lag periods. Although there is evidence that mHealth interventions can result in changes in dietary intake beyond reduced weight loss, such as increased fruit and vegetable intake and decreased takeout meals [7], our intervention modeling focused on the effects of the app on BMI and assumed no other impacts on diet or physical activity.

Our model included the health system costs associated with changing disease prevalence and population longevity, which were calculated using an established protocol [40]. These costs were specific to the condition, age, and sex and were based on the timing of health events (first year of illness, subsequent years of illness, and the last 6 months of life). The change in the proportions of the population in each disease state resulted in proportional changes in health system costs and unrelated health system costs from people living longer. The intervention's overall results reflect projected health gains and health system cost impacts over the remainder of the modeled population's life course.

Equity, Scenario, and Sensitivity Analyses

In addition to the main base case intervention, we conducted an equity analysis where an *equity adjustment* was applied in the model to eliminate differences in life expectancy between Māori (Indigenous) and non-Māori. Other scenario and sensitivity analyses were conducted to examine the potential impact of alternative modeling parameters and decisions. These consisted of the following: (1) the mass media campaign's design is enhanced, leading to wider recognition of the campaign's key message (68% recognition rather than 45%, using evidence from an evaluation of New Zealand's Health Promotion Agency *Small Steps* campaign [58]); (2) improved weight loss apps that have been developed since the meta-analysis we used, leading to a hypothetical 50% improvement in app effectiveness (modeled by increasing the mean BMI reduction by 50%); (3) all app users use the app for more time to test impact if there is good long-term engagement (modeled using the pooled effect size for trial lengths of >3-9 months); (4a) weight regain is delayed by 1 year; (4b) weight regain is delayed by 5 years; (4c) no weight regain occurs throughout the remaining life of the modeled population (ie, a highly hypothetical scenario that quantifies the envelope of potential benefit that could be obtained if weight regain was avoided); (5) the effect size for weight loss app effectiveness that was used in the previous modeling by Cleghorn et al [36] is applied in this study's updated model and intervention pathway; and (6) alternative discount rates of 0% and 6% are applied to health gains and healthy system costs to illustrate the impact of discount rates. This variation of discount rates is consistent with established health economic evaluation practices [41].

Simulation Analysis

The model was built in Microsoft Excel and run using Ersatz (version 1.34; EpiGear International). Uncertainty around health gains and cost-effectiveness was quantified using a Monte Carlo analysis. The parameters were sampled independently 2000 times from each of their respective probability distributions. The presented results are the mean values, with 95% uncertainty intervals (UIs). The exception to this is the expected values in the scenario and sensitivity analyses, which did not include uncertainty analysis.

Results

Health Gain and Cost Savings

Across the remaining lifetime of the modeled 2011 New Zealand population, the mass media campaign to promote weight loss app use in the base case analysis had an estimated overall health gain of 181 (95% UI 113-270) QALYs and health care costs of –NZ $606,000 (–US $408,000; 95% UI –NZ $2,540,000 [–US $1,709,000] to NZ $907,000 [US $610,000]). The mean of the health care costs is negative, representing an overall savings to the health system and a cost-saving intervention. However, the 95% UI spans positive values, indicating that there remains a possibility that the intervention is not cost saving, albeit still cost-effective (ie, below the threshold of NZ $45,000 [US $30,000] per QALY gained, approximately the gross domestic

product per capita for New Zealand that we use in our modeling [36]).

In the first 10 years after the intervention was implemented (2011-20), the mean health gain was 56 QALYs and net health system expenditures averaged NZ $850,000 (US $572,000) because of the cost of implementing that mass media campaign and few savings to the health system (although still below the cost-effective threshold of NZ $45,000 (US $30,000) per QALY gained). After 20 years (2011-30), the total health gain was 112 QALYs and the mass media campaign became cost-saving (–NZ $176,000 [–US $118,000]) for the health care system. Most of the health gain (62%) occurred between the years 2011 and 2030 (first 20 years after implementation), whereas most of the health system savings (71%) occurred after 2030 (ie, 20 years after implementation). The delayed health system savings was due to the initial up-front cost of implementing the intervention, which was also relatively high compared with the eventual reductions in downstream cost offsets because of altered disease rates.

Table 2 presents the results overall and by subpopulations over the remaining lifetime of the modeled population. The total health gains for non-Māori and Māori were 148 QALYs and 33 QALYs, respectively. Per 1000 population, this equated to 0.040 QALYS for non-Māori and 0.049 QALYS for Māori. When ethnicity was examined by sex and age group, the mean values consistently suggested greater per capita health gains for Māori. These mean values also suggest that the greatest health gain occurs among the age group 45-64 years and that, on average, the health gain was greater for men than for women. The exception to this was Māori women aged ≥65 years; this subgroup had a similar health gain to Māori men (0.079 QALYS per 1000 and 0.078 QALYS per 1000, respectively). Similar patterns were reflected in the health system cost estimates, which are, on average, savings to the health system. When the equity adjustment for Māori was applied (Table 3), the health gains for Māori increased to 40 QALYs and 0.060 QALYs per 1000. On the basis of the outcomes examined in this study, the modeled mass media campaign to promote weight loss apps among the general population would be expected to reduce health inequities arising from high BMI for Māori. However, the absolute reduction in health inequities would be small. In addition, this analysis assumed that the intervention would be as effective for Māori as it is for non-Māori (ie, the mass media campaign was culturally appropriate in design).

Table 2. Health gains and cost-effectiveness of a mass media campaign to promote smartphone apps for weight loss in New Zealand by age, sex, and ethnicity (lifetime impacts and 3% discount rate).

Sex, ethnicity, and age group (years)	Health gain in QALYs[a] (95% UI[b])	Health gain in QALYs per 1000 population (95% UI)	Health system costs[c], NZ $ (US $; 95% UI)
All	181 (113 to 270)	0.041 (0.026 to 0.061)	–606,000 (2,540,000 to –907,000); 408,000 (–1,709,000 to 610,000)
Non-Māori, all ages	148 (85 to 231)	0.040 (0.023 to 0.062)	–491,000 (2,310,000 to 921,000); –330,000 (–1,555,000 to 620,000)
Māori, all ages	33 (18 to 53)	0.049 (0.027 to 0.079)	–115,000 (–494,000 to 158,000); –77,400 (–332,000 to 106,000)
Men, all ages	97 (48 to 170)	0.045 (0.022 to 0.079)	–436,000 (–1,872,000 to 554,000); –293,000 (–1,260,000 to 373,000)
Non-Māori[d]			
25-44	19	0.038	–85,000 (–57,200)
45-64	46	0.094	–556,000 (–374,000)

[a]QALY: quality-adjusted life year.

[b]UI: uncertainty interval.

[c]A negative cost indicates that the intervention is cost-saving to the health system.

[d]The 95% uncertainty intervals for QALY and health system costs were not calculated for these subgroups.

Table 3. Results for Māori with equity adjustment applied (lifetime gains and 3% discount rate).

Population	Health gain in QALYs[a] (95% UI[b])	Health gain in QALYs per 1000 population (95% UI)	Health system costs[c], NZ $ (US $; 95% UI)
All	40 (23 to 65)	0.060 (0.034 to 0.097)	–132,000 (–513,000 to 152,000); –89,000 (–345,000 to 102,000)
Men	20 (9 to 39)	0.062 (0.026 to 0.118)	–67,000 (–341,000 to 115,000); –45,000 (–229,000 to 77,000)
Women	20 (9 to 37)	0.058 (0.025 to 0.109)	–65,000 (–331,000 to 111,000); –44,000 (–223,000 to 75,000)

[a]QALY: quality-adjusted life year.

[b]UI: uncertainty interval.

[c]A negative cost indicates that the intervention is cost saving to the health system.

The modeled lifetime health gains among adults experiencing overweight or obesity were 0.065 (95% UI 0.041-0.097) QALYs per 1000 target population. By ethnicity, the gains for non-Māori were 0.064 (95% UI 0.037-0.100) QALYs and for Māori 0.070 (95% UI 0.038-0.113) QALYs.

Scenario and Sensitivity Analyses

A range of results for scenario and sensitivity analyses are presented in Table 4. The modifications to the intervention pathway scenarios of either a more effective mass media campaign (eg, with better reach and targeting; scenario 1), more effective apps (scenario 2), or greater adherence to app use (scenario 3) all resulted in higher health gains and greater savings to the health system. When the model was altered to delay weight regain by 1 year (scenario 4a), 5 years (scenario 4b), or a highly hypothetical scenario of eliminating weight regain altogether (scenario 4c), the improved health gains and cost savings went from modest (eg, absolute increase in 20 QALYs for weight regain by 1 year) to markedly greater (eg, absolute increase in 14,544 QALYs for no weight regain). This highlights the substantial further health and economic benefits if weight regain was prevented across the remaining life course. The meta-analysis value [17] used in the previous modeling of mass media campaigns to promote weight loss [36] (scenario 5) yielded lower health gains and cost the health system, suggesting that apps have become increasingly more effective in weight management. The varied discount rates yielded results in the expected directions (scenarios 6a and 6b).

Table 4. Sensitivity and scenario analyses for a mass media campaign to promote weight loss smartphone apps by age, sex, and ethnicity (expected value analysis, lifetime perspective, and 3% discount rate, unless otherwise stated).

Sensitivity and scenario analyses[a]	Health gain in QALYs[b]	Difference in QALYs from base case, %	Health system costs[c], NZ $ (US $)	Difference in health system costs from base case, %
Base case analysis	183	—[d]	–625,000 (–421,000)	—
1. Mass media campaign: higher recognition at 68%	276	51	–2,414,000 (–1,620,000)	286
2. Increase effect size of app use by 50%	274	50	–2,375,000 (–1,600,000)	280
3. 100% of population use the app for more time	278	52	–2,454,000 (–1,650,000)	293
4a. Delaying weight regain by 1 year	203	11	–2,400,000 (–1,620,000)	284
4b. Delaying weight regain by 5 years	1,261	589	–21,271,000 (–14,300,000)	3305
4c. No weight regain	14,727	7948	–286,465,000 (–193,000,000)	45,762
5. Value from the previous Cleghorn et al [36] mobile health modeling study	69	–62	1,549,000 (–1,040,000)	–348
6a. 0% discount rate	334	83	–1,892,000 (–1,270,000)	203
6b. 6% discount rate	114	–38	186,000 (–125,000)	–130

[a]Expected values given for all scenarios.

[b]QALY: quality-adjusted life year.

[c]A negative cost indicates that the intervention is cost saving to the health system.

[d]Base case is the reference with which scenarios are compared.

Discussion

Principal Findings and Interpretation

The results from this updated health economic simulation modeling suggest that a hypothetical government-initiated mass media campaign to promote use of smartphone weight loss apps would result in modest health gains over the remaining lifetime of the New Zealand adult population. There was an estimated net saving to the health care system because of reductions in BMI-related diseases, although the UIs included estimates that were cost-effective (rather than cost saving). The intervention would be expected to generate greater per capita health gain for Māori and therefore potentially reduce health inequities attributable to BMI differences between Māori and non-Māori, assuming that the intervention would be as effective for Māori as it is for non-Māori.

Several key characteristics contributed to this modeled mass media intervention being cost-effective. First, and perhaps most importantly for this study, recent evidence from a meta-analysis of randomized controlled trials and case-control studies shows that the use of smartphone weight loss apps largely results in some degree of weight loss, even when accounting for variations in the duration of app use [46]. Several different behavioral theories suggest that self-monitoring progress toward a goal is a critical step between setting a goal and achieving a goal [59]. Apps can be a useful tool for self-monitoring dietary behaviors [9]. Monitoring progress helps to ensure that goals are translated into action, and the effect of an intervention on goal attainment is mediated by the frequency of monitoring [59]. Second, there was a sizable target population for this intervention: adults with excess weight who own a smartphone make up approximately 60% of the population. Accordingly, even small reductions in weight can achieve wide-reaching benefits in health [1]. Third, government-initiated mass media campaigns are relatively low

cost, especially in comparison with measures such as health service provision [60]. When designed well, mass media campaigns are effective at reaching a substantial proportion of the population with key health messages that can lead to modifications in behavior [29]. The World Health Organization has identified mass media as playing an important role in coherent national strategies for obesity prevention and management [61].

We found that there was very limited research examining whether mass media campaigns stimulate the specific action of adopting use of a smartphone app. Therefore, we relied on a UK evaluation of a mass media campaign that encouraged the use of a physical activity app [45]. A mass media campaign to promote a weight loss app would have been more appropriate. The tobacco control literature reports that media campaigns are associated with increased downloads of health apps (eg, smoking cessation apps) [62] and behavior changes further downstream (ie, attempts to quit smoking) [63]. There may be ways of making the mass media campaign more effective by targeting specific population groups in the messaging. For instance, there is evidence that mass media campaigns can better reach ethnic minorities using highly feasible social media or mass media that have reach to particular audiences [64] (eg, iwi radio and Māori Television in the New Zealand context).

Comparison With Prior Work

This paper provides new evidence using updated parameters on the potential health gain and cost-effectiveness of this health intervention. The previous Cleghorn et al [36] modeling conducted by some of our team found that there was very minimal health gain from the mass media campaign to promote mHealth interventions and that the intervention was not cost-effective [36]. However, there are 3 notable differences between the methods used in this study and the previous modeling by Cleghorn et al [36]. Most importantly, in this study, we used the results of a very recent meta-analysis of studies of smartphone weight loss apps showing a meaningful decrease in BMI (–0.454 kg/m^2, 95% CI –0.787 to –0.121 kg/m^2) [46]. The previous modeling used the best available evidence at the time, which was a meta-analysis of mobile device interventions that included apps as well as tools such as SMS text messaging [36]. The pooled effect size, which is measured in kilograms rather than BMI units, showed a comparatively smaller reduction in weight (–0.430, 95% CI –0.609 to –0.252 kg); this smaller effect size was the main contributor to the difference between the 2 studies. For some intervention pathway steps that were the same between the 2 modeling studies, we used different, more recent data. Specifically, smartphone ownership was higher than previously modeled and the reach of the mass media campaign was lower. We also conceptualized some of the pathway between the initial intervention (ie, the mass media campaign) to the effect size (ie, the effect of weight loss app use on BMI) based on new evidence that was incorporated into other modeling on mass media campaigns [37]. In our sensitivity analyses, we used the previously modeled effect size to isolate how much of a difference was due to the revised pathway versus the effect size. We found that most of the improved outcomes in our modeling were due to greater effectiveness of the apps, with only a small proportion of the gain due to the different conceptualization of the pathway. Our study adds to the very limited simulation modeling evidence on the cost-effectiveness of health apps [36-38].

Strengths and Limitations

A strength of this research is that it builds upon an established model [40], uses an effect size from a recent meta-analysis [46], and uses high-quality disease data that includes ethnicity-specific data [40]. There are a number of other ways that the mass media campaign could have been modeled, including alternative pathways that reflect numerous theories used to inform the development of mass media campaigns [29]. To account for a degree of uncertainty in input parameters and stochastic uncertainty, we modeled distributions of these inputs and quantified this variation using UIs. Parallel pathways for achieving impacts could be part of this intervention. For instance, we did not model that app uptake may also be by people who did not see the campaign but whose family members or friends saw it, started to use the app, and encouraged them to use it. In addition, the modeling might have underestimated the health benefits, given that there is evidence that mHealth interventions can result in changes in dietary intake beyond reduced weight loss, such as increased fruit and vegetable intake and decreased takeout meals [7] (which are typically high in sodium, sugar, and saturated fats). Some of these apps can also promote physical activity, which provides benefits to health beyond just a BMI pathway (eg, to mental health and cardiovascular health). It is unclear what proportion of the New Zealand population is already using a weight loss app and thus would not take up this intervention. However, despite the relatively high availability of mHealth apps, the level of awareness of such apps by individuals may be relatively low [65] and the apps being used may not be on the high-quality end of the spectrum. Our modeling did not account for differential impacts of either different apps or individual characteristics that could influence the adoption and engagement of apps, including the duration of this engagement and the quality of this engagement. Such differential impacts are too complex for inclusion in models of this design and also require highly detailed data for accurate measures. There is also no consistent definition for measuring constructs such as adherence to app use, which can encompass characteristics such as frequency, consistency, and detail of dietary monitoring [66].

Potential Policy Implications

As part of a wide range of interventions to address the obesogenic environment and unhealthy dietary patterns, governments should consider investing in promoting such weight loss apps, along with funding research that improves their effectiveness and uptake in the community. But all such interventions should also be well evaluated, particularly given the large potential for scalability. Laws and taxes can create a less obesogenic environment (and have been shown to be more cost-effective than nutrition mass media campaigns [60]). However, such actions can take time, and there is political and food industry resistance [67]. Hence, there is a role for tools (such as smartphone apps) that support using dietary changes that improve weight management as complementary measures.

Smartphone apps can also be combined with traditional interventions (eg, face-to-face counseling) [68], can form a component of a broader national social marketing health strategy [69], or they can be used as stand-alone treatments [54]. There may be further benefit from smartphone apps when face-to-face contact with patients must be limited [9], as in the case of the COVID-19 pandemic.

Conclusions

Using recent evidence on the effectiveness of smartphone weight loss apps, a modeled mass media campaign to encourage the adoption of smartphone apps to promote weight loss among the New Zealand adult population is expected to yield an overall gain in health and to be cost saving to the health system. This is an update of previous modeling that showed a smaller health gain and that the intervention was not cost-effective. Although other interventions in the nutrition and physical activity space are even more beneficial to health and cost savings (eg, pricing policies and food reformulation [60]), governments may choose to include strategies to promote health app use as a feasible complementary measure.

Acknowledgments

This research was funded by the New Zealand Ministry of Business Innovation & Employment (project number UOOX1406). The funding body had no role in the design of the study; the collection, analysis, and interpretation of data; or in the writing of the manuscript.

Authors' Contributions

ACJ led the conceptualization of the intervention, modeled the intervention, and wrote the first draft of the paper (excluding the introduction). LG wrote the first draft of the introduction. NW contributed to the study and intervention conceptualization and led the research grant that funded the study. NN provided foundational work in the costing of the modeled intervention. CC led the development of the diet model, contributed to the study and intervention conceptualization, and provided modeling expertise. All authors contributed to drafts of the manuscript and read and approved the submitted manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Much research in human-computer interaction has focused on well-being and how it can be better supported through a range of technologies, from affective interfaces to mindfulness systems. At the same time, we have seen a growing number of commercial digital well-being apps. However, there has been limited scholarly work reviewing these apps.

Objective: This paper aims to report on an autoethnographic study and functionality review of the 39 most popular commercial digital well-being apps on Google Play Store and 17 apps described in academic papers.

Methods: From 1250 apps on Google Play Store, we selected 39 (3.12%) digital well-being apps, and from Google Scholar, we identified 17 papers describing academic apps. Both sets of digital well-being apps were analyzed through a review of their functionalities based on their descriptions. The commercial apps were also analyzed through autoethnography, wherein the first author interacted with them to understand how these functionalities work and how they may be experienced by users in their daily lives.

Results: Our findings indicate that these apps focus mostly on limiting screen time, and we advanced a richer conversation about such apps, articulating the distinctions among monitoring use, tracking use against set limits, and 4 specific interventions supporting limited use.

Conclusions: We conclude with 6 implications for designing digital well-being apps, namely calling to move beyond screen time and support the broader focus of digital well-being; supporting meaningful use rather than limiting meaningless use; leveraging (digital) navigation in design for friction; supporting collaborative interaction to limit phone overuse; supporting explicit, time-based visualizations for monitoring functionality; and supporting the ethical design of digital well-being apps.

Introduction

Background

A significant growth of research in well-being [1] and affective health [2] has taken place in the last decade across a range of disciplines, from human-computer interaction (HCI) and science and technology studies to clinical psychology and psychiatry. This range reflects the interdisciplinary work in this space, and we argue the unique position of the HCI discipline to articulate the design knowledge required for digital well-being interventions. Such work includes novel affective interfaces

intended to support real-time awareness of emotions or their regulation [3-7], novel design approaches emphasizing the importance of the human body such as soma design [8], novel technologies supporting reflection and meaning making [9], and those intended to train meditation or mindfulness skills [10] or to conceptualize meaning [11]. Other strands of HCI work have focused on ill-health, such as mobile apps for cognitive behavioral therapy [12] and empirical studies exploring ways to support vulnerable users; such as those living with depression [13], dementia [14], addiction, or the compulsive use of technology; including screen time research [15,16]. Much of such work frames mental well-being as "positive emotional, psychological and social health" [17], whereas digital well-being is broadly seen as the result of being able to use technologies in productive and healthy ways without the negative consequences of dependency, distraction, or risks to users' privacy [18].

A specific body of work has focused on interventions supporting smartphone nonuse, for instance, by increasing interaction cost to discourage smartphone app use [19]. Both limiting phone use and increasing interaction cost can be conceptualized within the slow movement, where technology is reframed with the aim of pausing and reflecting on its use [20]. Other examples of interventions of smartphone nonuse include apps such as MyTime to make users aware of their tracked use data, which in turn prompt them to reflect upon their use and especially the problematic use [21]. In addition, Roffarello and De Russis [22] argued that current digital well-being apps' focus on self-monitoring may not be a sufficient mechanism to change users' behavior with smartphones. Moreover, Roffarello and De Russis [22] also pointed out the limited exploration of the effectiveness and theoretical underpinning of digital well-being apps, whereas van Velthoven et al [23] highlighted also the insufficient investigation of the positive effects of regulating problematic smartphone use with digital interventions. The nascent research exploring the effectiveness of digital well-being apps has been limited, with only 1 study focusing on the analysis of users' qualitative reviews of commercial apps [22]. Their findings indicate that such apps are liked, especially in studying, working, sleeping, parental control, and free time contexts, albeit limited in supporting behavior change and habit formation toward more conscious smartphone use.

In addition, the theoretical underpinning of digital well-being apps has also received limited attention. In this respect, most work has looked at their adoption [24,25], leveraging, for instance, technology acceptance theories [26,27], including the more recent technology acceptance life cycle model [28]; although these models are rather generic, they are leveraged for personal or domestic technologies. Scholars such as Douglas et al [25], Lukoff et al [29], Lyngs et al [30], Kim et al [31], or Colombo et al [3] have also identified other theories more relevant to digital well-being apps, such as the uses and gratification theory [19,31], theory of planned behavior [32], dual system theory [33], nudge theory [34], framework for behavior change [35], or theories for regulation [36]. However, it is less explored how such theories could actually inform the developing of commercial well-being apps.

Given the limited research on the theoretical and evidence-based aspects of digital well-being apps [23,25], we argue that unpacking the functionalities of the most used commercial apps is an important initial step toward better designing them. The exploration of functionalities and features of mobile apps is an emerging research area, with initial HCI work focusing on digital interventions and especially development of apps for specific conditions such as depressions [37,38] or for supporting, for instance, mindfulness [39,40] or physical activity [41]. In contrast, the functionalities of digital well-being apps have been less investigated. A noticeable exception is the exploration by Roffarello and De Russis [22] of 42 digital well-being apps and their descriptions on Google Play, whose findings indicate the following as key features: (1) tracking user behavior through phone unlocks, phone and app time, and app checking; (2) data presentation through phone and app summary, charts, daily or widget recap, and social comparison; (3) phone interventions through timers and blockers; (4) app interventions through timers, blockers, and notification blockers; and (5) extra features such as motivational quotes or rewards. However, given the brevity of apps' descriptions available on marketplaces, a richer source to identify their key functionalities is the actual use of the apps, with authors, as HCI experts, adopting the role of the user by directly interacting with the apps—a method previously used for app reviews [38,42,43].

Specific functionalities of digital well-being apps have been also explored through research prototypes usually implementing tracking and notifications [44,45], whereas others included also specific interventions for limiting use [21,46]. For instance, the Socialize [22,47] app integrates the most common functionalities of tracking, data presentation, real-time notifications, and blocking use, which were evaluated in the wild with 38 young people over 3 weeks. Findings indicate improvements in terms of problematic use, measured through the phone addiction scale, and self-regulation, measured through the general self-efficacy scale. Although this is one of the few studies involving measures to explore the effectiveness of a digital well-being app, the Socialize app itself does not appear to be novel, borrowing common functionalities of commercial apps, whose theoretical grounding is limitedly unpacked. The Focus app [48] is another research prototype that leverages Nielsen's heuristics to support tracking phone use and the blocking of any app, indeterminately or for a limited time set by the user, with the option to unblock them at any time, and provision of educational content on digital addiction. To mitigate overuse from a broader perspective, another research prototype, the FeelHabits app [49], tracks and notifies users about their use of specific apps; albeit rather than on a smartphone alone, this apps tracks use across devices and blocks them if limits set by the user are exceeded.

Another strand of scholarly work with richer theoretical underpinning has focused on restrictive and coercive interventions intended to be stronger than persuasive interventions by supporting users to commit to self-impose limits of use while the phone is blocked [31]. The framework for influencing behavior change [35] suggests the following four types of influence: persuasive (explicit and weak); coercive (explicit and strong); seductive (implicit and weak) and decisive (implicit and strong), which are based on the influencing force

(strong and weak); and salience (explicit and implicit). Inspired by this framework, Kim et al [31] designed and evaluated GoalKeeper, a smartphone app featuring both a *weak lockout*, that is, the phone is locked increasingly longer (eg, 1, 5, 15, 30 and 60 minutes) each time the user exceeds the time they have previously set for use, with each lockout being mitigated by a temporary 15-minute allowance time, and a *strong lockout*, that is, the phone is locked until midnight without any allowance. Their findings indicate that both mechanisms were more effective than mere notifications of use, with the strong lockout being the most effective, as users set longer limits for not using their phones. Although in the latter case users experienced also more frustration, this was mitigated by the flexibility of setting their own limits and one-time opportunity to modify it.

Objectives

Despite this growing academic interest in digital well-being, the commercial apps far outweigh the research prototypes in terms of uptake. Thus, the increased adoption of commercial well-being apps offers an opportunity to explore their potentially richer set of functionalities, and the aim of this paper is to articulate these functionalities as well as the novel design implications informed by them to better inspire the design of technologies for well-being. To address this aim, we focused on the following research questions:

1. What are the key functionalities of the top-rated digital well-being apps?
2. What theoretical underpinning supports these functionalities?
3. What design guidelines for digital well-being apps can be informed by these functionalities?

Our contributions are 3-fold. First, we unpacked richer insights about tracking and monitoring functionalities in terms of user profiling and understanding of monitoring as a *complete, location-based, and flexible practice* that can benefit from tailored, time-based visualizations. Second, we identified 4 interventions for limiting use including richer understanding of different types of obstacles for limiting use and specific features for less explored functionalities such as supporting awareness for reaching use limits, focused attention, and motivation to keep within set use limits. Third, grounded in our findings, we generated 6 design implications for digital well-being apps.

Methods

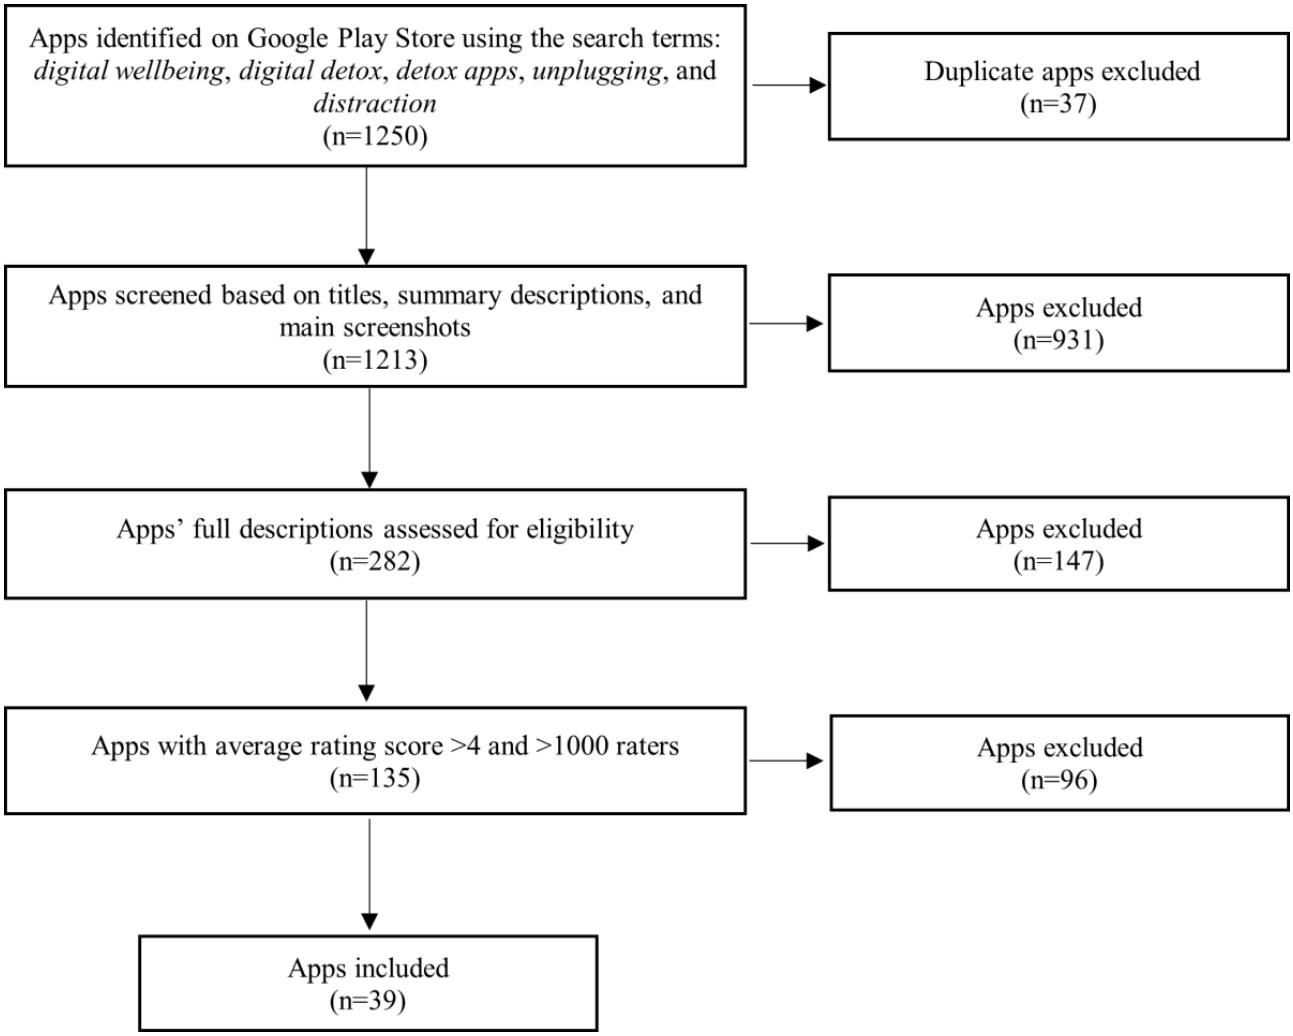
App Selection

To identify the digital well-being apps, in winter 2019, we searched for free apps in Google Play Store using the following search terms: *digital wellbeing*, *digital detox*, *detox apps*, *unplugging*, and *distraction*, which is a new direction given that extensive previous work on such apps has prioritized addiction and screen time [22]. We have focused on Google Play because its apps represent the largest global market share, >2.5 greater than iOS apps [50], whereas the latter is also more restrictive in terms of available information [22]. However, future work could extend this exploration to other platforms.

For each search term, the top 250 most relevant apps returned on Google Play were retained, totaling 1250 apps, with 37 duplicates. At the screening stage, after reading their titles, summary descriptions, and main screenshots, we excluded 931 less relevant apps such as fitness, activity planner, or nondigital detox apps. The eligibility of the remaining 282 apps was assesses based on their full descriptions, with further 147 apps being excluded such as utility apps, games, and general well-being and meditation practice apps. From the remaining 135 apps, we further excluded those with less than 1000 raters and with average rating score <4, leading to 39 apps to be included in our review. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) diagram for the searching and screening process for digital well-being apps is shown in Figure 1. We also note that of our 39 apps, 12 (31%) are also available on the Apple Store, with 7 (58%) of them having user rating >4.2.

Our final set consisted of 39 digital well-being apps (Multimedia Appendix 1 [19,21,22,31,34,44-46,48,49,51-57]), which were analyzed through two complementary methods: first, a review of their functionalities based on their descriptions from Google Play and, second, an autoethnography with the authors (SA and CS), as HCI experts directly interacting with them in order to viscerally understand how these functionalities work and are experienced by potentially users in their daily lives. Such interactions were iterated, involving at least two sessions for each app, lasting for at least 30 minutes. For the autoethnography, we used a Samsung Galaxy Note 9 phone with an Android mobile operating system.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) diagram for the searching and screening of digital well-being apps.



App Analysis

The first author (SA) evaluated all 39 digital well-being apps, whereas the second author (CS) evaluated 21% (8/39) of the apps. Through the use of both methods, the authors (SA and CS) iteratively revised the coding scheme over several months, a process that has followed a hybrid approach. This integrated deductive codes, informed by prior work on functionalities [22] such as tracking, data presentation, and interventions (Table 1). The inductive coding was informed the distinction between tracking and monitoring, the revision of intervention functionalities such as tracking phone or app use by setting limits and of data presentation or visualization and its subcategories such as numerical and diagrammatic format through charts, round diagrams, metaphors, heat maps, or reports. Particularly important are the new functionalities capturing 4 interventions for limiting use.

To better contextualize our review in scholarly work, we subsequently extended the list of apps with 17 digital well-being apps designed in academia, which we found through search on Google Scholar using the following keywords: *digital wellbeing application* or *digital wellbeing app*. This search returned 42 papers, which after reading their abstracts, led to 17 papers describing such apps [3,8,12,18,26,32,37,49,51,58-65]. The remaining 25 papers do not included digital well-being apps and for this reason they were excluded. We have explored the functionalities of the apps described in the 17 papers by applying the above coding system to their description, as not all of them were available to download from app marketplaces. All the tables provided in Multimedia Appendices 1-7 [19,21,22,31,34,44-46,48,49,51-57] include information on both commercial and academic apps.

Table 1. The main codes and subcodes from the app analysis.

Functionality codes and subcodes	Definitions
Tracking	
Recording phone or app use	The tracking functionality supports the recording of phone or app uses.
Visualizing tracked use data	The tracking functionality supports the visualization of tracked data.
Profiling users	The tracking functionality supports profiling users based on tracked data.
Monitoring	
Setting time limits of phone and app use, their scope and place	The monitoring functionality provides use time limits or supports users to customize them in terms of scope and place.
Visualizing monitored data	The monitoring functionality supports the visualization of monitored data against set time limits of use.
Providing flexibility for limiting monitoring	The monitoring functionality supports flexibility for limiting monitoring through allowances to extend use beyond the set time limit, excluding apps from being monitored, or discontinuing the monitoring.
Interventions for limiting use	
Creating obstacles to limit phone and app use	This intervention supports creating different types of obstacles to limit phone or app overuse.
Supporting awareness of reaching the set use limits of phone and app use	This intervention supports users' awareness of reaching the set use limits through different types of notifications varying in content and form.
Supporting focused attention away from phones and apps	This intervention supports users' focused attention on main task and away from habitual phone and app use through training or white noise.
Supporting motivation to keep within limited use	This intervention supports motivation to keep within limited phone and app use through rewards and penalties, motivational quotes or education, and social motivation.

Results

This section starts with a brief overview of the descriptive characteristics and ethical aspects of the 39 apps, continues with the identified main functionalities of top-rated digital well-being apps and how they compare with the apps developed in academia.

Descriptive Characteristics of Digital Well-being Apps: Ethics

The descriptive characteristics captured by our analysis include app category, target users, scientific underpinning and evidence base, and cost. Findings indicate that the top-rated digital well-being apps belong to 6 categories, albeit feature predominantly in the Productivity category (27/39, 69% apps), followed by fewer apps in the Tools (4/39, 10%), Personalization (3/39, 8%), Health and fitness (2/39, 5%), Parenting (2/39, 5%), and Lifestyle (1/39, 3%) categories. Together with their main aim of limiting phone overuse, this is an interesting outcome that can be linked to the ethical principle *of nonmaleficence* [2] to protect users from the negative impact of phone overuse. These can also be aligned with the ethical principle of *beneficence*, particularly the predominant instrumental value of digital well-being apps supporting increased productivity rather than their eudemonic value for supporting meaningful goals [66]. Arguably, the latter would further strengthen their beneficence potential.

Another important outcome, which can potentially hinder their beneficence is the limited science base of digital well-being apps, with 97% (38/39) of the apps not specifying if they are backed up by research, the only exception being the Focus To-Do app described as a *science-based app*. This indicates the importance of these apps unpacking in their descriptions the scientific underpinnings informing their design and any available outcomes from evaluation studies. This, in turn, will support users make more informed choices regarding their beneficence.

The target users of digital well-being apps appear to be unrestricted, with most of them available to users of all ages, which reflects the principle of *justice*. Indeed, all but 4 apps are rated on Google Play as "PGEI 3," which stands for "Pan European Game Information." The remaining four apps do not specify any age: Brain Focus Productivity Timer, Lock Me Out, SleepTown, and Sma-Phospital. Interestingly, the design of the apps does not vary with age, as we see the same functionalities for both children and adults. We also examined whether the target users include the clinical population. Findings indicate that of the 39 apps, 38 (97%) do not specify clinical user groups, whereas 1 (3%) app, that is, AppBlock, mentions its suitability for children or adults with attention deficit hyperactivity disorder. This suggests that digital well-being apps predominantly target users without specific conditions or health concerns. However, given their value for supporting attention, some of these apps may be beneficial for users with attention deficit. Future work should further explore this.

Also related to justice, the cost of the digital well-being apps is an important aspect that can increase or limit diverse users accessing them. Regarding cost, an important outcome is that although all the 39 apps are free to download, only 11 (28%) are entirely free to use, whereas 28 (72%) offer in-app purchase mostly for removing adds, unlocking premium features, or subscribing to premium versions of the apps. This is an

important outcome indicating that most functionalities of these apps are freely available, making their use particularly inclusive.

Digital well-being apps have an interesting relationship with the ethical principle of autonomy. On the one hand, these apps tend to limit one's use of phone or apps; on the other hand, consistent findings have shown that autonomy is already impaired [67] when people live with some form of addiction such as phone overuse.

Functionalities of Digital Well-being Apps

Overview

We now turn our attention to the key functionalities of digital well-being apps. The iterative analysis led to specific functionalities that can be broadly grouped into the following six main functionalities: tracking use of the phone or apps, monitoring use against set limits, and the four functionalities that highlight interventions for limiting use, namely, creating obstacles for the phone or app use, supporting awareness of reaching the set use limits, supporting focused attention, and support motivation to keep within limits of use. Each of these functionalities is further detailed.

Tracking Overall Phone and App Use: User Profiling

Findings indicate that 28 digital well-being apps automatically track or record overall phone use, use of specific apps, or both (Multimedia Appendix 2 [19,21,22,31,34,44-46,48,49,51-57]). In particular, (1) the overall use of the time spent on the phone was captured by 11% (3/28) of the apps through overall screen time across all apps measured per minute, hour, day, or week or the number of times the phone unlocks per hour or day; (2) the use of specific apps that provide users the choice to select them to capture only their screen time was captured by 54% (15/28) of the apps; and (3) 21% (6/28) of the apps tracked both the overall use of the phone and the use of specific apps. Other digital well-being apps provide users with the choice to select the time when the tracking can occur, for instance, between 9 AM and 5 PM, but not outside of the specified time window. Tracking can also be contextualized, with three apps (AppBlock, Instant-Quantified Self, and Lock Me Out), allowing its coupling with physical locations specified by users.

Regarding visualization, the tracked use data tends to be provided in numerical and diagrammatic format through reports (27/28, 96%), charts (21/28, 75%), round diagrams (9/28, 32%), metaphors (4/28, 14%), or heat maps (1/28, 4%; Multimedia Appendix 2). The four apps providing metaphoric visualizations are Forest: Stay focused, Focus To-Do: Pomodoro Timer & To Do List, SPACE, and SleepTown, with the latter's visualization consisting of raising in-app towns when maintaining regular sleep hours. In addition, from the 27 of the apps including reports, 20 (74%) provided daily and weekly reports of screen time and 7 (26%) provided only daily such reports.

Findings also indicate that of the 39 apps, 10 (26%) extend the tracking functionality to also inform user profiling. Of these 10 apps, 4 (40%) use either the tracked data of app use (App Usage and Screen Time) to generate categories of used apps for broader purposes such as productivity and social, or ask users to identify these categories (SaveMyTime and Boosted). In addition, of the 10 apps, 3 (30%) provide users the option of creating different profiles for different settings that could be used to support different levels of limited use of the phone or apps, both with payment (HelpMeFocus) or without payment (Stay Focused), for instance, by allowing them to specify the location or specific Wi-Fi network where set limits are activated (AppBlock). This is important, as it indicates the flexibility of the interventions for limited use to the situatedness of users' different contexts such as homes or work. Finally, the YourHour app also aims to identify levels of phone addiction based on tracked data, whereas the Digital Detox app offers predefined levels of limited use that users can choose from. These 2 apps are interesting, as they attempt diagnosis of smartphone addiction and prediction of the intervention intensity. Although smartphone addiction is not yet a clinical condition featured in the *Diagnostic and Statistical Manual of Mental Disorders*, its problematic behaviors as diagnostic criteria have started to be explored [68]. In addition, several scales have been developed for measuring phone addiction [65,69] that meet the psychometric properties of validity and reliability. If digital well-being apps aim to identify users' level of addiction, which will allow for a better tailored intervention, these scales are useful to consider.

Interestingly, of the 39 apps, the remaining 11 (28%) that do not provide tracking functionalities include 8 (73%) apps supporting focused attention usually on offline activities (Forest, Boosted, Pomodoro Smart Timer, Brain Focus Timer, SleepTown, Engross, Visual Timer, and Hold), 2 (18%) launcher apps minimizing the number of apps being displayed (LessPhone Launcher and Before Launcher), and 1 (9%) app for turning off email notifications (Quite for Gmail).

Monitoring Phone and App Use Against Set Use Limits or Set Time Limits for Focused Attention

Apart from tracking, most digital well-being apps also allow setting use limits to track phone or app use against them (25/39, 64%); Multimedia Appendix 3 [19,21,22,31,34,44-46,48,49,51-57]). The distinction between tracking and monitoring is that monitoring is based on user intentions to self-limit their use, whereas tracking merely captures the time spent on apps or phone without any such limits. Thus, tracking becomes a prerequisite activity, performed first to explore one's use patterns, and based on this information, use limits can be set. Indeed, all apps supporting monitoring also support tracking; however, 33% (13/39) of the apps, although supporting tracking, do not support monitoring. This is an important outcome as arguably, monitoring is better positioned to support behavior change toward limiting use than mere tracking; however, approximately 36% (14/39) of the top-rated apps do not support monitoring.

Whereas most apps (25/39, 64%) support setting limits for using the phone or its apps, the remaining 36% (14/39) of the apps include 8 (57%) apps that allow people to focus attention by setting time for offline activities and therefore away from phones and apps; 3 (21%) apps providing only the tracking functionality (Smarter Time, Sma-Phospital, and Usage Analyzer); 2 (14%) launcher apps minimizing the number of apps being displayed; and 1 (7%) app for turning off email notifications (Quite for

Gmail). The prevalence of apps for focused attention on offline activities is an interesting and less explored monitoring aspect of digital well-being apps.

The monitoring functionality allows user setting of the scope and place of limited use, visualization of monitored content, and, interestingly, options for limiting monitoring. With respect to the scope of the limited use, more than half of the monitoring apps offer options to reduce the use of some of the installed apps (13/25, 52%). This means that while using these digital well-being apps, some apps' use remains unmonitored. In contrast, the remaining digital well-being apps extend this option to monitor use to all apps on the user's phone (6/25, 24%) or to the phone itself (7/25, 28%). Setting use limits can also be activated at specific locations, either specified through the phone GPS (3/25, 12% apps) or Wi-Fi network (1/25, 4% apps), although only a few apps offer these options.

Findings also indicate that 56% (22/39) of the digital well-being apps support a more forgiving or *flexible monitoring* by allowing users to limit their monitoring in 3 ways. This includes allowances to extend use beyond the set time limit (9/22, 41% apps) and the option to exclude specific apps from being monitored (19/22, 86% apps). Allowances are breaks during the set nonuse time limit so that users can continue to use the phone or the apps despite being during their set nonuse time limit, with or without (financial) penalties, although the number of breaks, and their duration is either capped or uncapped. This can also include terminating the nonuse time limit earlier than it is actually due (4/22, 18% apps). A total of 49% (19/39) of the digital well-being apps also offer the option of excluding specific apps from being monitored against time limits, especially apps such as App Usage–Manage/Track Usage, AntiSocial, and My Phone Time. In addition, 36% (14/39) of the apps allow users to discontinue monitoring when they reached the set use limit.

Regarding visualizations, monitoring function engulfs tracking one, so that it supports the visualization of tracked data. However, visualizations specific to the monitoring functionality are offered by less than half of the digital well-being apps (19/39, 49%). This is an important outcome, suggesting the value of considerably extending such visualizations within the monitoring functionality. These 19 apps provide monitoring-specific visualizations of (1) time unspent out of the use time limit, that is, count down (n=12, 63% apps), (2) time spent out of the use time limit (n=6, 32% apps), or (3) even time overspent as a percentage of the time limit (n=1, 5% apps). These are provided in either text form (12/19, 63% apps) and diagrammatic one as circles (4/19, 21% apps) or progress bars filled or unfilled gradually with colors (3/19, 16% apps) until the set time limit is reached. Interestingly, the monitoring of focused attention, usually during offline activities, can also be visualized, usually through time unspent out of the focus time (or time for not using the phones and apps), through countdown timers (3/19, 16% apps), or circle progressively unfilled with color (1/19, 5% apps).

Interventions for Limiting Use of Phones and Apps

Findings indicate four interventions for limiting the overall use of the phone or its installed apps, which include creating obstacles to limit use, supporting awareness of reaching the set limits, supporting focused attention, and supporting motivation for limiting use, which are further detailed.

Creating Obstacles to Limit Phone and App Use

The first intervention consists of creating obstacles for excessive phone or app use (21/39, 54% apps). Obstacles can be classified according to their force (strong or weak); saliency (explicit or implicit); temporal aspects such as being activated before, during, or after excessive use; and social aspects such as parental control or social commitment (Multimedia Appendix 4 [19,21,22,31,34,44-46,48,49,51-57]). Obstacles also differ with respect to their source (being generated by the digital well-being app or by users) and could be tailored to user profiles.

The identified strong obstacles feature predominantly in commercial apps (18/39, 46%). These obstacles that cannot be circumvented include the lockout of phones and apps beyond the set time limit of use (14/18, 78% apps), interrupting use while the set use time has been reached (12/18, 67% apps), and unchangeable time limits of phone and app use (6/18, 33% apps). In contrast, weak obstacles have features in much fewer apps (5/39, 13%), with only one app providing both strong and weak obstacles, that is, StayFree. Weak obstacles do not directly restrict use but make it more difficult through notifications from phones or apps after overuse (4/5, 80% apps), notifications inside the digital well-being app when reaching the time limit (4/5, 80% apps), and microboundary interactions that make it more difficult for users to access their apps targeted by limited use (2/5, 40% apps). Microboundary interactions are particularly interesting, as although theoretically explored in academic research, they have been limited, implemented through design. Such interactions feature in two apps (LessPhone Launcher and Before Launcher) and consist of *launchers* as substitute home screens for users' phones that display only a reduced number of apps so that accessing other apps requires additional clicks for navigating from the launcher to them.

According to their saliency, most obstacles are explicit such as lockout (8/39, 21% apps), set time limits for phone and app use (14/39, 36% apps), and textual or visual notifications (4/39, 10% apps), whereas others are implicit such as launchers (2/39, 5% apps) or activation of the dimming mode of the phone's screen when a set time limit was reached (1/39, 3% apps). This much lower number of implicit obstacles is interesting, suggesting a less explored design space and their potential value of complementing explicit obstacles.

With respect to the temporal aspect, most obstacles are created before the use of a phone or app and activated during the set limited time for using the phone or apps. The exception is flexible time limits, which can be changed not only during but also after the set time limit for use has ended.

The obstacles also have a social dimension, albeit only 13% (5/39) of the apps implemented them, in two forms: parental control (4/5, 80% apps) or social commitment (1/5, 20% apps). Regarding the latter, the Forest app leverages the feeling of failure to social commitment as a type of obstacle to prevent users from accessing apps while with friends.

Regarding the source, obstacles can be created by the digital well-being app or the user. The former leads to automatically generated obstacles, usually through user profiling (11/39, 28% apps), whereas the latter leads to customized obstacles (13/39, 33% apps). Apps allowing users to set use limits usually restrict this option to specific apps rather than all apps. Examples of the automatic setting of use limits feature in the YourHour app, which provides users short quizzes to identify if the app is used for work or entertainment. Another example is the SPACE app, supporting limited phone use through automatically suggested limits. Interestingly, two apps allow users to create multiple profiles, each profile with a particular setting to be assigned to different tasks (HelpMeFocus and Stay Focused). This is an interesting option, allowing users different modes of engaging with specific apps, which could, for instance, help with the context setting such as work or leisure, and different phone use for each.

Finally, different types of obstacles may be tailored to different user profiles for matching, for instance, the level of addition (1/39, 3% app) or users' preference for a specific level of digital detox (namely, easy, medium, and hard) that are proposed to users to choose from (Digital Detox app). Interestingly, no apps attempt to recommend interventions at different levels (weak or strong) based on tracked data. This is a less explored feature with potential to provide adaptive interventions better tailored to users' needs.

Supporting Awareness of Reaching the Set Use Limits of Phone and App Use

The second intervention is supporting awareness of reaching the set limits of use and is provided by 33% (13/39) of the apps (Multimedia Appendix 5 [19,21,22,31,34,44-46,48,49,51-57]). Such awareness is predominantly supported through explicit notifications of reaching the set time limits (12/13, 92% apps), usually in textual or diagrammatic form, with both push notifications that appear when the screen is both locked and unlocked, usually at the top in the status bar; (4/12, 33% apps) or pull notifications that appear suddenly in the middle of the screen as a small window alerting the user of something, sometimes these are big, covering most of the screen (7/12, 58% apps). Notifications can be provided both in the digital well-being apps about the use of the phone or its installed apps (13/39, 33% apps) and as embedded within a specific app when the time limit relates to that app (11/39, 28% apps). In contrast to explicit notifications, implicit ways to support awareness of reaching the time limit include screen dimming. Although less common (1/39, 3% apps), these are interesting, more subtle ways to notify users of reaching their use limits for specific apps or phones and to persuade disengagement. Although both notifications and screen dimming are provided in real time, daily reminders to review tracked data support a higher level of awareness beyond a specific instance of *in the moment* use and more about the historic user over the day (7/39, 18% apps).

Supporting Focused Attention on Primary Tasks and Away From Habitual Phone and App Use

The third intervention supports focused attention and features in >70% (29/39) of digital well-being apps (Multimedia Appendix 6 [19,21,22,31,34,44-46,48,49,51-57]). These include all apps that support monitoring (25/39, 64%) and four additional ones: Boosted, Pomodoro Smart Timers, Engross, and Hold. By aiming to limit phone and app overuse, digital well-being apps implementing the monitoring functionality implicitly support focused attention on the main task because they prevent the user's attention from being hijacked by habitual phone and app use.

Findings also indicate that, of the 39 apps, 8 (21%; four that support monitoring and four that do not: Boosted, Pomodoro Smart Timers, Hold, and Engross) explicitly target the training of focused attention. These apps encourage users to stay away from their phone to focus on specific offline tasks for a set time. This use of a time limit is different from that in the monitoring functionality, as people are supported to practice the adaptive behavior of maintaining attention for a set time away from the phone rather than resisting for a set time the temptation to use the phone.

In addition, of these 8 apps for training focused attention, 5 (63%) also provide users with white noise to better facilitate concentration. This is an interesting outcome, and although these apps provide limited evidence for its value, scholarly work indicates that white noise, defined as "task-irrelevant auditory input containing many frequencies of equal intensities" [8], has potential to improve cognitive performance in both healthy adults [17] and those with attention deficit [70]. Mechanisms that could explain the benefits of white noise include its ability to moderate brain arousal by inducing neural noise, which at specific dopamine-based thresholds could stimulate cognitive performance [58].

Supporting Motivation to Keep Within Limited Use of Phone or Apps

The fourth intervention supports motivation for limiting phone and app use (12/39, 31% apps; Multimedia Appendix 7 [19,21,22,31,34,44-46,48,49,51-57]). Findings indicate 3 mechanisms for supporting motivation. The first is the reward and penalty feedback usually implemented by those apps that support monitoring (7/12, 58% apps), with rewards being provided when users successfully kept within their set use limits of their phones and apps. The main types of rewards leverage gamification principles and consist of badges at different levels (2/7, 29% apps), points (2/7, 29% apps), in-app coins (1/7, 14% apps), building in-app trees (Forest) or towns (SleepTown), or motivational quotes (4/7, 57% apps). The main categories of penalty content are metaphoric and consist of in-app tree withers (Forest) or town-building collapses (SleepTown). Interestingly, however, most monitoring apps (20/29, 69%) do not support such motivation through rewards and penalties.

Second, in addition to the reward and penalty feedback provided on the basis of successful or unsuccessful keeping within set limits of phone or app use, other types of motivation are provided to support behavior regulation of limiting use, both during and even before the actual behavior of limiting use. This less common type of motivation consists of motivational quotes, either provided by the app (two apps: Stay Focused and HelpMeFocus) number and names or generated by the user (two apps: StayFree and App Usage–Manage/Track Usage); educational content about phone and life balance (one app:

SPACE); or motivational stories written by other users (one app: YourHour).

Third, social support is another form of motivation, whose role in facilitating behavior change has been much acknowledged [71]. An important outcome is the limited number of apps that encourage social support to limit phone or app use, through competition (5/39, 13% apps), collaboration (5/39, 13% apps), or both (3/39, 8% apps). This is distinct from the identified emphasis on competition [72]. For instance, the SPACE app allows comparing such progress of limited use. In contrast to this competition social motivator, our findings also show 13% (5/39) of the apps leveraging collaboration, in which family members, friends, or broader social networks are used. For instance, the SleepTown app allows sharing sleep time goals with friends and setting similar sleep goals with them. Another example is the Hold app, which provides different ways to share focus time through finding nearby Bluetooth-enabled devices to encourage focused attention in the group. The Hold app also integrates collaborative and competitive aspects, for instance, by ranking users according to the points they gained from their time spent on focusing tasks, most often offline ones. Apps leveraging competition can also integrate social recognition. For example, the Hold app rewards the top-ranked users according to their points with a crown icon next to their username, and the Focus app rewards the first three users with a trophy icon next to their usernames: gold, silver, and bronze.

Comparison of Commercial Digital Well-being Apps With Academic Ones

This section focuses on the comparison of the functionalities of the apps developed in academia with those of commercial apps, with a specific focus on how they differ. It is not surprising that most academic apps share the tracking and monitoring functionalities available in commercial apps. For example, the lockout mechanism that blocks the phone until midnight when reaching the use limit [31] is similar to blocking apps and phone when the user exceeds the defined time limit in some commercial apps (ie, Ubhind). Similarly, blocking and scheduling blocking in the academic app Forest [48] are comparable with those in the commercial app AppBlock. An interesting distinction concerning tracking and monitoring is the new form of visualization of tracked data in academic apps, namely, timelines.

In terms of interventions for limiting use, findings indicate additional key distinctions between commercial and academic apps for digital well-being. Regarding creating obstacles to limit phone or app use, important distinctions concern the force and saliency of the created obstacles and their temporal aspect and source. With respect to force, commercial apps predominantly use strong obstacles such as phone or app blocks (14/39, 35% apps) instead of weak obstacles such as notifications or microboundary interactions (5/39, 13% apps), with only 3% (1/39) of the apps providing both strong and weak obstacles. In contrast, academic apps take a more balanced approach, using equally both strong (10/17, 59%) and weak (11/17, 65%) obstacles, with 29% (5/17) of these apps using both strong and weak obstacles. Given the nascent research exploring the effectiveness of digital well-being apps, academic work is more likely to use both types of obstacles to compare their effectiveness.

With respect to the saliency of obstacles, almost half of the commercial apps (17/39, 44%) specify saliency, with all but 1 featuring explicit obstacles (which also tend to be strong), whereas the SPACE app features implicit obstacles. In contrast, almost all academic apps (16/17, 94%) involve explicit obstacles, that is, mostly notifications. What is interesting here is the innovative use in academic apps of a new type of obstacles for restricting use through design frictions. These could involve mandatory cognitive tasks such as entering several digits as users attempt to start interacting with apps targeted for limited use [57] or entering 30- or 10-digits try [19], which, when compared with merely pressing OK, indicates that the more complex the cognitive task, the more likely that users will restrain from engaging with those apps. Commercial apps present limited such cognitive tasks, with one exception being the MMGuardian app, which requires entering a password by parents to prevent the child from removing the app or modifying the set time limit of use.

Findings also indicate differences regarding the temporal aspects of obstacles to use. Although commercial apps use these obstacles predominantly after use of the targeted apps (15/39, 38%), as opposed to during use (4/39, 10%), academic apps take a more balanced approach using such obstacles equally during (8/17, 47%) and after the use of targeted apps (8/17, 47%), with 12% (2/17) of the apps using them both during and after use. This suggests not only the value of providing flexibility and users' choice but also the importance of real-time obstacles in limiting phone or app overuse in real time.

Regarding obstacles' source, commercial apps use mostly obstacles set and customized by users (15/39, 38%) rather than obstacles set automatically (6/39, 15%); in contrast, academic apps feature more automatically set obstacles (10/17, 59%) than those set by users (6/17, 35%).

Scholarly work on digital well-being apps has also focused on the types of apps that users are more willing to limit use. In this respect, empirical findings indicate that users were willing to restrict the use of specific apps such as messaging ones [56], as well as social media or games apps [21]. Academic work has also explored limited use not only beyond individual devices such as phones but also across multi-devices and their context of use [46,49]. Similar work has looked, for instance, at chatbots to notify users of their smartphone use [51] or video platforms supporting preschoolers to self-manage their phone and app consumption [52].

The second intervention, intended to increase users' awareness of reaching their limits of phone or app use, also shows differences. Although both sets of apps use mostly explicit notifications to support such awareness, academic apps do so more (8/17, 47%) than commercial apps (11/39, 28%). Interestingly, both sets of apps also used implicit notifications such as screen dimming featuring in the SPACE app and vibrations for notifying users when they exceeded their set time limit for phone use featuring in the Good Vibrations app [34].

The intervention targeting focused attention has been supported by both sets of apps through training for focused attention, with 21% (8/39) of commercial apps and 29% (5/17) of academic apps providing such training. Interestingly, commercial apps also feature white noise as a specific mechanism for supporting focused attention, whose effectiveness as part of digital well-being apps has been less explored, although a body of scholarly work has shown its value for relaxation [17,70].

Finally, the fourth intervention for supporting motivation to keep within set limits shows similar findings for the 2 sets of apps, with emphasis on rewarding user behavior when the goal of keeping within limits has been reached (9/39, 23% commercial apps; 3/17, 18% academic apps), albeit commercial apps show more diverse forms of rewarding content, usually leveraging gamification principles, as opposed to academic apps, which use merely points. In contrast, findings show much fewer apps leveraging punitive feedback when users fail to keep within set use limits for both commercial apps (4/39, 10%) and academic apps (1/17, 6%). In terms of social support, a small number of apps provide it to support cooperation (5/39, 13% commercial apps; 2/17, 12% academic apps), competition, and recognition (5/39, 13% commercial apps; 3/17, 18% academic apps).

Also unique to research on academic apps for digital well-being is the extended focus of their audience to include not only individual users as commercial apps but also groups of users. For example, such academic apps focused on enhancing self-regulation through groups of users collaborating or competing toward limiting their collective use of phones and apps [45,54], through limiting use as a family activity [45], or through providing in-app spaces for college students to restrict their phone use during class time [44].

Discussion

Principal Findings

We now revisit the research questions advanced in the *Introduction* section and articulate the novelty of our key findings. The first 2 research questions focused on identifying the key functionalities of the top-rated digital well-being apps and their theoretical underpinning. Our review of top-rated digital well-being apps indicates the following six main functionalities: tracking use; monitoring use against set limits; and four interventions for limiting use, namely, creating obstacles to limit use, supporting awareness of reaching the set limits, supporting focused attention, and supporting motivation for limiting use. In this section, we also theoretically position these functionalities and leverage them to articulate new implications for better designing digital well-being apps.

Findings indicate that >70% (29/39) of digital well-being apps provide tracking of use of phone or app data, visualized mostly through reports and charts. More than a third (11/29) of the apps providing the tracking functionality also support user profiling, either automatically from tracked data or through users' entered data. This aspect of tracking has been limitedly explored in previous work [22,23]. Another key finding is that almost 30% (11/39, 28%) of the digital well-being apps do not support tracking phone or app use but support instead focused attention or tracking of offline activities. This is a key outcome with important design implications that we will revisit later.

The second functionality is monitoring phone or app use against set time limits, which is key for limiting their use. This functionality features in 64% (25/39) of our reviewed commercial apps. Interestingly, however, the remaining almost 35% (14/39) of the digital well-being apps do not support this functionality directly, albeit they monitor the time spent on offline activities, away from the phone and its apps. From the former set of apps monitoring phone and app use, most tend to target some of the apps installed on the phone, with fewer digital well-being apps monitoring the use limits of all the apps. An important implication here is designing for *complete monitoring* of all the apps installed on the phone and providing users with the choice of selecting the ones to monitor, as well as *location-based monitoring* currently limitedly supported, albeit useful for situating the monitoring behavior in a spatiotemporal context. We also suggest supporting *flexible monitoring* allowing circumventing the set use time limit, which can support ongoing motivation for monitoring phone consumption and regulating phone overuse behavior. Findings also indicate interesting time-based, monitoring-specific visualizations featuring in approximately half (20/39) of our reviewed apps, which are useful to be extended to all digital well-being apps.

With respect to the first intervention, almost half (16/39) of our reviewed commercial apps implement strong and explicit obstacles, such as blocking to limit phone or app use, with much fewer apps featuring weak or implicit obstacles, usually in the form of notification. Even fewer apps attempt to implement microboundary interactions using launchers as substitute home screens. Such obstacles can be generated either automatically or by the users, with only few apps tailing them to user profiles and none mapping the force of obstacles (strong or weak) to such profiles. These approaches suggest the value of using both sources, so that digital well-being apps could benefit from the customization of users' set obstacles and potentially even more so from extending the use of automatically set obstacles. Although previous work suggested that strong obstacles, despite inducing frustration, can be preferred by users and are likely to be more effective than the less restrictive obstacles [22,46], the value of providing both strong and weak obstacles can be further explored, in terms of both effectiveness and user experience for more sustained and long-term change of one's relation with their mobile phones. Our findings from academic apps also highlighted new explicit obstacles for restricting use through design frictions such as cognitive tasks, which, unfortunately, have been limitedly explored. However, these innovative obstacles open up an interesting design space, as frictions support users to pause before compulsively re-engaging with their phones and apps, and thus a more mindful interaction.

From the 25 apps that support monitoring, 13 (52%) support users becoming aware when they reach the set use limits of their phone or apps, mostly through explicit notification and much less through implicit ones such as screen dimming, whereas daily reminders support a high-level awareness of use patterns exceeding set limits. Academic apps also started to explore implicit notification, albeit in tactile modality, through

vibrations. These implicit notifications open up a less explored design space for this intervention. Arguably, vibration-based notifications are weak obstacles, and illustrations of how nudge theory [34] can be leveraged in the design of digital well-being apps. Implicit notifications may be less intrusive and therefore more persuasive, although future work is needed to explore their specific benefits when compared with explicit ones.

An important outcome is the 2 ways of supported focused attention that digital well-being apps implement: The first is implicit support through the monitoring and limiting of phone or app overuse, and the second is the explicit training of attention by focusing on offline activities without phone use, including also exposure to white noise to support concentration, which has strong research underpinning [17,70].

A key functionality, less explored in previous research on digital well-being, is supporting motivation for keeping within limited use. For this functionality, we identified the following three mechanisms: reward and penalty leveraging gamification principles, educational and motivational content, and social support provided, however, by a limited number of apps and where cooperation among users is limited.

The theoretical underpinning of digital well-being apps has received limited attention. However, Roffarello and De Russis [22] suggested the value of grounding the design of well-being apps to support behavior change, habit formation, and self-regulation. As shown in the *Introduction* section, scholars have identified a range of theories that may inform the design of digital well-being apps, such as those of uses and gratification [19,31], planned behavior [32], dual system [33], nudge [34], framework for behavior change [35], or regulation [36]. However, it is less explored how such theories have been actually informing the developing of commercial well-being apps. However, the operationalization of these theories in this respect has been limited. In this section, we argue for the value of self-regulation theories.

Previous work has shown that tracking is a key functionality of digital well-being apps that captures the use of the phone and its apps [22]. However, this does not make the important distinction between the digital well-being app running in the background to collect such information and the user's active effort to minimize phone use. The former is usually important in the early stage of digital detox when people want to understand their consumption patterns, whereas the latter follows with setting up limits to phone or app use. For this, we called the former tracking, and the latter monitoring, which is a better term for capturing or tracking data against a specific target. Most behavior-changing apps use monitoring toward specific goals such as exercising ones [41]; therefore, the link between monitoring and goal setting is crucial. We note the important alignment of monitoring functionality to the three ingredients of self-regulation as reflected in self-regulation theories: setting target standards, monitoring the current state against these targets, and activating processes to reduce any identified distance between the current state and the targets [59]. Thus, we argue that designing for monitoring functionality can benefit from theoretical grounding in self-regulation theories.

Regarding the intervention of creating obstacles to limit use, we have seen the value of both strong restrictive mechanisms and weak ones, mostly explored in academic research rather than reflected in commercial apps. We argue that weak and particularly implicit obstacles are illustrations of nudges, which nudge theory describes as persuasive attempts for behavior change that do not limit users' choices [73,74]. Future work is needed to understand how nudge theory can be sensitively leveraged to rigorously inform such obstacles to use.

The intervention for supporting focused attention is particularly interesting, as it marks a shift away from limiting excessive use toward more mindful activities, either technologically mediated or offline, whose valuable side effect is limited use of the phone or apps. Rather than steering away from undesirable behavior, this intervention encourages engagement in meaningful and ideally desirable activities, subsequently supporting the most powerful appetitive rather than aversive motivation. We also highlight in this context the value of supporting users to understand and support their meaningful goals [66], which subsequently can address the phone overuse and the boredom often associated with it. However, goal theories have been limitedly discussed in relation to digital well-being apps.

The final intervention focuses on supporting motivation to keep within use limits. Although limitedly mentioned in relation to digital well-being apps, we suggest the value of broaden and build theory [75], where positive emotions are leveraged for increased self-awareness and behavior change. Illustrations of how this theory may be underpinning some of the identified functionalities include the provision of allowances for overruling the set use limits during monitoring. This is important for instrumental reasons both allowing the completion of some immediate tasks, and maintaining motivation in case of setbacks in meeting the set limits. In turn, this could broaden users' resilience and more flexibly support the acknowledged high demands of self-regulation [36]. Future work is needed to explore effective ways for managing the negative emotions associated with setbacks.

Design Implications for Digital Well-being Apps

Overview

The third research question focused on the design guidelines for digital well-being apps informed by our identified functionalities. For this, we articulate 6 implications for designing digital well-being apps including calling to move beyond screen time and support the broader focus of digital well-being; supporting meaningful use rather than limiting meaningless use; leveraging (digital) navigation in design for friction; supporting collaborative interaction phone overuse; supporting explicit, time-based visualizations for monitoring functionality; and supporting the ethical design of digital well-being apps. These implications open up a larger design space for digital well-being apps, going beyond the main tracking and monitoring functionalities [19,34,57].

Beyond Screen Time: Broader Focus of Digital Well-being

Although most of these functionalities focus on limiting screen time, echoing previous findings on addiction and phone overuse

[22], an important outcome is that about a third (13/39) of our apps support focus of attention either by limiting distractions or by supporting focused attention often on offline activities, including training of attention. We argue that this bias toward screen time fails to reflect the larger body of HCI research on well-being that can inspire novel apps that may better support users' skills for more mindful use of technologies. We call for stronger engagement of HCI research in the design of digital well-being apps that addresses this limitation. Indeed, our findings could mark a shift away from addressing a problematic behavior by explicitly limiting it but rather by supporting a high-level function that can arguably better address the root of the problematic behavior. There is an extensive body of work on mitigating the impact of interruptions [62,63] and a growing interest in mindfulness technologies [39,40,64,76] that can support the design of these apps for digital well-being aiming to support focus of attention.

Supporting Meaningful Use Versus Limiting Meaningless Use

Findings also indicate an important limitation of digital well-being apps reviewed in this work and in particular their rather narrow view of limiting use. We argue that this overlooks the broader goals for using technology in the first place and users' different avoidance or approach motivations. For this, we can leverage goal theories and the distinction between hedonic and eudemonic or meaningful goals [66] and how the latter can be purposefully designed for. Emphasizing the meaningful use of technology [11] may be a better approach to avoid meaningless or habitual use leading to phone overuse, while accounting also for the scarcity of attention [77].

Leveraging (Digital) Navigation in Design for Friction

Findings highlight obstacles for preventing app use that can inform the design for friction [78] as a mechanism for slowing down interaction (such as information sessions at the start of using a mediation app), which we know little about. Our findings suggest harnessing the digital distance and navigation to the target app. This is supported by findings showing that navigation in the folder hierarchy and in the real world share the same neural correlates [61]. One can imagine that information architecture imposing additional digital navigation cost for reaching apps located deeper in the phone's information hierarchy, whose use is to be limited, may mitigate against their overuse. We can also think of leveraging physical navigation, for instance, by allowing access to some apps only in physical locations that the user has to purposefully travel to, supporting thus fitness goals. Kim et al [31] positioned their app and this family of restrictive and coercive interventions within the HCI work on uncomfortable interactions aimed at helping people toward important goals while tolerating discomfort [60] and on design frictions through microboundaries consisting of small barriers enforced before an interaction to prevent habitual phone use [57].

Supporting Collaborative Interaction for Limiting Phone and App Overuse

Much work has shown the value of social support for behavior change, and our findings confirm that this is also an important intervention for digital well-being apps. Our outcomes echo previous ones showing the benefit of social support for limiting smartphone use, albeit by leveraging competition. We argue that the value of cooperation can be better harnessed in the design of digital well-being apps, both for limiting overuse and for training focus of attention. Our findings indicate that only 16% (9/56) of the apps in our app review implement social support as a built-in feature. This supports the argument presented in a study by Czerwinski et al [62] that social support is a feature needed in digital well-being apps, as current apps do not seem to leverage social support as a mechanism to enhance self-regulation.

Supporting Time-Based, Explicit Visualizations Tailored to Monitoring Functionality

In terms of data visualization, findings indicate a richer range of formats available for the monitoring of phone or app use against set limits compared with their mere tracking. This makes sense because tracking aims primarily to support users' exploration and understanding, whereas monitoring aims mostly to support behavior change toward set goals [79,80]. Hence, although more ambiguous representations are useful to motivate and engage users during tracking, for the monitoring functionality, more specific formats and particularly those including timelines are more useful. However, we have seen that academic apps leverage timeline representations, whereas commercial apps do so to a lesser extent. The latter allow people to easily match on the timeline their behavior with the recorded data to not only understand the data but also use it for reaching the goals. These outcomes align with previous work on the value of the ambiguity of different types of captured data [4] to support users' engagement in understanding it, particularly relevant in the tracking stage. In contrast, although the rationale of timeline visualizations has been limitedly unpacked in scholarly work, it can be grounded in the growing HCI interest in temporality [24] and its value for reflection, both in and on action [81]. Future work can compare the value of different visualization forms for supporting such reflection on data.

Supporting Ethical Design of Digital Well-being Apps

Despite their potential for supporting users with their phone overuse, most digital well-being apps have limited scientific underpinning and evidence base. They tend to target users without health conditions and tend to be inclusive, as many of their functionalities appear to be free. However, we call for extending the efforts toward a more research-informed and evidence-based design of digital well-being apps. This is particularly important because their beneficence can be limited by the risk of harming users with mental health conditions, as well as those who experience phone addiction. Such recommendation can be addressed to app market places or policy makers for regulating the requirements for their research underpinning. The most ethical challenge pertaining to these apps is supporting autonomy of users experiencing smartphone addiction [67]. However, given the challenges of diagnosing phone addiction, increased ethical sensitivity is required in this respect. In addition, more work is needed to explore how the shift toward increased autonomy can be best supported and by what features of digital well-being apps.

Limitations and Future Work

We focused on Google Play, which limited our review of iOS apps not available on Google Play. Future work could extend this exploration to other platforms. Future work can also aim to further strengthen the scientific underpinning of the design principles of digital well-being apps, in terms of both their theoretical framing and evidence-based evaluation studies. Our findings indicate that despite the growing number of digital well-being apps, parts of their design space have been less explored, such as supporting awareness for reaching use limits, motivation to keep within set use limits, implicit obstacles rather than explicit ones, recommended interventions to determine the right type of obstacles according to the tracked data, and mechanisms for supporting focused attention. We encourage researchers and developers to focus on these aspects, and together with the key features identified in our study, they can significantly improve the design of digital well-being apps.

Conclusions

We report on a functionality review of 39 commercial and 17 academic digital well-being apps. Findings provide richer understanding of tracking and particularly monitoring functionalities, together with 4 interventions for limiting use. These provide new understanding of the different types of obstacles for limiting use, as well as of specific features for less explored functionalities such as supporting awareness for reaching use limits, focused attention, and motivation to keep within set use limits. We conclude with 6 design implications for digital well-being apps, namely, calling to move beyond screen time and support the broader focus of digital well-being; supporting meaningful use rather than limiting meaningless use; leveraging (digital) navigation in design for friction; supporting collaborative interaction to limit phone overuse; supporting explicit, time-based visualizations for monitoring functionality; and supporting ethical design of digital well-being apps.

Abstract

Background: Despite progress toward the Joint United Nations Programme on HIV/AIDS “95-95-95” targets (95% of HIV-positive persons tested, 95% of tested persons on treatment, and 95% of treated persons virally suppressed), a gap remains in achieving the first 95% target. Assisted contact tracing (ACT), in which health workers support HIV-positive index clients to recruit their contacts (sexual partners and children) for HIV testing, efficiently identifies HIV-positive persons in need of treatment. Although many countries, including Malawi, began implementing ACT, testing outcomes in routine settings have been worse than those in trial settings.

Objective: The aim of this paper is to use formative research and frameworks to develop and digitize an implementation package to bridge the gap between ACT research and practice.

Methods: Semistructured qualitative research was conducted in 2019 in Malawi with key informants. Barriers and facilitators to intervention delivery were identified using the Consolidated Framework for Implementation Research. Approaches to digitization were examined using human-centered design principles.

Results: Limited clinic coordination and health worker capacity to address the complexities of ACT were identified as barriers. Ongoing individual training consisting of learning, observing, practicing, and receiving feedback, as well as group problem-solving were identified as facilitators. Important features of digitization included (1) culturally relevant visual content, (2) capability of offline use, and (3) simple designs and basic editing to keep costs low.

Conclusions: Formative research and frameworks played a key role in designing and digitizing an implementation package for ACT delivery in a low-income setting such as Malawi.

Introduction

In 2014, the Joint United Nations Programme on HIV/AIDS set ambitious "95-95-95" global targets for 2030 [1]. These targets aim to have 95% of persons living with HIV aware of their HIV status, 95% of persons living with HIV on treatment, and 95% of treated persons virally suppressed. Although 81% of persons living with HIV in sub-Saharan Africa (SSA) are now aware of their HIV status, 4.89 million remain undiagnosed, and half a million HIV-exposed infants do not receive timely early infant diagnosis each year [2-5]. Furthermore, a large share of HIV-negative adults remains unaware of being in a relationship with a person living with HIV and are therefore less likely to use effective HIV-prevention strategies [6]. Index-based approaches, in which health workers support persons living with HIV "index clients" to recruit their "contacts" (sexual partners and children) for HIV testing, efficiently identify other persons living with HIV in need of HIV treatment and HIV-negative persons in need of HIV prevention [7]. Index-based approaches build on a fundamental tenet of infectious disease epidemiology: each HIV-positive index has one HIV-positive contact who transmitted HIV to them and other potential contacts who could acquire HIV from them. Index-based approaches have higher diagnostic yields than any other testing approach [7] and hold great promise for achieving the global target of 95% of persons living with HIV tested for HIV [8]. Nonetheless, index-based approaches have not been an integral part of HIV epidemic control in SSA until recently [9].

In 2016, the World Health Organization (WHO) revised its recommendations surrounding index testing from "passive" approaches, in which indexes recruit their own contacts, to voluntary "assisted" approaches, in which health workers support indexes with contact recruitment [10]. These assisted approaches are referred to as "assisted partner notification," when focused on sexual partners, or "assisted contact tracing (ACT)," when biological children and other household contacts are included. The WHO guidelines provide a "strong recommendation" that assisted contact tracing "should be offered as part of a comprehensive package of testing and care to people living with HIV" [10]. In the years since the WHO guidelines were issued, the President's Emergency Plan for AIDS Relief (PEPFAR) has promoted index-based approaches that include ACT options [11]. Dozens of countries, including Malawi, have adopted ACT policies and intensified ACT implementation [11,12]. However, real-world ACT testing outcomes have been inferior to those observed in ACT trials [12]. Implementation strategies, guided by theory and formative research, may support translation of ACT outcomes observed from trials into real-world settings.

In this paper, we seek to describe the process of developing an ACT implementation package. We explain the two phases that led its development, which are (1) design and (2) digitization. As qualitative formative research, we did not set out to test hypotheses, but rather to generate them.

Methods

Setting

This work was conducted in Malawi, a country in Southeastern Africa with 19 million people. Malawi has a 10.6% adult HIV prevalence and 1.1 million people living with HIV [13]. Malawi has a mature HIV program that is approaching the 95-95-95 targets [13]. Malawi has long had a passive index-based program, with the Department of HIV/AIDS promoting routine distribution of "family referral slips." In early 2018, through a PEPFAR-led demonstration project, implementing partners began introducing ACT in dozens of facilities, and in early 2019, voluntary assisted partner notification, Malawi's ACT approach, was adopted as part of Malawi's national HIV testing policy.

Malawi has a dire human resource shortage with less than 2 physicians, 0.02 psychiatrists, and 0.01 psychologists per 100,000 people, some of the lowest global rates [14,15]. To address its formidable HIV burden with limited human resources, Malawi has task shifted many HIV-related activities, especially counseling tasks, to lay cadres. In 2015, to respond to gaps in HIV testing, Malawi introduced a cadre of HIV diagnostic assistants to improve coverage of early infant diagnosis, viral load testing, and rapid HIV antibody testing [16]. HIV diagnostic assistants are lay persons with secondary education and 4 weeks of preservice training. In its first year, nearly 1200 HIV diagnostic assistants were deployed to 450 facilities, resulting in improved diagnostic indicators [16]. Community health workers hired by local nongovernmental organizations are another lay cadre responsible for a range of HIV-related tasks, including community tracing. HIV diagnostic assistants and community health workers conduct most ACT implementation [17]. HIV diagnostic assistants typically diagnose HIV-positive indexes and support contact elicitation and selection of ACT options, and community health workers typically conduct tracing.

Throughout Malawi's national program, nongovernmental organizations implementing partners play a critical role in hiring and supervising these lay cadres. Tingathe Program, one of the largest PEPFAR-implementing partners in Malawi, and the implementation lead on this research, was initiated by Baylor College of Medicine Children's Foundation-Malawi in partnership with the Malawi Ministry of Health. Tingathe takes a family-focused approach to the HIV epidemic by supporting the provision of high-quality, comprehensive HIV services. Tingathe has over 10 years of experience implementing HIV testing, care, and treatment programs in Malawi and currently provides support to Malawi's HIV care and treatment program with more than 1000 staff in 95 Malawi Ministry of Health facilities.

Research Procedures

As Malawi's National HIV testing program evolved from a client-led passive referral model to a provider-supported ACT model, we sought to understand the barriers and facilitators to ACT implementation. This process was guided by the Consolidated Framework for Implementation Research (CFIR) [18]. The CFIR is a determinants framework comprised of five

domains (intervention characteristics, individual characteristics, outer and inner organizational settings, and processes) and 39 constructs within these domains that interact with one another [18].

We were also interested in digitizing some or all of these implementation strategies. To facilitate meaningful and sustainable digital programs, technological, human, and cost features must be taken into consideration. We used human-centered design thinking to inform potential adaptations of our implementation strategies into a digital platform. Human-centered design thinking is an approach that integrates the possibilities of (1) technology, (2) the preferences of people, and (3) the requirements for business viability [19] in the process of product develpoment.

In October 2019, we conducted a series of in-person focus group discussions, each 2 hours long, on (1) barriers and facilitators to ACT implementation and (2) the potential role of digital modalities to enhance the program. Tingathe staff were considered key informants and were purposively selected if they held ACT training as well as supervisory and clinical mentorship roles within the organization (N=10). Thus, they had routine contact with hundreds of ACT implementers at dozens of facilities. We also conducted one 2-hour-long, semistructured in-depth interview with a key informant who was not available for the focus group discussions.

All participants provided informed consent to participate. The discussion was facilitated using a semistructured guide. Data were audiorecorded, summarized, and transcribed. Data were reduced into themes organized within the constructs of the CFIR and human-centered design.

Ethics Approval

The study was reviewed and approved by the National Health Science Research Committee (20/01/2467), the local ethics committee in Malawi, and the Baylor College of Medicine Institutional Review Board (H-47655). Informed consent was obtained from all participants.

Results

Population Characteristics

Of the 11 key informants, 3 (27%) were district-level supervisors, 4 (36%) were facility-level supervisors, 2 (18%) were health care workers who provided ACT services, and 2 (18%) were data collection supervisors; 5 (45%) were female, and 6 (55%) were male. All were employed by Tingathe program.

Themes Surrounding Implementation Package Design

Themes arose within the five following domains of CFIR, which guided our implementation package development process: (1) intervention characteristics, (2) individual characteristics, (3) outer organizational settings, (4) inner organizational settings, and (5) processes.

With respect to intervention characteristics, complexity of ACT implementation was identified as a formidable barrier. Complexities included sensitivities around discussing sexual behavior with indexes, multiple potential contacts for each index, multiple tracing options for each contact, challenges with obtaining correct locator information for sexual contacts, and concerns around index safety.

This level of complexity, along with the minimal preservice training of lay health workers delivering ACT [16], exposed a set of individual characteristics, which were low competence around basic training principles and poor self-efficacy among both health workers and supervisors. For example, Tingathe staff reported that health workers frequently were uncomfortable taking sexual histories, did not understand which partners needed to be tested, and did not know how to help indexes decide which tracing methods to select. Supervisors suggested that modeling these counseling behaviors would enhance skills.

In the outer setting**,** diverse patient needs of both indexes and contacts were not being met, as counseling was conducted generically in a non–client-centered manner and without sensitivity to potential stigma and intimate partner violence or abandonment.

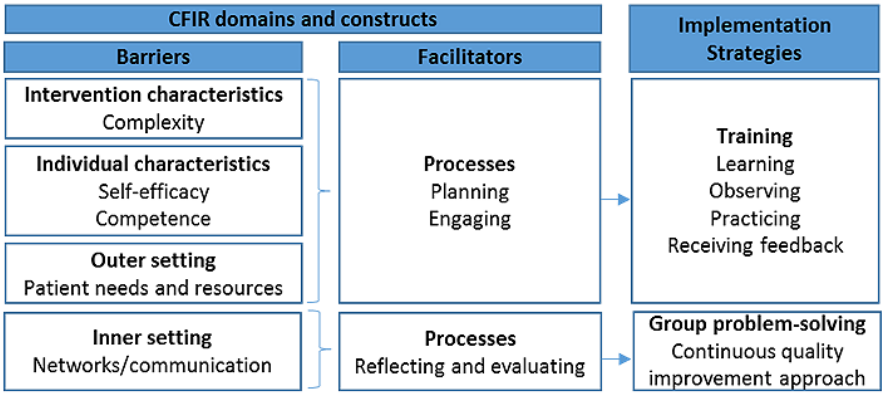
Networks and communication were identified as challenges in the inner setting: health workers in many sections of a single health facility (eg, antenatal care, pediatrics, and antiretroviral therapy) interacted with potential indexes and contacts, but responsibilities were not clearly delineated, and coordination between health workers was minimal.

To address these challenges, several processes were proposed: training that consisted of engaging strategies (role modeling) and planning strategies (practice and feedback) to address perceived intervention complexity, low health worker competence and self-efficacy, as well as patient needs. To address network and communication challenges, group problem-solving approaches that incorporated reflection and evaluation were suggested.

Resulting Implementation Strategies

Synthesizing these findings, we arrived at two sets of implementation strategies, which are as follows: (1) enhanced health worker training to improve ACT counseling sensitivity and competence; and (2) group problem-solving to facilitate ACT coordination (Figure 1). This set of strategies aligns with a seminal review showing the combination of training and group problem-solving to frequently improve health worker practices in low- and middle-income countries (LMIC) [20]. Our specific training and problem-solving approaches were guided by theory and evidence, which will be explained here in detail.

Figure 1. Application of Consolidated Framework for Implementation Research (CFIR).



Training

Training is the most common implementation strategy in LMICs; however, it is often conducted with suboptimal pedagogical practices and without any ongoing reinforcement [20]. We developed a training guided by the theory of expertise [21], an educational theory that considers deliberate practice and a core set of activities (learning, observing, practicing, and receiving feedback) as important for mastery of new skills [22,23]. Applying this theory to ACT, we developed a set of training activities consisting of the following: (1) explaining ACT counseling skills (learning); (2) modeling ACT counseling skills through vignettes (observing); (3) practicing counseling skills through role plays (practice); and (4) providing suggestions on improvement (feedback). This approach is supported by social cognitive theory, which posits that learning occurs in a social context with reciprocal interactions between the person, environment, and behavior [24]. Observation of modeled ACT vignettes facilitates social learning; practice solidifies behavioral skills and enhances self-efficacy; and feedback refines and reinforces behavioral skills. These activities have enhanced counseling skills across a range of behavioral interventions, including those related to HIV treatment, prevention, and psychosocial support [25-29].

Group Problem-solving

Group problem-solving draws on concepts from continuous quality improvement, which is a set of formal and systematic processes to identify and address health systems challenges [30,31]. The purpose is to identify challenges with ACT implementation and coordination, evaluate potential solutions, provide actionable recommendations, and revisit progress through a series of meetings. Similar processes have led to improvements in a range of implementation outcomes in several SSA contexts, including with lay cadres [32-37].

These sets of implementation strategies were combined into an "implementation package" with face-to-face health worker training and group problem-solving. In a previously published work, Tingathe delivered this package to nearly 500 health workers in 36 facilities in Mangochi, Malawi, and observed improvements in a range of ACT indicators: the number of sexual contacts elicited, the number tested, and the number newly identified as HIV-positive [17]. This work demonstrated the value of theory-driven training and problem-solving for improving ACT outcomes.

Themes Surrounding Implementation Package Digitization

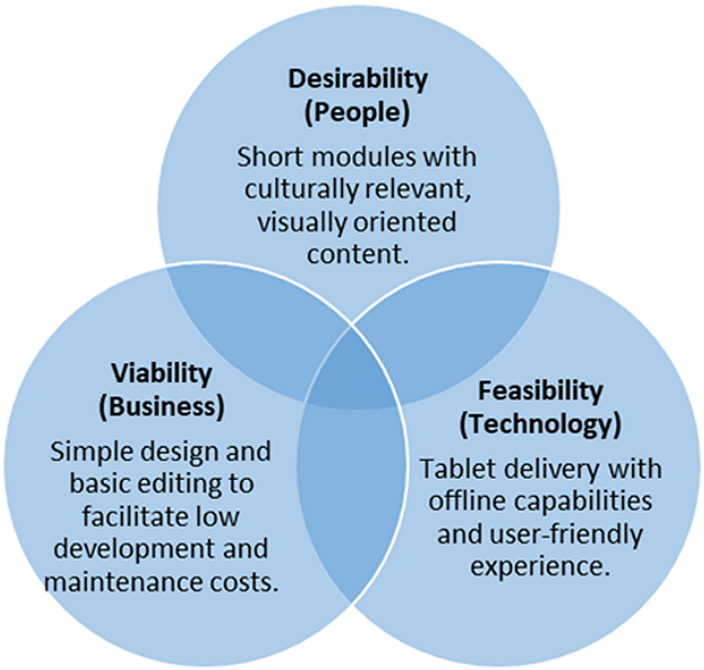
Themes were also categorized within human-centered design thinking domains, which guided the adaptation of these implementation strategies into a blended learning delivery platform (Figure 2). The results were organized around considerations of (1) technology, (2) desirability, and (3) the requirements for business viability [19].

Applied to rural Malawian health facilities, important technological challenges were discussed, including limited internet connectivity, limited computer literacy, and nonuniversal personal mobile devices, a theme observed in comparable studies in the region [38,39]. These considerations led us to deliberate on content that does not require continuous internet connectivity. They also suggested the importance of user-friendly applications, as has been observed in similar settings [40].

To address desirability for Malawian health workers, participants proposed content that was primarily audio- and video-based to ensure limited reading for this low literacy audience. Studies in similar low-resource environments also proposed similar multimedia elements to address challenges with computer literacy [41]. Participants suggested content be created with Malawian cultural and linguistic considerations in mind. Smaller segments were proposed to enable learning to occur in brief increments when workload permits.

With respect to business aspects, we selected tablets, which are less costly than laptops. We opted for simple visuals and basic editing to limit the budget. For digital learning packages to be cost-effective, it is important to minimize up front development costs, maximize the number of users, or, preferably, do both simultaneously.

Figure 2. Human-centered design framework.



Theme Synthesis: Final Implementation Package

We synthesized findings from the formative work to digitize the package. Based on the WHO's recommendation that digital modalities for training health workers in LMICs complement, rather than replace, face-to-face learning, we opted for a blended learning approach [42,43]. "Blended learning" combines the best features of digital learning (ie, quality, consistency, and convenience) with the best features of face-to-face learning (ie, interactivity and group engagement) [44,45]. Blended learning is typically more effective than either electronic or face-to-face learning alone for acquiring new knowledge and skills [25,46], and specifically for improving health worker counseling and communication [47-49].

The resulting blended learning implementation package translated our training plus group problem-solving approaches for the possibility of decentralized delivery. We included both individual asynchronous learning sessions and synchronous interactive small-group sessions. The individual learning sessions contain descriptions of ACT skills, video vignettes modeling these skills, and embedded questions assessing comprehension. The small-group learning session contains tablet-guided practice role plays, individual feedback, and facilitated group discussions. It was designed for facility-level conduct guided by ACT data. We developed a model where all health workers involved in ACT would meet to examine their facility's performance, identify gaps in performance, and propose actionable solutions. Each meeting would review progress toward proposed solutions, as well as their impact on ACT indicators.

Discussion

In this research trajectory, we used formative research, theory, and frameworks to guide the development of a novel implementation package. First, the consolidated framework for implementation research identified key barriers and facilitators to intervention delivery. Next, the theory of expertise, social cognitive theory, and principles of continuous quality improvement informed the development of an implementation package to address these barriers and facilitators. Finally, human-centered design principles guided the translation of the implementation package from in-person to digital delivery.

The facilitators we identified using the CFIR closely mirrored findings from successful ACT programs in SSA [50]. In 2017-2018, contacts form Kenya and Mozambique accounted for 51% of the 1.7 million contacts tested across 18 SSA PEPFAR countries, even though these countries only accounted for 14% of the population [12]. Similarly, several Cameroonian districts scaled and sustained ACT before the WHO guidelines were published [51]. In an analysis of ACT implementation in these three countries, the intensive ongoing nature of health worker capacity-building was essential [50]. Although the implementation contexts differed, the capacity-building processes were similar. Initial face-to-face trainings imparted ACT counseling skills through skill-based learning and practice role-plays. Ongoing on-the-job mentorship and refresher trainings reinforced and enhanced these skills, consistent with capacity-building best practices in the region [52,53].

Our contributions to ACT implementation science are novel, timely, and noteworthy. In the few years since the WHO issued its guidelines surrounding ACT, there has been widespread ACT implementation in SSA [11,12] and numerous descriptions of barriers, facilitators, and corresponding ACT indicators [50,51,54]. However, the role of theory and frameworks has been limited. Our research trajectory shows the key role that such approaches can play in the design of implementation strategies.

The final blended learning product was pilot tested with promising preliminary results regarding health worker fidelity and preliminary ACT effectiveness [55]. Our next step is to evaluate these ACT implementation strategies in a pragmatic cluster randomized trial to examine both implementation and effectiveness outcomes in a range of clinical settings. This design strength will allow for clear inferences about the impact of the blended learning ACT package on health worker behaviors, clinical indicators, and patient outcomes. This study will also contribute more broadly to the field of HIV implementation science, as only 14% of HIV studies involve implementation research and only 6% are cluster randomized [56].

Our work also represents an important innovation in health worker capacity-building in LMIC settings. A large-scale review of health worker practices in LMIC settings identified the combination of (1) health worker training and (2) group problem-solving as one of the few sets of strategies that routinely improves health worker practices across a range of countries and health conditions [20]. However, this promising combination of strategies has not been translated to a blended learning delivery modality and rigorously evaluated for patient outcomes in LMIC setting. Our research makes this innovative contribution.

Finally, to our knowledge, our planned research trajectory will be the first complete, rigorous evaluation of a blended learning package in a LMIC setting. Although there has been a proliferation of digital and blended learning tools for LMICs over the last decade, most evaluations have focused on proximal outcomes, such as adoption, health worker knowledge, and skills [46]. The WHO has highlighted the critical need for research assessing the impact of blended learning on health worker practices, patient outcomes, and cost-effectiveness in LMIC settings [43]. Our next step is to directly address this set of research questions in a cluster randomized controlled trial. If effective, this implementation strategy will provide an evidence-based solution for adaptation in settings with different characteristics and disease profiles. This research trajectory also represents an important contribution to digital and blended learning.

In recent years, digital learning has proliferated in the health sector, including in LMIC contexts, due to many enticing features, such as the following: (1) learning is not time- or place-dependent; (2) learning does not require an on-site instructor; (3) pace and degree of difficulty can be tailored to the learner; (4) progress and aptitude can be easily monitored; (5) high quality content can be delivered consistently; and (6) infrastructure needs are minimal [44-46]. For in-service training in LMIC contexts, these features are appealing. Digital learning can be delivered at the health facility, eliminating travel and lodging expenses associated with centralized face-to-face trainings. Individual sessions can be delivered asynchronously so all staff are not absent from the clinic simultaneously, minimizing understaffing. New staff can acquire necessary skills right away, rather than waiting for a scheduled training. Health workers can receive high quality instruction without relying on an on-site trainer. Finally, they can potentially be more easily adapted to new settings. Together, these features made digitizing our strategies enticing. Of note, this work was conceptualized in 2019, prior to the SARS-CoV-2 pandemic, but such digital approaches are also appealing for promoting physical distancing and minimizing SARS-CoV-2 exposures [57,58].

Our research has several important limitations. First, this formative study was small. Second, we focused on Tingathe staff (the target population for these implementation strategies), and not on other stakeholders, such as indexes, their contacts, and policy makers. Finally, it was conducted in a single country, and may not be generalizable to others, though these processes can be replicated elsewhere. Adaptation to new settings is an important potential future direction.

In conclusion, our research trajectory illustrates that theories, frameworks, and formative research can play an important role in designing and digitizing implementation strategies. The resulting implementation package provides a promising approach for enhancing ACT and ultimately achieving the 95-95-95 targets in Malawi and beyond.

Abstract

Background: Many parents frequently struggle with undesirable or problematic behavior (ie, temper tantrums and whining) displayed by their child. To support parents in promoting positive parenting skills (ie, recognizing challenging situations and reacting appropriately), the interactive video e-learning tool *ParentCoach* was developed. The tool aims to teach parents generic behavioral responses by means of situational learning, tailoring, and problem solving. The first demonstration focused on sleeping problems.

Objective: The aim of this paper is to illustrate the user-centered development of ParentCoach.

Methods: We conducted usability, understandability, and acceptance tests among the target group (29 parents, 7 youth health care professionals, and 4 individuals with former lower health literacy) in different phases of the development process via focus groups, interviews, and surveys. This allowed for relevant insights on specifications and user requirements to guide the development and revision of the tool in each iteration.

Results: Iterative testing and development allowed for the final demonstration of ParentCoach to be experienced as a relevant and accessible parenting intervention that can be used as a stand-alone program or in combination with another program.

Conclusions: This paper elaborates on the iterative development process and its benefits for the final demonstration of ParentCoach.

positive parenting; usability testing; lower health literacy; user-centered design; iterative development; eHealth; web-based intervention; mobile health; mHealth; parenting

Introduction

Background

Research has shown that 36% of parents with children living at home report concern regarding the upbringing of their children. Among this group, 60% look for help and advice outside their family, friends, and social environment [1]. In addition, an evaluation among users of the parental information platform GroeidGids (Growth Guide) in the Netherlands, a platform with >100,000 users yearly, showed that parents often have questions regarding diet, sleep, health, and parenting [2]. Hence, there is a substantial group of parents who do not know how to deal with common problems in their children, such as anxiety, stubbornness, disobedience, or temper tantrums, which may emerge in a certain developmental stage of the child [3]. It is important to provide early parenting education, advice, and support based on scientific knowledge about healthy and adaptive parenting. Effective parenting may prevent aggravation of relatively small and manageable problems, which could

otherwise result in more severe behavioral problems [4]. This might especially be true for vulnerable families (ie, lower-educated, lower-income, or migrant families) as these groups are more likely to experience problems that can negatively influence their parenting style (eg, less consistent or supportive parenting) [5].

The upbringing of children may affect various aspects early on, including social skills, brain development, self-control, emotional regulation, mental and physical health, and resilience [6]. According to Sandler [6], "effective parenting" consists of adequate discipline practices, advice, and guidance and a positive affective relationship between the parent and the child as well as instances to improve children's skills to adjust to environmental demands. A systematic meta-analysis by Kaminski et al [7] revealed several parenting strategies to be especially effective, such as consistently responding to one's child and using "time out" as a disciplinary strategy, with active acquisition of parenting skills revealing significantly large effects. In addition, improving parenting practices has been shown to benefit the well-being and overall development of both parents and children [8].

In the Netherlands, there are a number of effective parenting interventions available, but most focus on secondary or tertiary prevention; that is, the promotion of parenting skills for parents at high risk who already experience serious problems [9]. Moreover, most of these interventions are time-consuming; they consist of multiple individual or group meetings. This creates logistical difficulties for parents, such as inconvenience regarding location, transport challenges, limited flexibility in work schedules, and lack of childcare [10]. In addition, parents perceive stigma or concerns about confidentiality, which affects their willingness to participate in these interventions [10]. These interventions may also result in low program recruitment and retention as they require significant training- and supervision-related time and costs [11,12]. This poses a significant burden on participants and professionals, which potentially undermines their reach and impact [12]. The number of effective primary preventive parenting interventions is sparse [13]. There is a clear need for more easily accessible and effective primary preventive interventions that go beyond information provision [12,14].

Technology-assisted primary preventive parenting programs may be effective in overcoming some of the barriers of parenting programs. In a recent meta-analysis, the effectiveness of technology-assisted parenting interventions was examined, assessing the effects of 9 different programs among disadvantaged families [10], including programs such as Triple P Online [15], Parent-Child Interactions-Cellular [16], and Infant-Net [17]. This meta-analysis showed that such interventions can be effective in supporting positive parenting behavior and have a positive impact on parental well-being and child behavior. However, this study revealed considerable variation between programs. The difference between programs seemed related to programs that focused solely on information and demonstration of parenting principles and programs that also provided tailored feedback and advice (generally via phone or email). Programs without tailored advice and feedback proved far less effective than programs with tailored advice and feedback.

In this study, we describe the development of *ParentCoach*, a low-demand program that can be used depending on the experienced need of parents and to overcome potential taboos or reluctance to take part in parenting programs. Importantly, ParentCoach addresses some of the omissions of previous technology-assisted programs by not only providing information and demonstration of parenting practices but also providing a web-based environment to practice with common difficult parenting situations, in which parents receive personalized feedback and advice. Hence, we aim to make use of the advantages of technological possibilities and ensure tailored advice, which has been shown to improve the effectiveness of previous parenting programs, with the ultimate goal of enabling parents to practice adequate parenting skills to prevent more generally experienced parenting problems.

ParentCoach

ParentCoach is a web-based, tailored, interactive video e-learning tool [18]. A demonstration version of ParentCoach was developed to promote positive parenting skills with regard to children's healthy sleeping behaviors. This demonstration version provides a practice context with exercises and advice content, including tips and an explanation of how to apply the evidence-based principles. As sleep is a common concern for parents, ParentCoach was first developed with sleep in mind. The practice content addresses different aspects of getting children to bed by means of situated learning (ie, what to do when your child does not want to go to bed) and repeated rehearsal of (coping) skills (ie, how to cope with temper tantrums). Tips and resolutions are delivered through an animated female character as a relational agent.

ParentCoach consists of three scenarios in which parents can practice their parenting skills regarding the sleeping behaviors of their child (ie, *it's bedtime*, *putting on the pajama*, and *going to bed*). These scenarios depict a common situation that parents may experience to be difficult (ie, the child does not want to put on her pajama). Following short sequences in which a short dialogue between parent and child is shown, parents can choose between 2 options on how to react. In response to their choice, a relational agent provides instant feedback and reinforcement and offers further explanation of why a certain choice was (less) adequate. In each scenario, the child may act in different ways (ie, obedient, refusing, whining, or angry). Although the situation may be the same, as the child reacts differently, parents are expected to adapt their response (ie, reinforcing positive behavior or adequately responding to negative behavior). Thus, 12 practice situations can be completed. An overview of the scenarios can be found in the *Results* section. In these scenarios, parents can practice or are advised on how to deal with negative child behavior. In addition, they can receive advice on reinforcing positive child behavior. Therefore, parents can choose to receive a total of 6 tips regarding positive and negative behavior (eg, *reward your child*, *teach your child new things*, or *temper tantrums* and *refusal*). Upon opening the link, parents can decide whether to watch a short introduction or another segment. The intervention can be performed in one's own time

and repeated as many times as necessary as there are no time-bound restrictions. ParentCoach does not provide any additional human support as users interact with the animated web-based coach who provides tips and reacts to the users' choices on a 24/7 basis. Thus, the tool can be seen as an extension of other parenting programs.

ParentCoach was iteratively developed based on user-centered design principles, which means that the end user was closely involved in the developmental process to fine-tune the intervention as much as possible to their needs and preferences. Such a user-centered design approach is important as it enhances usability and user engagement and, hence, increases the likelihood of an intervention being effective and feasible [19,20]. Its multiple iterative cycles of concept generation, prototype design, and evaluation reveal important needs and preferences of the target group and result in enhanced usability and acceptability of the design by the end users [19,21]. Furthermore, early-stage prototype testing in terms of usability prevents the aggravation of use-related issues in later stages of the developmental process [19]. On the basis of early user acceptance testing, certain features are still flexible and can be further adapted or disregarded before a substantial amount of time, money, and effort has been invested without matching the users' requirements [22]. eHealth interventions often do not fit people with lower literacy skills and do not involve them in the intervention development [23]. This study also involved people with low literacy skills in the iterative user-centered design to examine and optimize the fit of the ParentCoach intervention to their needs and preferences.

In the following sections, we describe the phase-wise development and iterative testing of ParentCoach based on sleep problems in children.

Methods

Overview

ParentCoach was iteratively developed based on user-centered design principles. This process consisted of the following phases: (1) definition phase, (2) concept testing, (3) prototype testing, (4) usability testing, and (5) low-literacy testing. Potential end users (parents) and intermediate users (youth health care professionals [YHCPs]) were involved in the process by means of user-based assessments. An advisory board of professionals and parents provided feedback during the developmental process. First, the behavioral problem and program objectives were defined. Evidence-based methods were translated into behavioral strategies and included in ParentCoach. In the second phase, a concept version of ParentCoach was developed and tested among YHCPs in a focus group interview (n=3). The third phase consisted of incorporating the received feedback into the prototype of ParentCoach and testing this prototype among parents (n=3) and YHCPs in individual interviews (n=4). In the fourth phase, ParentCoach was tested among parents by means of a web-based survey (n=26). Finally, ParentCoach was evaluated among (former) people with low literacy skills (n=4) to ensure its acceptability and usability among vulnerable families. For each interview, a protocol was developed. All interviews (individual or group) were recorded. The input from the interviews was assessed using thematic analysis based on a topic list. The topic list consisted of topics such as relevance, usability, layout, and acceptability of the prototype intervention and was based upon the interview protocol. For each phase, a summary was made of the interviews by means of the topic list. The data from the web-based survey (phase 4) were processed using SPSS (version 25; IBM Corp), and descriptive statistics (frequencies, means, and SDs) were used to analyze the results. An overview of the different steps and sample characteristics can be found in Table 1.

Table 1. Overview of the iterative development steps and sample characteristics.

Step	Goal	Means	Sample
Definition phase	Definition of the behavioral problem and program objectives, translation of evidence-based methods into behavioral strategies	Literature study	N/A[a]
Concept testing	Storyboard development testing and testing of a concept version of ParentCoach: perceived relevance and user requirements	Focus group	3 female YHCPs,[b] mean age 38.7 (SD 4.5) years
Prototype testing	Early prototype development testing: exploring the acceptance and relevance of the script dialogue decision tree underlying ParentCoach	Individual interviews	3 mothers, mean age 34.3 (SD 2.1) years, and 4 female YHCPs, mean age 39 (SD 11.3) years
Usability testing	Refinement and usability (and acceptance) testing among the target group	Web-based survey	26 mothers, mean age 30.4 (SD 3.15) years
Low-literacy testing	Ensuring acceptability and usability of ParentCoach among vulnerable families	Individual interviews	4 parents with (former) low literacy skills

[a]N/A: not applicable.

[b]YHCP: youth health care professional.

To ensure the anonymity and privacy of the participants, data were processed in an anonymized way. Personal information

was not included in the reports of the interviews and surveys, and the contact information of the participants was deleted after they received a reward for participation.

Ethics Approval

ParentCoach was approved by the ethical board of the Netherlands Organisation for Applied Scientific Research (Institutional Review Board, 2018-068).

Results

Definition Phase

Sleep disturbances are strikingly common among preschool-aged and school-aged children (aged 2-6 years), with between 20% and 42% of these children experiencing sleep problems [24]. Sleep problems in children include bedtime resistance, night awakenings, short sleep duration, daytime sleepiness, and problems with falling asleep. These problems have been associated with behavioral, emotional, learning, memory, and health problems among children [25-28]. Sleep problems among young children also negatively affect parents and families; that is, parents may experience stress, sleep deprivation, health problems (including chronic fatigue), maternal depression, and irritability, whereas problems among families can be expressed as poor parenting strategies, family dissatisfaction, and relationship problems [29,30]. Thus, supporting parents to prevent sleeping problems among children is crucial for the health of both children and families.

Although it is essential for parents to learn how to deal with such problems, in the Netherlands, there are no proven effective programs to prevent sleeping problems among young children [31,32]. Providing preventive information alone is not sufficient; it has been shown that effective parenting is characterized by the ability to cope with difficult situations by implementing specific child interaction strategies. Moreover, repeated provision of problem situations in which parents can role-play and engage in situational learning activities (eg, calming, strategic ignoring, and consistent behavior) may enhance the effectiveness thereof [7,33]. Parents become more effective in interacting with their child or children when they are trained in positive behaviors (eg, enthusiasm, interest, and doing things together), are responsive to the emotional and psychological needs of their child, use time-outs efficiently, react to their child consistently, and learn which of their behaviors negatively and positively influence child (sleeping) behavior [6,7,34]. Situated learning and repeated rehearsal of (coping) skills are evidence-based methods to train parents in positive child interactions [7] and may help parents avoid child sleeping problems. Therefore, we formulated the following program objectives: to enable parents to (1) recognize challenging situations and (2) adequately react by training them in generic actions as suggested by the literature using evidence-based techniques, called *positive parenting principles*.

First, key elements and behavioral techniques were selected to match the goals of ParentCoach.

To realize the program objectives, ParentCoach will apply behavioral methods such as situational learning, tailoring, and problem solving. Possible applications identified were communication strategies such as narratives (also storytelling), video feedback in recognizable situations, or audiovisual materials to accomplish teaching generic behavioral options.

Situational learning of effective parenting practices could be stimulated by guiding a user through different scenarios in which the interaction between a parent and a child is observed so that they can interact, for example, by choosing an adequate reaction. Narrative communication has been shown to contribute to better recognition, relevance, realism, and active learning [35] and may increase active processing and understanding of the content [36]. In addition, narratives have been shown to improve comprehensibility in individuals with varying levels of health literacy [37] and, therefore, will be applied. Moreover, the use of audiovisual information (as opposed to textual information) can improve attention and comprehension in groups with lower socioeconomic status (SES) [38,39].

To improve information processing, active involvement, enhanced personal relevance, and positive effects on skills compared with universal interventions [40-42], tailoring could be an effective method to provide personalized feedback and scenarios depending on the user's choice. Tailoring (health) messages enhances the attractiveness, salience, and, thereby, effectiveness of the information [43], which may consequently lead to greater maintained behavior changes [44].

To facilitate the attainment of problem-solving skills, users may practice with a variety of potential problem scenarios that also integrate a range of different dialogues (eg, the child immediately listens to the parent vs a child who is reacting in a whiny manner). The application of various situations enhances the learning experience by providing the user with a greater number of practice situations as well as personalized feedback, which reinforces the learned content so that parents can practice different parenting strategies.

On the basis of the objectives and chosen methods stated above, a first concept was developed, which was consecutively tested in 4 iterative phases to be discussed in the following sections.

Storyboard Development and Testing

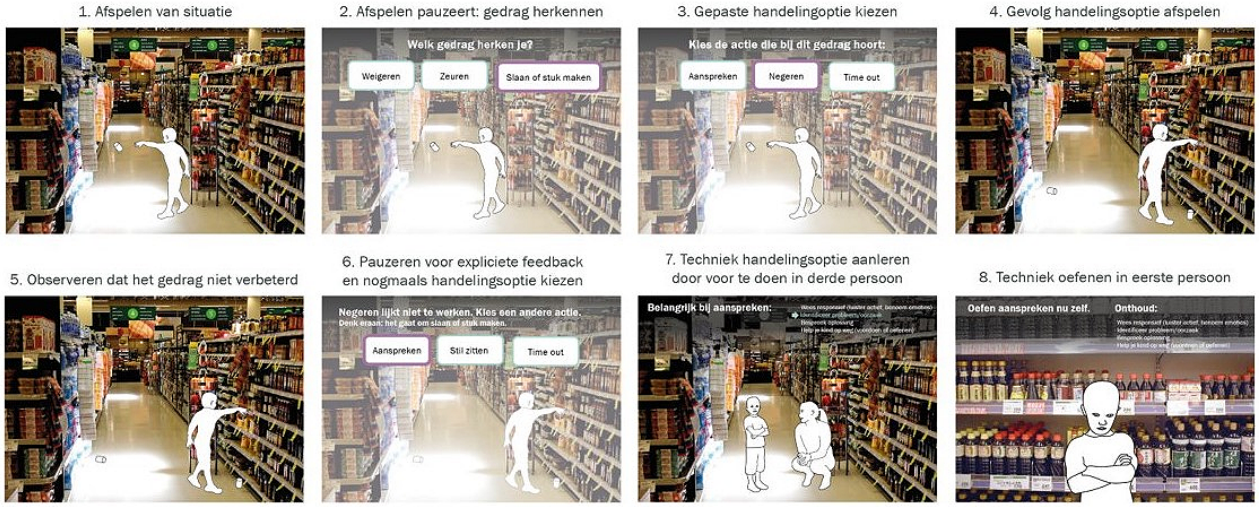
To test the idea of ParentCoach, a storyboard was developed. This test aimed to examine perceived relevance and user requirements. The concept scenario was tested by means of a focus group interview with 3 YHCPs in December 2017. Professionals were recruited via the child health center in Leiderdorp, the Netherlands. The interviewees were all female (3/3, 100%) with a mean age of 38.7 (SD 4.5) years and 10.5 (SD 6.1) years of work experience mostly with children aged between 0 and ≥7 years.

The first concept of ParentCoach incorporated a scripted 2D-based storyboard describing possible intervention features and functionalities. The storyboard as presented to the YHCPs offered various contexts (eg, at the beach or zoo) where parents could practice parenting skills in different situations that varied in degree of difficulty. In addition to personalization of the settings, including when to receive feedback and whether to suggest options on how to act, users were offered the possibility to personalize the child. A scoreboard sought to indicate the number of situations the user had already engaged in as well as

a *score* of correct answers given (Figure 1). A particular scenario was created (*supermarket scene*): while grocery shopping, the child is shown displaying rebellious behavior (throwing something; Figure 2). The user is then provided with a menu of options to indicate what kind of behavior they recognize in the situation (eg, refusal or whining), followed by the choice to react in a certain way (such as ignoring it or taking a time-out). Upon choosing a reaction, the scenario displays how the child reacts to the user's response.

Figure 1. Mock-up of the main menu of ParentCoach.

Figure 2. The scenario as depicted in the first iteration.



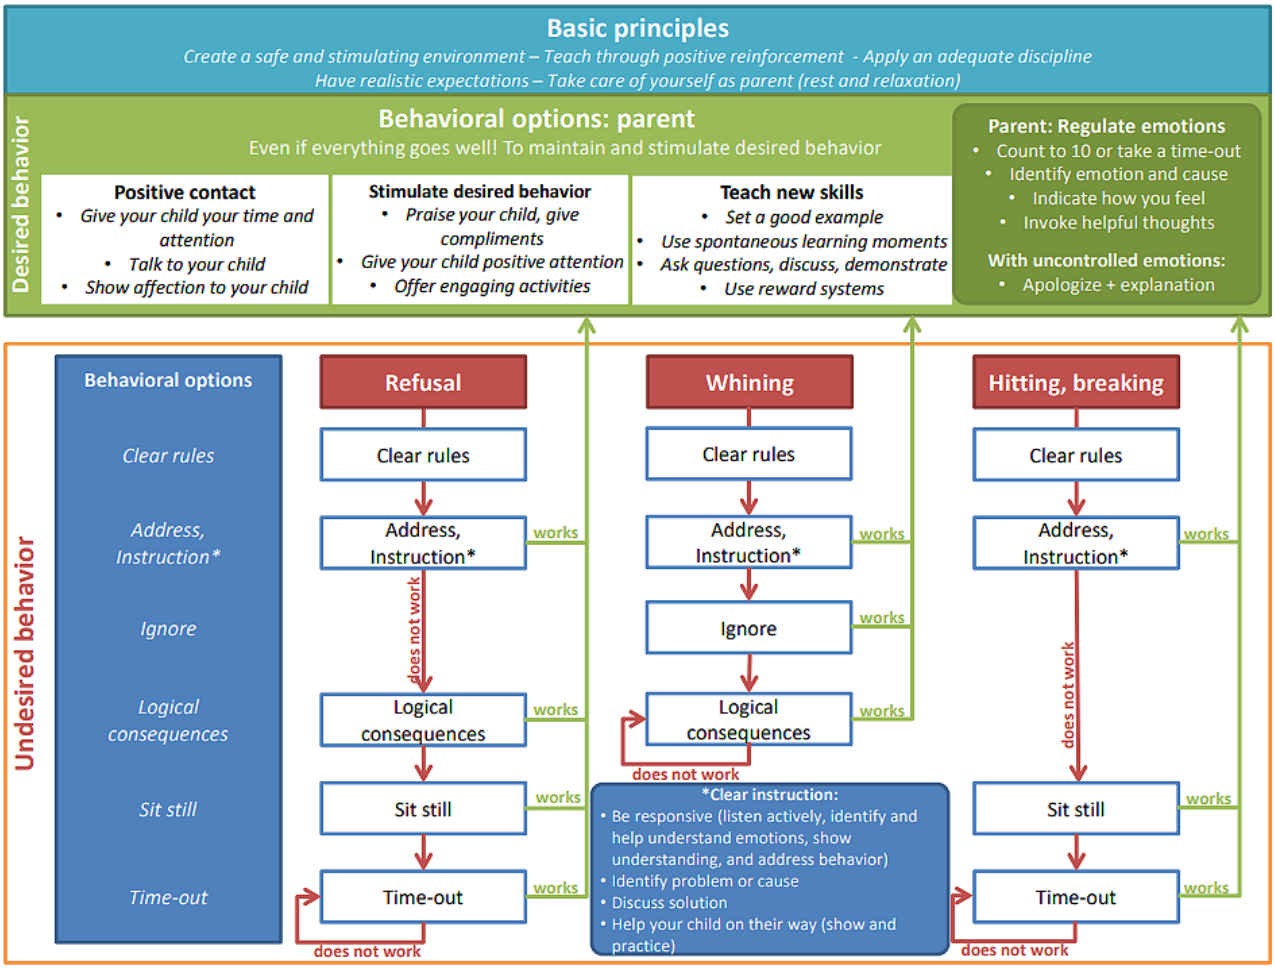
Regarding added value, all YHCPs (3/3, 100%) indicated that the scenario of ParentCoach was useful. The envisioned program was assessed to be "fun" in terms of enjoyment, and the mode of delivery was said to be innovative by all interviewees (3/3, 100%). Furthermore, the appearance was rated as attractive. Approximately 67% (2/3) of the health professionals reported that they would advise ParentCoach to all parents, whereas 33% (1/3) stated that they would rather advise the program to parents with parenting problems. The YHCPs found ParentCoach to be relevant, but certain points of improvement were shared. Although approving of the overall script and feedback provided to the user, the professionals indicated the concept to be relevant and realistic.

Hence, the evaluation strengthened the idea of the potential utility of ParentCoach. In addition, the YHCPs made improvement suggestions for further development of ParentCoach. Specifically, they pointed out that we should ensure that accessibility and the low literacy of potential users were taken into account, such as the use of simple language and starting off with the basic principles with potential for expansion on the topic.

Early Prototype Development and Testing

Next, a prototype was developed. First, a logical sequence of actions was defined (Figure 3).

Figure 3. Basic positive parenting principles underlying ParentCoach.



This model provides the user with instructions based on an operationalized problem. This consists of a stepwise instruction on how to (1) reinforce desired behavior and (2) discourage the undesirable behavior of a child. The scheme aims to offer users a structured approach to positive parenting and can be downloaded by the users.

Actions were then translated into scripts to mimic a dialogue between parent and child.

First, for the interactive videos, dialogues were scripted, and decision trees were defined to be able to tailor videos. The decision tree includes (1) type of situation, (2) type of child response, (3) type of options parents could choose, and (4) feedback from the relational agent, resulting in 24 potential situations. An example of such a decision is presented in Table 2.

The scenarios were integrated into an interactive video prototype and tested in the second iteration. This test explored the acceptance and relevance of the script dialogue decision tree underlying ParentCoach.

The updated prototype was assessed among 3 parents and 4 YHCPs by means of individual interviews in October 2018. Parents were recruited via flyers at the child health center in Leiderdorp, the Netherlands; via an advertisement at Kidsproof (a regional site for parents of young children with activities in the region of the Hague, the Netherlands); and via an email to parents of young children working at the Netherlands Organisation for Applied Scientific Research, Leiden, the Netherlands. All parents were female (3/3, 100%) with a mean age of 34.3 (SD 2.1) years. Their highest completed level of education was higher education, and they had 1 or 2 children aged between 2 and 5 years. YHCPs were recruited via the child health center in Leiderdorp, the Netherlands; via the Municipal Health Service in Leiden, the Netherlands; and via an email to a national network of YHCPs. All YHCPs were female (4/4, 100%) with a mean age of 39 (SD 11.3) years, had between 7 and 22 years of work experience, and worked with children in all age groups. This test focused, among other things, on attractiveness, utility, identification, and recognition. Questions elaborated, for example, on users' first impression of the program, the added value of the program according to the user, in which cases the user would want to use ParentCoach, and how they experienced the overall visualization.

Table 2. Extract from the decision tree indicating the possible dialogue between the user and coach in the case of the child (1) listening to the mother instantly and (2) showing refusal behavior within the scenario *It's bedtime*.

Type of situation and possible scenarios	Child response	Parent response options		Feedback from ParentCoach	
		Parent+	Parent–	Parent+	Parent–
"It's 6:45, bedtime. I want you to put on your pajama."					
Child listens	"Okay I will put on my pajama. Be right back."	"Great. How nice that you do this so quickly. I'll be right there."	"Hurry up hey."	Well done. This was positive behavior. In this case, you can indeed react with a compliment.	Look out. Your child shows positive behavior. Reward this; for example, by giving a compliment.
Child refuses	Child goes on playing	"I want you to put on your pajama."	"Okay, 5 more minutes then."	Well done, your child shows refusal behavior. Clear instructions are required here!	Look out. Your child displays refusal behavior. Do not reward this, but stick to your rules.

In general, the evaluation indicated that the examples were useful, and the scenarios were recognizable, short, and accessible. The relational agent was said to be pleasant. However, the options of parenting reactions that users could choose were declared to be too obvious, with the user experiencing a tendency toward the "right choice." This implied that the user did not have the full opportunity to learn from their mistakes as they were not provided with information on why a certain choice may be less adequate. Furthermore, concerning visualization, the mother in the scenario was said to be illustrated too much like a grandmother, and the explanation given by the coach was said to be too long and difficult to understand.

The professionals evaluated ParentCoach as relevant, especially for "short, simple problems." However, they suggested potential adaptations regarding the inclusion of lower-SES populations as well as taking cultural factors into account without stereotyping. Another suggestion to increase relevance comprised the provision of an explanation concerning the importance of the positive parenting principles.

Mothers experienced the scenarios in ParentCoach as recognizable. The child's voice and way of talking were said to be very realistic. Concerning the use of the program, the interviewees experienced ParentCoach as a short (ie, not too time-consuming), accessible program that could be used in one's own time. Both the fact that the coach was an independent character and the delivery format of ParentCoach as a whole were strong points according to the mothers. However, the amount and length of information and tips given by the coach were said to be too much as well as too scientific. The interviewees reported that they preferred alternations between explanations, short example movies, and exercises.

Both parties (parents and professionals) indicated a felt need to be able to get in contact with one another in case there was an indication of the need to provide or receive professional human support, which suggests embedding ParentCoach in the broader context of youth health care services (YHCSs). On the basis of the results of this test round, ParentCoach was further adapted taking into account the feedback received.

Refinement and Usability Testing

The third iteration comprised a survey evaluating usability and acceptance among the target group. This version incorporated adaptations and improvements based on the feedback and suggestions retrieved during the second iteration.

The participants evaluated the 3 animation figures that were shown in the videos (ie, the mother, child, and coach), the assignments and skill training, the design, and the idea of ParentCoach. Thereby, we assessed the third version of the web-based ParentCoach, which was complemented with a web-based survey among a convenience sample of 26 participants. Recruitment took place in March 2019 via Facebook advertisements targeting young mothers with children aged 2 to 6 years. The participants were female parents, each with 1 to 3 young children in the age range of 2 to 5 years. The mean age of the participants was 30.4 (SD 3.15) years. Most participants were higher educated (21/26, 81%) and had a Dutch background (23/26, 88%).

The survey consisted of close-ended and open-ended questions. Close-ended questions related, among other things, to the videos; for example, *I experienced practicing with the videos to be (i) certainly clear, (ii) certainly not educational, (iii) certainly not recognizable*, to be answered on a 7-point Likert scale, or *How did you experience the mother character?* regarding (1) recognizability, (2) trustworthiness, or (3) irritation, again to be answered on a 7-point Likert scale. Furthermore, the questions concerned the explanations given by the coach (eg, *I experienced the explanations of the coach to be (i) relevant, (ii) clear, (iii) educational, (iv) easy to follow*, to be answered on a 7-point Likert scale). Open-ended questions assessed what the users experienced as most and least pleasurable, what they missed, and tips and recommendations for further development.

Of the 26 participants, 24 (92%) reported having watched the practice videos, whereas 23 (88%) watched the explanation videos (referring to tips and basic parenting principles). Positive points taken from this usability test revealed that the situations were recognizable, and the overall program was accessible, concise, and clear. The relational agent was evaluated most positively (7.3 out of 10) of the animation figures, followed by the mother (7.0) and the child (6.9). In general, 46% (12/26) of the users reported that they would use ParentCoach themselves, whereas 81% (21/26) would recommend it to someone else. Table 3 shows the overall usability and acceptability scores of ParentCoach. The most positive ratings (all scores ≥4 on a 5-point scale) were for (1) ease of use, (2) accessibility, and (3)

recognizable situations. Nevertheless, *fit for personal purpose* was rated lower (3 on a 5-point scale).

Table 3. Usability and acceptability of ParentCoach (N=26).[a]

Item	Rating, mean (SD)
ParentCoach illustrates situations that I personally recognize.	4.12 (1.18)
ParentCoach teaches me what to do in challenging parenting situations.	3.62 (0.75)
ParentCoach includes practical tips.	3.77 (0.71)
ParentCoach fits my needs well.	3.08 (1.16)
ParentCoach stimulates me to apply the exercises and explanations at home.	3.50 (1.07)
ParentCoach is a helpful means to practice.	3.69 (1.19)
ParentCoach is accessible.	4.35 (0.69)
ParentCoach is easy to use.	4.31 (0.68)
ParentCoach is fun to use.	3.85 (0.97)

[a]Likert scale (range 1-5).

From the open-ended questions, we could gather recommendations for improvement. The participants perceived the child as somewhat unrealistic in difficult situations. The feedback and explanation by the coach were found to be too wordy and complicated. In addition, users missed the possibility to either pause or replay certain segments. Some participants pointed out that the assignments were too short and should consist of more information about how to react in a certain situation (eg, when your child does not want to go to bed). Parents also reported that they wanted to receive more emotional support (eg, through the coach saying that practicing can be hard and that there are moments when parenting strategies may not work even though they are doing their best). Finally, parents requested more options, further indicating that the coach should emphasize that, besides the given parenting principles, other parenting strategies could also be good.

Low-Literacy Testing

On the basis of the last iteration, further improvements were made. A final evaluation was aimed at also assessing a fit with people with lower health literacy skills given that the convenience sample did particularly comprise people with higher education. This final prototype was evaluated with 4 participants who had (formerly) low literacy skills by means of individual interviews in May 2019. Participants were recruited from a test panel of language ambassadors of ABC Foundation in the Netherlands, a panel consisting of members with (formerly) low literacy skills. All participants (4/4, 100%) had children; 50% (2/4) had young children, and the other 50% (2/4) had adult children. This test focused on evaluating ParentCoach in terms of accessibility for users with low literacy, poor health skills, and low abstract thinking ability. Low-literacy testing consisted of methods requesting the testers to read aloud written text (eg, *Would you please read aloud what is written here?*), summarize and teach back information in their own words (eg, *What did you just hear?What do they mean with* refusal behavior*?* or *What can you do here?*), and give advice on how to rephrase certain expressions to increase comprehensibility (eg, *What was (un)clear?How would you resolve this?*).

The test panel was very positive and enthusiastic about ParentCoach and its features. The testers perceived the content as useful and comprehensible, and the videos were perceived as instructive. For this reason, they graded ParentCoach with an 8.3 on a scale of 1 to 10. The panel also mentioned some points of improvement. For instance, they pointed out that a short introduction video should be added to explain how ParentCoach works and how to use it, with an explanation of the menu. Furthermore, to enhance usability and acceptability, the panel advised the adaptation of some specific design features (eg, increasing font size and adapting symbols and text to enhance readability) and syntax (eg, rewording *undesirable behavior* into *negative behavior* and explaining difficult words). Reported difficulties included the time indication integrated in the menu. Here, users mistook the length of the video sequence (0:20) as the time when the action should take place (ie, 20 minutes after midnight). To resolve this issue, the indication was clearly labeled *duration*. In addition, examples of options for action were asked to be illustrated through animation. All feedback and advice from the test panel was processed in the final version of ParentCoach.

Finalization of Prototype

On the basis of the input from the last evaluation, a final version of ParentCoach was created [14]. As a result of user-centered design and iterative testing, an introductory movie was included explaining how ParentCoach can be used. The menu included enables the user to either run chronologically through the program or choose from 3 practice scenarios or advice regarding positive and negative behavior (Figure 4). In each of the 3 scenarios, the audiovisual material is delivered within 18 to 20 seconds. Scenarios to practice positive parenting principles include *it's bedtime*, *putting on one's pajama*, and *going to bed*. The scenarios start with a short sequence in which the problematic behavior of the child is depicted (eg, the mother makes it clear that it is time to go to bed, and the child whiningly responds saying that she does not want to). Following the short sequence, parents are offered two reactions; for instance, *I want you to put on your pajama. It is quarter to seven* or *Okay, 5 more minutes then*. Upon choosing one of the possible reactions, the user receives immediate feedback from the animated coach,

providing the user with advice and information regarding the given response. To enable users to practice with different situations, there are several ways in which the child may react so that the user is offered a broad range of situations to foster their learned skills.

Figure 4. Introductory home screen of ParentCoach (on the left hand side, the menu of the interactive video is shown).

In addition to practicing skills through scenarios, ParentCoach provides several tips and advice (eg, having positive contact or rewarding the child). Parents can either choose between positive or negative behavior as a response to the dialogue with the coach or directly select the desired element through the menu. Each piece of advice includes certain examples of how to stimulate positive behavior (eg, *give your child a compliment* by praising how well the child tidied up their room by themselves). This advice is accompanied by animations that support the audio text. Advice regarding negative behavior includes the topics *refusing*, *whining*, and *fierce behavior*, which can be accessed via the dialogue with the coach or in the menu. These behaviors are addressed in the enlisted steps that the user can take to engage with a child displaying the respective behavior. Each step is followed by a consecutive step in case the earlier measure failed to succeed.

Discussion

Principal Findings

In this paper, we elaborated on the application of a user-centered approach toward the development of the innovative web-based video tool ParentCoach. The tool empowers parents to recognize challenging situations and teaches them generic behavioral responses to stimulate the positive behavior of their child or children by means of interactive video e-learning using behavioral techniques such as situational learning, tailoring, and problem solving.

As a result of iterative usability testing, adaptations were made to ParentCoach to address wishes and needs and overcome perceived obstacles. These included the addition, adaptation, or extraction of some features such as text blocks, certain ambiguous symbols, optical change of the coach character, and look of the virtual environment. In addition, the spoken text was changed in terms of (1) ease of wording and (2) breaking up texts into smaller chunks. Furthermore, the response options were adapted content-wise as well as regarding syntax for easier understanding. To make ParentCoach more educational, response options were altered to ensure that the most appropriate response was not too obvious, thereby contributing to a better learning environment for parents. Low-literacy testing enabled the program to be inclusive.

ParentCoach may provide relevant evidence-based tips and practice situations that empower parents to tackle everyday parenting challenges without the need for further human support, thereby relieving pressure on the health care system and increasing the efficiency of support provision. Moreover, the basic parenting principles processed in ParentCoach comply with the national sleep guidelines for preventive child health care professionals [45]. Overall, ParentCoach was well received by parents and professionals. Parents reported (1) recognizable situations; (2) useful examples; (3) accessible use; (4) a pleasant coach; and (5) understandable and clear text, audiotext, and videos. Approximately 46% (12/26) of participants indicated wanting to use ParentCoach, whereas 81% (21/26) reported that they would recommend the tool.

In summary, ParentCoach offers a unique, low-demand, and accessible tailor-made preventive parenting support program in which we hope to have overcome some of the limitations of previous technology-enabled programs [10] that did not provide a practice setting with tailored feedback and advice. ParentCoach could be used as a stand-alone program or be integrated into other parenting programs or YHCSs such as the web-based platform Growth Guide, a platform by YHCSs. Its features allow users flexibility regarding time and duration to pass through the scenarios and tips as suggested by the literature advocating addressing such limiting factors and barriers that comprise childcare and transportation issues [46,47]. By means of ParentCoach, parents are enabled to train their parenting skills in their own time in the comfort of their own home. As such, it seems an important contribution to the existing

information-only or secondary preventive interventions, as was recognized by the YHCPs in the study and a recent review by the steering committee of Growth Guide (representing 18 YHCSs); it also addresses commonly experienced problems of a considerable number of parents in the general population. Furthermore, ParentCoach is unique in its approach as it is built to be inclusive for all parents and, therefore, seems particularly useful for parents with lower health literacy skills as it combines tailoring, interactive learning, and the use of both audio and visual information—strategies that have been shown to be effective in improving the attention and comprehension of this particular group [38,39]. Inclusive design in eHealth applications ensures that products are accessible and usable by the majority and, hence, helps overcome health inequalities, especially for lower-SES groups as it further minimizes the risk of growing health inequalities [48]. Therefore, cocreation with lower-SES groups is a means to ensure that ParentCoach is accessible and functional for everyone.

As pointed out by Davis and Venkatesh [22], early acceptability testing among the target group offers various benefits in the development process. First, initial acceptability testing allows for the prevention of potential pitfalls early on as it provides relevant insights into barriers and postimplementation user acceptance. Thus, it is crucial to promote user acceptability testing early in the design process as it may mitigate later financial deficits because of failing to meet the users' needs and wishes for functionalities before making significant investments [22]. As the expected user population may fall short, predicting user acceptance may not only save significant losses but also guide important decisions in the design process. On the basis of usability testing, certain initial decisions may be abandoned or progressed in an alternate way to focus on certain functionalities to match the end users' needs, as was done during the development of this program. Early testing goes along with a low cost compared with the implications of a huge investment that is not accepted and used by the end user [22].

Conclusions

As a conclusion, early testing of relevance and understanding of factors that contribute to esthetics, utility, understanding, and usability enabled the progressive development of ParentCoach according to the needs and wishes of the potential end users. Cyclical testing among this group positively affected the overall interface and interaction by revealing and correcting certain barriers. Moreover, the user-centered development of ParentCoach in cocreation with participants with lower health literacy skills contributes to the literature in that it offers an example of inclusive development.

Although in this paper we have shown that the working principle of ParentCoach can work, future research may address the extent to which the program actually enables parents to learn and apply positive parenting principles. Furthermore, future directions may include the incorporation of different contexts and other common problems that parents face, such as eating behavior, screen time, or physical activity.

Abstract

Background: Patients with limited English proficiency (LEP) are at a higher risk of poor health outcomes and are less likely to use telehealth than English-speaking patients. To date, there is no formal evaluation of inpatient (IP) telehealth user experience of patients and their families by language preference during visits with their clinicians.

Objective: This study aims to compare the experiences of English- and Spanish-speaking patients and their families using IP telehealth, as well as to evaluate the experience of Spanish interpreters providing services through IP telehealth.

Methods: We prospectively administered a survey to English- and Spanish-speaking patients and their families who used IP telehealth from October 1, 2020, to March 31, 2021. We performed semistructured phone interviews of hospital-based Spanish interpreters who provided services through IP telehealth.

Results: A total of 661 surveys were administered, with completion rates of 18% (112/621) in English and 62% (25/40) in Spanish. On a 10-point scale, the overall satisfaction of Spanish speakers (median 10, IQR 10-10) was higher than that of English speakers (median 9, IQR 8-10; *P*=.001). Both English- and Spanish-speaking patients used IP telehealth for visits with their primary IP care team, subspecialty consultants, and other clinicians. Hospital tablets were used more often than personal devices, and only English-speaking patients used personal laptops. Patients and their families encountered challenges with log-in, team coordination with multiple users, and equipment availability. Interpreters encountered challenges with audio and video quality, communication, safety, and Wi-Fi access.

Conclusions: Both English- and Spanish-speaking patients reported high satisfaction using IP telehealth across multiple disciplines despite the workflow challenges identified by interpreters. Significant investment is needed to provide robust infrastructure to support use by all patients, especially the integration of multiple users to provide interpreter services for patients with LEP.

Introduction

Health care delivery required redesign during the COVID-19 pandemic. Given the limited availability of personal protective equipment, several aspects of health care were transformed to safely deliver high-quality care from a distance [1,2]. Critical to this redesign was the expansion of telehealth. Although telehealth use in inpatient (IP) settings is not new [3-7], it previously had poor market penetration due to strict regulation and low rates of reimbursement that varied by state [8,9]. IP telehealth expansion during the pandemic was used to support infection control practices, including minimizing personal protective equipment use and the surge of patient demand on hospital systems [10-12].

Beyond infection control, there were simultaneous, ongoing public health crises illuminated during the COVID-19 pandemic, which included health inequity [13]. Equity is a core component of health care access and quality and should be explicitly considered during system design and quality improvement [14]. The legal expectation to provide language access across all federal programs, including health care, originated from the Civil Rights Act and has been expanded under Section 1557 of the Affordable Care Act [15,16]. Successful telehealth implementation is critical to addressing health inequity, which includes linguistic barriers. Patients with limited English proficiency (LEP) have increased risks of poor health outcomes, adverse hospital events, and 30-day emergency department revisits compared to English-proficient patients [17]. Although non–English language preference is associated with higher interest in ambulatory video visits, having LEP is associated with a lower likelihood of ambulatory or urgent care video visits [18-20].

We previously described the rapid implementation of an IP telehealth program to facilitate IP care during the COVID-19 pandemic [21]. Prior evaluation of patient satisfaction with IP telehealth has shown high satisfaction with COVID-19 medical units, rehabilitation, and psychiatric partial hospitalization [22-24]. However, there has not yet been a formal evaluation of IP telehealth user experience by language preference. The experience of users with LEP is dependent on the seamless integration of interpreters; thus, to support this population, we also need to support the interpreter workflow. Our objective is to compare the experiences of English- and Spanish-speaking patients and their families using IP telehealth, as well as to evaluate the experience of Spanish interpreters providing services through IP telehealth.

Methods

Study Setting and Data Collection

This prospective survey study was conducted at Boston Children's Hospital, an academic quaternary care pediatric facility in Boston, Massachusetts. We conducted a mixed methods study of quantitative patient survey data and qualitative interpreter interview data.

Evaluation of the Experience of Patients and Their Families Using IP Telehealth

An 8-question survey (Multimedia Appendix 1) was developed via REDCap (REDCap Consortium) and modified based on the institution's outpatient virtual visit survey. The survey was reviewed and edited by the health literacy team to ensure accessible language use. The survey was translated into Spanish by Boston Children's Hospital Interpreter Services.

Patients and their families who used IP telehealth from October 1, 2020, to March 31, 2021, were identified by crossreferencing reports from the videoconferencing software with IP encounters in the enterprise data warehouse. We further filtered the report by selecting all patients with English or Spanish as their primary language. *Language* in this study is defined as the preferred language listed in the patient's electronic health record. Emails and phone numbers were used for survey distribution. Use of IP telehealth in dialysis, operating rooms, and radiological imaging were excluded as these visit types could not be linked to specific patient encounters. Patients with email listings were sent the survey in their listed language. Patients without email listings were called via phone, and the survey was administered in their listed language by author LP or a trained Spanish interpreter. Due to an initially low Spanish survey response rate and fewer email listings, starting from December 1, 2020, all surveys were administered by phone to patients with Spanish listed as their preferred language. Survey results of de-identified patients were downloaded from REDCap.

Evaluation of the Experience of Interpreters Providing Services Through IP Telehealth

The hospital has a dedicated interpreter services department with 23 staff members available either in person or by phone or videoconferencing, in addition to external interpreters via contracted agencies. During the COVID-19 pandemic, interpreters initially transitioned to remote work exclusively, but during the study period, they were available in person and remotely. Clinicians typically contacted interpreters by paging to arrange a meeting time. With the launch of an IP telehealth initiative, clinicians were instructed to provide a telehealth meeting link to the interpreter when requesting services. There is also a virtual interpreter system provided by a third-party vendor via tablets on wheels in each hospital unit; however, this system was not integrated with IP telehealth at the time of this study. We conducted semistructured phone interviews of 5 hospital-based Spanish interpreters who provided services through IP telehealth to assess their experience with the program and how it may be improved. The semistructured interview guide consisted of the following questions: (1) What issues did you experience during the IP telehealth session? (2) What do you like about IP telehealth? and (3) What are the opportunities for IP telehealth improvement? Responses were reported to include a representative sample and were categorized inductively.

Ethical Considerations

This project was part of a larger quality improvement effort at Boston Children's Hospital and was thus deemed exempt from

Institutional Review Board review by the Department of Pediatrics Performance Excellence Group.

Statistical Analysis

Medians and IQRs were calculated for continuous variables. A *P* value of .05 was considered statistically significant. Wilcoxon rank sum test with continuity correction was performed.

Results

Evaluation of the Experience of Patients and Their Families Using IP Telehealth

Of the 8422 unique patients admitted to the hospital during the study period, 505 (6%) had Spanish listed as their preferred language. Of these 505 unique Spanish-speaking patients, 40 (7.9%) used IP telehealth during the study period. A total of 661 eligible patients were identified and administered the survey, with completion rates of 18% (112/621) in English and 62% (25/40) in Spanish. On a 10-point scale, the overall satisfaction of Spanish speakers (median 10, IQR 10-10) was higher than that of English speakers (median 9, IQR 8-10; *P*=.001). On a 10-point scale, the median scores for how well they felt their questions were answered during their visit were equal: 10 (IQR 10-10) for Spanish speakers and 10 (IQR 9-10) for English speakers (*P*=.03). Both English- and Spanish-speaking patients reported IP telehealth visits with their primary IP care team, subspecialty consultants, and other clinicians (Table 1).

Hospital tablets were used more often than personal devices, and notably, only English-speaking patients used personal laptops (Table 2).

Of patient and family respondents with Spanish listed as their preferred language, 80% (20/25) reported using an interpreter during their visit. Feedback on how to make the system easier to use was most frequently regarding log-in, team coordination with multiple users including interpreters, and equipment availability (Table 3). We coded the responses into categories.

Table 1. Comparison of inpatient telehealth visit type by language.

Telehealth visit type	English-speaking respondents[a] (n=112), n (%)	Spanish-speaking respondents[a] (n=25), n (%)
Primary inpatient care team	54 (48)	12 (48)
Specialist consult	50 (45)	12 (48)
Other	48[b] (43)	9[c] (36)

[a]The sum of each column is greater than the number of respondents because the survey question permitted multiselect answers. The denominator for each cell is the number of respondents.

[b]Other telehealth visit types for English-speaking respondents included behavioral health therapy, child life, dietician, music therapy, nasogastric pump instructions, parent calling patient, patient calling provider from outside facility, patient unsure of type, pet therapy, and social work.

[c]Other telehealth visit types for Spanish-speaking respondents included dietician, music therapy, patient unsure of type, pet therapy, and social work.

Table 2. Comparison of inpatient telehealth device type by language.

Device type	English-speaking respondents (n=112), n (%)	Spanish-speaking respondents (n=25), n (%)	All respondents (N=137), n (%)
Hospital tablet	50 (45)	14 (56)	64 (47)
Personal phone or tablet	36 (32)	11 (44)	47 (34)
Personal laptop	26 (23)	0 (0)	26 (19)

Table 3. Categorized comment responses (N=52) to the survey question “How can we make the system easier to use?”

Categories for improvement	Responses, n (%)
Log-in	8 (15)
Multiple users/team coordination	5 (10)
Equipment availability	3 (6)
Privacy	3 (6)
Poor internet connection	2 (4)
Patient engagement	2 (4)
“Unreliable” interpreter	1 (2)
Audio quality	1 (2)
Advertising	1 (2)
Positive comments	26 (50)

Evaluation of the Experience of Interpreters Providing Services Through IP Telehealth

Feedback categories derived from phone interviews with Spanish interpreters include audio and video quality, communication, safety, and Wi-Fi access (Table 4).

Table 4. Interpreter phone interview feedback.

Category	Sentiment	Illustrative quote
General	Positive	• Thank you for caring about our Latino population!
Safety	Positive	• This helped me and my family stay safe from the virus. • I have children at home and was worried about working in person and spreading COVID to them.
Audio quality	Constructive	• It is challenging to hear the team when they are in full PPE [personal protective equipment]. • Make sure the iPad is close to the patient, volume is high, and it is clear who is taking turn to speak. Otherwise it is overwhelming.
Communication	Constructive	• Our Latino population is more responsive with texts than emails. Can we send the invite link through a text instead of an email? • Physical therapy was difficult because we could not touch the patient to instruct them to turn around.
Video quality	Constructive	• It is tough to visualize the patient and family at the same time. • We need more family education on pointing the camera at the correct angle.
Wi-Fi access	Constructive	• Most patients [who I interpret for] do not have Wi-Fi at home so they use data on their cell phones. We should help them use hospital Wi-Fi to download the application on their phones while inpatient. This will help them with their follow-up outpatient televisits.

Discussion

Principal Findings

We found that the patients in this sample had high satisfaction with IP telehealth, but Spanish-speaking patients' median satisfaction scores were higher than those of English speakers despite the workflow challenges identified by interpreters. Broad use cases of IP telehealth were present for both language groups, including visits with the primary IP care team, specialty consultants, social workers, and dieticians. Overall, hospital tablets were used more than personal devices, especially by Spanish-speaking patients. This finding suggests the need for further investment in dedicated hospital devices. Survey respondents provided useful feedback that was shared in departmental educational sessions and can inform future improvements (eg, regarding session log-in and audio and video quality with multiple team members).

Notably, interpreters expressed appreciation for the opportunity to deliver care from a distance during the COVID-19 pandemic. This finding highlights the value of IP telehealth as a tool to ensure staff safety from infectious diseases.

Comparison With Prior Work

Previous literature on IP telehealth implementation has described a broad range of use cases and patient satisfaction that is comparable to in-person care [22-26]. Our study adds to this literature by specifically addressing the experience of patients and their families who have LEP. The positive experience reported by Spanish speakers in our survey aligns with prior work in ambulatory settings that shows high interest in telehealth among non–English speakers [20].

Spanish-speaking patients primarily using hospital tablets and not personal laptops emphasizes the importance of investing in IP telehealth infrastructure for patients with LEP [27]. In one paper, narratives of patients with LEP who experience social isolation while hospitalized highlight the importance of careful tablet technology implementation to address communication barriers [28]. Other hospital systems describe the use of Amazon Echo Show devices, laptops on wheels, and tablets on wheels as part of telehealth [25,26]. Carts with the ability to pan and tilt, hands-free voice-activated command devices, and supplementary speakers may also help address the audio and video quality challenges noted by survey respondents.

Similar to previous findings, we found that work-arounds for integrating multiple users to include interpreters compromised audio and video quality [25]. Literature has shown better communication outcomes for interpreters connected by video than by phone, further supporting the need for robust infrastructure, including integrated interpreter services, to support IP telehealth initiatives [29].

Limitations

This study has limitations, particularly the switch to phone-administered surveys for Spanish-speaking patients due to a low response rate and fewer email listings than English-speaking patients. The use of phone surveys may introduce acquiescence or conformity bias, which may explain the higher median satisfaction score among Spanish-speaking respondents than English-speaking respondents. Satisfaction may also be inflated due to a perceived lack of anonymity or a fear of disapproval from health care professionals [30,31]. In addition, language preference as documented in the electronic health record may not accurately identify patients with LEP.

This could lead to miscategorization, affecting both our survey response rate and survey results. Our mixed methods approach meant that the interpreters—a small cohort—were interviewed, whereas the larger cohort of patients received the structured survey. Survey data have limitations that include inflexibility and lack of depth, which we attempted to address by including textboxes for open-ended questions. Finally, our findings may not apply to patients who speak languages other than English and Spanish, although this institution supports 15 languages through in-house interpreters and more than 100 languages through externally contracted interpreter services.

Conclusions

Both English- and Spanish-speaking patients reported high satisfaction using IP telehealth across multiple disciplines despite the workflow challenges identified by interpreters. Significant investment is needed to provide robust infrastructure to support use by all patients, especially the integration of multiple users to provide interpreter services for patients with LEP.

Acknowledgments

We would like to give special thanks to Boston Children's Hospital Interpretation Services for administering surveys to Spanish-speaking patients and their families.

Abstract

Background: Technology acceptability and usage surveys (TAUS) are brief questionnaires that measure technology comfort, typical daily use, and access in a population. However, current measures are not adapted to low- and middle-income country (LMIC) contexts.

Objective: The objective of this pilot study was to develop a TAUS that could be used to inform the implementation of a mobile health (mHealth) intervention in Nigeria.

Methods: A literature review of validated technology comfort and usage scales was conducted to identify candidate items. The draft measure was reviewed for face validity by an expert panel comprised of clinicians and researchers with cultural, methodological, and clinical expertise. The measure was piloted by radiologists at an oncology symposium in Nigeria.

Results: After expert review, the final measure included 18 items organized into 3 domains: (1) comfort with using mobile applications, (2) reliability of internet or electricity, and (3) attitudes toward using computers or mobile applications in clinical practice. The pilot sample (n=16) reported high levels of comfort and acceptability toward using mHealth applications in the clinical setting but faced numerous infrastructure challenges.

Conclusions: Pilot results indicate that the TAUS may be a feasible and appropriate measure for assessing technology usage and acceptability in LMIC clinical contexts. Dedicating a domain to technology infrastructure and access yielded valuable insights for program implementation.

Introduction

Background

Over the past decade, mobile Health (mHealth)–based interventions have become affordable, accessible options for health education and care, particularly in low- and middle-income country (LMIC) contexts [1,2]. Developing an mHealth-based intervention typically involves iterative cycles of design, testing, and rapid adaptation, as well as retesting in the targeted population. Technology acceptability and usage surveys (TAUS) may streamline these cycles by providing insight into the social context of device implementation and use. TAUS are brief questionnaires that measure technology comfort, typical daily use, and access in a population. Although TAUS have been used to inform digital interventions such as telehealth [3], they are seldom adapted to LMIC contexts or developed in the local language, despite their potential to support pre-implementation planning.

For global health intervention planning, there is a need for validated TAUS that are appropriate for use in LMIC settings, particularly in locations with limited electricity or digital infrastructure. Previously developed TAUS are either out of date, referencing technology platforms that no longer exist (eg, Alta Vista), or were developed in settings with large technology infrastructures such as the United States [4]. Additionally, previous literature also indicates that the use of mobile devices is culturally patterned [5,6]. For instance, in sub-Saharan Africa, the use of mobile applications has "leapfrogged" over computer-based platforms as a primary tool for work information-seeking in digital spaces [7]. Thus, it is necessary to develop TAUS tools that are not only adapted to local infrastructure but also tailored to the local cultural context.

Goal of This Study

The objective of this pilot study was to develop and pilot a TAUS that could be used to inform the implementation of an mHealth intervention in Nigeria. In this paper, we describe our methods for developing the TAUS and preliminary insights from piloting the measure among a group of Nigerian health professionals.

Setting

Nigeria is the most populous country in Africa and has the highest breast cancer mortality rate [8]; breast cancer is the leading cause of death among Nigerian women [9]. Although breast cancer is typically diagnosed via ultrasound-guided breast biopsy in most high-income countries, this approach is less frequently available in LMICs due to the prohibitive costs of imaging devices, materials, and maintenance [10]. In the absence of imaging, breast cancer is commonly diagnosed in LMICs either through blind biopsy, which is less accurate, or surgical excision, which increases morbidity [10].

However, battery-operated, mHealth tablet-based devices have the potential to expand ultrasound access in LMICs. An mHealth tablet-based ultrasound device is both less expensive and less costly than hospital-grade ultrasound machines. This device consists of a portable, high-frequency, ultrasound probe that attaches by USB to either a tablet or smartphone, which displays and send images to a secure mobile application. The device proposed for use in this intervention was developed in the United States (Philips Ultrasound Inc, Bothell, WA) but has been successfully used by midwives at Aga Khan hospital in Nairobi, Kenya [11]. However, this device has not been piloted in oncology settings nor within the context of the Nigerian hospital system. Therefore, this project presented an ideal opportunity to develop and administer a novel TAUS to help us understand radiologists' current technology use, access, and comfort in clinical settings, which would inform the implementation strategy of this tablet-based ultrasound intervention.

Methods

Measure Development

To select candidate items for the measure, we conducted a literature search of questionnaires related to physician technology usage as well as validated technology comfort and usage scales developed for clinical settings [2,3,12-14]. Drawing on themes identified in the literature, we created a first draft of the TAUS, organized into 4 domains: (1) comfort with using mobile applications; (2) reliability of internet, Wi-Fi, and electricity; (3) utilization of computers or mobile applications in clinical practice; and (4) attitudes toward using computers or mobile applications in clinical practice. Each domain contained 7 to 10 closed-ended or 5-point Likert scale items. The draft measure was then reviewed for face validity by an expert panel comprised of clinicians and researchers with cultural, methodological, and clinical expertise. This review enabled us to tailor the measure to the local Nigerian context and reduce the number of items needed to assess each construct to reduce respondent fatigue. Experts gave feedback independently and then convened to reach consensus on item consolidation and removal during a 60-minute feedback session. After revising the measure, experts re-reviewed and approved the final version prior to piloting.

Ethical Review

To pilot the measure, we obtained approval from the Institutional Review Board at Memorial Sloan Kettering Cancer Center (number IRB 18-114) for our study. All pilot study procedures were performed in accordance with the 1964 Helsinki declaration and its later amendments. Informed consent was obtained from all individual participants included in the study.

Piloting the Measure

Data collection occurred in April 2019 at the sixth annual symposium of the African Research Group for Oncology (ARGO), a National Cancer Institute–recognized cancer consortium that aims to improve outcomes for cancer patients in Nigeria. The symposium was hosted by Obafemi Awolowo University Teaching Hospital in Ile-Ife, Nigeria. This setting was chosen because it presented an opportunity to simultaneously survey Nigerian radiologists working in diverse community and geographic contexts. During the conference, radiologist attendees attended a didactic and training session focused on mHealth tablet-based ultrasound device–guided breast biopsy. Following a hands-on demonstration of the

mHealth device, radiologists completed a paper copy of the TAUS. Responses were analyzed descriptively.

Results

After expert review of the responses, we consolidated "Comfort" and "Utilization" into a single domain given the overlap in constructs, expanded the "Reliability" domain to 10 items to reflect local infrastructure challenges, and reduced the "Attitudes" domain to 4 key items to reduce potential respondent fatigue. The final measure included 18 items organized into 3 domains: (1) comfort with using mobile applications (n=4), (2) reliability of internet and electricity (n=10), and (3) attitudes toward using computers or mobile applications in clinical practice (n= 4). The full measure can be found in Multimedia Appendix 1.

The survey was completed by 16 radiologists (Table 1). The survey took respondents approximately 5 minutes to complete. Respondents reported high levels of comfort and acceptability toward using mHealth applications in clinical settings. However, they reported a low level of technology infrastructure: 12 (12/16, 75%) reported that their hospital does not use an electronic medical record, and 9 (9/16, 56%) indicated that they are responsible for funding their own internet/Wi-Fi at their clinical practice. Approximately two-thirds (10/16, 63%) indicated that their hospital loses electricity more than once per day; 13 (13/16, 81%) noted that when electricity goes out, internet access is also disabled. In addition, 9 (9/16, 56%) indicated that it can take over 1 month for a malfunctioning device to be repaired at their hospital.

Table 1. Results of the technology comfort and use survey (n=16) in Ile-Ife, Nigeria in 2019.

Questions and Responses	Results, n (%)
Comfort with using mobile applications: "How comfortable are you with using computers or mobile applications for clinical purposes?"	
Very comfortable	8 (50)
Extremely comfortable	8 (50)
Comfort with using mobile applications: "How comfortable are you with using computers or mobile applications for professional educational purposes?"	
Somewhat comfortable	1 (6)
Very comfortable	7 (44)
Extremely comfortable	8 (50)
Utilization of computers or mobile applications in clinical practice: "I have taken an online/e-learning course in the past."	
No	3 (19)
Yes	13 (81)
Utilization of computers or mobile applications in clinical practice: "What is the primary way you communicate clinical information with your colleagues?"	
In-person	1 (6)
Phone call	6 (38)
Multiple forums (including text message, mobile application)	9 (56)
Technology access: Reliability of internet, Wi-Fi, and electricity: "I have reliable access to the internet/Wi-Fi at my hospital."	
Disagree	2 (13)
Neutral	1 (6)
Agree	9 (56)
Strongly agree	3 (19)
Technology access: Reliability of internet, Wi-Fi, and electricity: "Who provides funding for your access to the internet/Wi-Fi for your clinical practice?"	
Self	9 (56)
Hospital	1 (6)

Discussion

This pilot study demonstrates promise for TAUS' applicability and use in LMIC contexts. By including a domain with detailed questions related to technology infrastructure and access, this survey uncovered key concerns for mHealth use, despite high reported levels of technology comfort and acceptance. Although mHealth-based interventions are widely used, it is necessary to evaluate their feasibility and acceptability with TAUS that are tailored to the cultural context of the targeted population. Pilot results indicate that the TAUS is a feasible and appropriate measure for assessing technology usage and acceptability in

LMIC clinical contexts. Dedicating a specific domain to technology infrastructure and access yielded valuable insights for program implementation. For example, administering the TAUS in the context of the current project identified the need for precharged or battery-operated devices, given electricity instability. A limitation of this study is the fact that, while participants completed the measure, they did not provide direct feedback on the measure itself. Future directions include cognitive interviews to assess content validity among the target population.

The findings of this study justify the need to create a flexible TAUS that can be tailored to specific settings. The pilot reveals that the TAUS is a promising measure to support mHealth intervention planning in LMIC contexts. Future directions include larger-scale trials to support validation of the TAUS measure.

Acknowledgments

This work was partially supported by the National Institutes of Health/National Cancer Institute (R21 CA239784 and the Cancer Center Support Grant P30 CA008748). The authors wish to thank Joanne Chin, MFA, ELS, for her support on manuscript development. We would also like the thank the Obafemi Awolowo University Teaching Hospital student research assistants for their support in survey data collection.

Authors' Contributions

All authors contributed to the study conception and design. KAL, TMA, ADO, and ES contributed to the development of the methodology. KAL, ADO, and ES contributed to the acquisition of the data. All authors contributed to the analysis and interpretation of data. All authors contributed to the writing, review, and revision of the manuscript. ADO contributed to the administrative, technical, or material support. ES, TPK, and OIA contributed to the study supervision. All authors read and approved the final manuscript. All authors agree to be accountable for all aspects of the work in ensuring that questions related to the accuracy or integrity of any part of the work are appropriately investigated and resolved.

Conflicts of Interest

EAM reports funding from Grail Inc for breast cancer research not related to the present work. The remaining authors have no conflicts of interest to disclose.

Abstract

Background: Smoking cessation is an essential part of preventing and reducing the risk of smoking-associated morbidity and mortality. However, there is often little time to discuss smoking cessation in primary care. Decision aids (DAs) designed for clinic visits (encounter DAs) need to be clear, short, and concise to optimize therapeutic education, increase interaction, and improve the therapeutic alliance. Such a DA for smoking cessation could potentially improve counseling and increase the use of pharmacological treatments.

Objective: We aimed to collect feedback on an electronic encounter DA that facilitates physician-patient interaction and shared decision-making for smoking cessation in primary care.

Methods: We developed an electronic, encounter DA (howtoquit.ch) from a paper version created by our team in 2017 following user-centered design principles. The DA is a 1-page interactive website presenting and comparing medications for tobacco cessation and electronic cigarettes. Each smoking cessation medication has a drop down menu that presents additional information, a video demonstration, and prescribing information for physicians. To test the DA, we submitted a questionnaire to approximately 20 general practitioner residents of an academic general medicine department, 5 general practitioners, and 6 experts in the field of smoking cessation. The questionnaire consisted of 4 multiple-choice and 2 free-text questions assessing the usability or acceptability of the DA, the acquisition of new knowledge for practitioners, the perceived utility in supporting shared decision-making, perceived strengths and weaknesses, and whether the participants would recommend the tool to other clinicians.

Results: In all, 6 residents, 3 general practitioners in private practice, and 2 tobacco cessation experts completed the questionnaire (N=11), with 4 additional experts providing open-text feedback. On the 11 questionnaires, the DA was rated as practical and intuitive (mean 4.6/5), and providers felt it supported shared decision-making (mean 4.4/5), as comparisons were readily possible. Inclusion of explanatory videos was seen as a bonus. Several changes were suggested, like grouping together similar medications and adding a landing page to briefly explain the site. Changes were implemented according to end-user comments.

Conclusions: The overall assessment of the encounter DA by a group of physicians and experts was positive. The ultimate objective is to have the tool deployed and easily accessible for all to use.

decision aid; smoking cessation; electronic tool; shared decision-making

Introduction

Smoking is the leading cause of avoidable, premature death worldwide, with over 8 million deaths per year [1], including 9500 in Switzerland [2]. This excess mortality is explained by increases in cardiovascular and pulmonary diseases and of different types of cancer, including lung cancer (of which 90% is attributable to smoking) [3]. Currently, 30% of men and 21% of women regularly or occasionally smoke in Switzerland, and 18% of the population smokes daily [3]. After many years of decreases, these figures have stagnated over the last decade. Smoking cessation progressively and sustainably reduces the risk of death and the development of smoking-related diseases [4]. Patients wish to discuss smoking during consultations, and more than half of them want counseling about smoking cessation [5].

Primary care physicians play an essential role in promoting tobacco control and smoking cessation. Current international recommendations propose that physicians use every opportunity to discuss smoking during consultations to assess patients' level of addiction, knowledge, and motivation to stop smoking; to support an eventual quit attempt; and to provide an efficient follow-up [6].

Different pharmacological treatments for smoking cessation are available, including nicotine replacement therapy in the form of bupropion (a dopamine, noradrenaline reuptake inhibitor) and varenicline (a nicotinic cholinergic receptor partial agonist). These treatments, when accompanied by medical follow-up, are associated with quit rates as high as 30% [7] as opposed to rates of 3% to 6% when no aid is provided. Electronic cigarettes (e-cigarettes) are emerging as alternative nicotine delivery devices, are very popular, and seem to be effective aids for smoking cessation [8]. However, long-term data about their safety and efficacy remain limited. Treatments should be prescribed in parallel with intensive follow-up during quit attempts, as repeated consultations have been shown to increase the success of quit attempts [9]. Indeed, the combination of behavioral therapy and pharmacotherapy has demonstrated better results than has either separately [10]. Other nonpharmacological interventions such as hypnotherapy, acupuncture, or mindfulness meditation have less strong evidence of efficacy [11-13].

These different therapeutic alternatives differ by their dosing, mechanisms of action, adverse effects, contraindications, costs, and insurance reimbursement. Giving clear, concise, and appropriate information can be challenging within the time constraints of a consultation. However, guiding patients toward smoking cessation and in the choice of and adherence to a treatment is crucial.

An increasing amount of evidence shows that the relationship between the physician and the patient, often referred to as the therapeutic alliance, plays an important role in treatment adherence and outcomes. Sharing information during shared decision-making can strengthen the physician-patient relationship, involve the patient in the decision-making process, and thus empower the patient to engage in the treatment schedule and adherence. Shared decision-making is described as a 3-step process [14], in which the health care provider formulates the existence of multiple alternatives, describes these options, and finally supports the patient in the assessment of the risks and benefits while exploring their values and preferences. Establishing and strengthening the therapeutic alliance is thereby essential to increasing the number of quit attempts and smoking cessation rates.

Decision aids (DAs) facilitate shared decision-making; they can improve patient knowledge and risk perception while helping to create consistency between the patient's choices and values [15]. These tools come in different forms: pamphlets, brochures, audiovisual material, web-based apps, or websites. DAs can be employed during consultations (encounter DAs) or can be designed to be used before, after, or independently of clinical encounters [16]. They optimize therapeutic education by increasing interaction [15] and by allowing the patient to be more active in the decisional process [16]. Several DAs have been developed to aid with tobacco cessation, most often as paper or website-based documentation. Their efficacy is supported by a recent systematic review by Moyo et al [17] that analyzed 7 studies evaluating smoking cessation DAs. The systematic review showed a tendency toward an increase in the smoking cessation knowledge, decisional quality, and the number of quit attempts.

A DA was developed in 2017 by our study group [18] through use of an illustrated chart condensing the different methods of delivery, dosing, daily price, efficacy, and principal adverse effects of smoking cessation treatments.

Given the growing evidence about the efficacy of DAs [17] and their impact on the success rate of smoking cessation, this aforementioned tool was reproduced and adapted in an electronic form. In this paper, we aimed to document the characteristics of this new DA and provide results of formative user testing during consultations by general practitioners and experts in the field. The information collected during the testing could lead to changes and improvements to this DA.

Methods

Design and Setting of the Study

Herein, we describe the formative testing of a novel DA, exploring the acceptability of the electronic, encounter DA to assess its design, usage, content, and perceived changes in consultation. A formative test is conceived to assess if a product meets users' needs and to identify potential usability issues [19]. Our assessment was conducted in an urban, academic, primary care practice with approximately 40 residents in Lausanne, Switzerland.

Ethical Considerations

Ethics approval was not required as no information was collected from patients and the study is considered quality improvement by local definitions [20].

Description of the DA

The DA used in this study is based on the one developed in 2017 using a user-centered design [21], which is a methodology centered on the user that gathers information about the utilization and progressively adapts the tool in order to optimize usage. Six general practitioners used iterative versions of the model in consultation over several months and helped define which items and criteria seemed to matter most to patients. Price and insurance reimbursement were considered more important than was the possible effect of medications on weight gain. The tool was inspired by Elwyn's model of shared decision-making [22].

The original paper-based DA was a 1-page table containing essential information to compare available treatments for smoking cessation (Multimedia Appendix 1). Patients and providers identified several inherent limitations of this DA that could not be addressed in its paper format: notably, the small size of the pictures showing each medication, a difficulty in understanding the differences between nicotine replacement therapies, a lack of information about e-cigarettes (vapes), and a lack of prescribing information for physicians.

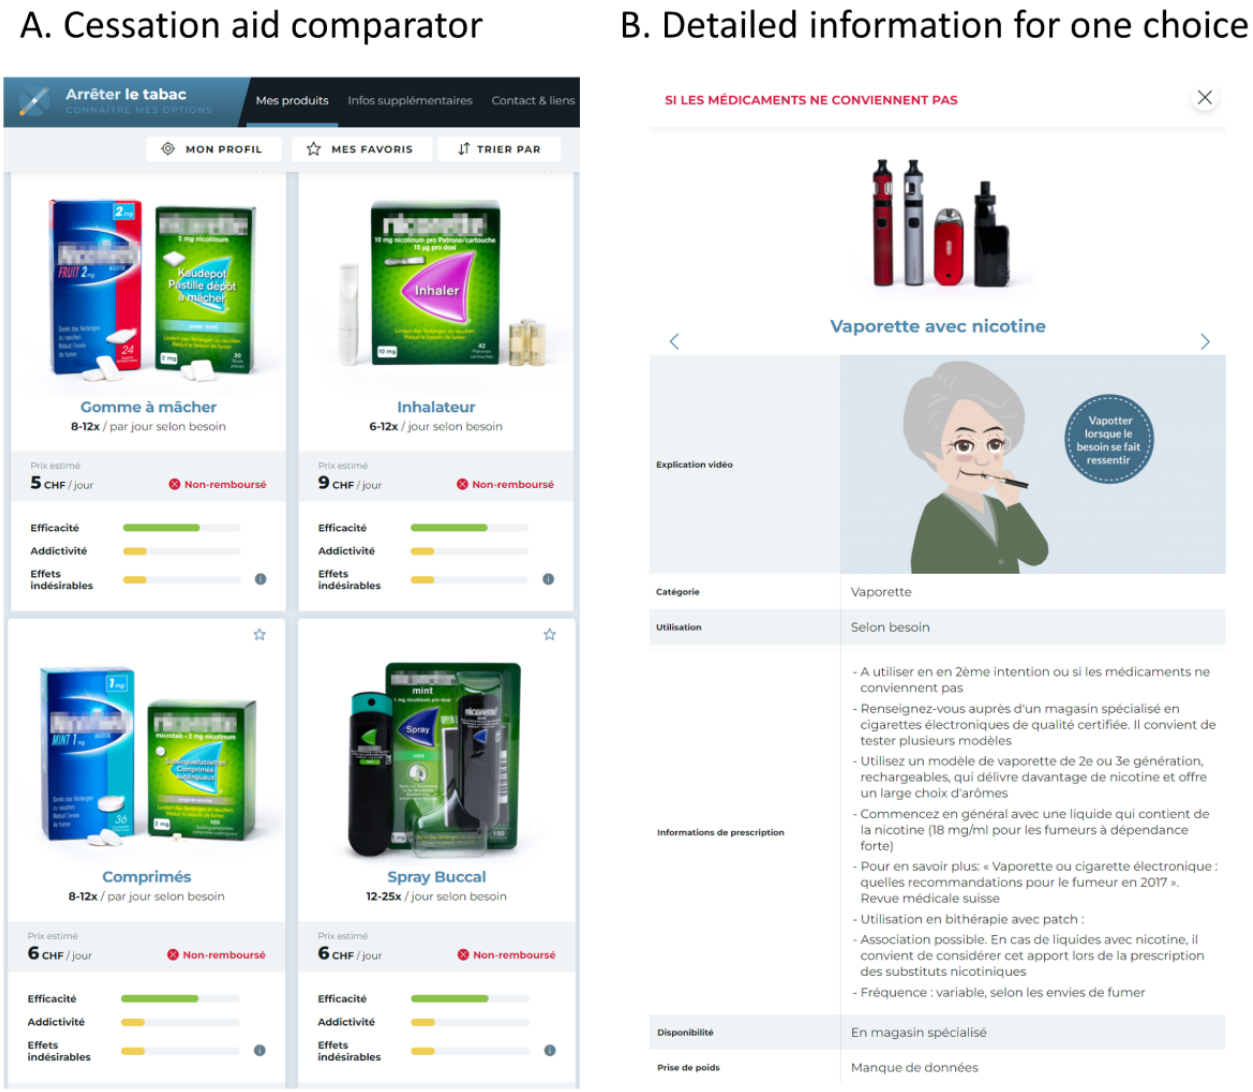
The new electronic form described in this study contained the same information, including the form of delivery, price per day, main adverse effects, contraindications, and visual analog rating scales that compared the efficacy, addiction potential, and adverse effects of each agent. Comparisons between the treatments were based on data from systematic reviews for efficacy [7] and weight gain [23], on expert opinion for addictiveness, and on published drug information for adverse effects. Finally, short, animated video clips were incorporated, offering animated explanations on the delivery method and tips for use. The new DA also integrated information about e-cigarettes, noting that they are only recommended when medications are not effective and underlining their addictive potential. An image presented examples of vape pens, a box mod (tank system), and a pod mod. Comparisons between e-cigarettes and medications were based on expert opinion.

This DA was designed for use during consultations, making it an encounter DA or a conversation aid. Encounter DAs encourage and directly support patient-clinician conversations when making decisions together [24]. In our opinion, smoking cessation consultations focused on a quit attempt should include an assessment of the patient's level of addiction that presents the therapeutic alternatives to stop smoking and value clarification. By facilitating the comparison between medications and e-cigarettes, the DA offers implicit value clarification, which can be further explored with the clinician during the consultation. Nonpharmacological treatment alternatives were not included in this DA although the DA should be used in parallel to behavioral counseling during multiple consultations. The combination of behavioral and pharmacological treatments is most effective. We felt that given the limited evidence to support hypnotherapy, acupuncture, and exercise, these should not be included as first-line therapies.

A tool calculating the level of addiction was integrated into the DA, based on the 2 questions from the Heaviness of Smoking Index. Furthermore, a means for patients to specify if they are pregnant or lactating was included. This information is used to create an automatic contraindication alert located above the treatments, written in red, and specifying if the treatment is a contraindication or if it is to be used with precaution. The user has to choose to click on this tool on the left side of the web page to open it.

An illustrative image of the decision aid can be seen in Figure 1.

Figure 1. Illustrative screenshots of the decision aid taken on howtoquit.ch. (A) Three of nine available smoking cessation aids in the comparator. (B) Detailed information about one option (electronic cigarettes).



Population

The population enrolled consisted of potential general practitioner and tobacco cessation specialist end users. A convenience sample of approximately 20 residents from the General Practice of Unisanté (academic service for general medicine) both familiar and unfamiliar with smoking cessation practices were asked to provide feedback after using the DA in consultation at least once with their patients. Participating physicians were free to choose the patients with whom they would use the DA. Physicians used the DA during specialized tobacco consultations or during primary care consultations. Subsequently, 5 selected general practitioners in a private practice were sent an email that explained the study, invited them to familiarize themselves with the DA and, in case of interest, gave them the opportunity to try the tool and give feedback. Finally, the questionnaire was submitted to 6 smoking cessation specialists affiliated with our institution. The expert group included general practitioners, psychologists, and psychiatrists specialized in tobacco cessation or shared decision-making. Two experts in clinical practice were asked to test the DA with their patients and complete the questionnaire.

Questionnaire

The participants were invited to fill out an online questionnaire. The questionnaire was developed locally and included 4 quantitative and 5 qualitative questions. The quantitative questions assessed the usability or acceptability of the electronic encounter DA, the acquisition of new knowledge for practitioners, the perceived utility in supporting shared decision-making, and whether the participant would recommend the tool to other clinicians. The answers were based on a 5-point Likert-scale (1=strongly disagree, 2=disagree, 3=neutral, 4=agree, 5=strongly agree). We also inquired about the participants' level of medical training, age, and gender. Two open-text questions asked about the strengths and weaknesses of the DA, and requested recommendations for improvements.

Analysis

The answers to the quantitative questions based on the 5-point Likert-scale measured the responders level of agreement to the different questions. These results were assembled, and the mean values and SDs were calculated. The open-text questions allowed us to collect information about the enrolled physicians. The questions exploring the weaknesses and strengths of the

DA and subsequent recommendations for improvement were considered one by one. They were sorted by categories to allow for better visibility and to help identify recurrences. This brought us to consider the possible changes to the DA.

Results

We collected the questionnaires described above from 6 residents and 3 general practitioners in private practice who tested the DA. A further 6 smoking cessation experts gave qualitative feedback, 2 of whom also responded to the questionnaire after testing the DA with patients during a consultation. Of the 11 people who completed the questionnaire, 55% (n=6) were women, and all had obtained their medical diploma between 1983 and 2018.

The various groups who provided feedback on the DA and their characteristics are listed in Table 1.

The responders found the electronic interface practical and intuitive, with a mean rating of 4.6 on the 5-point Likert-scale (Table 2). They felt the DA helped improve their knowledge (mean rating 4.4/5). They perceived the tool as facilitating their patients' decision-making process (mean rating 4.4/5). Finally, globally the physicians strongly agreed that they would recommend the tool to a colleague (mean rating 4.8/5).

The open-text feedback was generally related to content and interface. Content was described as sufficient and relevant. Smoking cessation experts gave advice suggesting to provide more detailed information for e-cigarettes, particularly regarding the fact that e-cigarettes are not considered to be a medication, and that the first-line treatment recommendation include the other presented alternatives only.

Users found the interface to be clear, intuitive, and easy to use. Advice for improvements consisted of making information more noticeable and easier to find. For example, some physicians recommended separating the different types of treatments in groups to facilitate their introduction during the consultation. In the experts' opinion, the automatic contraindication alert based on the users' characteristics should be completed with inclusion of other comorbidities and users should be required to answer the questions regarding their level of addiction with a pop-up to draw attention to it. Some physicians recommended separating the different types of treatments in groups to facilitate their introduction. A landing page was suggested as a means of engaging users at their moment of arrival on the website and to provide preliminary information about the tool.

Based on qualitative feedback, the research team ultimately changed the DA in order to improve its content and usability (Table 3).

Table 1. Description of user groups providing feedback and their responses.

Group	Participants, n	Type of feedback	Description
General internal medicine residents	6	Quantitative and qualitative	Residents provided feedback after using the DA[a] in consultation
General practitioners	3	Quantitative and qualitative	GPs[b] provided feedback after using the DA in consultation
Smoking cessation experts	6 (2 completed questionnaire, 4 open-text responses)	Qualitative	Local experts provided feedback after exploring the DA

[a]DA: decision aid.

[b]GP: general practitioner.

Table 2. Overview of quantitative feedback (N=11).

Questions	1=strongly disagree, n	2=disagree, n	3=neutral, n	4=agree, n	5=strongly agree, n	Mean (SD)
1. Interface is practical and intuitive	0	0	0	4	7	4.6 (0.52)
2. DA[a] helped me improve my knowledge	0	0	1	5	5	4.4 (0.68)
3. DA enhanced patient's decision-making process	0	0	0	6	5	4.4 (0.52)
4. I would recommend this DA to my colleagues	0	0	0	2	9	4.8 (0.42)

[a]DA: decision aid.

Table 3. Changes made to the DA in response to feedback.

Categories of changes to the DA[a]	Users' comments from open text	Description of changes
Landing page as an entry pop-up	"It was difficult to understand quickly the objective of the website."	A landing page was added explaining the tool's objective and advising use with a medical practitioner.
Level of addiction calculator	"Addiction level score isn't noticeable enough. A popup would be better to draw attention on it."	A pop-up exploring the level of addiction and patients' specifications (current pregnancy or lactation) was added.
Item layout	"1.It would be simpler to cluster treatments according to their type. 2. It would be better to separate NRT[b]/varenicline/bupropion/e-cigarette[c]."	Order of the different therapies was adjusted according to a logical setting: short-acting nicotine replacement/long-acting nicotine replacement/combined short and long-acting nicotine replacement/oral medication (bupropion, vernicline)/e-cigarette.
Additions to the content	"E-cigarette: specify that it isn't a medical treatment and is not recommended as first line treatment."	Content was upgraded with more detailed information.
Documentation for practitioners	"Would be helpful to better integrate other electronic resources."	A link was added containing documentation on management of smoking cessation.
Documentation for patients	Should interact with other official websites for smoking cessation in Switzerland	Useful links to official websites giving information, resources, and support for smoking cessation, as well as a local smoking cessation hotline number, were added.
"About us" tab	"It is unclear who made the site and whether they can be trusted"	A tab was added describing the Unisanté tobacco cessation unit, smoking cessation consultation with contact details, and information on project funding and the ongoing randomized trial [25].

[a]DA: decision aid.

[b]NRT: nicotine replacement therapy.

[c]e-cigarette: electronic cigarette.

Discussion

This paper describes the preliminary user testing and subsequent improvements made to a newly created electronic DA to facilitate decision-making between different types of smoking cessation treatments. Overall, the physician end users found the content to be clear, concise, and useful, and the interface to be practical and intuitive. Based on the self-reported answers to the questionnaire and thus, according to the physicians' perspective, the tool helped improve users' knowledge about smoking cessation treatments and assisted patients' decision-making process.

The development of this new DA was based on user-centered design, an approach originally used to develop products and services [26,27] and used in the health field to create DAs [28]. Hence, a first DA prototype was created based on the content of our first paper-based DA developed in 2017. The user tests allowed us to gather information and comments on this DA. This led to a greater knowledge of users' needs, as well as the strengths and limitations of the DA. Ultimately, the user feedback identified inherent limitations of the paper format, leading to the elaboration of an electronic format.

The current DA, for use during medical encounters, is not a classic, stand-alone DA with content about disease processes and values clarification. Traditional DA development should follow guidelines from the International Patient Decision Aid Standards (IPDAS) Collaboration, whose extensive criteria allow a standardized assessment of quality in terms of content development and effectiveness [25,29]. Instead, encounter DAs like ours need to be short and intuitive while fitting patient-provider interactions in order to encourage its adoption, as this is dependent on its perceived usability and usefulness by physicians. In this respect, this study chose to specifically focus on the physicians as the DA's end users and testers.

A few existing DAs for smoking cessation have been developed and are mentioned in the literature. Their formats are diverse, but there is a trend toward implementing computerized DAs. Like ours, some of them collect information on patients' smoking behaviors to provide personalized information and contain written and multimedia-based information [30,31]. One recent study evaluated an app-based DA (iPad app) including, like our DA, information about e-cigarettes, explaining its risks and benefits. This DA was used prior to the clinical encounter. The study showed a higher rate of clinical discussions about smoking cessation, overall patient satisfaction, and acceptability about giving information about e-cigarettes among smokers [32].

Willemsen et al [33] developed a multicomponent DA containing several materials, such as an informative booklet with information on smoking cessation treatments, videos, and samples of some pharmacological treatments. Informative websites exist as well, providing information on smoking cessation treatments and resources functioning as DAs [34]. Most of these DAs are designed to prepare patients for a future clinical encounter. To our knowledge, there are no existing DAs for use during consultations (encounter DAs) that can provide structure, guide information transmission, and promote interactivity and shared decision-making between the practitioner and the patient.

One of the upgrades made to the DA was the inclusion of online material to inform physicians and patients about other existing smoking cessation resources in Switzerland. This includes a reference document with the local epidemiology and recommendations on smoking cessation counseling and treatments (6), web links to the specialized tobacco cessation consultation in Unisanté [35], and 2 official Swiss websites [36] offering information and support to help patients willing to stop smoking. These resources, integrated into the DA, can inform physicians of local resources. It can be easily adapted to other countries and their tobacco-control programs.

After completion of testing and upgrading, the DA has become a new tool for use during a consultation (encounter DA), allowing for better information sharing and ultimately guiding patients into a high-quality decision-making process. Some providers told us of patients' reactions, but patients were not asked to assess the DA directly.

The strengths of this study include the following: the electronic DA builds on previous experience with a similarly organized paper DA that was tested with patients, responses were collected from target users (clinicians), and feedback was collected at a stage when substantial changes could still be made to the DA.

There are also several limitations. First, the small sample size might not have provided perspectives from all types of physician users and might have reduced the number of suggestions of other upgrades. However, in the field of usability testing, it is common to have only a few testers as end users, based on the 5-user assumption [37] where a small number of testers can identify the most usability issues although this concept is debated [38]. In our case, the DA content was mostly developed by one of the final end users (medical doctors), tested by physicians during consultations, and reviewed by experts; thus, most of the critical content and usability issues should have been identified. A selection bias is probably present, given that a significant part of the enrolled physicians (general internal medicine residents) worked in our institution. Thus, a more solid assessment would probably have been obtained with a more diversified physician enrollment. Second, we collected the perspectives of general practitioners as end users but not those of patients. Although general practitioners were likely influenced by patient reactions, we are unable to report patient satisfaction with the DA, usability issues from the patients' perspective, or whether patients felt the DA aided with shared decision-making. However, our DA was designed to be used during a consultation as an encounter DA to help physicians present and describe various treatment alternatives for smoking cessation. In this way, we considered the general practitioners as the end users and the ones most likely to influence uptake of the DA. This study was not designed to evaluate the DA's effectiveness in terms of number of quit attempts, smoking cessations, or its impact on consultation duration. A clinical trial integrating use of the DA is underway [39]. Finally, we are currently implementing the DA in a study setting where we train general practitioners to use the DA in parallel with intensive counseling; in the future we should clarify for all users that pharmacological treatments and behavioral counseling should be used in parallel.

A new, electronic, encounter DA was generally well received and appreciated by physicians. With their feedback, we were able to implement useful upgrades. This tool will hopefully improve patients' knowledge and enhance their decision-making regarding smoking cessation. Future objectives include a clinical trial incorporating the DA and making it accessible to all health care providers.

Acknowledgments

We would like to thank Alan Vonlanthen and Julien Thabard from the Unisanté informatics unit for their work creating this decision aid.

Funding was provided by the Swiss Tobacco Prevention Fund (reference #240.00005-22/5437326).

Conflicts of Interest

MAD has developed Option Grid patient decision aids, which are licensed to EBSCO Health, and has received consulting income from EBSCO Health and royalties. KS receives salary support from the Leenaards Foundation. The other authors have no conflicts of interest to declare.

Abstract

Background: Physical activity (PA) is known to improve quality of life (QoL) as well as reduce mortality and disease progression in individuals with chronic neurological disorders. However, Latina women are less likely to participate in recommended levels of PA due to common socioeconomic barriers, including limited resources and access to exercise programs. Therefore, we developed a community-based intervention with activity monitoring and behavioral coaching to target these barriers and facilitate sustained participation in an exercise program promoting PA.

Objective: The aim of this study was to determine the feasibility and efficacy of a community-based intervention to promote PA through self-monitoring via a Fitbit and behavioral coaching among Latina participants with chronic neurological disorders.

Methods: We conducted a proof-of-concept study among 21 Spanish-speaking Latina participants recruited from the Los Angeles County and University of Southern California (LAC+USC) neurology clinic; participants enrolled in the 16-week intervention at The Wellness Center at The Historic General Hospital in Los Angeles. Demographic data were assessed at baseline. Feasibility was defined by participant attrition and Fitbit adherence. PA promotion was determined by examining change in time spent performing moderate-to-vigorous PA (MVPA) over the 16-week period. The effect of behavioral coaching was assessed by quantifying the difference in MVPA on days when coaching occurred versus on days without coaching. Change in psychometric measures (baseline vs postintervention) and medical center visits (16 weeks preintervention vs during the intervention) were also examined.

Results: Participants were of low socioeconomic status and acculturation. A total of 19 out of 21 (90%) participants completed the study (attrition 10%), with high Fitbit wear adherence (mean 90.31%, SD 10.12%). Time performing MVPA gradually increased by a mean of 0.16 (SD 0.23) minutes per day (P<.001), which was equivalent to an increase of approximately 18 minutes in MVPA over the course of the 16-week study period. Behavioral coaching enhanced intervention effectiveness as evidenced by a higher time spent on MVPA on days when coaching occurred via phone (37 min/day, P=.02) and in person (45.5 min/day, P=.01) relative to days without coaching (24 min/day). Participants improved their illness perception (effect size g=0.30) and self-rated QoL (effect size g=0.32). Additionally, a reduction in the number of medical center visits was observed (effect size r=0.44), and this reduction was associated with a positive change in step count during the study period (P.=04).

Conclusions: Self-monitoring with behavioral coaching is a feasible community-based intervention for PA promotion among Latina women of low socioeconomic status with chronic neurological conditions. PA is known to be important for brain health in neurological conditions but remains relatively unexplored in minority populations.

Trial Registration: ClinicalTrials.gov NCT04820153; https://clinicaltrials.gov/ct2/show/NCT04820153

KEYWORDS

exercise; quality of life; motivation; promotion; community study; clinical trial

Introduction

In the last decade, studies have established the vital role of physical activity (PA), particularly sustained moderate-to-vigorous PA (MVPA), in chronic neurological disorders due to its ability to improve neurological outcomes, quality of life (QoL), and reduce disease progression [1-5]. Currently, the generalizability of these findings to US minority populations and different socioeconomic status groups in the United States is unclear given the fact that the vast majority of clinical research has been predominantly conducted on White males with affordable access to medical care.

Studies examining individuals who are regularly engaged in exercise in the United States have indicated that lack of PA is prevalent in Latinx groups compared to other ethnic groups [6]. In terms of sex, a high percentage (74%) of Latina women do not participate in exercise activities, and this number increases with age [7,8]. While there are numerous reasons for this occurrence, a substantial contributor includes the lack of resources and accessibility to programs that promote PA and exercise [9]. Therefore, it is paramount that clinical studies focus on development of accessible interventions that are capable of increasing PA in underrepresented communities and ethnic groups. One potential approach includes the implementation of a community-based intervention consisting of activity monitoring by personal activity monitors, such as wrist-worn Fitbit devices, with behavioral coaching. Numerous studies have demonstrated that this approach is impactful and successfully promotes PA among healthy individuals as well as those with medical conditions, including obesity, diabetes, and neurological disorders [10-12]. It is yet to be established whether specific motivational strategies can demonstrate efficacy in a Latina population among individuals with chronic neurological conditions.

The purpose of this proof-of-concept study was to examine the feasibility and efficacy of a community-based wellness center intervention to promote PA in a Latina population with chronic neurological disorders.

Methods

Ethical Considerations

The University of Southern California Institutional Review Board (IRB) approved all study procedures (IRB No. HS-18-00993). The funder did not require registration; however, the trial was retrospectively registered at ClinicalTrials.gov (NCT04820153) for publication. The authors confirm that any related clinical trials have been registered. All study participants provided written informed consent.

Study Participants

The target sample size for this proof-of-concept study was 20 participants, as this is similar to sample sizes used in previous preliminary Fitbit wear studies [11,13]. Inclusion criteria included the following: (1) diagnosed with a neurological disorder, (2) able to use the Fitbit activity monitor as determined by participant self-report after receiving instructions from a study coordinator, (3) own a smartphone device, (4) ambulatory without assistance, (5) able to provide informed consent, (6) live within commuting distance to The Wellness Center (TWC) at The Historic General Hospital in Los Angeles, (7) Spanish speaking, and (8) have internet access. Exclusion criteria included any physical condition that precluded engagement in exercise or PA.

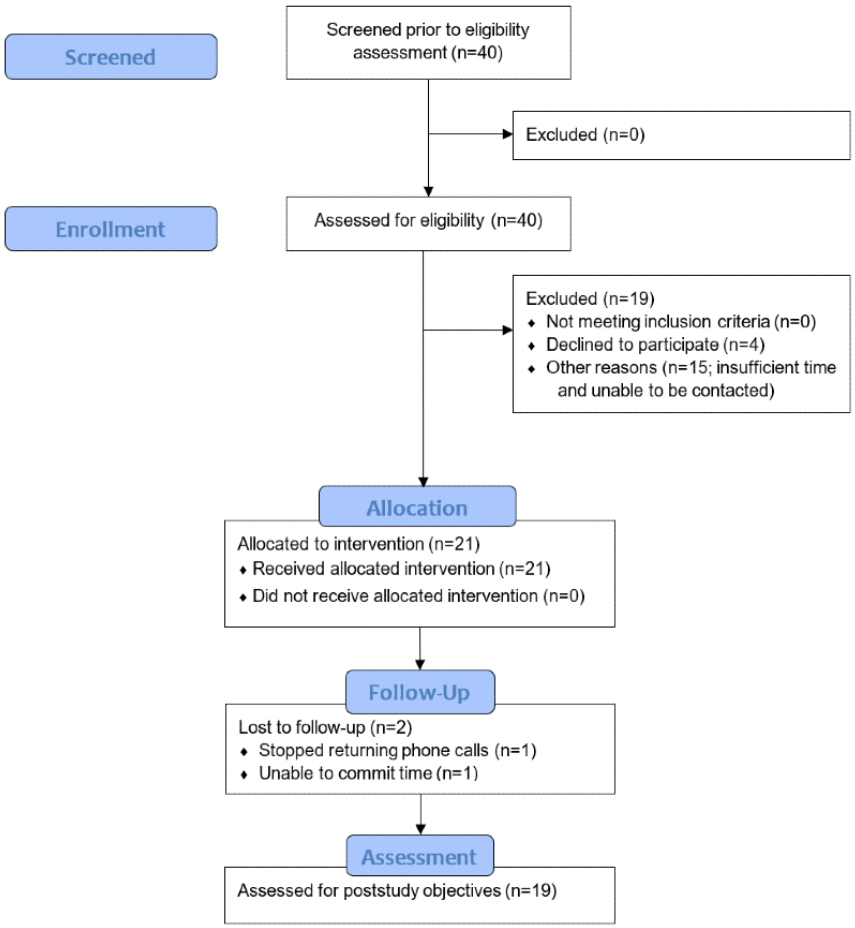
Study Design

Recruitment and Community Site

Candidate Latina participants living in Central and East Los Angeles were identified by bilingual attending neurologists in the Department of Neurology; candidates were identified in the clinic at the Los Angeles County and University of Southern California (LAC+USC) Medical Center. The LAC+USC neurology clinic primarily serves a Latinx population of low socioeconomic status who have a wide spectrum of neurological conditions, including epilepsy, chronic headache, migraine, stroke, Parkinson disease, and multiple sclerosis. A total of 21 individuals consented to participate in the study (Figure 1); these participants enrolled in the study at TWC, a community center located within the Boyle Heights community of East Los

Angeles that offers free health and wellness classes and programs. TWC was founded in 2014 and provides a wide range of services to patients, caregivers, and their families.

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram.



Community-Based PA Intervention

The study consisted of a 16-week community-based intervention aimed at promoting PA through behavioral coaching and self-monitoring via a Fitbit Alta HR activity device (Fitbit, Inc). Intervention length was based on the success of similar PA promotion studies using Fitbit devices among healthy individuals and those with various medical disorders [11,12]. Upon enrollment, individuals received Fitbit personal activity monitors and were instructed on their usage and maintenance. Participants were notified at the commencement of the study that they would be allowed to keep their Fitbit activity monitor upon study completion.

Fitbit Personal Activity Monitors

Individuals were provided with the Fitbit device and charger and were asked to wear the Fitbit device every day during the 16-week study except when bathing or swimming. Individuals had the Fitbit app program set up on their smartphones, thus allowing for continuous self-monitoring of PA by the Fitbit device and longitudinal monitoring to collect data by the Fitbit app throughout the 16-week study period. Participants' Fitbit wear compliance was encouraged by a once-a-week behavioral coaching phone call. Monitored PA data from the Fitbit were downloaded weekly.

Behavioral Coaching

Navigators at TWC are Latina women who come from Central and East Los Angeles communities. Their role at the TWC is to perform outreach, perform health coaching, and guide members to health resources. Within the study, navigators provided assistance by motivating participants and providing support for any technological issues. Behavioral coaching consisted of the following: (1) 1 hour of Lifestyle Redesign at baseline and at week 4 with an occupational therapist of Latino background located at TWC and (2) weekly contacts of 5 to 10 minutes in length from TWC navigators by telephone. Lifestyle Redesign is a well-established program for promoting behavioral modification including PA by addressing physical, psychosocial, and environmental barriers to health. It incorporates self-care strategies and goal setting and has been validated in Latinx populations [14]. For this intervention, goal setting centered on supporting increased PA for each participant. This was accomplished by asking participants at baseline what activities they wanted to do to increase PA in their lives and by subsequently collaborating on plans to incorporate these activities into their daily lives. The weekly contacts from navigators occurred either in person or via phone and focused on promotion of PA, Fitbit wear, and goal review.

Study Participant Characteristics

Sociodemographics

Sociodemographic information included age, sex, primary language, highest education level achieved, health perception, neurological diagnoses, primary care provider status, insurance status, housing status, and food insecurity. Zip code data were collected and subsequently assessed to infer income category [15]. Specifically, median incomes for participant zip codes were compared to the Los Angeles County (LAC) median income and were categorized as very low income (<50% of LAC median income), low income (50%-80% of LAC median income), or not low income (>80% of LAC median income) per the US Department of Housing and Urban Development recommendations.

Acculturation

Acculturation is defined as the cultural modification of an individual or group by adapting to or borrowing traits from one culture and displacing characteristics, habits, attitudes, and mode of life of another culture. Acculturation was assessed through the Short Acculturation Scale for Hispanics (SASH), a 12-item questionnaire where questions are answered using a 5-point Likert scale. The SASH is used to assess the level to which participants acculturate or adopt the attitudes, values, customs, beliefs, and behaviors of another culture. The scale provides an overall score as well as three subscale scores in language use, media preference, and ethnic and social relations. A higher score indicates higher acculturation with the culture of the United States [16].

Outcomes Measures

Fitbit Data Measures

Objective PA and wear-time data gathered from the Fitbit device were stored, visualized, and aggregated through a commercially available service (Fitabase Inc, Small Steps Labs) using Health Insurance Portability and Accountability Act–compliant deidentified unique participant emails. PA measures included step count and time spent on (1) sedentary activity; (2) light, moderate, and vigorous PA (LMVPA); or (3) MVPA. Activity intensity was quantified via a Fitbit proprietary algorithm based on metabolic equivalents of task. To evaluate compliance to Fitbit device wearing, day wear was calculated as the "total wear minutes" (derived from minutes where Fitbit captured heart rate value) minus the "in-bed minutes" (derived from the Fitbit proprietary sleep detection algorithm). Data for each day were first inspected for technical adherence, defined as having accurate sleep data (ie, in-bed minutes greater than 180 minutes if day wear minutes were greater than 1080 minutes out of the maximum of 1440 minutes per day) and activity data (ie, LMVPA minutes greater than 0 minutes if day wear minutes were greater than 600 minutes [10 hours]). Personal adherence, defined as greater than 10 hours of Fitbit wear per day, was subsequently assessed for days that were technically adherent. Fitbit-recorded PA measures were only analyzed for days with valid technical adherence and personal adherence.

Quality of Life Scale

The Quality of Life Scale (QoLS) was used to assess an individual's view of their health, how well they feel, and how well they were able to complete their usual activities [17]. The QoLS is a 16-item assessment, with items rated on a 7-point Likert scale, measuring five life domains: (1) material and physical well-being; (2) relationships with others; (3) social, community, and civic activities; (4) personal development and fulfillment; and (5) recreation. A higher score is indicative of a higher perceived QoL.

Illness Perception Scale

The Brief Illness Perception Questionnaire (BIPQ) was administered to assess individuals' perceptions of their health and well-being [18]. The BIPQ is a 9-item questionnaire, with questions rated on a 10-point Likert scale. Each question assesses one dimension of illness perception, including cognitive and emotional representation, level of personal and treatment control, and sense of identity and concern. A higher score indicates a more threatening view of a participant's illness.

System Usability Scale

The System Usability Scale was used to ascertain an individual's opinion on the usability of the Fitbit phone app, Fitbit activity monitor, and the combination of the Fitbit device and app [19].

LAC+USC Medical Center Visits

The total number of outpatient and inpatient visits to the LAC+USC Medical Center was determined during the 16-week period prior to study initiation and during the period of the study intervention using electronic medical records. LAC+USC Medical Center visits were monitored to gather insight into participants' overall health behaviors as well as to specifically understand the impact of PA promotion on health care use.

Data Analysis

Analyses were completed using the statistical analysis package R (version 3.6.0; The R Foundation) [20]. The mean and SD of the data were calculated to describe the sociodemographic characteristics, scale outcomes, and Fitbit-recorded PA. Individuals' rates of change in Fitbit-recorded PA measures were quantified by an activity (eg, MVPA) by day regression slope. Promotion of PA was determined by examining whether time spent performing MVPA increased throughout the 16-week intervention period or stayed stationary. To accomplish this, a Kwiatkowski-Phillips-Schmidt-Shin (KPSS) test was performed on the time-series MVPA data. If the KPSS test was significant, indicating that MVPA data were nonstationary, an MVPA by time (day) Pearson correlation was calculated to determine whether time spent performing MVPA significantly increased or decreased throughout the intervention period. A Kruskal-Wallis test was employed to evaluate differences in PA measures on days with varying behavioral coaching contact types (ie, phone, in person, or no contact). When appropriate, the Dunn test was performed to determine the locus of significance [21]. Changes in scale outcomes from baseline to postintervention and medical center visits from baseline to the study period were assessed by paired *t* tests (2-tailed) or Wilcoxon signed-rank tests depending on normality. Hedges *g*

was used to calculate effect size when changes were quantified by paired *t* tests. The *r* statistic—obtained from the formula *r* = *Z* statistic / sqrt(n)—was used with the Wilcoxon signed-rank test. A Pearson correlation assessed the relationships between participant-level rates of change in PA measures and changes in medical center visits. An α level of less than .05 was considered statistically significant.

Results

Participant Characteristics

Key demographics of study individuals are presented in Table 1. A total of 21 Latina participants were enrolled, and 19 (90%) of them completed the study, giving an attrition rate of 10%. The mean age of the sample was 47 years (SD 9.0, range 29-64). Neurological diagnoses included chronic headaches and migraines (n=13, 68%), Parkinson disease (n=2, 11%), multiple sclerosis (n=2, 11%), and trigeminal neuralgia (n=2, 11%). The majority of individuals were considered to be of low socioeconomic status. A total of 76% (13/17) of participants were living in low- or very low–income areas; 63% (12/19) completed less than a high school–level education; 41% (7/17) reported housing insecurities, defined as not having housing or being worried about losing housing; and 53% (9/17) reported food insecurities, defined as being worried about running out of food before having money to buy more. Overall, study participants had low acculturation to United States culture, as evidenced by a mean acculturation score of 1.81 (SD 0.65).

Table 1. Sociodemographic characteristics of the study participants.

Characteristics	Values (N=19)
Age (years), mean (SD, range)	47 (9.0, 29-64)
Sex (female), n (%)	19 (100)
Neurological diagnosis, n (%)	
Chronic headaches and migraines	13 (68)
Parkinson disease	2 (11)
Multiple sclerosis	2 (11)
Trigeminal neuralgia	2 (11)
Primary language, n (%)	
Spanish	18 (95)
English	1 (5)
Self-reported overall health (n=17), n (%)	
Excellent or good	5 (29)
Fair or poor	12 (71)
Socioeconomic status (n=17), n (%)	
Zip code family income category	
Not low income	4 (24)
Low income	10 (59)
Very low income	3 (18)
Highest education level achieved	
≤11th grade	12 (63)
≥12th grade	7 (37)
Housing status (n=17), n (%)	
Have housing	10 (59)
Worried about losing housing or do not have housing	7 (41)
Insurance status	
Public insurance	11 (58)
Other, none, or do not know	8 (42)

No	8 (47)
Acculturation, as measured by the SASH[a], mean (SD)	
Average score	1.81 (0.56)
Language use score	1.52 (0.73)
Media preference score	2.09 (1.10)
Ethnic and social relations score	1.96 (0.53)

[a]SASH: Short Acculturation Scale for Hispanics. Total average and subscale scores range from 1 to 5. Higher scores indicate higher acculturation.

Intervention Adherence and Safety

A total of 19 out of 21 (90%) participants completed the intervention study, while 2 (10%) participants were lost to follow-up. No adverse events were reported by participants. A mean of 93.6% (SD 9.5%) of days during the intervention period had valid technical adherence. There was also high personal adherence, as the average participant wore their Fitbit for 10 hours or greater on a mean of 90.31% (SD 10.12%) of days throughout the 16-week trial (mean 5.95, SD 1.02 days/week). Further, while the recommended day wear time was 10 hours, the average participant wore their Fitbit for a mean of 15.44 (SD 1.06) day waking hours. Participants rated the usability of the Fitbit device and app as good (score 71.4) to excellent (score 85.5) [22], potentially reflecting the high adherence (Table 2).

Table 2. Fitbit wear adherence, physical activity, and system usability feedback.

Measure	Mean (SD)
Adherence	
Technical adherence (% days)	93.6 (9.50)
Personal adherence (% days)	90.31 (10.12)
Valid personal adherence days per week	5.95 (1.02)
Wear minutes per day waking hour	926.61 (63.27)
Physical activity per day	
Number of steps	9859.99 (2616.22)
Sedentary minutes	583.51 (80.15)
LMVPA[a] minutes	336.84 (80.09)
MVPA[b] minutes	36.63 (18.26)
Individual rate of change per day	
Number of steps	–0.91 (27.69)
Sedentary minutes	–0.07 (0.62)
LMVPA minutes	0 (0.71)
MVPA minutes	0.16 (0.23)
System Usability Scale[c] feedback (%)	
Fitbit device	76.3 (7.4)
Fitbit app	78.4 (8.0)
Fitbit device and app combined	82.9 (10.5)

[a]LMVPA: light, moderate, and vigorous physical activity.

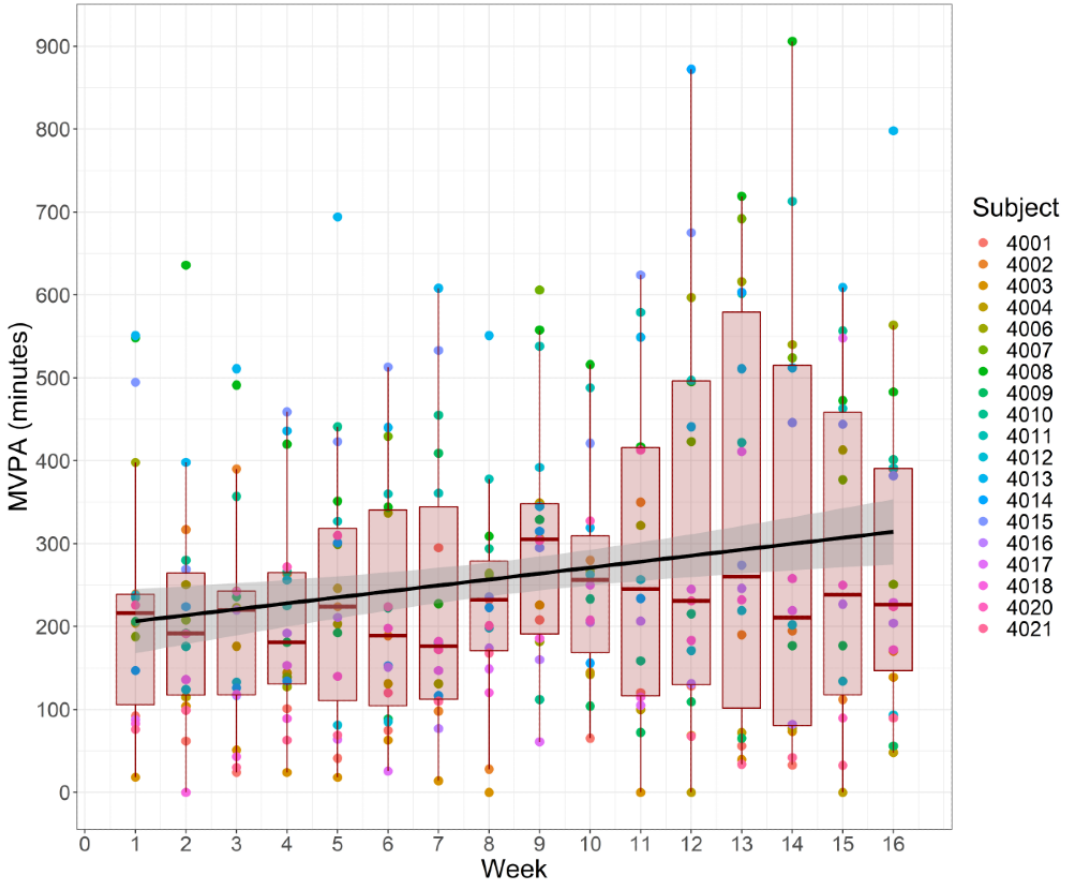
[b]MVPA: moderate-to-vigorous physical activity.

[c]Higher percentages of feedback for the System Usability Scale indicate higher usability.

Promotion of Physical Activity

The average participant increased their time spent performing MVPA by a mean of 0.16 (SD 0.23) minutes per day over the 16-week study period, which was equivalent to a cumulative increase of approximately 18 minutes. PA was promoted as indicated by a significant KPSS test (P=.01 and subsequent significant positive Pearson correlation [r=0.457, 95% CI 0.297-0.592]; P<.001) detailing that time spent performing MVPA increased throughout the 16-week study period (Figure 2). No changes were observed during the intervention period for other PA measures (Table 2).

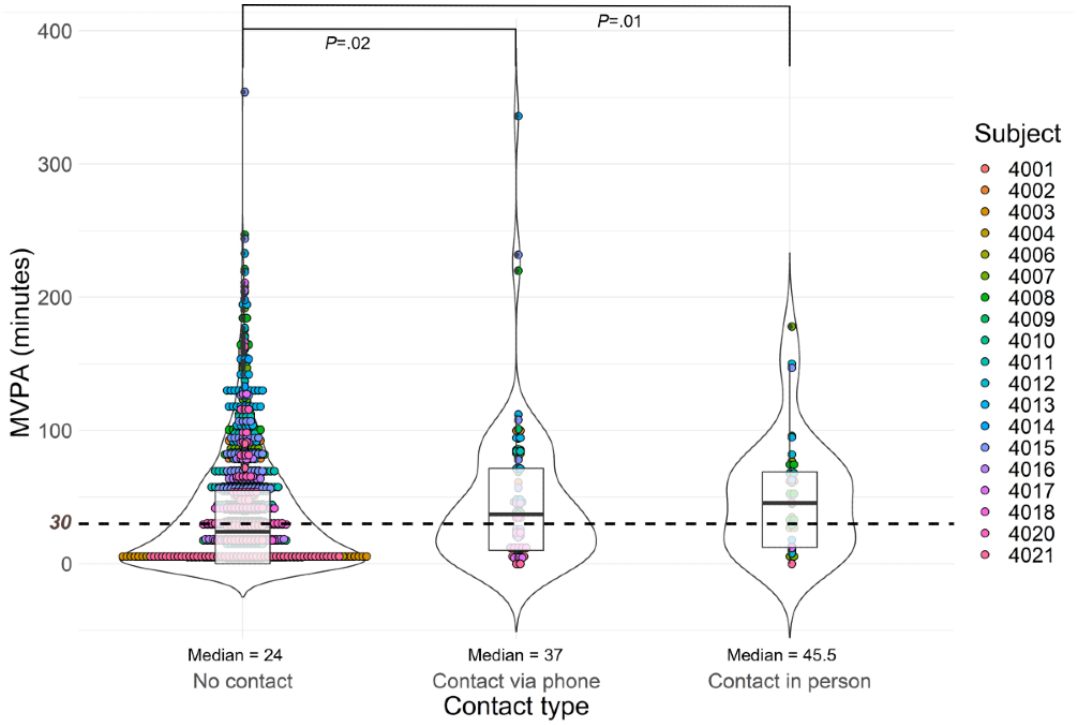
Figure 2. Moderate-to-vigorous physical activity (MVPA) throughout the 16-week intervention. Each dot represents a single week, with the color of the dot specifying the participant. Numbers beside the colored dots represent participant numbers. The box plots detail weekly medians (horizontal red lines) and quartile minutes performing MVPA for the group, while the black line illustrates the slope of MVPA over time for the group.



Impact of Behavioral Coaching

Participants were contacted for behavioral coaching an average of 5.26 (SD 1.88) times by phone and 2.11 (SD 1.63) times in person over the 16-week study period. A Kruskal-Wallis test revealed that median steps and MVPA were greater on days when individuals were contacted via phone (10,495 steps/day, IQR 8547.5-12,979.5, *P*=.03; MVPA: 37 min/day, IQR 10-71.5, *P*=.02) and in person (11,369.5 steps/day, IQR 9886.23-14,214.8, *P*=.01; MVPA: 45.5 min/day, IQR 12.3-69, *P*=.01) compared to days when individuals were not contacted (10,161 steps/day, IQR 6639-12,371; MVPA: 24 min/day, IQR 0-55; Figure 3). Median sedentary minutes were reduced on days when participants were contacted by phone (561 min/day, IQR 470-639.5, *P*=.04) but not in person (580 min/day, IQR 516.3-637.8, *P*=.43) relative to days with no contact (580.5 min/day, IQR 493-669). No differences were seen in LMVPA regardless of contact (contact by phone: 351 min/day, IQR 282-416, *P*=.10; contact in person: 364.5 min/day, IQR 278.5-422.8, *P*=.16; no contact: 334 min/day, IQR 255-408).

Figure 3. The effect of contact type on daily moderate-to-vigorous physical activity (MVPA) minutes. Each dot represents a single day, with the color of the dot specifying the participant. Numbers beside the colored dots represent participant numbers. The violin outline details the overall distribution of each contact type condition, while the box plots depict the medians and quartiles. The horizontal dashed line at 30 MVPA minutes illustrates the recommended number of MVPA minutes per day.



Scales

Small effect sizes were observed for improvement in BIPQ scores (g=0.30, P=.19) and increases in QoLS scores (g=0.32, P=.16). A medium effect size was observed for reductions in visits to the LAC+USC Medical Center (effect size r=0.44, P=.06; Table 3). A positive rate of change in steps correlated with reduced LAC+USC Medical Center visits (correlation coefficient r=–0.47, P=.04; Figure 4). There was no correlation between change in medical center visits and change in other PA measures.

Table 3. Measurements before, during, and after the intervention study period.

Measure	First measurement[a], mean (SD)	Second measurement[b], mean (SD)	*P* value	Effect size
Brief Illness Perception Questionnaire score[c]	43.05 (13.11)	39.21 (14.32)	.19	0.30[d]
Quality of Life Scale score[e]	82.37 (19.05)	87.53 (11.72)	.16	0.32[d]
Number of medical center visits (4 months)	4.32 (2.43)	3.47 (2.84)	.06	0.44[f]

[a]The first measurements for the scales took place at baseline, whereas those for medical center visits took place during a period 16 weeks prior to the start of the study.

[b]The second measurements for the scales took place after the intervention study period, whereas those for medical center visits took place during the 16-week study.

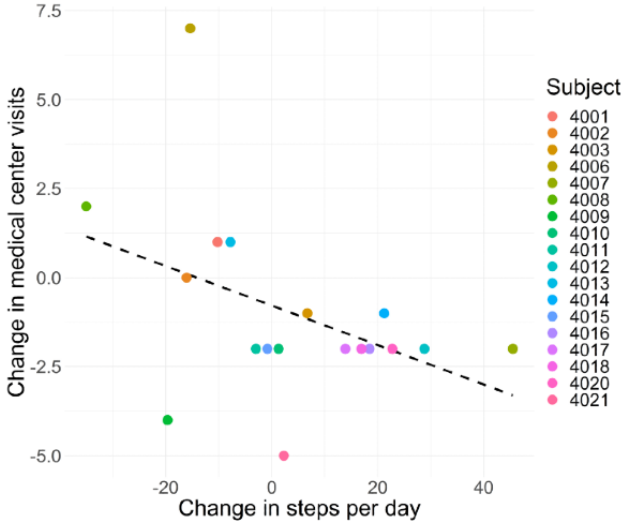
[c]Total scores range from 0 to 80; a higher score indicates a more threatening view of a participant's illness.

[d]This effect size was Hedges *g*.

[e]Total scores range from 16 to 112; a higher score indicates a higher perceived quality of life.

[f]This effect size was the *r* statistic.

Figure 4. The association between change in medical center visits with rate of change in steps. A negative change in medical center visits indicates that a participant went to the medical center fewer times during the study period than during the period 16 weeks prior to study initiation. Numbers beside the colored dots represent participant numbers.



Discussion

Principal Findings

The aim of this proof-of-concept study was to assess the feasibility and efficacy of a community-based intervention to promote PA through (1) a wearable Fitbit and (2) behavioral coaching in a sample of Latina women of low socioeconomic status with chronic neurological disorders recruited from the LAC+USC county outpatient neurology clinic. Studies have demonstrated the importance of PA and exercise in reducing morbidity and improving QoL for individuals with chronic neurological disorders, including Parkinson disease, multiple sclerosis, and chronic pain [1,2,4,23]. However, these studies typically do not include individuals from minority populations of low socioeconomic status. In general, underserved populations, particularly Latina women, are also less physically active due to numerous barriers to exercise, placing them at high risk for disease burdens associated with chronic illness [6-8]. These barriers include environmental factors, such as great distances with limited public transportation; low socioeconomic status; long working hours; lack of health literacy; limited social support, including extensive family and caregiver demands; and lack of facilities, including gym spaces, outdoor parks, or recreational sites [9]. Health care–related resources delivered at the community level may remove these barriers by maximizing accessibility and redesigning lifestyles [24]. For example, behavioral coaching and encouragement delivered within the community can help individuals identify goals and develop strategies to incorporate PA into their daily lives that otherwise would have not been considered [14]. Additionally, recent personal activity monitoring technology, such as Fitbit devices, enable individuals to monitor their goals through continuous and goal-directed real-time feedback emphasizing self-selected PA rather than structured exercise.

This proof-of-concept study provided preliminary evidence that programs designed to promote PA through self-monitoring with a personal activity monitor, such as a Fitbit wearable device, in conjunction with behavioral coaching are feasible and impactful among Latina women of low socioeconomic status and acculturation. Specifically, we observed high adherence to Fitbit wear, consistent with similar intervention studies using the same personal adherence definition (10 waking hours/day) in samples largely consisting of non-Latina, White females [11]. Potential motivating factors underlying high adherence include (1) initial goal setting, (2) frequent contact with wellness center navigators [25] to motivate the participants and help with any technological issues, and (3) the incentive for individuals to keep the Fitbit after study completion. Further, it is likely that the community-based nature of the intervention facilitated adherence by reducing barriers to exercise commonly experienced by this population of low socioeconomic status.

Importantly, this study demonstrated the efficacy of the intervention to promote PA over a 16-week period. In general, participants experienced an increase of approximately 18 minutes in daily MVPA over the course of the 16-week period, which nears the World Health Organization recommendations for approximately 20 minutes of PA per day (150 minutes of PA/week) to improve general and brain health [26]. This increase in MVPA was steady (0.16 minutes/day), which suggests that these gains in PA are gradual in nature. Taken together, these findings suggest that reaching recommended MVPA levels may be an achievable and realistic goal. While an increase in MVPA has been observed in similar self-monitoring intervention studies [12,27], it is notable that Latina women and individuals with chronic neurological conditions typically do not achieve recommended levels of PA [7,28] and report many barriers to exercise [9,29].

Interestingly, this study demonstrates that the observed PA promotion was significantly influenced by behavioral coaching within the setting of a community wellness center. Specifically, both behavioral coaching by phone from a wellness center navigator and by in-person visits with an occupational therapist increased individuals' activity as reflected by time spent performing MVPA and daily step count. This finding is consistent with previous reports demonstrating that community-based interventions can promote PA among Latina

women, particularly when led by those within their own community [30,31]. While the use of Fitbit wearable devices as an intervention is rising in popularity and studies have demonstrated its benefit in promoting PA in the general population of women [11-13], our results support the importance of a community-based intervention model that combines Fitbit wear and behavioral coaching to promote PA for Latina women with low socioeconomic status and acculturation characteristics.

Group-level changes in the number of daily steps, illness perception, QoL, and clinical visits were not significantly altered in this study. However, further analyses revealed that an increase in daily step count during the study period was correlated with a reduction in clinical visits. Two potential drivers of this relationship may include either the following: (1) increasing step count to improve the health of individuals, thus reducing medical center visits, or (2) the degree of health-related problems that required medical center visits resulted in reduced step counts. While the former demonstrates the importance of interventions that increase step count, both potential drivers show how monitoring change in daily number of steps may inform health status and the need for clinical visits. In fact, previous work has found that increased step count during inpatient recovery from cancer surgery is predictive of reduced likelihood for hospital readmission [32]. Results from this preliminary study suggest that the predictive strength of daily step count extends to community-based activities. A larger-scale study aimed at examining the relationship between steps and medical center visits is required to better understand the precise underlying mechanisms of this association.

There are limitations to this study due to its nature as a proof-of-concept study assessing feasibility and efficacy of an intervention in a targeted population. The sample size was relatively small, drawn from a specific geographical area, and consisted of a narrow range of neurological disorders, thus limiting our ability to generalize our findings to a larger population of Latina women with chronic neurological disorders. However, this study can be used as a guide for a future large randomized clinical trial examining PA promotion in this population with specific neurological disorders, including individuals suffering from chronic pain, Parkinson disease, or multiple sclerosis. While not a limitation, variability, including a potential ceiling effect in some individuals, was observed in activity levels between participants throughout the 16-week study. This variability is unsurprising given the proof-of-concept nature of this study focusing on an understudied and underresourced population commonly at risk for adverse health conditions in which little is known about PA engagement. As such, the authors did not use exclusion criteria or stratify based on preintervention activity levels. An additional limitation includes a lack of prestudy PA measurements. Due to this limitation, it is not possible to determine whether the high initial activity levels and step counts observed in the study were due to an initial increase that was secondary to Fitbit wear or whether individuals were already physically active at a high level. Similarly, PA levels or other outcomes following cessation of the formal intervention period were not measured, so we cannot determine whether the long-term benefits of the intervention persisted. Lastly, participants did not keep sleep or activity logs, which resulted in an overreliance on Fitbit data to accurately record these metrics.

Conclusions

This proof-of-concept study supports the feasibility and efficacy of a community-based intervention consisting of self-monitoring by a personal activity monitor, such as a Fitbit, combined with behavioral coaching by phone or in person promoting PA in a sample of Latina women with chronic neurological conditions. Behavioral coaching appears to enhance PA promotion when delivered by a culturally competent intervention team consisting of wellness center navigators from the community as well as an occupational therapist of Latino background. These initial results support the development of future large-scale intervention studies with the goal of providing evidence for the feasibility and effectiveness of PA promotion in this underrepresented population.

Acknowledgments

Thank you to Michael Higgins, Margaret Burnett, and Soma Sahai for their contributions to the study. Special thanks go to our community members for making this study possible, including The Wellness Center navigators, patients, and families of patients. These studies were supported by a grant awarded to GP from the James H Zumberge Faculty Research and Innovation Fund at the University of Southern California.

Abstract

Background: Augmented reality (AR) and brain-computer interface (BCI) are promising technologies that have a tremendous potential to revolutionize health care. While there has been a growing interest in these technologies for medical applications in the recent years, the combined use of AR and BCI remains a fairly unexplored area that offers significant opportunities for improving health care professional education and clinical practice. This paper describes a recent study to explore the integration of AR and BCI technologies for health care applications.

Objective: The described effort aims to advance an understanding of how AR and BCI technologies can effectively work together to transform modern health care practice by providing new mechanisms to improve patient and provider learning, communication, and shared decision-making.

Methods: The study methods included an environmental scan of AR and BCI technologies currently used in health care, a use case analysis for a combined AR-BCI capability, and development of an integrated AR-BCI prototype solution for health care applications.

Results: The study resulted in a novel interface technology solution that enables interoperability between consumer-grade wearable AR and BCI devices and provides the users with an ability to control digital objects in augmented reality using neural commands. The article discusses this novel solution within the context of practical digital health use cases developed during the course of the study where the combined AR and BCI technologies are anticipated to produce the most impact.

Conclusions: As one of the pioneering efforts in the area of AR and BCI integration, the study presents a practical implementation pathway for AR-BCI integration and provides directions for future research and innovation in this area.

Introduction

Augmented reality (AR) and brain-computer interface (BCI) technologies are among the most promising technologies to date offering to revolutionize human-computer interaction in health care and health professional education. AR provides a mixed user experience where virtual and real elements seamlessly coexist to allow the user to see the real world supplemented by virtual objects and data. Most modern AR implementations represent a fusion of computer-generated imagery and real environment using a head-mounted display (HMD) or goggles typically used in gaming, maintenance training, rehabilitation, and surgical performance support. An HMD allows the users to maintain a clear line-of-sight alignment with real elements

in the actual environment, which can be beneficial in any data-intensive setting [1]. This is particularly important in clinical environments where a physician's situational awareness depends on multiple sources of information and simultaneously maintaining effective communications and eye contact with members of the clinical team as well as the patients [1,2].

The BCI represents a communication pathway between the brain and a computer device using a variety of biosensors that gather and interpret the signals from body and mind to enable neural controls over computer functions. The BCI has been used in a wide variety of applications, including rehabilitation, robotics, entertainment, and virtual reality [3-6]. No longer seen as a purely assistive technology, BCI has been gaining interest as a noninvasive physiological observation mechanism applicable to health care and education settings [7]. AR provides an opportunity to integrate feedback into a real-world environment and enhance a user experience by advancing human-computer interaction capabilities, while the BCI enables a new hands-free interaction modality and provides information about the user's mental state, which supports adaptive training and performance improvement [8,9].

While there has been a growing interest in the AR and BCI technologies in the recent years, the combined use of these technologies remains a relatively uncharted territory both in research and practice. The last decade has brought significant advancements in the area of AR and BCI technologies; however, both of them still exist in a relative isolation from each other. While the idea of bringing these two technologies together has prevailed among futurists, technology enthusiasts, and government research silos for quite some time, it still remains a fairly unexplored area, which had been associated with the realm of science fiction requiring paradigm shifts in digital innovation dynamics [10].

As the researchers and consumers are starting to recognize the benefits for combining BCI and AR fields, this interest continues to fuel the innovation around improved technology interaction and visualization capabilities. There is a growing body of literature suggesting the potential to revolutionize health care through the use of emerging AR and BCI technologies, with a few intriguing examples starting to demonstrate the applicability of these emerging technologies in a variety of health care contexts; for example, surgery, ophthalmology, elderly care, sensory system rehabilitation, and others [8,11-13]. Despite the growing interest in the AR and BCI technologies, the research in this area is currently somewhat fragmented, and the awareness of the true potential of AR and BCI is still rather limited [1,14].

A combination of AR and BCI technologies can offer an enhanced user experience both for patients and health care professionals, particularly from procedure-intensive specialties, by allowing them to interact with a mix of real and virtual objects, contextual elements, and each other, while using the BCI as an additional communication vehicle, besides the spoken word and hand gesture traditionally used in AR. For instance, through interactive 3D visualizations, an AR component can be used to help a health professional explain a disease or a medical procedure to a patient during a clinical encounter or provide visual cues to a physician during a complex procedure, while a BCI component can simultaneously use biosensors, such as an electroencephalogram (EEG), to enhance the range of options for performing clinical tasks through a combination of verbal, tactile, and neural triggers as well as provide new information about the user's mental state.

This paper presents the results of a recent effort aimed to advance an understanding of how AR and BCI technologies can work together to transform modern health professional education and clinical practice by providing practical mechanisms to support the established principles of patient-centered care [15] as they relate to patient safety, effective patient-provider communication, shared decision-making, and patient education. The aim of this study was to explore the integration of commercially available wearable AR and BCI technologies that can be applied in medical education, clinical practice, and other areas to address a variety of real-world challenges in health care. The study produced a novel integrated AR-BCI technology solution, which was demonstrated within the context of practical use cases focused on health professional education and clinical performance support.

Methods

Methods Overview

The study methodology included an environmental scan and analysis of modern AR and BCI technologies, a use case analysis of practical applications for combined use of AR-BCI technologies in health care, and the development of a proof-of-concept AR-BCI technology integration prototype situated within the modeled use case scenarios, as summarized in the following paragraphs.

Environmental Scan and Analysis of Modern AR and BCI Technologies in Health Care

The environmental scan [16] and analysis component constituted a broad-scale review of existing applications of AR and BCI technologies in health care through literature review, research and industry reports, technology demonstrations in health care settings, and other sources. The literature review included publications identified from health care and technology research databases (eg, PubMed, IEEE, EBSCO, and others) using the following Medical Subject Headings (MeSH) terms: "augmented reality," "brain-computer interfacing," "healthcare," "clinical performance support," and "health professional education." The survey of industry reports and technology demonstrations was performed at a number of major technology innovation venues (eg, Consumer Electronics Show, Interservice/Industry, Simulation, Training, and Education Conference, Healthcare Information and Management Society, International Meeting for Simulation in Healthcare, and others). The environmental scan revealed the strong potential for bringing the AR and BCI technologies for health care applications, particularly within the context of complex medical interventions and treatment planning (eg, surgery, invasive testing procedures, intensive therapies, and others). Leveraging the combination of AR and BCI in such cases would help improve communication and shared decision-making between providers and patients as well

as members of an interprofessional team. At the same time, the environmental scan has confirmed that while the use of AR and BCI technologies in health care is growing, their combined use remains an unexplored area where the majority of innovations currently reside in research laboratories and apply to a limited range of clinical applications and disease conditions.

Use Case Analysis of Practical Applications for Combined AR-BCI Technologies in Health Care

To explore the potential for the combined use of AR and BCI technologies in health care, a use case analysis technique [17] was used, which helped identify the requirements for the AR-BCI within the context of practical health care applications. Through multidisciplinary collaboration with experts from health professional education, clinical sciences, and computer and cognitive sciences, a series of use cases were developed, which focused on the following key areas where the combined use of AR-BCI technologies can produce the most impact:

- Medical or health professional education
- Patient education
- Patient-provider communication
- Shared decision-making
- Clinical performance support
- Interprofessional teamwork

These use cases provided the basis for modeling the simulation scenarios used to demonstrate and validate the AR-BCI proof-of-concept technology, which is described in the *Results* section.

AR-BCI Technology Integration Prototype Development

The prototype development effort involved a proof-of-concept integration of AR-BCI technologies with the intent of demonstrating the potential of the combined technologies within the context of the practical use cases and serve as a test bed for future use case scenarios and implementation. The prototype development effort focused on the integration of commercially available consumer AR and BCI devices to minimize the common barriers associated with the use of specialized technologies, which frequently stand in the way of technology implementation and adoption.

The proof-of-concept AR-BCI integration was performed using Microsoft HoloLens as the AR technology component and NeuroSky Mind Wave 2 as the BCI component. While neither of the two devices were designed to work together "out of the box" in a plug-and-play fashion, they do come equipped with a software development kit and application programming interface components, which make integration with other technology platforms and devices possible in principle. It is important to note, however, that coupling these devices involved a technology development and programming effort to create a software interface to enable the communication between them. A WebSocket relay server was implemented as an intermediary component between HoloLens and NeuroSky Mobile Wave 2 because both devices support the internet connection over an HTTPS internet protocol. The WebSocket protocol was selected on the basis of its effective real-time performance as a relay messenger, which, in this case, listened for the messages from the BCI device (NeuroSky) and relayed them to the connected AR device (HoloLens). As part of the prototype validation efforts, this technology integration method was also successfully coupled with other consumer-grade BCI or neurosensing devices, such as MUSE, and is currently being extended to other AR devices, such as Magic Leap and MERGE.

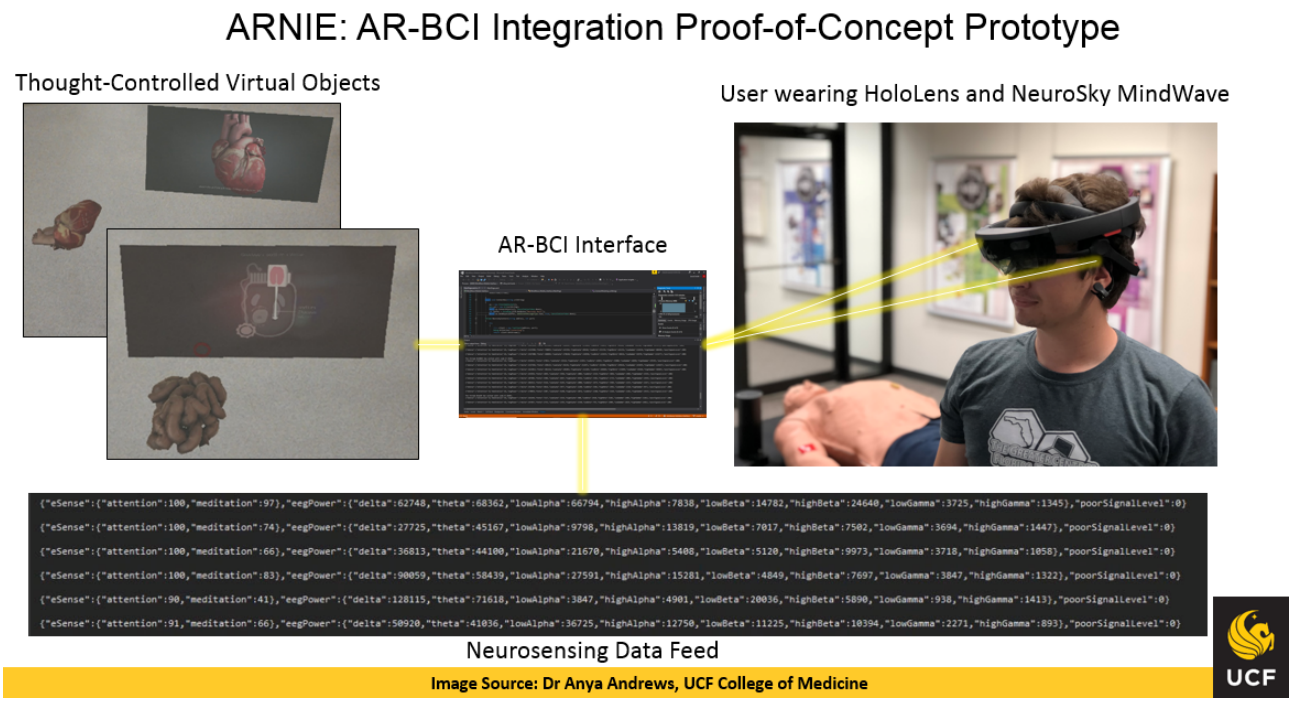
Results

The principal outcome of this exploratory assessment and prototype development is that the new technology interface that resulted from it enables the coupling and communication between these devices—a capability that previously did not exist. Specifically, the study resulted in a proof-of-concept integration of mainstream consumer AR and BCI technologies and development of a novel integrated technology platform to demonstrate their potential within the context of medical education and clinical performance support use cases and serve as a test bed, based on which future developments can be performed and evaluated.

Named "*Augmented Reality and Neurosensing Interaction Environment (ARNIE)*," the resultant solution represents a flexible AR-BCI interface platform and a technology test bed that is specifically intended for consumer-grade devices and is technology brand–agnostic. This solution is designed to enable an enhanced learning experience for health professionals in training and enhanced clinical experience for patients and physicians. The ARNIE platform currently enables thought-controlled manipulation of multiple virtual and data objects in AR similar to a simple computer "mouse click." Figure 1 illustrates a working model of the ARNIE system within the context of a medical education use case represented via two learning modules—one focused on the cardiovascular disease and the other one on Crohn disease.

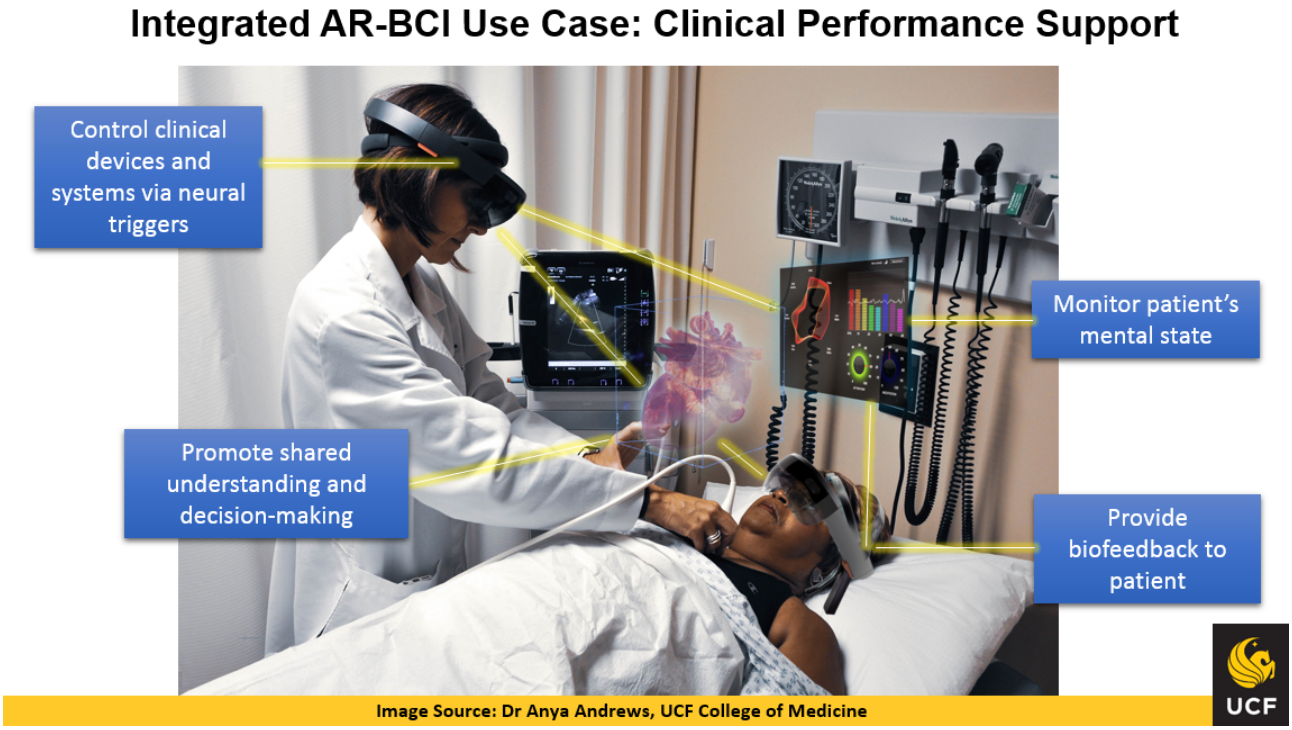
The ARNIE system enables the 3D models visualizing a human heart and a gastrointestinal tract to be controlled by a neurosensing BCI component using a unique communication protocol developed to enable coupling of AR-BCI components. As pictured in Figure 1, the student demonstrates wearing an AR headset integrated with a BCI headband and controls the virtual objects—that is, the human heart and gastrointestinal tract—in the AR environment entirely with his thoughts. Specifically, by concentrating on a particular virtual object—for example, "the heart" presented in the AR environment—the student's EEG waves are captured by the BCI headband, and upon reaching a predetermined attention measure threshold, send a signal using the communication protocol to launch a training video illustrating the functions of the cardiovascular system.

Figure 1. Augmented reality and brain-computer interface (AR-BCI) proof-of-concept integration prototype: medical education use case. ARNIE: Augmented Reality and Neurosensing Interaction Environment, UCF: University of Central Florida.



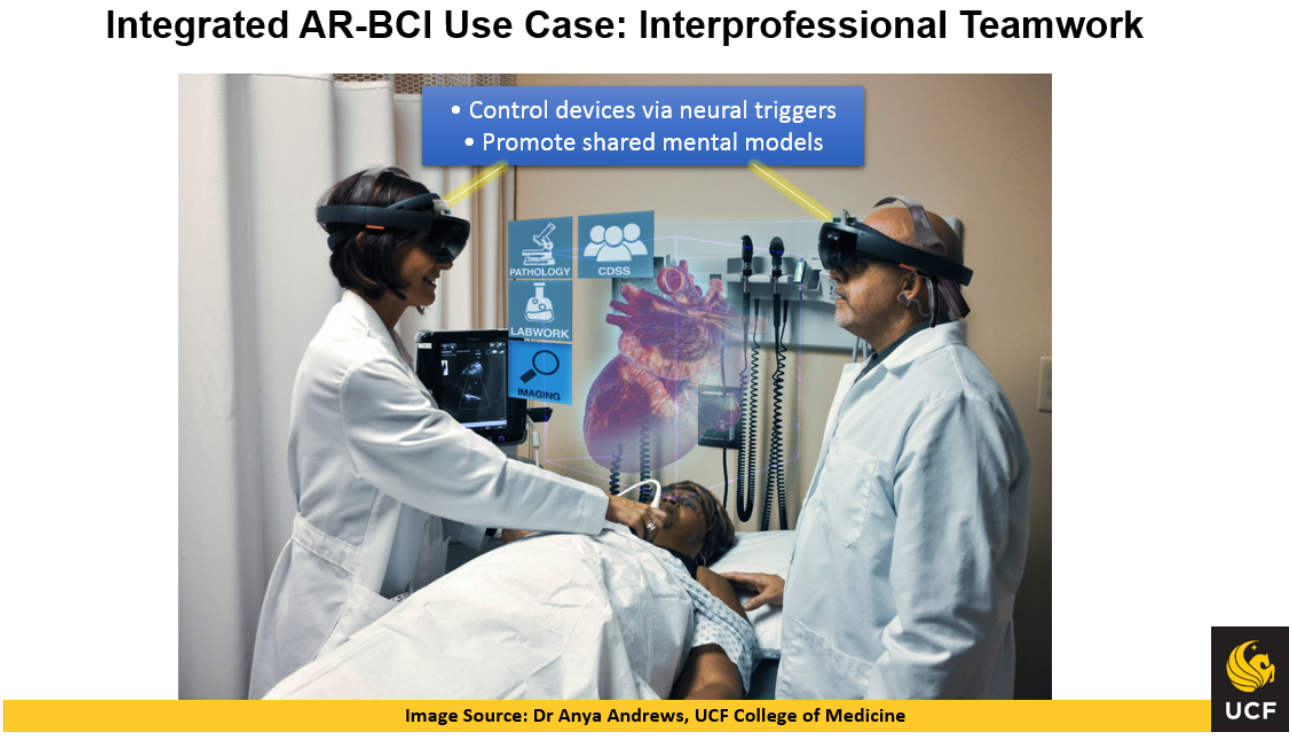
Besides the education and training use cases, the potential of the integrated AR-BCI solution was explored within the context of clinical performance support modeled in a health care environment. Thus, Figure 2 below illustrates a clinical scenario where the integrated AR-BCI capability would allow the physician performing a clinical procedure (eg, an ultrasound of the heart) to control certain clinical devices and systems using neural triggers (ie, attention and concentration), use shared visualizations with the patient (also wearing the AR-BCI devices) to promote effective communication and shared decision-making, while also maintaining enhanced clinical awareness of the patient's mental state enabled by the patient's BCI component, which can also be used to provide biofeedback to patient, as needed.

Figure 2. Integrated augmented reality and brain-computer interface (AR-BCI) use case: clinical performance support. UCF: University of Central Florida.



The clinical applications of the integrated solution can also augment interprofessional teamwork by allowing members of the health care team to control devices and data in the clinical environment via neural triggers, which would help maintain situational awareness and promote shared mental models and shared decision-making as illustrated in Figure 3.

Figure 3. Integrated augmented reality and brain-computer interface (AR-BCI) use case: interprofessional teamwork. UCF: University of Central Florida.



Shared mental models are shared cognitive structures that enable members of an interprofessional team to function collaboratively through implicit coordination while performing clinical tasks that require coordination, cooperation, and mutual support. Shared mental models represent a key prerequisite for shared decision-making in interprofessional teamwork.

The medical education, clinical performance support, and interprofessional teamwork use case scenarios described above were modeled within the academic technology research and clinical skills simulation environment and provided the context for demonstrating the potential of the integrated AR-BCI prototype solution. The medical education use case scenario illustrated in Figure 1 has served as the primary mechanism for demonstrating and validating the functionality of the prototype. The initial testing and validation of the technology prototype was performed within a small group of approximately 10 health care simulation and multimedia technology experts familiar with a variety of both AR and BCI platforms whose formative inputs helped calibrate the prototype for broader testing and implementation.

After the initial testing by the technology experts, the prototype has been demonstrated to a diverse mix of 2500 potential user representatives, including students, educators, and health care and technology professionals, approximately 600 of whom volunteered to further examine and perform hands-on testing of the integrated AR-BCI solution within the simulation laboratory. The testing volunteers were instructed to don both the HoloLens and NeuroSky Mind Wave 2 devices simultaneously and concentrate their attention on specific 3D objects within the AR environment; for example, “the heart” in order to activate the learning content associated with these objects via neural triggers. All of the volunteers have been able to go through the use case scenarios using the two devices without any problems, which indicates that the technical targets of the integrated AR-BCI system and its individual components have been met under basic operating conditions within the testing environment. The volunteers’ reactions and feedback regarding the overall AR-BCI integration concept and the experience using the prototype have been overwhelmingly positive, ranging from comparisons with science fiction coming to real life to sincere expressions of awe from being introduced to a novel capability that holds tremendous potential for health care applications.

Discussion

Principal Findings

This study has successfully proved the concept of integrating commercially available consumer AR and BCI technologies. The results of the described effort present new advancements in the areas of cognitive and computer sciences by providing new capabilities for (1) human-machine interfacing, (2) advanced technology interoperability and Internet of Things networking, (3) multimodal data analytics, and (4) smart and mobile learning technologies in health care. These new capabilities have been realized within the ARNIE technology interface solution that enables interoperability between

consumer-grade AR and BCI devices demonstrated within the context of the practical use cases for health professional education and clinical performance support. The proof-of-concept demonstration scenarios involved participation of a broad community of potential end users, including physicians, allied health professionals, medical students, technologists, scientists and researchers, health care administrators who helped validate the integrated AR-BCI technology capability and provided early feedback regarding the prototype, which has been consistently optimistic and supportive in terms of its perceived usability and utility, and also encouraging in terms of its broader testing and implementation in real-life settings.

The resultant new technology solution offers a research test bed and enabler for advancing knowledge and understanding about human-computer interaction in health care by creating an opportunity to connect people (health professionals, patients, and trainees), systems, and data in health care environments through a combination of AR and BCI. This test bed represents a foundation for moving toward plug-and-play integrated AR-BCI technology interoperability, which currently represents a significant barrier to adoption of these new technologies for health care applications.

Limitations

The study represents an exploratory and developmental technology integration and use case modeling effort, which, thus far, has been successfully demonstrated and implemented in a simulation-based education and research setting, but not in an actual health care delivery environment. The focus of the effort was on technology development and proof-of-concept demonstration of the integrated AR-BCI capability within the realistic use case scenarios. The volunteer participant interaction with the platform was not systematic, and their feedback is considered informal.

Comparison With Prior Work

The following three major differentiators of the described study from the current state of the science in this area can be distinguished:

Expanded Range of Controls for AR Technology Interaction

The world of human-machine interfaces is rapidly transitioning from legacy physical instrumentation to a world driven by gesture, spoken word, and now neural command, which is likely to become far more precise than gesture or spoken word in the future. The results of this study demonstrate an expanded range of AR controls, which includes a neurosensing capability that allows the users to control digital objects in an AR environment using the power of their mind.

Consumer-Grade AR-BCI Technologies and Broader Application Focus

A growing body of research suggests the great potential to revolutionize human-computer interaction through the use of emerging AR and BCI technologies, with several early examples starting to demonstrate the applicability of these emerging technologies in a variety of health care contexts, including prosthetic interfaces [18], sensory system rehabilitation [19], behavioral health [20], and others. However, many existing combined AR-BCI implementations use highly specialized technologies and devices that are custom-built for a narrow focus, experimental in nature, and may not be easily adaptable or extensible for wider use, which makes it challenging for them to cross a so-called technology adoption chasm [21] in order to enter mainstream use any time soon. The ARNIE solution brings together the AR-BCI capabilities using the consumer-grade technology and devices available today with the intent to accelerate the transition of this new integrated capability to the consumers in health care in the near future.

Technology-Agnostic Solution

The described effort represents a new step toward bringing the AR-BCI technologies together in a device-agnostic way via a novel interface solution that enables communication between consumer-grade wearable AR and BCI devices and provides the user an ability to control digital objects in AR using neural commands. Envisioned to promote effective communication and shared decision-making between health care providers and patients, this new interface represents an extensible and device-agnostic test bed for evaluating future development efforts in this area. Intended to support a wide range of AR and BCI devices, the technology-agnostic integration approach will help promote the adoption of integrated AR-BCI technologies in health care.

Future Directions

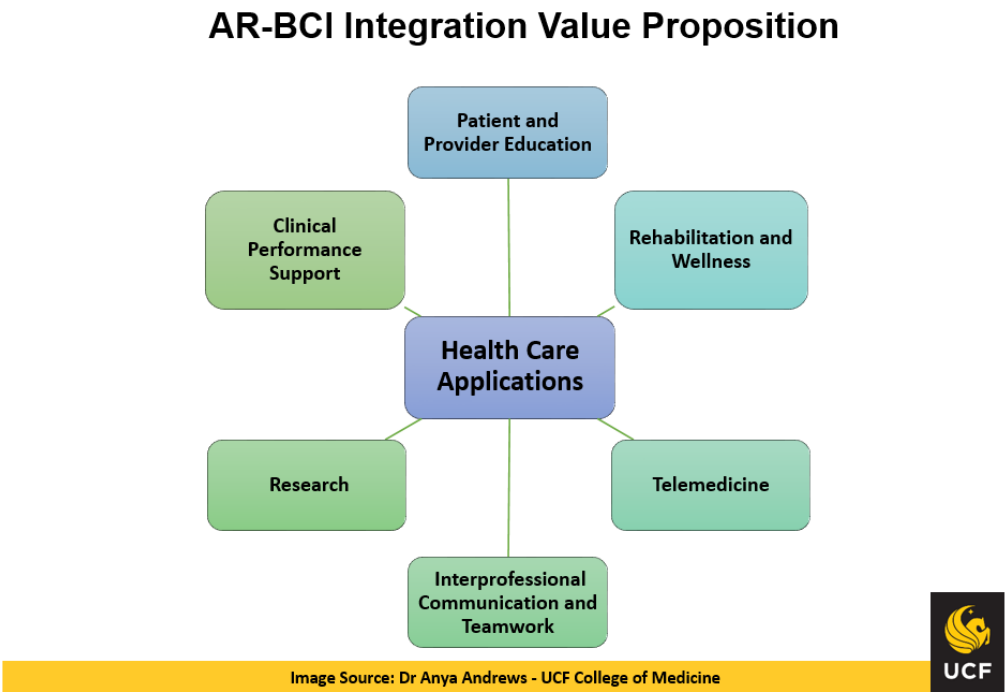
Next steps in this direction would include the development of an expanded set of integrated AR-BCI capabilities and include further testing and implementation of this platform within the health professional education curriculum of the University of Central Florida (UCF) Academic Health Sciences Center. Further research efforts need to advance an understanding about how AR and BCI technologies can be used to (1) facilitate or enhance shared understanding between human agents in health care, (2) support teaching and learning of complex biomedical and medical information, (3) enable strategies to capture mental states and promote metacognition and comprehension in medical trainees and patient populations, and (4) support the identification of neural signatures of complex cognitive, metacognitive, and affective processes during clinical training and performance.

Broader Impacts

There are many opportunities for broader impacts from the application of integrated AR-BCI solutions in health care, including patient and provider education, physician clinical performance support, interprofessional teamwork, rehabilitation, wellness, telemedicine, and research, as summarized in Figure 4. The results of this study can play an important role in transforming health professions education by enabling the integration of people, systems, and data during the learning process. They can also serve as a powerful enabler for enhanced clinical experiences for patients and providers by improving communication, shared decision-making, and patient health literacy, all of which are associated with patient-centered care [22,23]. The clinical applications of the integrated solution can

also augment interprofessional teamwork and help clinical teams maintain situational awareness and shared mental models, which also have a direct impact on patient health outcomes [24]. Additionally, the integration of AR and BCI technologies offers unique opportunities for supporting telemedicine and remote rehabilitation and wellness approaches, which have become particularly important during the COVID-19 pandemic. Finally, the AR-BCI value proposition includes opportunities to advance research in the areas of health care quality improvement and the other health care application areas highlighted in Figure 4.

Figure 4. Augmented reality and brain-computer interface (AR-BCI) integration for health care applications: value proposition.



This described study offers a foundation for future efforts to accelerate the integration of AR and BCI technologies to connect people, data, and systems to enable transformation in health and medicine. As our society continues to become more diverse and global, every effort should be made toward the development of shared understanding in health care [25]. The results of this study and future efforts in this area should help promote shared understanding between health professionals and patients from all walks of life, including underrepresented minorities, patients with limited education background, immigrants, patients in rural communities, and others. A famous quote by a historical figure in medicine, Martin H Fischer, stating that "*In the sick room, ten cents' worth of human understanding equals ten dollars' worth of medical science*," still holds true today, particularly as patient-centered care remains one of the fundamental aims of the US health care system. Whether it is about communication between providers and patients or between members of an interprofessional team, the development of shared understanding and mental models is an important prerequisite and enabler for shared decision-making.

Conclusions

Technology-based innovations can serve as a game-changer for supporting patient and provider education, communication, and shared decision-making, which would improve care and engagement of patients and ultimately population health [22]. Through the purposeful integration of multiple disciplines, including cognitive and computer sciences, engineering, and medicine, this study explored the integration of wearable AR and BCI technologies and resulted in a novel integrated AR and BCI technology solution and test bed that brings together two of the most promising technologies to date, both of which have tremendous potential to revolutionize health care. Broad applications for this technology are anticipated in health professions education, clinical performance support, surgery, telemedicine, and patient education. Future research directions in this area should aim to expand the range of current AR-BCI capabilities while addressing existing technical challenges and also generate new evidence on human-computer interaction in health care and health professional education.

Acknowledgments

This study was funded by a seed grant program sponsored by the Department of Internal Medicine, University of Central Florida College of Medicine. I would like to thank Dr David Metcalf and Dr Analia Castiglioni for scholarly collaboration, Mr Mike Eakins and Mr Jarod Smith for technical contributions, the UCF COM EdTech team for digital photography, and Dr Edward Ross for departmental support during the study.

Abstract

Background: Military members and veterans exhibit higher rates of injuries and illnesses such as posttraumatic stress disorder (PTSD) because of their increased exposure to combat and other traumatic scenarios. Novel treatments for PTSD are beginning to emerge and increasingly leverage advances in gaming and other technologies, such as virtual reality. Without assessing the degree of technology acceptance and perception of usability to the end users, including the military members, veterans, and their attending therapists and staff, it is difficult to determine whether a technology-based treatment will be used successfully in wider clinical practice. The Unified Theory of Acceptance and Use of Technology model is commonly used to address the technology acceptance and usability of applications in 5 domains.

Objective: Using the Unified Theory of Acceptance and Use of Technology model, the purpose of this study was to determine the technology acceptance and usability of multimodal motion-assisted memory desensitization and reconsolidation (3MDR) on a virtual reality system in the primary user group (military members and veterans with treatment-resistant PTSD, 3MDR therapists, and virtual reality environment operators).

Methods: This mixed methods embedded pilot study included military members (n=3) and veterans (n=8) with a diagnosis of combat-related PTSD, as well as their therapists (n=13) and operators (n=5) who completed pre-post questionnaires before and on completion of 6 weekly sessions of 3MDR. A partial least squares structural equation model was used to analyze the questionnaire results. Qualitative data from the interviews were assessed using thematic analysis.

Results: Effort expectancy, which was the most notable predictor of behavioral intention, increased after a course of 3MDR with the virtual reality system, whereas all other constructs demonstrated no significant change. Participants' expectations of the technology were met, as demonstrated by the nonsignificant differences in the pre-post scores. The key qualitative themes included feasibility and function, technical support, and tailored immersion.

Conclusions: 3MDR via a virtual reality environment appears to be a feasible, usable, and accepted technology for delivering 3MDR to military members and veterans who experience PTSD and 3MDR therapists and operators who facilitate their treatment.

Introduction

Background

Military services commonly involve engagement in high-risk activities, whether during physical training, daily trade-related tasks, overseas deployment or in response to natural disasters. Such activities place military members, individually and collectively, at a heightened risk of physical and psychosocial injury. Canadian Armed Forces (CAF) military members and veterans exhibit higher rates of injuries and illnesses, such as posttraumatic stress disorder (PTSD), major depressive disorder, generalized anxiety disorder, substance abuse, sleep disorders, and mild traumatic brain injury compared to their civilian counterparts [1,2]. These conditions can have far-reaching implications such as occupational, social or familial, and psychological impairment and can affect activities of daily living. Numerous studies conducted in Canada, the United States, and the United Kingdom have demonstrated a high prevalence of PTSD specific to deployments during conflicts in the Middle East from 2001 to 2013 [1-5]. The rate of probable PTSD among UK military personnel has been reported to be 6.2% [3] and, among veterans who were deployed in combat roles, 17.1% [4]. The rate of PTSD among Canadian veterans is estimated to be 16% [5]. Owing to the prevalence of these mental health conditions among military personnel and veterans, evidence-based interventions and treatments are needed to assist in recovery and rehabilitation. As our understanding of trauma evolves, novel interventions for PTSD in this population are needed. In particular, the use of technology as a facilitator of treatment may introduce avenues of recovery that were not previously possible.

Multimodal Motion-Assisted Memory Desensitization and Reconsolidation

Multimodal motion-assisted memory desensitization and reconsolidation (3MDR) is an innovative, technology-assisted, exposure-based trauma therapy that holds promise for treating combat-related PTSD (crPTSD). 3MDR is a structured, personalized, exposure-based, virtual reality (VR)–supported intervention developed in the Netherlands and used with military members and veterans with PTSD in the Netherlands, the United Kingdom, the United States, Israel, and Canada [6]. 3MDR is an emerging VR-assisted therapy delivered in an immersive VR environment (VRE) such as the Motek Gait Realtime Analysis Interactive Lab or Motek Computer Assisted Rehabilitation Environment (CAREN). The most commonly used VRE for 3MDR has been CAREN, which is a room-sized, 3D VRE with a central treadmill surrounded by 240° floor-to-ceiling motion-capture screens.

The 3MDR intervention comprises 10 sessions, including selecting images and music, trauma processing, and reconsolidation, and six 90-minute therapy sessions in the VRE, including a 30-minute debrief [7]. The 3MDR sessions include a *preplatform session* (session 1), during which the participant selects and orders images and music. Symbolic representations in the form of images (ie, photographs and sketches) related to their traumatic experiences are selected and ordered from least to most distressing. Music that reminds the participant of the traumatic event or events and facilitates the emotional memory network is also identified, which supports a return to the present. Sessions 2 to 7 are *platform sessions* that involve 3 phases. In the *preplatform phase* of the session, the therapist and participant confirm the order of the images and music for the session. During the *platform phase*, the participant dons a safety harness and is accompanied by a 3MDR therapist while walking continuously on a treadmill at a self-selected pace. The participant first warms up by walking on the treadmill while listening to self-selected music connecting them to traumatic experiences and then, during each of seven 3- to 5-minute cycles, walks down a 3D hallway on the screen toward a self-selected trauma-related image. The participant describes the image, physical sensations, and feelings, followed by communicating descriptive words and phrases with the help of a therapist. These words and phrases are projected in front of the image and then read aloud by the participant. For a duration of 30 seconds, the participant then reads aloud numbers as they appear on a ball oscillating horizontally in the foreground of the image and words. The participant cools down after the seventh cycle by walking while listening to self-selected music, which facilitates reconnection to the present. Each session is concluded with a *postplatform phase*, which includes discussion, reconsolidation, and a mental wellness check or self-care plan. *Postplatform session*s 8 to 10 focus on reconsolidation and contribute to the meaning making of the acquired gains [7]. In-depth descriptions of 3MDR have been published elsewhere [6,7,8].

Initial randomized controlled trials with 3MDR participants have shown a reduction in PTSD symptoms, which was maintained over time [9,10]. Although these results indicate that 3MDR may be a promising new therapeutic treatment for PTSD, key areas of exploration are required before 3MDR can be implemented as a frontline trauma modality. One such area of needed exploration is the technology acceptance and usability of 3MDR from the perspective of the end users, including CAF military members and veterans with crPTSD and the therapists and operators delivering 3MDR. Questions on feasibility must be addressed before in-context clinical investigations regarding specificity, reliability, validity, and sensitivity can take place. Without addressing acceptance and usability, technological innovations may not be adopted or implementations sustained. For 3MDR specifically, the combination of a military context and the intervention potentially affects multiple user levels; careful exploration to determine whether the technological

components of 3MDR are acceptable and beneficial is warranted.

Technology Acceptance and Usability in Contexts

Technology offers health care professionals a variety of benefits, including improving the efficacy, efficiency, safety, and cost-effectiveness of assessments, interventions, data collection, data analysis, reporting, record keeping, and communication. The acceptance of such technologies by health care professionals is an important topic for health care professionals and researchers [11,12]. Without technology acceptance and usability for the user, technological assessments, interventions, and other aspects that would assist with evolving health care needs may not be adopted into clinical practice despite their potential effectiveness. Therefore, evaluation of the acceptance and usability of emerging technology is integral to advancing best practices in health care [12].

The use of digital and mobile health innovations is becoming widespread in military and veteran populations [13, 14-17]. This has been amplified by the recent COVID-19 pandemic, when web-based health solutions have become increasingly common in all health care practices, including military environments [14-17]. It is essential to, directly and indirectly, assess the technology acceptance of different user groups, including military personnel, within their context using a framework or model to ascertain this factor, which contributes to the feasibility of implementing technological innovations.

Purpose

The purpose of this mixed methods pilot study is to use the Unified Theory of Acceptance and Use of Technology (UTAUT) model to determine the technology acceptance and usability of 3MDR within a VRE in the end user groups of (1) military members and veterans with crPTSD, (2) 3MDR therapists, and (3) VRE operators. On the basis of previous research in this area, it is hypothesized that performance expectancy (PE) and facilitating conditions (FC) will be the most influential variables on behavioral intentions (BI) and use, respectively. In addition, it is hypothesized that social influence (SI) will have the least influence on BI.

Methods

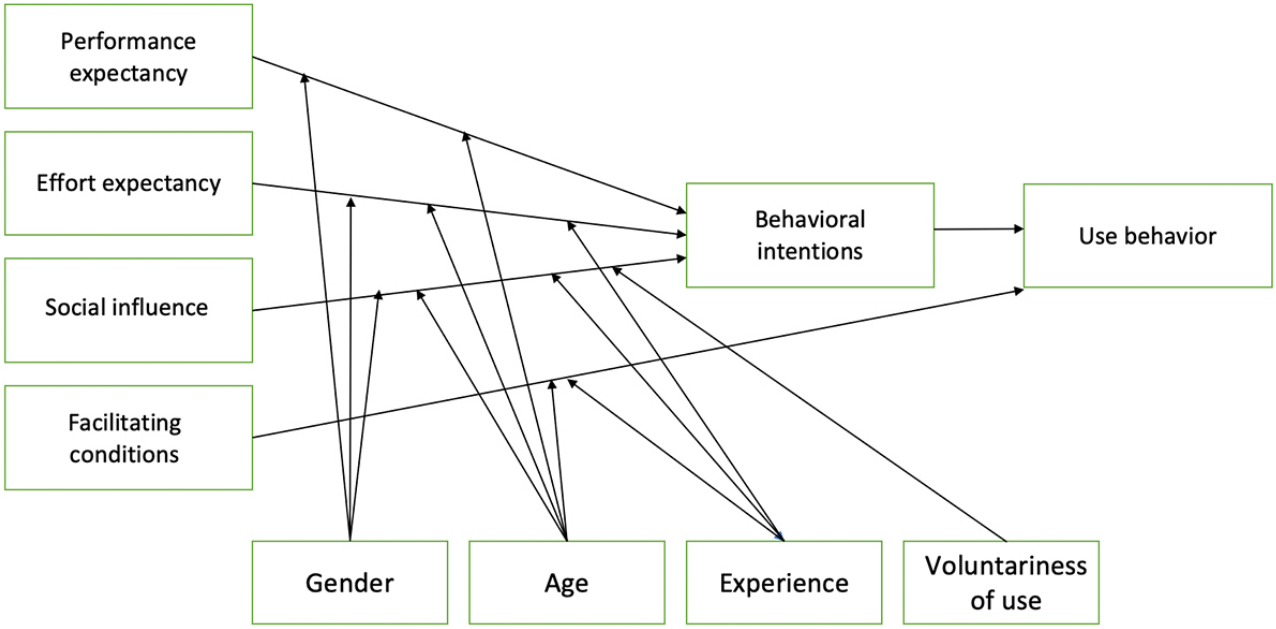
Study Design

This study used a mixed methods, embedded study design with a pre-post quasi-experimental approach. A quantitative approach using partial least squares structural equation modeling (PLS-SEM) and other nonparametric statistics was the primary method of data collection; a qualitative thematic analysis was secondary to this. This study was embedded in a larger study that used a mixed methods staggered entry clinical trial to test the efficacy, effectiveness, and safety of 3MDR [8].

The UTAUT Model

The UTAUT model was developed based on previous theories and models for the acceptance and adoption of technologies and consumer products that address the perceived technology acceptance of a user group with the goal of predicting use behavior (Figure 1) [18]. UTAUT has been demonstrated to explain as much as 70% of the variance in the intention to use technology compared with its technology acceptance model predecessors [18].

Figure 1. The Unified Theory of Acceptance and Use of Technology Model [18].



The UTAUT model addresses the perceived expectations of technological acceptance of new technology in five constructs: PE, effort expectancy (EE), and SI (direct determinants of BI), as well FC and BI, which have a direct impact on use behavior [18]. This model was developed from the point of view of the implementation of new technologies in practice within specific organizations rather than the technology for mass consumer consumption [18-20]. The UTAUT is a model that is commonly tested using PLS-SEM and is an example of a reflexive partial least square (PLS) path model [18]. The exogenous latent

variables (PE, EE, and SI) have an effect on the endogenous latent variable (BI), which in turn affects the construct of use [18]. In addition, FC can also have a direct effect on use [18]. Moderator variables, which include age, gender, experience, and voluntariness of use, also affect the interaction between indicators and constructs [18,19].

BI is defined as the intention to use technology, and use is defined as the actual use [18]. BI predicts whether the technology in question will be adopted by the user in reality. The three direct determinants of BI to use technology are PE, EE, and SI. PE is defined as the degree to which an individual believes that using the system will help a person attain gains in task performance [18]. The EE construct is defined as the degree of ease associated with the use of the system, and SI is the degree to which an individual perceives the importance of others believing that they should use the new system [18]. FC is defined as the degree to which an individual believes that an organizational and technical infrastructure exists to support the use of the system [18]. FC, PE, and EE are considered beliefs or the information a person has about an object, and SI is considered the subjective norm [18]. The UTAUT has well-established construct and content validity.

The UTAUT has been used in recent years as a model and framework for addressing technology use and acceptance in health care [11,12,21]. To date, most research on health technology using the UTAUT has involved the exploration of computerized medical records where the primary intended user, or end user, is a health care professional [11,12]. Studies that focus on the patient as the end user are beginning to emerge in the literature for specific demographics, such as older adults and youth, as well as specific populations with specific diagnostic categories such as cardiovascular disease, mental health, and diabetes. These studies evaluated the technology acceptance and usability of a multitude of digital and mobile health technologies, including health apps, wearable measurement technology, augmented reality, and web-based access to medical records. Hypotheses regarding the effect of the latent variables on BI and use have been formed regarding health care professionals as end users [11]. Studies focusing on the patient as the end user have demonstrated variable results, making the formation of a directional hypothesis challenging. In addition, studies examining technology acceptance models among military personnel are scarce [22,23].

Sample Eligibility and Size

The target study sample size was set at a minimum of 40 military members and veterans to account for a 20% dropout rate and allow for power at 32 participants. With 4 latent variables, for 80% significance at a 5% significance level, the sample size required for this study was 24 (R^2=0.50) [24].

Recruitment and Sampling

Recruitment of regular and reserve CAF military members and veterans was conducted by word of mouth among potential participants and their mental health providers as convenience and snowball sampling. Service providers supporting CAF military members and veterans, after being informed of the study via word of mouth and institutional email, informed patients who met the study inclusion and exclusion criteria. Potential participants who showed interest in participation were provided with a *Permission to Share Contact Information with the Research Team* form by their service provider. The completed forms were then forwarded to the research team. The researchers then contacted the potential participants via phone or email with a request for them to meet with the research team to learn more about the study and be evaluated to confirm eligibility to participate. Voluntary verbal and written informed consent were obtained from all CAF military members and veterans participating in the study.

Recruitment of the 3MDR therapists and operators was initiated via email circulated by key stakeholders associated with the 3MDR studies at 7 sites within Canada, the Netherlands, the United Kingdom, and the United States. 3MDR therapists and operators interested in participating in the study were instructed to email the research team to indicate consent to be contacted. Participants who met the inclusion criteria were forwarded a web-based consent form via a secure server (REDCap [Research Electronic Data Capture]) or hard copy, and an interview time was scheduled. Potential participants were informed that engagement in the study was voluntary.

Ethics Approval

This study received approval from University of Alberta Research Ethics Board (Pro00084466) and CAF Surgeon General Research Program (E2019-02-250-003-0003).

Inclusion and Exclusion Criteria

The 3MDR study participants included regular and reserved CAF military members and veterans aged 18 to 60 years under the care of a mental health clinician or service provider working at or associated with a Canadian Forces Base, an Operational Stress Injury Clinic, or Veterans Affairs Canada. All participants met the Diagnostic and Statistical Manual–Fifth Edition [25] criteria for PTSD diagnosis and had a score of ≥30 on the Clinician-Administered PTSD Scale for the Diagnostic and Statistical Manual of Mental Disorders–Fifth Edition Worst Month version. Participants were required to be stable on their current psychotropic medication for at least 4 weeks before entering the study. Individuals with comorbidities were included if they satisfied other inclusion and exclusion criteria. The participants were English speaking and able to provide informed written consent. The detailed 3MDR protocol has been previously published [8].

The 3MDR therapists and operators included in this study were English-speaking current or previous 3MDR therapists and operators who were trained by the developer of 3MDR. Participants must have completed a full course of 3MDR delivery with at least one patient (ie, had completed six 3MDR platform sessions using a VRE).

Measurements and Instruments

A demographic questionnaire was provided via email to participants through the REDCap server or in hard copy form. Variables collected from patient participants included age, sex, marital status, employment status, military status, enrollment era, rank, element, and years of service. For the 3MDR therapists

and operators, the collected variables included the participants' sex, profession, role in delivering 3MDR, years using 3MDR, location, VRE used, and level of education.

Two UTAUT questionnaires specific to the end users were developed specifically for this study. Version 1 (time point 0 [T0]) included questions in the future tense, whereas version 2 (time point 1 [T1]) included the same questions but was modified to reflect the past tense. The 12 questions' outcome measures were based on a Likert scale, with a score of 1 to 7 assigned to each question, with 1 being *strongly disagree* and 7 being *strongly agree*. A Likert scale with 7 points was used as the original UTAUT questionnaire by Venkatesh et al [18] used a 7-point scale. The maximum and minimum scores were 105 and 15, respectively. The 15 included questions addressed the five different constructs of the UTAUT (n=3, 20% PE; n=3, 20% EE; n=3, 20% SI; n=3, 20% FC; and n=3, 20% BI) that influence the use of technological innovations. Gender and age demographic information were also collected via the UTAUT questionnaire as they are modifier variables within the UTAUT model. The UTAUT questionnaire was provided only to those participants in the Canadian arm of a larger study who used the CAREN as the VRE.

Data Collection

The UTAUT questionnaires were completed by patients, therapists, and operators before and after 6 sessions of the 3MDR. The questionnaires were administered by a member of the research team before the qualitative semistructured interviews. Version 1 of the UTAUT questionnaire was presented before its first introduction to the CAREN and 3MDR. This version was future tense oriented and intended to measure expectations of the technology. After completing this questionnaire, the participants engaged in 3MDR for 6 sessions over approximately 6 weeks before completing the version 2 UTAUT questionnaire. This version was written in the past tense, intending to measure the actual intention to use technology once the participants had some experience with it.

A semistructured interview guide was developed to collect qualitative data. The research team conducted individual 40- to 60-minute semistructured interviews either in person or via telephone or a secure Zoom videoconferencing platform with the 3MDR patients, therapists, and operators. All interviews were recorded and subsequently transcribed by the research team.

Data Analysis

The research team conducted both quantitative and qualitative analyses. Quantitative analysis was based on the UTAUT, which uses a reflexive path model and PLS-SEM. The expectations from T0 and actual experience from T1 were statistically analyzed using PLS-SEM with a within-sample path model. Structural equation modeling (SEM) is considered a second-generation technique of multivariate analysis that allows researchers to incorporate unobservable variables measured indirectly by indicator variables [26]. PLS-SEM is variance based, as it accounts for the total variance and uses this to estimate the parameters [27]. In this method of analysis, the algorithm computes partial regression relationships in the measurement and structural models using ordinary least squares regression [26,27]. In an exploratory study such as this, data analysis is concerned with testing a theoretical framework from a prediction perspective, making PLS-SEM an ideal method for analysis [27].

The path model must be analyzed through measurement and structural model assessments [26,27]. Reflexive measurement models were evaluated based on internal consistency (Cronbach α), convergent validity (average variance extracted [AVE]), and discriminant validity (cross-loading analysis, Fornell-Lacker Criterion Analysis, and heterotrait-monotrait ratio) [26]. Evaluation of the structural model included an analysis of collinearity, significance, coefficients of determination (R^2), size and significance of the path coefficients, effect size (f^2), and predictive relevance (q^2). Goodness of fit was not assessed as this was an exploratory PLS path model with both reflexive (measurement model) and formative (structural model) components, rendering current model fit measurements unnecessary and inappropriate [28].

As PLS-SEM does not assume that data are normally distributed—it relies on a nonparametric bootstrap procedure to test the significance of the estimated path coefficients in PLS-SEM. With bootstrapping, subsamples are created with randomly drawn observations from the original set of data (with replacement) and then used to estimate the PLS path model [28].

SmartPLS [29] was used for the PLS analysis. The maximum iterations were set at 300 with +1 as the initial value for all outer loadings, and the path weighting scheme and the stop criterion at 1×10^7. Basic bias-corrected bootstrapping was used with 1000 samples at a significance level of $P<.05$. SPSS (2017) [30] was used for the analysis of descriptive statistics (mean and SD), and frequency counts, the Harman single-factor test, and a Wilcoxon signed-rank test was used to detect before and after changes in scores [31,32]. Webpower [33] was used to verify the nonnormality of the data before the analysis.

Qualitative interview data were subjected to thematic analysis (inductive and deductive) to identify, analyze, and report patterns (themes) in rich detail and allow the researcher to interpret various aspects of the topic [34]. Although inductive analysis allowed for themes to emerge from the data, deductive analysis was guided by the research questions regarding the perceived technology acceptance and usability of 3MDR among end users, including the perceived strengths, weaknesses, and recommendations for future use. Following a review of the data and completion of the secondary level of analysis, the themes were narratively summarized with the aim of organizing, describing, exploring, and interpreting the data. Key quotations were selected to substantiate these findings. To ensure the validity, reliability (dependability), and conformability of the analysis, researcher bias was clarified and bracketed, and an external audit of the analysis was conducted by other members of the research team [35-37]. The main theme with 3 subthemes emerged through thematic analysis of the data, which was relevant to the question of technology acceptability.

A concurrent parallel approach following a data transformation model was used in the data analysis process to convert data to compare quantitative statistical results with qualitative findings [38].

Results

Demographics

A total of 29 end users of 3MDR participated in this study. The demographic information of the military (3/29, 10%) and veteran (8/29, 28%) sample is displayed in Table 1 and of the 3MDR therapists (13/29, 45%) and operators (5/27, 17%) in Table 2. Of the total sample, only some military members and veterans (9/11, 82%), 3MDR therapists (4/13, 31%), and 3MDR operators (2/5, 40%) had the ability to fill out the pre- and post-UTAUT questionnaires. All participants (N=29) participated in the qualitative interviews. The sample was largely composed of men (19/29, 66%), which prevented the use of gender as a moderator variable in the UTAUT research model. In addition, the age of participants (young or middle-aged) did not demonstrate an effect in the research model and was, therefore, removed from the final PLS model.

UTAUT Analysis

The psychometric properties of the raw data of the survey items used to measure the latent variables are shown in Table 3. The difference between the means of the pre-post summative scores is a 0.82% increase. When mean pre-post total scores indicate <5% difference in change, it indicates that the expectations of the participants regarding technological innovation were met within the constructs tested [19]. Using a Mann-Whitney *U* test, no significant difference was found between the therapists and operators and participants (*P*=.55).

The results of the measurement model evaluation, including the factor analysis, internal consistency (Cronbach α), convergent validity (AVE), and composite reliability, are shown in Table 4 The factor indicators, known as the outer loadings or reflexive indicator loadings, should be ≥0.5, demonstrating that the indicator variable is a good measurement of the latent variable [26]. Only one outer loading for SI was below this threshold, indicating good indicator reliability (Table 4). All latent variables, with the exception of SI, demonstrated values >0.70 for both Cronbach α and AVE, which would indicate good validity and reliability of the latent variables [26,38]. Composite

reliability is displayed in Table 4 for all values, with the exception of SI ≥0.7, which is acceptable.

To evaluate discriminant validity, cross-loading, Fornell-Larcker Criterion, and heterotrait-monotrait ratio (Table 5) were used. These measures demonstrated good discriminant reliability for all the latent variables. FC demonstrated the highest correlation with BI based on this analysis. Potential common method bias was assessed with the Harman single-factor test, yielding cumulative and variance loadings <50%.

The measure of lateral collinearity of the structural model demonstrated inner variance inflation factor values <5 for 10 (66.67%) latent variables, with the exception of indicator variables number 1 (5.649), 2 (9.215), and 3 (5.410) for PE, 11 (5.584) for FC, and 14 (7.392) for BI. The coefficient of determination (R^2) measures the proportion of variance in a latent endogenous variable that is explained by other exogenous variables, expressed as a percentage. The explained variance (R^2) of the structural model was 0.410, demonstrating moderate predictive accuracy [26,38]. The effect sizes (f^2) for each latent variable are presented in Table 6. On the basis of this analysis of the structural model, EE had the largest path coefficient and effect size, indicating that it was the strongest predictor of BI, although this was not significant (P=.40; Table 5 and Figure 2). The predictive relevance (q^2) was >0 (0.026). None of the latent variables were statistically significant (P=.05).

A multigroup analysis with the PLS path model attempted to compare pre-post scores; however, this was not possible because of sample size restrictions. Instead, a Wilcoxon signed-ranks test was used to determine if there were any statistically significant changes in scores from before the technology was used (before to T0) to after the occurrence of the 3MDR course (after to T1). This showed a significant pre-post increase in the EE score only (Z=65; P=.004), with pre-post scores for all other variables yielding a nonsignificant change (Table 7). This demonstrates that the participants felt that the perceived ease of use of the technology was likely to increase after using 3MDR in the VRE, whereas the scores regarding the other latent variables remained largely unchanged from before to after.

Table 3. Psychometric properties of indicators used to measure latent variables.

Exogenous latent variables (indicators)	Values, mean[a] (SD[b])	Values, median[c]
Performance expectancy (3 indicators)		
• Using the CAREN[d] system improved my medical condition (patient) • Using the CAREN improved the medical condition of my patient (therapist and operator)	5.714 (1.082)	6
• Using the CAREN system had a positive effect on my medical condition (patient) • Using the CAREN system had a positive effect on the medical condition of my patient (therapist and operator)	5.643 (0.961)	6
• The CAREN system improved my quality of life (patient) • The CAREN system had improved the quality of life of my patient (therapist and operator)	5.357 (1.060)	6
Effort expectancy (3 indicators)		
• Interacting with the CAREN system was easy for me (patient, therapist, and operator)	6.429 (0.632)	6
• I believe my interaction with the system was clear and understandable (patient, therapist, and operator)	6.500 (0.516)	7
• I found the system easy to use (patient, therapist, and operator)	6.429 (0.516)	6
Social influence (3 indicators)		
• People who are important to me think that I should be involved in using the CAREN system (patient, therapist, and operator)	5.214 (1.496)	6
• I would use the CAREN system because my colleagues will use it too to improve their medical condition (patient) • I used the CAREN system because my colleagues used it too to improve the medical condition of my patient (therapist and operator)	3.714 (1.944)	6
• In general, my organization has supported my involvement in this initiative (patient, therapist, and operator)	6.286 (1.290)	6
Facilitating conditions (3 indicators)		
• I believe guidance was available to me during my interaction with the CAREN system (patient, therapist, and operator)	6.571 (0.507)	6
• I believe specialized instruction concerning the interaction with the CAREN system was available to me (patient, therapist, and operator)	6.500 (0.640)	6
• A specific person (or group) was available for assistance with CAREN system difficulties (patient, therapist, and operator)	6.500 (0.834)	6
Behavioral intentions (3 indicators)		
• I am willing to use the CAREN system in the next weeks (patient, therapist, and operator)	6.571 (0.632)	6
• I plan I would use the CAREN system if I am willing to do so (patient, therapist, and operator)	6.071 (1.246)	6
• I predict I will use the CAREN system in the future (patient, therapist, and operator)	5.857 (1.438)	6

Thematic Analysis

Overview

Thematic analysis was conducted by analyzing the responses to the open-ended questions from the UTAUT questionnaires and interviews after 3MDR for the participants, therapists, and operators. Three themes emerged: (1) feasibility and function, (2) technical support, and (3) tailored immersion (Table 8).

Table 8. Thematic analysis results of open-ended questions from the Unified Theory of Acceptance and Use of Technology questionnaire and qualitative interviews.

Theme	Illustrative quote
Feasibility and function	• "The look of the program, it just looks a bit outdated and its small, can be more attractive to make it more user-friendly...but it does work, then with the new session [we] have a.PDF file with all the pictures and associations and units of distress, walking speed average...[with] this new system [documentation] looks way better—not just a sheet with all the information...being able to download the data in a clean way." [T13] • "Improve resolution of photos." [T7]
Technical support	• "I suppose that there is a lot of moving pieces, so it is technology dependant, so if something goes down and there is a glitch it throws a monkey wrench in it. You need 'techy' people." [T1] • "I would just give the pictures to the operator, everything worked fine. I feel, like I said, I feel comfortable being in that, or working with that technology." [T5]
Tailored immersion	• "I want to make it more personalized, now the virtual reality has been chosen by a developer who thinks this is the correct virtual environment, but I think this is the wrong way around. I think we should let our patients decide which virtual environment they want to walk in." [T20] • "When people walk fast they are also walking fast to the picture. I would like to have an option to increase the length of the tunnel, so people can walk fast, but so the photo doesn't come up as fast." [T21]

Feasibility and Function

Overall, the CAF military members, veterans, therapists, and operators found that 3MDR was feasible and functional within their given environments for the purpose of the research study. That said, the end users, particularly therapists and operators, noted a number of items that they felt could be improved to enhance the overall functioning and patient experience in hopes that it would lead to better outcomes. Improvements to the technology that would assist with the delivery and functionality of 3MDR for therapists and operators included more streamlined documentation, ease of downloading of data, and overall intuitiveness of the software. This theme fits within the construct of EE, as many of the suggested modifications and improvements targeted to improve the ease of use of the overall 3MDR system elements [19]. In addition, some aspects, such as improving the quality of the images, correlate with PE, for which improved performance or outcomes is a potential goal.

Technical Support

Similarly, CAF military members, veterans, therapists, and operators identified that they felt satisfied with the level of technical support they received. The participants felt that the team was knowledgeable and able to operate the hardware and software with a high level of competence. When there were glitches, they could be troubleshooted and resolved within a reasonable amount of time. Therapists generally felt that the 3MDR operator was their main source of technological support and that the operators were proficient in providing this. The operators generally felt that they were able to receive support from other VRE operators globally, who had also used 3MDR. The experience of the operators with software and hardware support from vendors was variable, with some reporting that the vendor's expertise with technology geared toward physical health interventions rather than mental health was a barrier. The theme of technical support falls under the construct of FC as it regards that organizational and technical infrastructure exists to support the use of the system [19].

Tailored Immersion

The desire to customize the experience of 3MDR for the patient through technology was the strongest theme among the CAF military members, veterans, therapists, and operators. The vast majority of feedback regarding the technological aspects of 3MDR and the associated VRE provided recommendations on how population-specific stakeholders should be used to adapt the hardware and software for future tailoring of the 3MDR intervention. 3MDR therapists desired to have the ability to tailor aspects of the software, such as the length of the tunnel, length of the image exposure, default VRE, and the number of images, in real time based on their clinical observations and needs. Therapists and participants also identified the need to make 3MDR software and hardware accessible to those who may have reduced mobility and who may use a wheelchair. Tailored immersion is correlated with the construct of PE. The desired customization of software and hardware stems from the belief that the system will help the patient or participant attain gains in performance or improved outcomes regarding their PTSD symptoms.

Discussion

Principal Findings

In this preliminary study, the UTAUT model was used as the theoretical foundation for understanding the behavioral intention of CAF military members and veterans with crPTSD, as well as their therapists and operators, in using 3MDR. On the basis of the study results, 3MDR delivered within a VRE appears to be promising as a feasible, usable, and accepted technological intervention for end users, with EE being the most notable predictor of BI and deemed to be the most important to end users. Although the qualitative data support this, it is worth noting that none of the latent variables yielded statistical significance with PLS-SEM. There was also no significant difference detected between the patient end user (CAF military members and veterans) and the health care end user (therapists and operators) scores for PE, EE, SI, FC, or BI. The analysis of the open-ended questions and qualitative interviews revealed

several subthemes that can be attributed to the latent variables, including EE, PE, and FC of the UTAUT, as well as BI as a construct. To triangulate the quantitative and qualitative data, possible explanations for the results were formulated [37].

Overall, end users rated all the latent variables (PE, EE, FC, and SI) and BI favorably for the technological aspect of 3MDR. The data demonstrated that participants generally agreed or strongly agreed with the statements made in the UTAUT questionnaires, especially for the variables of PE, EE, and FC. The results of PLS-SEM analysis demonstrated good internal consistency, convergent validity, composite reliability, and discriminant validity of the indicators, with a moderate predictive accuracy of the model.

EE is the degree of ease associated with the use of a system [19]. EE had the largest path coefficient and effect size, indicating that it was the strongest predictor of BI when compared with the other latent variables. A statistically significant increase in EE was noted in the pre-post analysis, whereas the pre-post changes in the other latent variables were nonsignificant. A change of <5% (0.82%) in the before and after scores indicates that the expectations of the technological aspects of 3MDR were generally met or exceeded. This was further verified by a statistically nonsignificant difference in pre- and post-UTAUT questionnaire results based on the Wilcoxon signed-ranks test.

This is contrary to the hypothesis that FC is the strongest predictor based on previous literature regarding patients and health care professionals in a North American context [12,21]. However, previous literature has hypothesized that military organizations' approach to technology is to measure and maximize operator performance to increase system efficiency, which translates to success in military missions [23]. This may provide some insight into why the CAF military members and veterans felt that ease of use or efficiency was the most important aspect of a favorable user experience. Many of the qualitative quotes within the subthemes fell into the category of EE, demonstrating that 3MDR within the VRE was perceived as easy to use by all study end users, which was of utmost importance. Given that both the qualitative and quantitative data demonstrated that this latent variable was important to the end users in the study, it should be considered further in modifications and adaptations to 3MDR and the used VRE.

As previously mentioned, PE refers to the degree to which an individual believes that using the system will help the person attain gains in performance [19]. In the context of 3MDR within a VRE, performance is measured and communicated via clinical outcome measures, live biofeedback data, feedback from the therapist or patient, and the subjective experience of PTSD symptoms after the intervention session [9]. During the 3MDR platform sessions, the participant is limited to their intrinsic subjective insight to speculate on their performance without any immediate feedback on their performance. Only after the actual 3MDR sessions would the military member or veteran notice any changes in their PTSD symptoms and attribute them to 3MDR and thus their PE. In addition, therapists and operators do not have any direct feedback during the sessions on their own performance unless there is a technological event during the session in which they cannot reconcile, such as a technological malfunction. These notions may be logical explanations as to why PE did not register as an important factor in BI and did not demonstrate a significant pre-post change. It should also not be ignored that the indicator variables for PE demonstrated issues with lateral collinearity, as demonstrated by their variance inflation factors, which may affect the accuracy of this latent variable.

SI is the degree to which an individual perceives that it is important that others believe that they should use the new system [19]. As 3MDR was administered within a research study with limited persons present and confidentiality was maintained, it is unlikely that the patients perceived SI as being relevant specifically to the 3MDR technology. This was demonstrated to be an accurate hypothesis as SI was the least influential latent variable in the prediction of BI. Previous studies have demonstrated that SI is less likely to factor into the perceived acceptance and usability of health care technology than other latent variables for health care professionals [14,21,22]. On the basis of the previous literature, health care providers have demonstrated emphasis on PE, EE, and FC as constructs that influence BI and, therefore, use.

FC is the degree to which an individual believes that organizational and technical infrastructure exists to support the use of the system [19]. This latent variable did not have much impact on BI based on PLS-SEM, as predicted in the hypothesis. In the qualitative themes, technical support came through as a priority for end users in different ways, which would fall under the FC. For the 3MDR therapists, having the belief that the 3MDR operator had the infrastructure and knowledge to effectively run the VRE and facilitate the 3MDR software was important. Subsequently, this confidence in the operator was also transmitted to the participant, who had confidence in both the operator and the therapist that any technological challenges could be quickly and seamlessly fixed. It is logical that the 3MDR participants felt supported by their therapists, operators, study team, organization, and other facilitators in the immediate environment.

Limitations of Study

Although PLS-SEM is ideal for exploratory research and flexible with its nonparametric lack of assumptions regarding data distribution, several limitations need to be considered. First, measurement errors always exist to some degree and are challenging to quantify accurately. PLS-SEM bias refers to the tendency of the path model relationships to be frequently underestimated, whereas the parameters of the measurement model, such as the outer loadings, are overestimated when compared with covariance-based SEM. Measurement errors can also be introduced by variables such as the participants' understanding of the questionnaire items. In addition, the administrative burden of the study, when combined with other outcome measures attributed to the greater clinical trial with which this study was affiliated, may have caused some participants to rush through final questionnaires or experience fatigue and a reduced level of engagement. Second, the lack of global goodness-of-fit measures is an unavoidable drawback of PLS-SEM. Finally, the small sample size because of COVID-19

related shutdowns made it impossible to incorporate the moderator variables of age and gender, as was originally planned in the research model, and the desired sample power was not met (Figure 1). Despite these shortcomings, it is important to discuss preliminary findings and address technology acceptance and usability early in the process of implementing novel interventions to ideally detect and avoid problems with end user buy-ins, which could hinder the uptake and spread of potentially valuable innovations in health care settings. The research team will be continuing data collection to reach the desired sample size in the future.

Future Research

The technology acceptance and usability of 3MDR within a VRE, as well as other interventions using technology, warrant evaluation within military and civilian health care contexts and at multiple user levels, including the patient, health care professional, and organization. This also extends to the use of web-based health care technologies where the patient is in a separate location from the health care professionals—a practice that is becoming increasingly widespread, especially in the wake of a global pandemic [17,18]. Future research that could support the advancement of 3MDR might include studies with larger samples to allow for the ability to incorporate moderator variables such as age, gender, voluntariness of use, and experience, as well as to use other models of technological acceptance and usability. In addition, the exploration of the utility of the UTAUT as a model for health care technology warrants continued investigation in both civilian and military settings, where research is extremely scarce [22,23]. Equally, the improvement of 3MDR hardware and software has evolved at a rapid pace, further complicating accurate research. Since this study, a number of the themes mentioned by end users have already been addressed, and tailored immersions and customizability of the hardware and software for other trauma-affected populations are being trialed. As 3MDR evolves to be more accessible and uses new hardware such as wearable VR, acceptability and usability perceptions of end users will need to be considered. In addition, a cost analysis of 3MDR would also be beneficial to study, as this also affects the implementation of technological innovation in health care. Finally, future research is needed to address its acceptability and effectiveness among other trauma-affected populations, which may improve accessibility to 3MDR.

Conclusions

Numerous military personnel and veterans from around the globe who have returned from deployment continue to struggle with the symptoms of PTSD. Despite the plethora of research, publications, and attention that PTSD has received in recent years, many questions remain regarding the complexities of treating the psychological symptoms attributed to this diagnosis. 3MDR challenges traditional conventions and configurations. It is important to incorporate the study of technology acceptance and usability into the implementation of novel VR-supported health care processes to ensure that technological advances aimed at assisting patients will be embraced by the primary intended users. This is important at the micro, meso, and macro levels, especially within unique organizational contexts such as military and health care systems. 3MDR appears to be a promising intervention for crPTSD, with good acceptability by end users, including CAF military members and veterans, as well as 3MDR therapists and operators. The future for the usability of 3MDR is promising, and new and exciting intervention avenues for crPTSD will emerge because of continued research. As civilian and military health care systems increasingly integrate technological innovations to improve the services and care provided to their patients, research must continue to address questions of technological acceptance of the intervention before its wide-scale adoption.

Acknowledgments

The research team would like to acknowledge that this research was supported by the Royal Canadian Legion Alberta/Northwest Territories Command, Government of Alberta Grant, Glenrose Rehabilitation Hospital Foundation, and Government of Canada Innovation for Defense Excellence and Security Grant. The research team would also like to thank the study participants for sharing their time and experiences; the funders for enabling the study; the Glenrose Rehabilitation Hospital, Canadian Armed Forces, Alberta Health Services, the Royal Canadian Legion Alberta/Northwest Territories, and Veterans Affairs Canada for their continued support; and Ms Melissa Voth for her help in formatting the paper for publication.

Conflicts of Interest

EV created the 3MDR but would not stand to benefit financially were it to be adopted into routine clinical practice.

Abstract

Background: Message frame–tailoring based on the need for autonomy is a promising strategy to improve the effectiveness of digital health communication interventions. An example of a digital health communication intervention is Personal Advice in Stopping smoking (PAS), a web-based content-tailored smoking cessation program. PAS was effective in improving cessation success rates, but its effect sizes were small and disappeared after 6 months. Therefore, investigating whether message frame–tailoring based on the individual's need for autonomy might improve effect rates is worthwhile. However, to our knowledge, this has not been studied previously.

Objective: To investigate whether adding message frame–tailoring based on the need for autonomy increases the effectiveness of content-tailored interventions, the PAS program was redesigned to incorporate message frame–tailoring also. This paper described the process of redesigning the PAS program to include message frame–tailoring, providing smokers with autonomy-supportive or controlling message frames—depending on their individual need for autonomy. Therefore, we aimed to extend framing theory, tailoring theory, and self-determination theory.

Methods: Extension of the framing theory, tailoring theory, and self-determination theory by redesigning the PAS program to include message frame–tailoring was conducted in close collaboration with scientific and nonscientific smoking cessation experts (n=10), smokers (n=816), and communication science students (n=19). Various methods were used to redesign the PAS program to include message frame–tailoring with optimal usability: usability testing, think-aloud methodology, heuristic evaluations, and a web-based experiment.

Results: The most autonomy-supportive and controlling message frames were identified, the cutoff point for the need for autonomy to distinguish between people with high and those with low need for autonomy was determined, and the usability was optimized.

Conclusions: This resulted in a redesigned digital health communication intervention that included message frame–tailoring and had optimal usability. A detailed description of the redesigning process of the PAS program is provided.

Introduction

Background

In 2018, a total of 22.4% of the adult Dutch population indicated to be occasional smokers [1]. In 2017, an attempt to quit smoking at least once was undertaken by 35.7% of Dutch smokers; however, most smokers did not succeed in stopping smoking permanently [2]. Therefore, it is important to provide effective interventions to support smokers to stop smoking and prevent the relapse of smoking. For instance, computer-tailored interventions appear to be a promising and cost-effective solution [3-6].

Computer tailoring refers to an automated communication strategy intended to reach every individual with tailored messages by adapting these messages to the individual's unique characteristics and his or her behavioral and motivational state [3,7,8]. Generally, computer tailoring focuses on tailoring the content of health communication interventions [9-11]. An example of a web-based computer-tailored intervention is Personal Advice in Stopping smoking (PAS) [12]. This is a computer-tailored smoking cessation program, which provides tailored feedback based on respondents' answers to web-based questionnaires based on the Integrated-Change (I-Change) Model [13]. The I-Change Model combines insights from several behavior change theories, such as the Transtheoretical Model [14], Theory of Planned Behavior [15], Social Cognitive Theory [16], and the Health Belief Model [17]. As such, the I-Change Model assumes a person's behavioral intention to be the most proximal predictor of behavior. In turn, this behavioral intention is proposed to be predicted by three motivational constructs: attitude (represented by perceived advantages and disadvantages of the behavior), perceived social influence (composed of perceived social norms, social modeling, and social pressure), and self-efficacy (a person's perceived ability to perform the behavior). Furthermore, the I-Change Model includes several premotivational factors: predisposing (eg, past behavioral experiences), awareness (eg, knowledge), and information (eg, message source) factors. Finally, the I-Change Model suggests that although a positive behavioral intention is needed for behavior change to occur, several postmotivational factors play a role in bridging the gap between intention and behavior [18], with perceived barriers to change widening this gap and ability factors (eg, skills and the formation of action plans) narrowing this gap.

Given its theoretical grounding, the PAS program starts with a baseline assessment consisting of questions on sociodemographic characteristics, smoking behavior, and addiction level, but, then, continues to ask questions about the respondent's intention to quit smoking, attitude, social influence, self-efficacy beliefs, and action and coping planning on how to stop smoking and prevent the relapse of smoking [12]. Then, the PAS participants receive tailored feedback messages based on their answers [12]. Questions and feedback messages alternate, meaning that, participants answer a question—or a set of related questions—and immediately receive the feedback message associated with their answer and, then, receive the next question. At the end of the program, participants receive an overview of their tailored feedback messages, which can be printed and sent to them through email if desired. A detailed description is provided elsewhere [12,19].

An investigation of the effects of PAS among Dutch smokers indicated a significant effect on smoking abstinence, reported 6 weeks after the initiation of participation in the program. However, 6 months after participation initiation, significant intervention effects could no longer be found [19]. In other web-based computer-tailored interventions to promote health behavior, intervention effects also declined after intervention completion [20]. Therefore, and because overall effect sizes remain small [3,20], it is worth exploring additional strategies that might enhance intervention effects. A proposed strategy to improve the effectiveness in addition to tailoring *what* information is presented (ie, content tailoring), is tailoring *how* this information is presented, which is known as message frame–tailoring [10].

Message frame–tailoring refers to an integration of the message frame theory [21] and theory around tailoring of health information [22]. According to the message frame theory, the manner in which information is presented is referred to as framing of information, which contains 2 aspects: selection and salience [21]. Selection refers to choosing several aspects to communicate, and salience is defined as "making a piece of information more noticeable, meaningful, or memorable" [21]. Selecting elements to communicate and making them more (or less) salient to the audience will capture the audience's attention and, as a result, make the information more likely to be read and processed. This is where tailoring theory comes in, as tailoring of information is also done to increase the likelihood that information is read, processed, remembered, and acted upon. Tailoring is "any combination of information or change strategies intended to reach one specific person and increase the personal relevance of the information for this particular person, based on characteristics that are unique to that person, related to the outcome of interest, and derived from an individual assessment" [8]. Relevance of the presented information for an individual is a key concept in this definition, as personally relevant information may lead to more in-depth information processing [22]. Combining message frame theory with theory around tailoring leads us to the definition of the main concept described in this paper, that is, message frame–tailoring, which is "adjusting the perspective when formulating a message based on people's individual needs" [10]. In this study, message frames were tailored to respondents' *need for autonomy*, a theoretical concept derived from self-determination theory (SDT) [23]. Tailoring health messages to respondents' need for autonomy is important because health messages should not only be read and considered as personally relevant but, above all, should encourage behavior change by increasing the recipients' autonomous motivation for change. According to SDT, autonomous motivation plays an important role in enhancing the initiation and maintenance of health-related behavior [24]. To be autonomously motivated, people need to experience a sense of volition and freedom to make their own choices. On the other hand, people are likely to not feel autonomously motivated when they feel controlled and experience pressure to think, feel, or behave in a manner that has been imposed on

them [25]. In SDT, this prerequisite for autonomous motivation is called fulfilling the need for autonomy [23]. However, according to SDT, individual differences in the need for autonomy exist regarding health and health-related decision-making. For example, some people prefer to choose their own path toward lifestyle improvement, whereas others prefer to be guided by clear-cut expert advice [26,27]. To meet these individual differences in the need for autonomy, the manner of information provision in health messages can be tailored based on this need, to accommodate an individual's associated processing and communication style preferences and further increase the personal relevance of the message [10].

In our operationalization, message frame–tailoring based on the need for autonomy consists of 2 components: language (ie, autonomy-supportive or controlling) and choice (ie, provision of choice or no choice) [28,29]. Autonomy-supportive language, or noncontrolling language, is defined as "a vocalization that would allow choice or support self-initiation" [30] and can be used for individuals with high need for autonomy. Autonomy-supportive language encourages individuals to take responsibility for their own behavior and make decisions based on their own values [28,30]. This involves minimizing pressure [28] and using words such as *could*, *might*, and *would*. Controlling language is defined as "a vocalization to pressure a person to behave (or think or feel) a particular *way*" [30] and can be used for individuals with low need for autonomy. Controlling language is characterized by the use of commands, orders, imperatives, and suggestive questions [30]. Examples are words such as *must*, *should*, and *ought*. Choice is operationalized as offering participants the option to receive additional information about a certain topic [31]. Tailoring message frames to a person's need for autonomy may enhance the motivation to change and maintain health-related behavior. As such, message frame–tailoring based on the need for autonomy has been suggested as a promising avenue to explore further [10,26,27,32]. However, to date, to the best of our knowledge, no health-related computer-tailored intervention has been reported that incorporates message frame–tailoring based on the need for autonomy, except the study by Smit et al [10].

Objective

To investigate whether adding message frame–tailoring based on the need for autonomy increases the effectiveness of content-tailored interventions, the PAS program [12] was redesigned to incorporate message frame–tailoring. This paper describes the process of extending framing theory, tailoring theory, and SDT by redesigning the PAS program to include message frame–tailoring. The redesigning process was conducted in close collaboration with communication science students, experts, and the actual end users (ie, smokers).

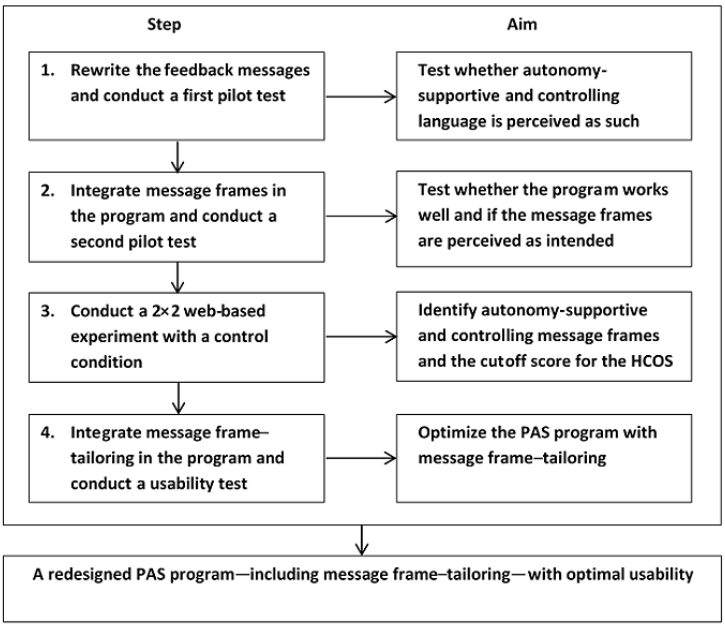
Methods and Results

Overview

The process of redesigning the original PAS program to incorporate message frame–tailoring consisted of four steps: (1) the feedback messages were rewritten in an autonomy-supportive and a controlling manner and a first pilot test was conducted, (2) the message frames were integrated into the program and a second pilot test was conducted, (3) a web-based experiment with a 2×2 between-participants design with a control condition was conducted, and (4) message frame–tailoring was integrated into the program and a usability test was conducted. An overview of the steps is presented in Figure 1, and the 4 steps are described in detail in subsequent sections. OverNite Software Europe provided technical support and usability advice during the redesign process.

The study was registered in the Netherlands Trial Register (NL6512/NRT-6700).

Figure 1. Overview of the redesign process. HCOS: Health Causality Orientations Scale; PAS: Personal Advice in Stopping smoking.



Rewrite the Feedback Messages and Conduct a First Pilot Test

To tailor message frames based on the need for autonomy, the message frames needed to be developed. The feedback messages of the original PAS program were rewritten using autonomy-supportive and controlling language strategies. To test whether the language strategies were perceived as such, a pilot test was conducted among communication science students. After consenting to participate, students were randomly assigned to either evaluate the autonomy-supportive or controlling messages. The students received a questionnaire with 5 messages to be reviewed using a 5-point response scale, ranging from very autonomy-supportive to very controlling [33]. Students were also able to write comments on each message in a textbox. A total of 19 students participated (mean age 23.2, SD 1.44 years; 2/19, 11% were men; 15/19, 79% were nonsmokers). Of the 19 students, 10 (53%) students received the autonomy-supportive messages and 8 (42%) students received the controlling messages. Quantitative results were analyzed using an independent sample *t* test (2-tailed) using SPSS (IBM Corp), and the qualitative comments were inspected to identify relevant comments regarding language use.

As the 5-point scale ranged from very autonomy-supportive (rating=1) to very controlling (rating=5), we expected lower scores for the autonomy-supportive messages than the controlling messages. Results showed significantly lower scores for the autonomy-supportive messages (mean 2.46, SD 0.62; $P<.001$) than the controlling messages (mean 3.68, SD 0.32), which means that participants detected the language manipulation as intended. However, based on participants' comments and inspection of the differences between messages that had high or low scores and those that had average scores, we further emphasized communication style (autonomy-supportive vs controlling). The main change consisted of emphasizing with *signal words* on the type of language style—autonomy-supportive or controlling—used at the beginning of each message (eg, starting the message with "you must..." in a controlling message).

Subsequently, the second message frame element, choice, was added. The following question was included 6 times throughout the program: "Do you want to receive these tips?" which could be answered with "yes" or "no." In addition, participants were asked if they wanted to choose a quit date themselves. Furthermore, participants could choose whether and for which potential difficult situations they wanted to formulate coping plans to refrain from smoking in these situations.

Integrate Message Frames in the Program and Conduct a Second Pilot Test

Adding message frames (autonomy-supportive vs controlling language and provision of choice vs no provision of choice) to the feedback messages of the original PAS program resulted in four versions of the program: (1) autonomy-supportive language and no choice, (2) autonomy-supportive language and choice, (3) controlling language and no choice, and (4) controlling language and choice. Besides the 4 message frames, 1 control condition was added to the program, consisting of generic smoking cessation advice with a neutral message frame (ie, the message frame was not manipulated and was the same as in the original smoking cessation intervention) and no content tailoring (ie, the messages were not tailored based on participants' answers). Following is an example of a control message:

> *When smokers are stressed, tensed, or dreary, they often find it difficult not to smoke. To help you with this, we give you a few tips. If you find yourself feeling emotional and wanting a cigarette, it's good to do something else. You can take a walk: the outside air may do you good. Or you can exercise. This helps you to change your mind and reduces the desire for a cigarette.*

Examples of feedback messages for the 4 message frames are presented in Table 1. For more examples, refer to the study by Altendorf et al [31].

The next step in the redesign process was conducting a second pilot test to investigate the intervention from experts' and smokers' perspectives. Totally, 5 experts (4/5, 80% men) and 11 smokers (8/11, 73% men) participated in the usability test and the subsequent interviews. The experts were working as professionals or researchers in the fields of health communication, public health, eHealth intervention development, and smoking cessation support. First, participants received a link to the website and were instructed to complete the program, while paying attention to the comprehensibility of the program and the feedback messages. Subsequently, a researcher interviewed the participants on the following topics: time taken to conduct the program; comprehensibility of instructions, questions, and answer categories; and awareness of the message frame used. Participants were rewarded with a shopping voucher worth €10 (US $11). During the usability tests and the interviews, the researcher took notes. Results were discussed within the research team to determine whether changes to the program were required to resolve issues mentioned in the feedback.

The participants took between 20-60 minutes (average 35 minutes) to complete the program. As the introduction was perceived as very long, it was shortened. In addition, some questions seemed to be unclear; therefore, a brief instruction was added. Some questions needed to be reformulated (eg, using more familiar words and not using double negatives). In addition, participants wished to receive the summary of feedback messages by email; thus, this option was added. The message frames were generally perceived as intended; therefore, no modifications were made regarding this aspect. After incorporating these changes, the PAS program with message frames was ready for use in the next step.

Table 1. Examples of feedback messages for the different message frames.

Condition and process	Autonomy-supportive language	Controlling language
No choice		
Message	You answered that you will succeed in not smoking if you are stressed, tensed, or dreary. You doubt whether you will succeed in not smoking when you are angry. We would like to offer you some tips. If you notice that you are emotional and would like to have a cigarette, you can try to do something else. For example, you could take a walk: the outside air might do you good. Or you could exercise. This might help you to change your mind and it reduces the desire for a cigarette.	You think that you will succeed in not smoking if you are stressed, tensed, or dreary. You doubt whether you will succeed in not smoking when you are angry. You need to do something else when you are emotional and want a cigarette. Take a walk: the outside air often works well. Or go exercise: this should help to change your mind and reduces the desire for a cigarette.
Choice		
Message 1	You answered that you will succeed in not smoking if you are stressed, tensed, or dreary. You doubt whether you will succeed in not smoking when you are angry. Below, you can choose whether you would like to receive some tips on what you can do when you are emotional and would like to have a cigarette.	You think that you will succeed in not smoking if you are stressed, tensed, or dreary. You doubt whether you will succeed in not smoking when you are angry. Below, you can choose whether you would like to receive some tips on what you can do when you are emotional and would like to have a cigarette.
Choice question[a]	Do you want to receive these tips?	Do you want to receive these tips?
Answer	Yes	Yes
Message 2	If you notice that you are emotional and would like to have a cigarette, you can try to do something else. For example, you could take a walk: the outside air might do you good. Or you could exercise. This might help you to change your mind and it reduces the desire for a cigarette.	You need to do something else when you are emotional and want a cigarette. Take a walk: the outside air often works well. Or go exercise: this should help to change your mind and reduces the desire for a cigarette.

[a]If respondents answered "no" to the choice question, the intervention continued without the provision of the tips.

Conduct a 2×2 Web-Based Experiment With a Control Condition

To tailor message frames based on individuals' need for autonomy, we had to identify (1) the most autonomy-supportive and the most controlling message frame based on participants' perceived autonomy support and (2) the cutoff point to distinguish between people with high need for autonomy and those with low need for autonomy. Therefore, a web-based experiment with a 2×2 (language: autonomy-supportive vs controlling; choice vs no choice) between-participants design with a control condition was conducted. An extensive description of the method and results of this experiment is provided elsewhere [31]. However, we summarize the most important outcomes below.

Participants' need for autonomy was measured using the Health Causality Orientations Scale (HCOS), consisting of 4 vignettes, each of which contained 3 items that could be answered on a 5-point Likert scale (1=low need for autonomy; 5=high need for autonomy) [34]. The primary outcome measure was participants' perceived autonomy support, which was measured with the Virtual Climate Care Questionnaire, consisting of 15 items that can be answered on a 7-point Likert scale (1=low perceived autonomy support; 7=high perceived autonomy support) [35]. Therefore, the HCOS measured participants' general need for autonomy and the Virtual Climate Care Questionnaire measured how the participants perceived the messages in the PAS program; that is, whether they perceived them as autonomy-supporting.

Results showed that participants' perceived autonomy support was generally high (mean 3.46, SD 0.78). On the basis of the results, it was not possible to identify the most autonomy-supportive and the most controlling message frames. Therefore, we decided to follow SDT principles, according to which the provision of choice and the use of autonomy-supportive language enhances an individual's autonomy [23]. Additional inspection of the data supported this decision, as it appeared from the evaluative comments that especially participants with high need for autonomy mentioned that the word *must* was salient in the advice and not appreciated. Furthermore, especially participants with high need for autonomy chose to receive more information when offered choice and wanted to choose a quit date themselves more often than participants with low need for autonomy.

Regarding participants' need for autonomy, the results also showed a high overall score (mean 3.87, SD 0.76). The Johnson-Neyman procedure was followed to identify the need for autonomy score at which the three-way interaction of the need for autonomy, language use, and provision of choice on perceived autonomy support changed from insignificant to significant, resulting in a range of 3.8 to 4.4. The qualitative data showed that participants with need for autonomy ≥3.8 more often made unappreciative comments about not being able to set a quit date themselves and about the word *must* used in their feedback messages. On the basis of these results, 3.8 was chosen as the cutoff point of the HCOS to distinguish between individuals with high need for autonomy and those with low need for autonomy.

On the basis of the evaluative comments from participants, some changes were implemented. First, the participants perceived a period of 2 weeks to set a quit date as very soon. In the original PAS program, the quit date was set 4 weeks after participation initiation, but based on results that showed the importance of immediate action when a quit attempt was considered [36,37], it was decided to shorten the period to 2 weeks. To clarify this to the participants, a brief explanation about the benefits of setting a quit date within a short period was added. Participants in the no choice conditions were still given a quit date within 2 weeks, whereas participants in the choice conditions were offered an additional question of whether they wanted to choose a quit date within 2 weeks. On the basis of their answer ("yes," "no," or "I am not sure yet"), the participants would see a different calendar to set a quit date (ie, a calendar with dates within a time span of 2 weeks, a calendar with dates with a time span of >2 weeks, or a commenting section to enter a date). Second, participants wished to comment on their former quit attempts. Therefore, a question was added about the number of previous quit attempts, followed by a feedback message in which the participants were asked to note why former quit attempts did not succeed and what they have learned from this. Third, participants wanted to receive more information about smoking cessation support tools (eg, medication or nicotine patches), the costs of smoking, and the use of replacing smoking with other oral stimuli (eg, chewing sunflower seeds). New feedback messages regarding these topics were added. Fourth, it was noted that the program was not suitable for a tablet or mobile phone; therefore, the program was made compatible with different devices. This included automatic adjustments to the screen size, alignment of the buttons (eg, forward and print) and pictures, and centering error messages. Finally, as the participants seemed to have difficulties in answering questions that were presented in matrices, all questions were presented as separate questions.

Integrate Message Frame–Tailoring in the Program and Conduct a Usability Test

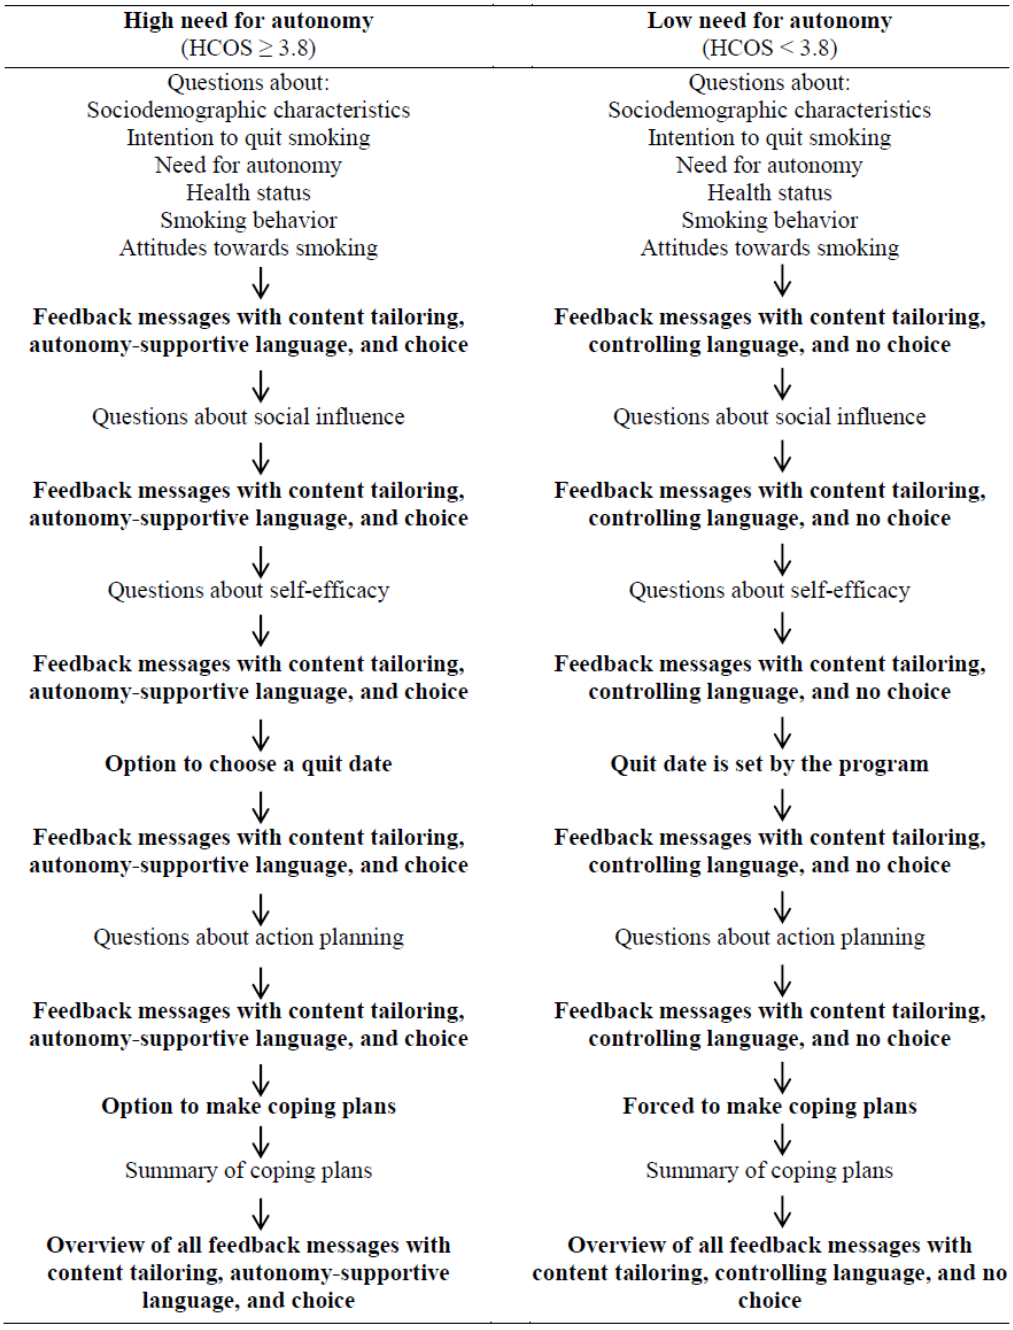
On the basis of the results of the web-based experiment as described in the previous step, the PAS program was developed into a program with message frame–tailoring. The message frame for participants with high need for autonomy (HCOS score ≥3.8) consisted of feedback messages with autonomy-supportive language and choice, and the message frame for participants with low need for autonomy (HCOS score <3.8) consisted of feedback messages with controlling language and no choice. The flow of the redesigned PAS program with content tailoring and message frame–tailoring is presented in Figure 2.

To optimize the PAS program with the tailored message frames, a usability test among experts and smokers was conducted. Regarding user experience, it is argued that, besides the aspect of ease of use, perceived usefulness is also important, which refers to the extent to which the content of the program satisfies the information needs of the participant [38]. Therefore, we aimed to not only identify problems with the use of the program but also to test the content of the program from experts' and smokers' perspectives. Experts were working as professionals or researchers in the fields of health communication, public health, eHealth intervention development, and smoking cessation support.

Both smokers and experts were asked to evaluate the program using the think-aloud method, based on which they were asked to verbalize their thoughts while using the program [39]. As verbalizing one's thoughts while conducting a task is not common, the participants first received a brief task to practice. After completing the usability testing, a semistructured interview was conducted with the smokers to evaluate the program and further explore the problems mentioned. Examples of questions are, "What do you think of the layout of the program?" and "Which are the two most important elements that could be improved?" To identify 80% to 90% of the user issues, 5 to 9 end users were needed [40,41]. The semistructured interviews with experts were based on the heuristic evaluation method [39,42]. The heuristic evaluation method consists of ten heuristic principles, such as simple and natural dialogue, speak the user's language, consistency, and good error messages [42]. To identify most problems by using the heuristic evaluation method, 3-5 experts were needed [39].

As the program will be used on different devices, smokers and experts were instructed to use the program on a laptop, tablet, or mobile phone. The entire procedure took approximately 1 hour to complete, and the participants were rewarded with a shopping voucher worth €25 (US $27.5). Experts and smokers were recruited through the network of the research team. A total of 5 experts (2/5, 40% were men; 4/5, 80% were nonsmokers) and 7 smokers (mean age 31.86, SD 14.15 years; range 20-62 years; 4/7, 57% were men) participated in the usability test. All sessions were video-recorded, which were selectively transcribed and coded using ATLAS.ti 8.0 [43]. The data were analyzed according to the content analysis approach [44]. Deductive content analysis allows us to go beyond general findings and validate theories and models that guided the research. Inductive content analysis allows for inclusion of codes and categories that are derived from the data in an iterative process [45]. First, codes were derived using the heuristic evaluation method [39,42]. Then, the transcripts were thoroughly read and coded. In the next step, categories were identified and ordered into themes that represented the answers to the research questions. When new themes emerged from the collected data, they were added to the analysis [45]. Initially, 2 transcripts were coded independently by 2 coders (ISvSK and MBA). Disagreements were resolved through discussion, and after reaching consensus, 1 coder continued coding the remaining transcripts (ISvSK).

Figure 2. Flowchart of the redesigned Personal Advice in Stopping smoking program that incorporates both content tailoring and message frame–tailoring based on the need for autonomy. HCOS: Health Causality Orientations Scale.



As we aimed to test the content of the program and identify problems with its use, user experience was divided into 2 dimensions: the content of the program and the usability of the program. Modifications that were made regarding the content of the program included the following: replacing difficult words, shortening the introduction and instructions, reformulating questions, changing the labels of answer categories, and adding the quit date to the summary. Modifications that were made regarding the usability of the program included the following: adding a sidebar to show the different parts of the program, modernizing the logo and the colors, displaying only the core messages in bold font, aligning the illustrations on a mobile phone, adding a red frame signaling an unanswered question on the mobile phone, and adding the option to directly add the quit date to a personal agenda. An overview of the codes, subcodes, definitions, examples, and modifications is presented in Table 2.

It is worth noting that participants also wished to receive feedback messages with more illustrations and that some participants wished for shorter feedback messages with more bullet points. However, as the original feedback messages were effective in supporting smokers to quit smoking [19] and making large modifications to this content would mean retesting the effectiveness of the feedback messages, it was decided to stay as close to the original feedback message format as possible.

Table 2. Overview of the codes, subcodes, definitions, examples, and modifications of the usability test.

Code and subcode	Definition	Example	Modifications
1–Language use			
Level and style	Words, concepts, or sentence structures that are unclear or ambiguous. In addition, the use of formal language.	"I don't even know what this is." [smoker]	Difficult words were replaced or explained. Spelling mistakes were corrected.
Amount of information	The amount of information provided in the program, especially in the instruction, introduction, and informed consent.	"Uhm...well...it's a lot of text, I know that a lot of low educated people really hate a lot of text." [expert]	The introduction and instruction were shortened.
2–Questions and answers			
Number and content of questions	The number, relevance, understandability, and topics of the questions in the program.	"I have to read this sentence four times [...] I find it hard to follow. So, I don't know what I have to answer." [expert]	Questions were reformulated.
Answer categories	The answer possibilities, way of answering, and unclarity and inconsistencies regarding scale questions.	"Maybe you also need some kind of range here, don't you? Never, uhm, a few times, very often or I try to do it regularly." [smoker]	The labels of some answer categories were changed. Some answer options were changed from a textbox to a dropdown menu.
3–Feedback messages			
Content and number	The number, length, topics, and content of the feedback messages.	"This is good, good arguments here, especially at the end. With time and money, that is good." [smoker]	A short explanation of the summary of the feedback messages was added. In addition, the quit date was added to the summary.
Credibility and relevance	The concreteness, reliability, and credibility of the feedback messages and whether the messages are perceived as true and suitable to support in quitting smoking.	"They are all things that I have already read and heard, but it is all true." [smoker]	No modifications were made regarding this aspect.
Illustrations	The support of illustrations to the text and the number of illustrations.	"I do indeed see here a picture of someone who gives some kind of support, so that does support the text." [expert]	No modifications were made regarding this aspect.
4–Tailoring			
Content tailoring	The relevancy of the content for a particular participant.	"I think it's good that for each answer category a story is told what really applies." [smoker]	No modifications were made regarding this aspect.
Message framing	The use of autonomy-supportive or controlling language and the provision of choice.	"You must, there is a lot 'must.' I don't feel like quitting smoking anymore." [expert]	No modifications were made regarding this aspect.
5–Program structure			
Structure	The order and structure of the different parts of the program and whether the order is clear. In addition, the feedback that a participant receives via the progress bar and whether it is possible to return to the program.	"Step 3. [...] I don't remember so well that I saw step 2, but those steps are a bit out of the blue. Maybe I should be taken a little more by the hand." [expert]	To make the structure of the program clearer, a sidebar was added, which continuously shows the different parts of the program throughout the completion process, including which part a participant is working on. In addition, the titles of the different parts were made larger.
Instructions	The unclarity of content of the instructions, especially concerning how to complete the program and how to answer the questions.	"How to complete the questionnaire. [...] Well, all basic things." [smoker]	No modifications were made regarding this aspect.
Duration	The duration of the program and time required to complete the program.	"It is long, so maybe people will get bored at some point." [expert]	No modifications were made regarding this aspect.
6–Layout			

Code and subcode	Definition	Example	Modifications
Design	The font size and style, colors, logos, buttons, and illustrations.	"It is very straightforward, so well...there is little...it will be made more beautiful? It is not very inviting." [smoker]	A modern logo was developed and modern colors were used. In addition, the buttons were changed into modern icons. As the print button seemed to appear too often, this was resolved; some inconsistencies in the font size were also resolved.
Readability	The readability of the text, with regard to the layout of the pages, the feedback messages, the summary of the feedback messages, and sentence alignment.	"Shorter sentences, only graphic now in terms of location, you read more easily. This sentence is easier to read than, for example, this sentence, whereby your eye has to go all the way from left to right." [smoker]	The alignment of the sentences was modified. Furthermore, it seemed unclear which information was displayed in bold font; thus, it was decided to display only the core message in bold font.
Layout on various devices	The layout of the program on the various devices (ie, laptop, mobile phone, and tablet).	Someone with a mobile phone: "There is also a picture next to it, that makes the text a bit narrower." [expert]	Changes were made to the alignment of the illustrations on mobile phones.
7–Error messages			
Time of appearance	Whether the error messages appear at the right time.	"I have to give an answer, so that works." [expert]	A red frame signaling an unanswered question was added on mobile phones.
Content	The content of the error messages and whether they are perceived as helpful.	"It was clear that it was about the age question. It was not mentioned that it was about the age question, but I think that's also not possible in an error message." [expert]	No modifications were made regarding this aspect.
8–Features			
Calendar	The appearance and ease of use of the calendar.	"You can also place a link here, or something like that so that it will be added to your agenda automatically." [smoker]	The option to directly add the quit date to a personal agenda was added.
Print or email	The option to print or email the summary of the feedback messages and whether this works. In addition, the layout of the printed summary.	"I like that I can print it because it's a lot to read at once." [expert]	No modifications were made regarding this aspect.

After incorporating the modifications in response to the usability test, the redesign process was completed. The redesigned PAS program—including message frame–tailoring—is shown in Figures 3 and 4. For a comparison with the original interface, refer to the study by Smit et al [19]. This redesigned PAS program has been evaluated in a real-life setting for effectiveness and cost-effectiveness; results of the effectiveness evaluation were recently published elsewhere [46], and the results of the cost-effectiveness evaluation are currently being prepared for publication.

Ethics Approval

This study was approved by the institutional review board of the University of Amsterdam (reference number 2017-PC-7599).

Discussion

Principal Findings

This study aimed to extend the message framing theory, tailoring theory, and SDT by including message frame–tailoring in a digital health communication intervention. In addition to tailoring *what* information is presented (ie, content tailoring), we wanted to improve the effectiveness of a digital health communication intervention by tailoring *how* this information is presented (ie, message frame–tailoring). This paper offers a detailed description of the incorporation of message frame–tailoring in a web-based computer-tailored smoking cessation program, PAS. The PAS is taken as an example to explore the effects of—in addition to the known effects of content tailoring—the promising strategy of message frame–tailoring [10]. The process of incorporating message frame–tailoring was conducted in close collaboration with

experts and smokers, and a usability test was conducted to optimize the redesigned program. An extensive description of the various methods through which experts' and smokers' opinions were included throughout the redesigning process is provided. If the redesigned PAS program is more effective in supporting smokers in their quit attempt than the original PAS program, adding message frame–tailoring to other digital health communication interventions also might be of value.

Potential Strengths

This study has several potential strengths. First, to the best of our knowledge, this study is the first to explore message frame–tailoring in web-based computer-tailored health communication. The existing literature on message framing mostly includes studies on gain and loss framing, focusing on positive (health) outcomes and costs in terms of health loss, respectively. Regarding tailoring, so far, scholars have mainly tailored the content of web-based interventions; that is, adjusting *what* health information is provided based on individuals' current health behavior or their self-reported scores on known predictors of the desired health behavior (change) [9]. To build on tailoring theory, advance the strategy of web-based computer tailoring, and further increase its effectiveness, it has been argued that tailoring *how* information is provided, in addition to tailoring *what* information is given, appears to be a promising strategy [10,32]. To our knowledge, message frame–tailoring based on the need for autonomy and operationalized as differences in the provision of choice and the use of autonomy-supportive or controlling language has not been studied previously. By developing a redesigned PAS program including message frame–tailoring, we were able to test whether message frame–tailoring increases the effectiveness of the PAS program. The results of the effect evaluation were published elsewhere [46]. These results indicated that message frame–tailoring based on the need for autonomy can be an effective additional strategy to include in the computer-tailored interventions in addition to content tailoring, but only for people with high need for autonomy and not for people with low need for autonomy. Regarding cost-effectiveness, the combination of message frame–tailoring and content tailoring in web-based smoking cessation programs seems to have high potential for both cost-effectiveness (ie, considering smoking abstinence as the outcome of interest) and cost-utility (ie, considering quality of life as the outcome), thereby providing good value for money. However, when the willingness to pay for each abstinent smoker becomes high (ie, ≥€5000 [≥US $5500]), the addition of message frame–tailoring might not be worth the effort and only content tailoring is preferred. A manuscript reporting on the results of this economic evaluation is currently in the preparation phase. Given these results, it is plausible that adding message frame–tailoring to other web-based computer-tailored or digital health communication interventions will also increase their effectiveness and cost-effectiveness, at least for people with high need for autonomy. This is important because the overall effect sizes of such interventions are generally positive but small [3], limited evidence suggests that such interventions may be cost-effective [4-6], and the internet is highly accessible [47,48]. This paper provides detailed insight into how to integrate this novel tailoring strategy with more traditional tailoring efforts. Furthermore, the application of message frame–tailoring can support the offering of person-centered care by providing feedback in a manner that matches the individual's preferences and needs, which is one of the key characteristics of person-centered care [49,50]. Moving beyond the tailoring of *what* information is provided to additionally tailoring *how* this information is provided takes into account individual differences in communication style preferences. As such, message frame–tailoring can be considered as the next step in the field of tailored and person-centered health communication. Self-management support interventions, such as the PAS program, have shown to be the most frequent category of interventions with the potential to result in positive health impact for patients with chronic diseases [51]. Therefore, continuation of (research) efforts aimed at the development of improved versions of such programs is warranted.

Another strength concerns the approach taken in developing the redesigned PAS program: scientific and nonscientific experts, smokers, and communication science students were actively involved throughout the process. Involving different types of stakeholders, including end users, in research removes barriers regarding the implementation of research findings and interventions, such as the redesigned PAS program, in practice [52,53]. By describing the process of involving participants in redesigning the PAS program and the valuable insights we have gained as a result, we aim to encourage researchers to involve participants in the development and redesign process of digital health communication interventions.

Finally, we chose to use an existing, already effective intervention [19]. Using an existing intervention as a starting point and adding an additional tailoring strategy to it is a cost-effective and efficient approach because the intervention does not have to be developed from scratch and the time and money that has already been invested are optimally used.

Potential Limitations

This study also has few limitations. First, in the 2×2 web-based experiment, most participants' need for autonomy was moderately high. This may not be representative of the need for autonomy in the general population; therefore, the cutoff point of the need for autonomy, based on which the message frame is tailored, might be very high, resulting in suboptimal message frame–tailoring. In addition, research has shown that the need for autonomy might be different for different groups of people [46]. More research is needed to assess the optimum cutoff point for the need for autonomy and to test whether this point differs between subgroups.

Second, we mainly focused on the communication of information in an autonomy-supportive or controlling manner, especially pertaining to the type of words used; for example, *could* in the autonomy-supportive condition and *must* in the controlling condition. Moreover, in the case of the quit date, we also tried to design the way of responding in an autonomy-supportive versus controlling manner; that is, the smokers in the choice conditions received different types of calendars to enter their quit date based on their individual choices in this regard; for example, a calendar to choose a date from or a commenting section in which they could enter the

date themselves, whereas smokers in the no-choice conditions were given a prespecified date by the intervention. This method of designing could be further explored as a way to make the interface more compatible with the individual's need for autonomy. For instance, more questions can be designed such that individuals with high need for autonomy would receive open entry fields, whereas individuals with low need for autonomy would receive limited multiple-choice answers. In addition, how the program is run can be adapted to an individual's need for autonomy; for example, a fixed order for those with low need for autonomy and a self-determined order for those with high need for autonomy. More attention to the design of the intervention as tailored to an individual's need for autonomy could possibly further increase the effects of this and similar interventions—therefore, such possibilities warrant more attention in future research.

Third, although using an existing, already effective intervention is a cost-effective and efficient approach, it also has limitations. For example, some participants requested shorter feedback messages with more bullet points or more illustrations. However, as we wanted to be able to make a comparison between the effectiveness of the PAS program with and that without message frame–tailoring, it was decided to make no adaptations regarding these aspects. By changing the content of the program, it would not be possible to attribute any differences in effectiveness between the original PAS program and the redesigned PAS program to the effect of message frame–tailoring. When choosing between developing a new intervention from scratch and redesigning an existing effective intervention, we recommend considering both the cost-effectiveness and efficiency of the approaches and the potential limitations of the approaches, such as (not) being able to meet all participants' needs regarding the usability of the program.

Acknowledgments

The authors would like to thank OverNite Software Europe for the technical support and usability advice during the redesign of the Personal Advice in Stopping smoking program. The authors would also like to thank Fairouz Kasri for transcribing the video recordings. They also thank all the smokers, students, and experts who participated in the redesign process. This study was supported by the Dutch Cancer Society (KWF Kankerbestrijding; grant number UVA 2015-7913). The Dutch Cancer Society was not involved in the study design, data collection, data analysis, or report writing.

Abstract

Background: The Ontario electronic consultation (eConsult) service allows a primary care provider (PCP) to access specialist advice through 2 models: the direct-to-specialist (DTS) model, where PCPs select a specialist from a directory, and the Building Access to Specialists Through eConsultation (BASE)–managed specialty service, where PCPs choose a specialty group and are assigned a specialist from a qualified pool based on availability.

Objective: The aim of this study is to examine patterns of use between the 2 models of eConsult delivery.

Methods: We conducted a cross-sectional analysis of utilization data collected from eConsults completed between October 2018 and September 2019. Cases were grouped based on the model used for submission (ie, BASE or DTS). Each model was assessed for the number of cases over time, specialty distribution, proportion resulting in new or additional information, impact on PCPs' decisions to refer, and billing time.

Results: PCPs submitted 26,121 eConsults during the study period. The monthly case volume increased by 43% over the duration of the study, primarily in the BASE model (66% compared to 6% for DTS). PCPs were able to confirm a course of action that they originally had in mind in 41.4% (6373/15,376) of BASE cases and 41.3% (3363/8136) of DTS cases and received advice for a new or additional course of action in 54.7% (8418/15,376) of BASE cases and 56.3% (4582/8136) of DTS cases. A referral was originally contemplated but avoided in 51.3% (7887/15,376) of BASE cases and 53.3% (4336/8136) of DTS cases, originally contemplated and still needed in 19.4% (2986/15,376) of BASE cases and 17.7% (1438/8136) of DTS cases, and neither originally contemplated nor needed in 21.7% (3334/15,376) of BASE cases and 21.9% (1781/8136) of DTS cases.

Conclusions: Both eConsult models had strong uptake. Use patterns varied between models, with the majority of growth occurring under BASE, but survey responses showed that both models provided similar outcomes in terms of new information offered and impact on decision to refer.

Introduction

Canadians face prolonged wait times for specialist care in comparison to other developed countries. In Canada, patients do not access specialty care directly in most cases. Rather, they must first see a primary care provider (PCP), a family physician or nurse practitioner, who completes an assessment and refers them to a specialist, often one in their professional network or with whom they have had a positive experience [1-4]. Once the referral is complete, patients must wait for an appointment, which for some specialties can take months or even years [5,6]. However, electronic consultation (eConsult) can greatly improve access to specialist advice in many cases by allowing requesting providers, usually PCPs, to communicate directly with specialists electronically regarding a patient's care, often avoiding the need for a traditional consultation. Studies of eConsult services have found that they improve access, lower costs, and deliver high rates of patient and provider satisfaction [7,8].

As early as 2010, regional services in Ontario provided access to specialist advice for PCPs operating in their jurisdictions [9]. However, the availability of these services varied geographically, with some PCPs limited in their ability to access services in their regions. This changed in 2018, when Ontario's Ministry of Health supported the creation of the Ontario eConsult Service, building on existing programs and expanding their reach across the entire province [10].

The Ontario eConsult Service provides access to 2 models of multispecialty provider-to-provider eConsult. In the direct-to-specialist (DTS) model, PCPs select an individual specialist from a directory and send their question to them directly via the eConsult platform [11]. In the Building Access to Specialists Through eConsultation (BASE)–managed specialty service model, PCPs select a specialty group from a menu and the case is then assigned to an individual specialist by the operations team, which has oversight of availability, timeliness, and the specialists added to the pool [9]. To our knowledge, this is the only eConsult service that offers PCPs 2 models of accessing specialist advice on one eConsult platform [12,13].

In this study, we aimed to identify and compare patterns of use between the 2 models of eConsult delivery available through the Ontario eConsult Service. A better understanding of how PCPs use each model will help inform the service's continued expansion and provide insight for innovators looking to establish an eConsult service tailored to their jurisdiction's needs.

Methods

Design

To identify patterns of use between models, we conducted a cross-sectional analysis of utilization data emerging from the Ontario eConsult Service.

Setting

The Ontario eConsult Service operates in Canada's most populous province, with a population of over 14 million people (nearly 40% of all Canadians) [14] served by approximately 15,000 family physicians (ie, those with general practice as their primary or secondary specialty) [15] and 4000 registered nurse practitioners [16]. Like all Canadian provinces, Ontario oversees a federally funded but provincially run Medicare program, which provides health care services to residents free of charge. At the time of this evaluation, the province was divided into 14 health regions known as Local Health Integration Networks (LHINs). Each LHIN coordinated health care services for the needs of its unique population. As of 2020, this model was phased out and the 14 LHINs were reorganized as 5 regions.

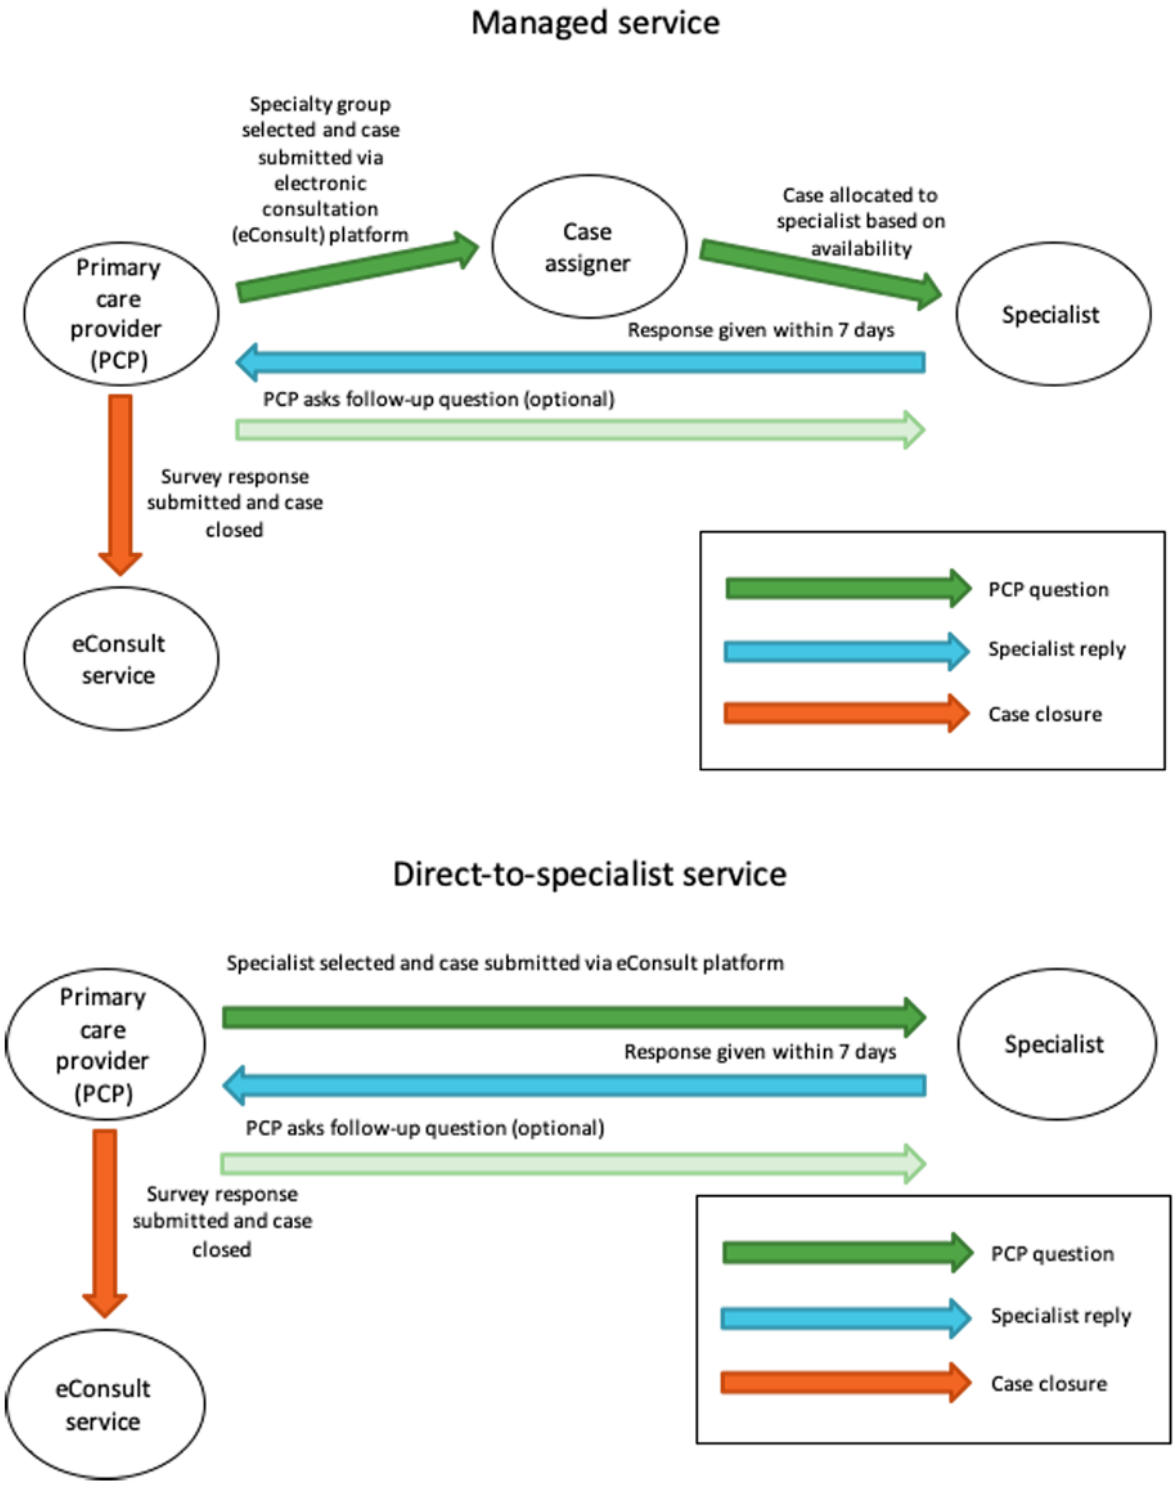
The Ontario eConsult Service

The Ontario eConsult Service was launched in June 2018 and is supported by the province's Ministry of Health. Prior to the launch of the new service, there were 2 provincial services with different models of specialist access. The Champlain BASE service, which began as a regional pilot project in the Champlain LHIN (comprising Ottawa and Eastern Ontario) in 2010 before expanding to other regions, notably the South East LHIN, provides specialist access through the managed specialty service model. The Ontario Telemedicine Network (OTN) was launched in 2012 in Toronto and uses the DTS model. The newly formed Ontario eConsult Service was launched on the OTN and includes both specialist access models. Both services are provider-to-provider, meaning that patients do not use them directly, but PCPs submit questions to specialists concerning their care. It is the PCP's choice which way they access a specialist for each case.

All practicing specialists in Ontario can join the service through the DTS model. BASE operates using a pool of specialists recruited based on need, geographic location, and experience. The number of specialists in each specialty group ranges from 2 to 18 (Multimedia Appendix 1). Specialists in a BASE group may also participate in the DTS option.

The Ontario eConsult Service operates at no charge to PCPs and patients. Specialists are remunerated at an hourly rate prorated to their self-reported billing time. PCPs are also remunerated via the publicly funded Ontario Health Insurance Plan at a flat rate per case. To use the service, PCPs log into the site via an OTN account, select the eConsult model they want to use (DTS or BASE), choose a specialist (DTS) or specialty group (BASE), enter their question, and submit (Figure 1). DTS cases are sent to the specialist; under the BASE model, a case is assigned to a specialist within the chosen group, ensuring cases are evenly distributed among the group's specialists while taking into consideration current availability, desired case volume, and other special factors (eg, specialists who only see patients of a certain age or from a specific region). To build communities of practice, BASE operates regionally where possible, referring PCP questions to specialists operating in their region.

Figure 1. Workflow chart for electronic consultation cases submitted through the Building Access to Specialists Through eConsultation (BASE) and direct-to-specialist models.



In either model, the specialist receives a notification and responds to the question within 1 week by providing guidance, recommending a referral, or requesting more information. Discussion can proceed iteratively back and forth until the PCP is satisfied with the response, at which point they complete a mandatory closeout survey assessing the case's outcome, impact on decision to refer, and educational value. An optional free-text field allows for additional comments.

Outcomes

Cases were grouped based on the model used for submission (BASE or DTS). Each model was assessed for the number of cases over time, proportion of cases resulting in new or additional information, impact on PCPs' decisions to refer, and billing time.

Data Collection

We used routine utilization data automatically collected for each case. This includes user ID, region, billing time, cost, specialty, specialist, and results of the mandatory closeout survey asking PCPs to identify (1) whether the response confirmed their original course of action or provided them with new or additional information and (2) what impact it had on their decision to refer the patient. Our team extracted data from all cases submitted over a 1-year period between October 2018 and September 2019. Subspecialties from both models were grouped into the most relevant specialty (eg, cases sent to pediatric dermatology were grouped as dermatology).

Data Analysis

We conducted a descriptive analysis (eg, mean, median, count, and distribution) to compare metrics between models of care. A time series analysis was conducted to observe growth and changes in the proportion of cases provided to the DTS model compared to the BASE model. Data were grouped by each PCP's LHIN to observe trends in different regions of the province. Additional statistical analyses for time billed and response intervals were performed using the statistical software package SPSS Statistics (version 27.0; IBM Corp). Time billed at or under 25 minutes by specialists (in discrete time blocks of 5, 10, 15, 20, and 25 minutes) and time billed over 25 minutes (continuous variable) were analyzed independently. The Kolmogorov-Smirnov and Shapiro-Wilk tests were used to test the normality of the data. Due to the data not being normally distributed, the nonparametric Mann-Whitney U test and Pearson chi-square test were used to assess the differences between groups.

Ethics Approval

This project was approved as a quality improvement initiative by the Ottawa Hospital Health Sciences Network Research Ethics Board.

Results

PCPs submitted 26,121 eConsults to the Ontario eConsult Service during the study period, out of which 24,178 eConsults were responded to by a specialist during the study period. (Table 1). A total of 65% (16,985/26,121) of cases were submitted through the BASE model. A total of 2880 requesting providers submitted at least 1 eConsult, of whom 39.3% (n=1133) used BASE exclusively, 19.1% (n=551) used DTS exclusively, and 41.5% (n=1196) used both. Of the 2880 requesting providers, 27.8% (n=801) submitted 10 or more eConsults during the study period. Among this smaller, high-volume user group, 21.2% (170/801) used BASE exclusively, 5.2% (42/801) used DTS exclusively, and 73.5% (589/801) used both models.

Table 1. Comparison between BASE[a] and DTS[b] models.

Electronic consultation model	Cases submitted (N=26,121), n (%)	Mean time billed in minutes	Response interval in days	Referral avoidance, n (%)[c]	Referral initiation n (%)[c]	Cases cancelled or declined (n (%)[d]
BASE	16,985 (65)	17.5	1.14	7887 (51.3)	494 (3.2)	749 (4.4)
DTS	9136 (35)	21.7	0.99	4336 (53.3)	257 (3.2)	261 (2.9)

[a]BASE: Building Access to Specialists Through eConsultation.

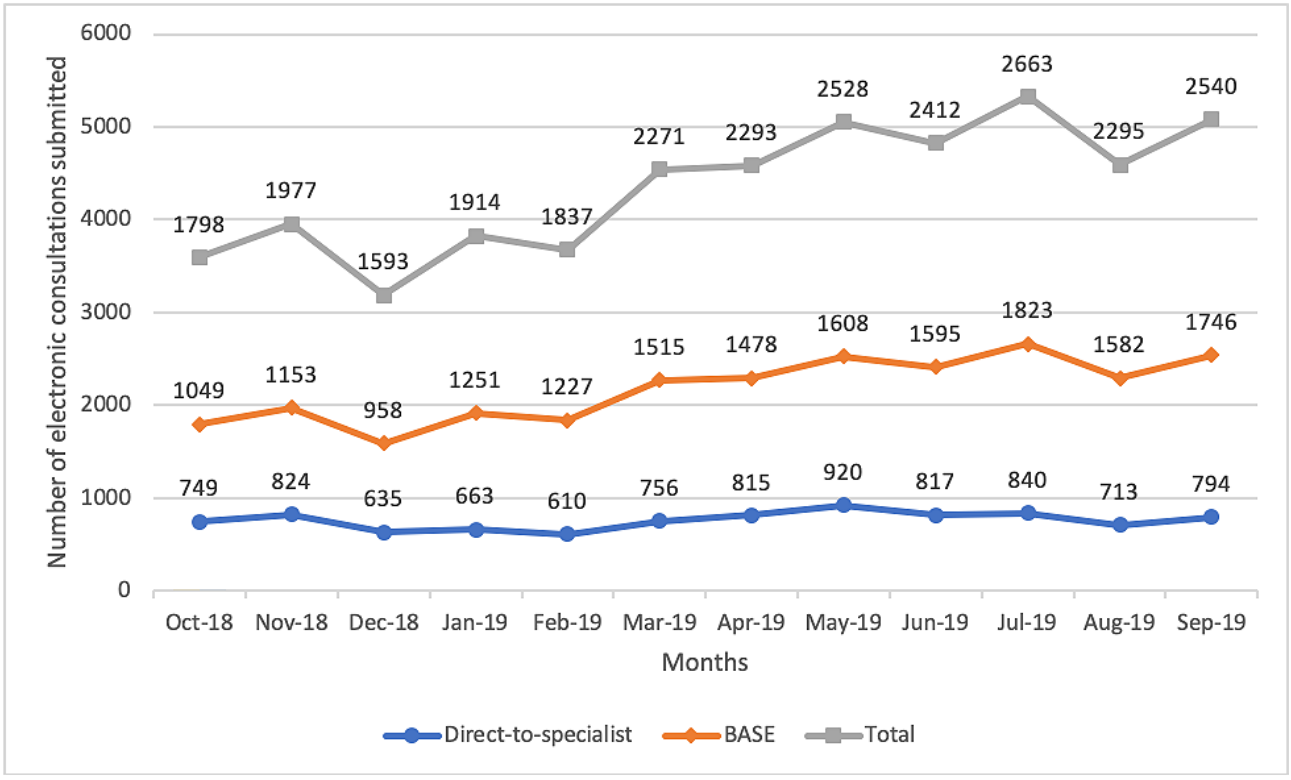
[b]DTS: direct-to-specialist.

[c]For this category, n=15,376 for BASE and n=8136 for DTS; percentages have been calculated accordingly.

[d]For this category, n=16,985 for BASE and n=9136 for DTS; percentages have been calculated accordingly.

The number of eConsult cases submitted increased by 41% over the duration of the study (Figure 2). Most of this increase occurred for BASE, which saw a 66% increase in use compared to a 6% increase in the use of DTS. The service also demonstrated a growth in the number of active users, defined as those who submit or answer 3 or more eConsults in a 6-month period. The service saw a 48% increase in active PCPs and a 28% increase in active specialists.

Figure 2. Historical time series of cases submitted to the Building Access to Specialists Through eConsultation (BASE) and direct-to-specialist models.



The 20 most frequently accessed specialties are outlined in Figure 3. Only 2 of the specialties in this group, psychiatry and internal medicine, had a higher proportion of DTS cases than BASE cases. Figure 4 outlines the proportion of BASE cases in the first and last 6 months of the study period for the top 20 specialties.

Figure 3. Proportion of cases involving the 20 most frequently accessed specialties for the Building Access to Specialists Through eConsultation (BASE) and direct-to-specialist models.

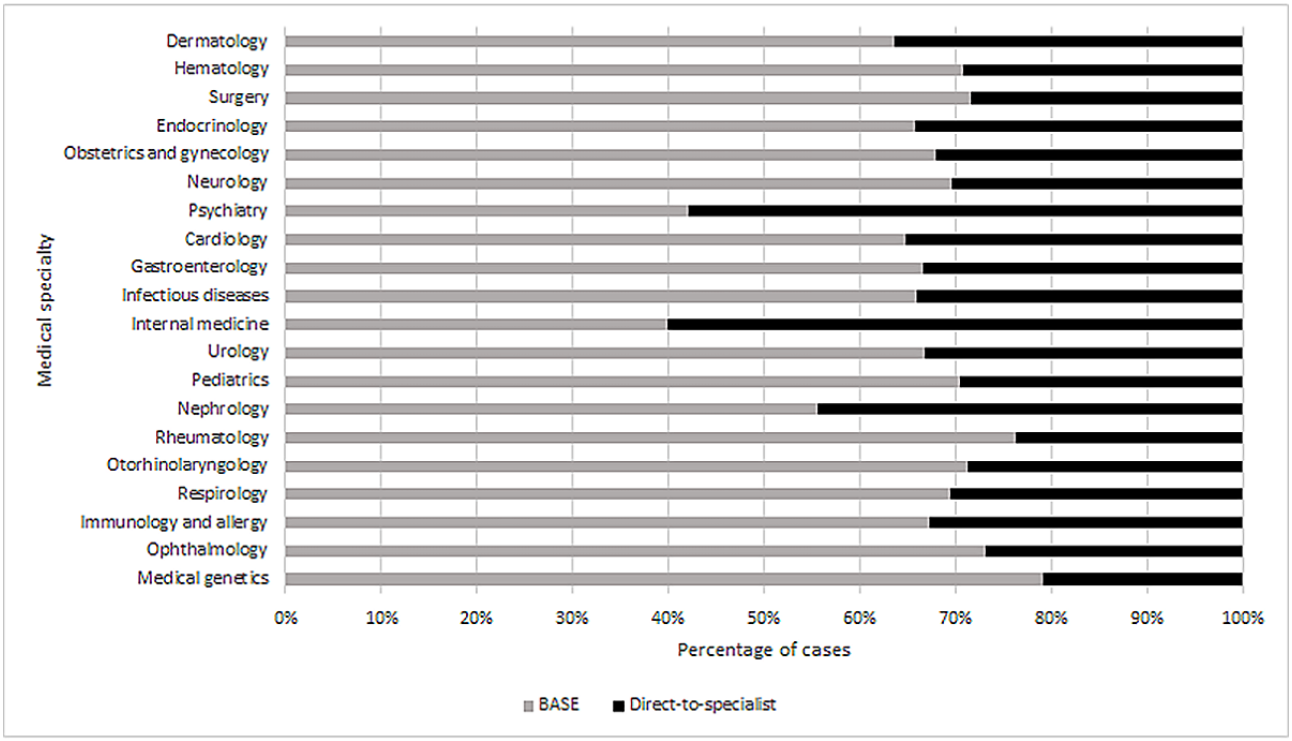


Figure 4. Comparison of the percentage of Building Access to Specialists Through eConsultation (BASE) cases provided for the top 20 specialties in the first 6 months (October 2018 to March 2019) and last 6 months (April 2019 to September 2019) of the study period.

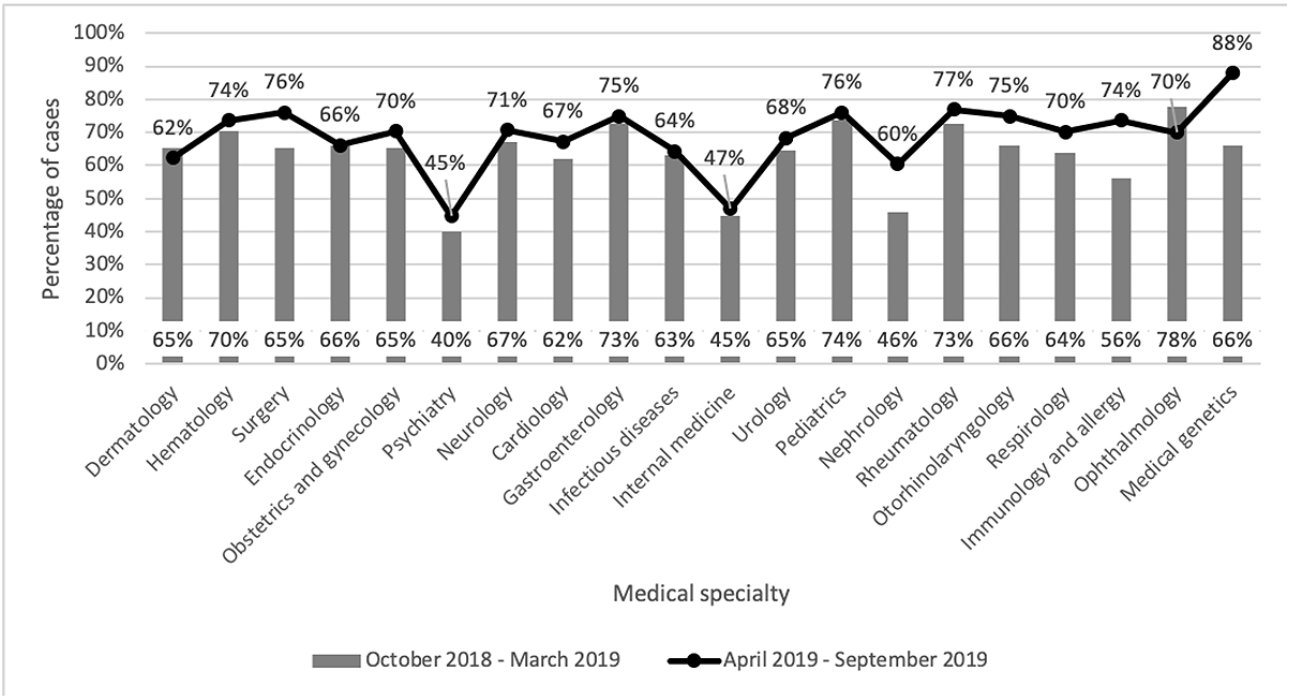

In 12 of the 14 LHINs, requesting clinicians submitted more cases through BASE than DTS. Only 2 LHINs had a greater proportion of DTS cases compared to BASE cases: Erie St. Clair and South West. The Champlain (650/726, 89.5%) and South East LHINs (2575/2972, 86.6%) sent the highest proportion of cases through BASE.

Closeout survey data were available for 23,512 closed cases (Table 1). Based on their responses to the mandatory closeout survey, PCPs had similar experiences across models. PCPs were able to confirm a course of action that they originally had in mind in 41.4% (6373/15,376) of BASE cases and 41.3% (3363/8136) of DTS cases and received advice for a new or additional course of action in 54.7% (8418/15,376) of BASE cases and 56.3% (4582/8136) of DTS cases. When asked about each case's impact on their decision to refer, PCPs stated that a referral was originally contemplated but avoided in 51.3% (7887/15,376) of BASE cases and 53.3% (4336/8136) of DTS cases, originally contemplated and still needed in 19.4% (2986/15,376) of BASE cases and 17.7% (1438/8136) of DTS cases, and neither originally contemplated nor needed in 21.7% (3334/15,376) of BASE cases and 21.9% (1781/8136) of DTS cases.

Among cases with billing times of 25 minutes and under, specialists responding through DTS had a higher mean billing time (14.12 minutes) than those responding through BASE (13.96 minutes; $\chi^2_{5, N=21,768}$=80.471; *P*<.001). Time billed over 25 minutes also differed significantly between models, with cases provided through DTS having a mean billing time of 45 minutes compared to a mean of 37 minutes for BASE (*U*=1,570,925; *Z*=13.326; *P*<.001; *r*=0.24). The response interval of cases provided through DTS (median 0.99 days) was slightly lower than the response interval for cases provided through BASE (median 1.14 days; *U*=63,495,746; *Z*=–9.6; *P*<.001; *r*=–0.06).

Discussion

Principal Results

The Ontario eConsult Service processed over 26,000 cases across 2 models of care, registering growth in the number of monthly cases (41% increase), active PCPs (48% increase), and active specialists (28% increase). Two-thirds of cases were provided through the BASE model. PCPs who used the service frequently tended to use both avenues to access specialty advice. Cases provided through the DTS model had a longer median billing time and a shorter median response interval.

Exploration of Findings

The BASE and DTS models each offer advantages and drawbacks. In the BASE-managed service model, eConsult requires a smaller number of specialists; for some less commonly used specialty groups, 2 specialists are sufficient to handle case volume. As a consequence, the frequency of cases sent to a specialist can be adjusted, ensuring that a given provider does not become overwhelmed by demand but also receives enough cases to keep them in practice with the platform. The BASE model also allows PCPs from underserved areas to gain access to advice from specialists practicing in different parts of the province. This is vital to ensuring equity of access and of particular importance to rural and remote patients, many of whom must travel many hours for in-person specialist appointments. However, a drawback to the model is that PCPs cannot choose which specialist their case will be assigned to, which they may wish to do if they have a past working relationship with a particular specialist or if they know the

specialist is familiar with their patient's condition. In these cases, DTS offers a distinct advantage as PCPs can reach out to a particular specialist in their region when available. This direct connection facilitates collegiality and makes it easier for patients to see a specialist who has already communicated with their PCP about their issue in the event the PCP decides to refer them. For a PCP who does not have a prior relationship with a practitioner from a given specialty, the choice of a particular specialist may actually be more difficult than relying on a central case assigner. Fortunately, the various advantages and drawbacks of each model make them complementary, allowing PCPs to choose the service that best fits their situation. It was this in large part that caused our team to incorporate both models as this allowed users to select the service type that best met their needs.

The proportion of cases sent using BASE compared to DTS varied between specialty groups and regions. In some cases, the discrepancy in use patterns between regions may be structural. For instance, the 2 LHINs with the highest proportion of BASE cases, South East and Champlain, have regional BASE groups that predate the Ontario eConsult Service; the South East LHIN launched eConsult in 2015, while BASE first began as a pilot program in Champlain in 2010 and continues to operate in the region outside of the Ontario eConsult Service. As such, it is perhaps not surprising that PCPs who had already used BASE for years would continue to use that model under the Ontario eConsult Service. However, the broader use pattern goes beyond this explanation and may be affected by how many specialists from a given group practice in the PCP's region. Although all but the most remote communities in Ontario have practicing PCPs, specialists tend to practice in higher-density urban areas, where a larger population size can better support a narrower scope of practice. As a result, PCPs in regions with fewer local specialists may be more likely to use the BASE model as it allows them to access advice through the provincial service in cases where local specialists are unavailable. Additionally, it is worth noting that of the 20 most frequently used specialties, only 2 were accessed predominantly through DTS: psychiatry and internal medicine. This may speak to the importance of established relationships and communities of practice in these specialty groups.

Most of the growth on the Ontario eConsult Service was a result of an increase in the use of the BASE model, which accounted for two-thirds of all cases. We hypothesize the following reasons for the growth of the BASE model: (1) This model eliminates dependency on a PCP having an established network of individual specialists by providing a network of specialty services to access. This promotes equity of access and is especially advantageous for new graduates or a physician who has relocated to a new area. (2) The low resourcing required to launch a BASE group (ie, only 2 specialists are needed to launch a group) allows for a large offering of specialty and subspecialty groups that meet PCPs' wide variety of needs. Finally, (3) BASE has an easy workflow and intuitive user interface, making it simple to adopt and use. Our data indicate that the growth of the BASE models was not accounted for by a specific specialty (Figure 4) or by the cancellation rates (Table 1). Further study to understand the influencing factors on BASE model use, such as a PCP's year of graduation or impacts of promotional activities by the eConsult team on DTS versus BASE use, should be explored.

Limitations

Our study has several limitations. Though focusing on Canada's most populous province across a wide geographical area, our data set nevertheless can account for only one segment of the country, and results therefore may not be generalizable nationally or in other countries. The study relied on utilization data and survey results. Although useful, these data can provide only an incomplete picture of the service's use. Other data, including case logs, patient-level data, or electronic medical record surveys would provide more information and should be sought in future studies.

Conclusions

The Ontario eConsult Service successfully offers 2 models on a single platform. Both models received strong uptake and the service demonstrated growth in cases and levels of adoption by PCPs and specialists during the study period. Use patterns varied between models, with the majority of growth occurring under BASE, but survey responses showed that both models provided similar outcomes in terms of new information offered and impact on decision to refer. DTS and BASE provide complementary benefits, allowing more flexibility for PCPs. Services that are capable of adopting both models should consider offering this option to maximize use and ensure equity of access to prompt and high-quality specialist care.

Acknowledgments

The authors wish to thank JJ Hupka for his support in this project, Sathya Karunananthan for her assistance with data analysis, and Jessika Hammond and Justin Joschko for their assistance in preparing the manuscript for publication. Funding for this project was provided by the Ontario Ministry of Health and Long-Term Care (MOHLTC). The opinions, results, and conclusions reported in this paper are those of the authors and are independent of the funding sources. No endorsement by the Ontario MOHLTC is intended or should be inferred.

Conflicts of Interest

CL and EK are cofounders of the Champlain Building Access to Specialists Through eConsultation (BASE) electronic consultation (eConsult) Service, but they have no commercial interest in the service and do not retain any proprietary rights. As coexecutive directors of the Ontario eConsult Centre of Excellence, they receive salary support from the Ontario Ministry of Health. EK answers occasional eConsults (less than 1 per month) as a specialist through the service, for which she is reimbursed.

Multimedia Appendix 1
List of Building Access to Specialists Through eConsultation (BASE) specialty groups, when they were added on the service, and the number of specialists answering electronic consultations (eConsults) in each group.

Abstract

Background: One of the most difficult areas in the fight against HIV/AIDS is reaching out to youth aged 13 to 24 years. The proportion of youth living with HIV/AIDS on antiretroviral therapy (ART) and who are virally undetectable is low, highlighting significant challenges for reaching the Joint United Nations Program on HIV targets.

Objective: This study aimed to assess the feasibility of obtaining key clinical indicators and monitoring treatment, viral suppression, and retention components of the youth HIV treatment cascade in Adolescent Trials Network for HIV/AIDS Interventions clinics using electronic health record (EHR) downloads and to provide baseline characteristics for the study participants.

Methods: EHR data were systematically obtained from multiple clinical sites and used to meaningfully capture clinical characteristics, initiation of antiretrovirals, and retention in care, which are part of the Centers for Disease Control and Prevention's 4 continuum of care measures. In addition, this study used standard cost values attached to Current Procedural Terminology codes to estimate the cost per visit.

Results: Only 2 of the 4 Centers for Disease Control and Prevention treatment cascade measures were assessed using routine EHR data. EHR data are not adequate for monitoring HIV testing or linkage to care because denominator data are not available. However, the data work well for measuring ART initiation and adequately for retention in care. The sites were broadly able to provide information for the required data. However, in most cases, these data are insufficient for identifying patterns of missed appointments because such misses are not captured in the EHR system. Sites with good access to data management resources can operate more efficiently for cascade monitoring study purposes.

Conclusions: Data other than EHRs are needed to measure HIV testing and linkage to youth care. EHR data are useful for measuring ART initiation and work moderately well for measuring retention in care. Site data management resources should be part of the selection process when looking for site partners for clinical studies that plan to use EHR data. Study planners should determine the feasibility of additional funding for organizations in need of additional information technology or data management resources.

Introduction

Background

We have made substantial progress in preventing HIV infection in the United States during the past decade, and the federal government has recently released a national strategic plan to end the HIV epidemic in the United States by 2030 [1]. However, one of the most difficult areas in the fight against the HIV and AIDS epidemics is reaching youth. In the United States, in 2016, approximately 21% of the 39,782 new HIV diagnoses occurred among youth aged 13 to 24 years [2]. We will not be able to end the HIV epidemic in the United States unless we reach this age group. However, preventing new HIV-positive diagnoses will require a 2-pronged attack, because prevention must reach youth at risk of acquiring HIV and treatment must reach those already living with HIV. The latter is an often-neglected group [3]; however, we cannot conquer the HIV epidemic in the United States without solving the youth *treatment cascade* (ie, HIV testing and diagnosis, linkage to care, and viral suppression) problem.

National-level strategies specify goals related to early HIV diagnosis and effective care. The Centers for Disease Control and Prevention (CDC) HIV care continuum identifies a dynamic series of steps from the time a person receives a diagnosis of HIV through the successful treatment of their infection with HIV medications [4]. The HIV care continuum consists of several steps that are required to achieve viral suppression. Specifically, CDC tracks the following: (1) diagnosed—receives a diagnosis of HIV, (2) linked to care—visited an HIV health care provider within 1 month after learning they were HIV positive, (3) received or were retained in care—received medical care for HIV infection, and (4) viral suppression—their HIV viral load (VL) was at a very low level. Although the HIV care continuum is often presented as a static framework, individuals who are HIV positive often exit and re-enter the continuum at varying steps [5]. Although relatively straightforward conceptually, programmatic implementation to systematically monitor the HIV treatment cascade is quite challenging [6]. Despite the fact that studies have used study coordinator data entry of cascade variables for consented participants [7], this does not adequately reflect the range of youth at Adolescent Trials Network for HIV/AIDS Interventions (ATN) clinics who may not consent to such trials. To date, no studies have been published on multisite youth cascade variables using electronic health records (EHRs). To that end, Scale It Up (SIU), a collaborative program (U19) within the ATN, aims to bring to practice evidence-based self-management interventions via hybrid implementation trials to positively impact the youth HIV prevention and care cascades.

Objectives

The Cascade Monitoring (CM) protocol (ATN Protocol 154) was designed to monitor the cascade within the ATN using EHR and provide longitudinal effectiveness outcomes and cost estimates [8]. The first goal of ATN 154 and the purpose of this report are to assess the feasibility of assessing the youth HIV treatment cascade [9] among those linked to care within the ATN using EHR downloads. To this end, this study aims to assess the feasibility of obtaining key clinical indicators and monitoring treatment, viral suppression, and retention components of the youth HIV treatment cascade in ATN clinics using EHR downloads. In addition, this study will use the first data submissions from 10 study sites to estimate the cost per visit and provide baseline study participant characteristics.

Methods

Ethics Approval

In compliance with ethical standards, the SIU CM study (ATN 154) was approved by an expedited review process by the single institutional review board of Florida State University (approval IRB00000446). All the procedures performed in this study were in accordance with the ethical standards of the institutional review board.

Study Sites

Limited EHR data were collected retrospectively, from 10 clinical sites, also known as subject recruitment venues, participating in SIU: (1) Johns Hopkins University, Baltimore, Maryland; (2) University of Alabama at Birmingham, Birmingham, Alabama; (3) SUNY Downstate Medical Center, Brooklyn, New York; (4) Children's Hospital Los Angeles, Los Angeles, California; (5) St Jude Children's Research Hospital, Memphis, Tennessee; (6) University of Miami, Miami, Florida; (7) Children's Hospital of Philadelphia, Philadelphia, Pennsylvania; (8) University of California San Diego, San Diego, California; (9) University of South Florida, Tampa, Florida; and (10) Children's National Health System, Washington, District of Columbia.

The first data extract requested treatment visits in the full year of 2016 and associated care data for all youth living with HIV/AIDS, aged 15 to 24 years, treated at sites. Subsequently, 1-year data EHR extracts were received from sites annually, with the final year of data uploaded in 2022 for the full year of 2021. Data were requested for a set of variables that were considered invariant for the year 2016 (demographics) and for variables where multiple annual values should be captured to measure the treatment cascade changes. The variables requested included demographics (age, sex, race, and ethnicity), height, weight, International Statistical Classification of Diseases and Related Health Problems–10th Revision (ICD-10) codes, and Current Procedural Terminology (CPT) codes. A complete list of the requested variables has been published elsewhere [8] and is also included in Multimedia Appendix 1.

Study Clinical Measures

EHR data were systematically obtained from multiple clinical sites and used to meaningfully capture clinical characteristics (including viral suppression), initiation of antiretrovirals (ARVs), and retention in care, which are part of the CDC's diagnosis-based HIV care continuum measures (Multimedia Appendix 2) [10]. Two of the four CDC treatment cascade measures—retention in care and viral suppression—were assessed using routine EHR data. For the *retention in care* measure, we used the CDC definition of an interval of >190 days (approximately 3 months) between laboratory visits for CD4 or VL testing to indicate less-than-optimal laboratory visit

patterns. We were able to obtain laboratory visit dates and use data from the subsequent year to determine whether the participant was retained in care. *Viral suppression* was defined as having a nondetectable baseline VL. Laboratories used by individual study sites have varying lowest detectable limits for VL; therefore, this study records undetectable VL as defined by each study site. Additional measures calculated using EHR data included ARV medication percentage and AIDS status. *Antiretroviral medication (%)* was defined as the percentage of patients with at least one recorded ARV therapy (ART) prescription. The data in the EHR did not allow us to estimate patients' adherence to ARV because adherence is not documented in the EHR and only issued prescriptions, not prescription fills, are recorded. *AIDS status* was determined by an absolute CD4 T-cell count of <200.

Feasibility of EHR Data Extraction Process by Study Sites

Multiple EHR platforms are available for the computerized entry of patient medical information. Although a close examination of EHR platforms is important, information on the types of EHR software was not collected because the intent of the CM study was to examine the feasibility of standardized extraction of clinical and cost data of relevance to CM data across multiple EHR systems. Following interviews with study coordinators about the consistency of EHR variable capture, 9 variables were deemed as primary and could be consistently calculated. The following information was provided if available: date of visit, age, sex, height, weight, race, ethnicity, VL, and ICD-10 codes for other diagnoses. Data were requested as comma-delimited files in Excel (Microsoft Corporation). Because the sites have very different access to local technical support for file extraction, the file structure was left to decisions by the sites to ease the workload on the site staff. Data extraction was supported by the provision of an example study data dictionary for each site. This document shows how the variables are optimally defined and delivered. However, the actual extraction files differed for each of the 10 sites in terms of design, organization, variable definition, and completeness. Files had to contain the minimum primary variables, be deidentified with a site-specific patient identifier, and a report provided explaining the reason why any variables were missing. CM study personnel received and approved a variable checklist for each site before the data were approved for uploading. Upon initial receipt of the 2016 data, the data were checked for patterns of variable missingness, congruence with the data request, and the presence of variables for linking relational data by anonymous patient identifiers.

Data Management

Once the data extract was certified for a site, data were cleaned and transformed into a common data model format. Most of the data cleaning and construction of common data model files were performed using SAS (version 9.4; SAS Institute Inc). Once files for all sites were cleaned and variable values were transformed to fit the common data model for the CM study, we constructed a baseline demographics flat-file with one observation per patient and a set of relational vertical files organized by visit (laboratory test or prescription) date. We constructed separate files for visits, laboratory values, ARV medications, and other medications. The visit file contained all CPT and ICD-10 diagnosis codes and formed the basis for the development of a cost value for each encounter.

Data Analysis

Costing information was necessary to evaluate whether it was possible to produce visit cost weights using CPT codes from EHR data in lieu of extracting billing and administrative data, which are often difficult to obtain from a clinic. The ability to estimate cost is important for measuring variations in resource use and efficiency in the process of care at clinical sites. These estimated costs will be examined for validity using a time-driven activity-based costing approach once more data are collected. We used a standard costing approach to assign a cost value to each encounter, because EHR data rarely contain cost data. Cost data for individual sites are usually located in a Charge Master file, which is updated as prices at the site change. The Charge Master files are combined into billing costs for a visit using the clinic accounting data system. Thus, EHR data do not contain cost data per se but can be used to identify costs per event by combining CPT codes with standard cost data. This approach decreases the internal validity of cost estimates for an individual site but greatly improves the validity of estimation of any resource use and cost differences between sites and has greater external validity of economic estimates made using the study costs [11]. The CPT codes in each visit record were used to assign a visit cost based on the median charge for the CPT code published for all medical practices in the United States in 2016 [12].

An exploratory data analysis was conducted to understand the breadth and specificity of the available data. Descriptive statistics, including measures of central tendency, were generated to identify outliers and to track data consistency for future downloads. This study provides the first descriptive analysis performed on the 2016 data as part of the development of a common data model for the study. The analysis was performed using SAS (version 9.4). Groups were compared using chi-square tests for categorical variables and 2-talied *t* tests (normally distributed) or Mann-Whitney *U* or Wilcoxon tests (nonnormally distributed) for continuous variables.

Results

Feasibility of Variable Downloads by Study Sites

The parent SIU study was launched in December 2017 at 10 clinical sites, with 2016 EHR data due on January 31, 2017. Site personnel often reported a lack of consistent access to information technology (IT) and data management specialists as the primary explanation for the delay in data submission. Although the sites varied in the length of time to obtain and prepare data (2-6 months), all sites successfully submitted data to the designated data repository by May 2018. The primary variables requested to monitor the cascade of care included the date of visit, age, sex, height, weight, race, ethnicity, VL, and ICD-10 codes for other diagnoses. In total, 70% (7/10) of the sites provided data for the primary variables via the extraction of electronic records from their EHR system. The remaining

sites provided the primary variables using manual data extraction.

The process of data cleaning and transforming the data into a common data model format was an extremely labor-intensive process that required >400 hours of expert programming and data management work. More importantly, it required extensive consultation between individuals with informatics programming expertise and researchers with HIV-specific treatment data experience. The extent of the work required to transform the data into a common analyzable data model was unexpected. Some of the most time-consuming tasks were needed because the EHR systems for a site did not use clearly defined uniform values for many of the variables. Definitions for some demographic variables (sex, gender, race, and ethnicity) varied within a site's data download owing to the hand entry of variables, and the use of upper and lower cases, codes, and narrative descriptions. Visit variables that contained ICD-10 diagnosis codes and CPT codes were often problematic because they were sometimes extracted as string variables, separated by a mix of spaces and semicolons. Medication files were especially labor-intensive because similar medications had different names, spellings, abbreviations, and patterns of upper cases and hyphens. Laboratory tests had different definitions of VL and CD4 cell counts, and the names of other laboratory tests varied greatly and were sometimes not clearly identified. These difficulties were resolved by querying sites for information and by using site-specific detailed cleaning programs written for this purpose. Laboratories have varying lowest detectable limits for VL; therefore, this study records undetectable VL as defined by each study site.

Baseline Participant Characteristics

A total of 1093 patients were enrolled in 2016 (Table 1). The demographic variables had the lowest frequency of missing values (4%-5%). ARV medication records were not available for 17.75% (194/1093) of the patients. The VL was missing for 6.40% (70/1093) of the patients. This variable was hand-extracted at the site if missing, indicating that some patients did not have a VL record entered as structured data into their EHR system. A CD4 cell count, an important measure of immune status, was missing for approximately 28.81% (315/1093) of cases. However, we did not require this variable to be hand extracted, so it is possible that CD4 cell tests for many patients may have been performed in an external laboratory with results uploaded as a report. It may be important to make CD4 cell count required by hand extraction when electronic extraction is not possible, if we need to use this variable to measure changes in immune status over time.

Table 1. Characteristics of the cascade monitoring study population at baseline (N=1093).

Characteristic	Patient value	Number of patients for whom 2016 data were missing[a]
Age (years), mean (SD)	20.8 (2.5)	41
Height (cm), mean (SD)	169.9 (10.9)	104
Weight (kg), mean (SD)	76.8 (18.5)	84
BMI (kg/m^2), mean (SD)	26.6 (6.6)	106
Male sex, n (%)	730 (70.67)	60
Race, n (%)		50
Black	769 (73.73)	
White	89 (8.53)	
Hispanic	105 (10.07)	
Other	80 (7.67)	
Antiretroviral medication, n (%)	884 (98.3)	194
Patients with AIDS, n (%)	77 (9.9)	315
Site reported sample size, n (%)		
Baltimore, Maryland	94 (8.60)	N/A[b]
Birmingham, Alabama	69 (6.31)	N/A
Brooklyn, New York	115 (10.52)	N/A
Los Angeles, California	85 (7.78)	N/A
Miami, Florida	54 (4.94)	N/A
Memphis, Tennessee	193 (17.66)	N/A
Philadelphia, Pennsylvania	78 (7.14)	N/A
San Diego, California	105 (9.61)	N/A
Tampa, Florida	219 (20.03)	N/A
Washington, District of Columbia	81 (7.41)	N/A
Mean total cost per visit (US $) across CPT[c] codes, mean (SD)	325 (376)	N/A
CD4 Laboratory results, mean (SD)	609.4 (316)	315
Viral load laboratory results, mean (SD)	25,608 (114,184)	70
Visits, mean (SD)	5.4 (4.6)	24
Patients with laboratory visits >190 days apart in 2016, n (%)	84 (8.15)	N/A
Patients in 2016 with no record in 2017, n (%)	202 (18.48)	N/A

[a]Missing 2016 data elements for race, age, sex, height, and weight were extracted from 2017, if available.

[b]N/A: not applicable.

[c]CPT: Current Procedural Terminology.

Patient Care Continuum Outcomes

Only 2 of the 4 CDC treatment cascade measures can be assessed using routine EHR data. EHR data are not adequate for monitoring HIV testing or linkage to care because the denominator data are not available. However, the data work well for measuring ART initiation and adequately for retention in care. The criterion used to indicate less-than-optimal retention visit patterns for CD4 or VL testing is detailed in the *Methods* section. On the basis of this criterion, approximately 82.97% (887/1069) of the patients met the minimum criteria for laboratory visit frequency. On average, our patient cohort had 5.4 (SD 4.6) laboratory visits per year in 2016, with a range of 1 to >150 visit records. All prescribed ARV and other medications were requested for the study participants. A total of 98.3% (884/899) of the patients from sites that were able to extract medication records had at least one record of prescribed ARV medication. This finding is in line with the Joint United Nations Program on HIV proposed target that 90% of all people with diagnosed HIV infection receive sustained ART by 2020 [13].

We compared patients with undetectable baseline VL to those with a VL value above the level of detection used by the VL

test in their center (Table 2). Minority race and ethnicity patients were more likely to have detectable VL (*P*=.03) with 77.9% (313/402) of patients with detectable VL being of Black or African American race compared with 72.6% (355/489) of patients being Black or African American with undetectable VL. The findings showed poorer immune marker values for patients with a detectable VL. A total of 45.6% (194/424) of these patients had a mean VL of >10,000, and 29% (41/141) had a CD4 cell count that classified them as having AIDS. In addition, a small number of patients in the group with suppressed VL at baseline (7/521, 1.3%) also had a CD4 cell count that classified them as having AIDS.

The mean CD4 cell count was 619 (SD 310), indicating that many of the 945 patients with CD4 cell count values had a relatively good immune status. However, 5.7% (54/945) of patients with available CD4 cell count values had a baseline count of <200, which classified them as having AIDS by the CDC. The VL burden was reported to be undetectable in 55.1% (521/945) of the patients. However, a total of 20.5% (194/945) of all patients with a VL record had a baseline (first VL available in 2016) VL of >10,000 copies/mL.

Table 2. Characteristics of patients with undetectable and detectable VL[a] at baseline (N=945).[b]

Characteristics	Patients with undetectable baseline VL	Patients with detectable baseline VL	*P* value
Patients in the study, n (%)	521 (55.1)	424 (44.9)	.002
Age (years), mean (SD)	20.8 (2.6)	20.8 (2.5)	.71
Male sex, n (%)	328 (62.9)	296 (69.8)	.06
Race and ethnicity, n (%)			.03
Black	355 (68.1)	313 (73.8)	
White	46 (8.8)	20 (4.7)	
Hispanic	26 (5.0)	28 (6.6)	
Other	62 (11.9)	41 (9.7)	
VL >10,000, n (%)	N/A[c]	194 (45.7)	—[d]
Log_{10} VL if VL was detectable, mean (SD)	N/A	3.6 (1.2)	—
CD4 cell count, mean (SD)	707 (274)	512 (321)	<.001
CD4 count <200 or with AIDS, n (%)	7 (1.3)	47 (11.1)	<.001

[a]VL: viral load.

[b]A total of 148 patients had no baseline VL measures.

[c]N/A: not applicable.

[d]Statistical testing was not performed.

Discussion

Principal Findings

In preparation for the study, it became clear that some sites that were considered for inclusion were unable to provide specific variables. Therefore, the study team identified 9 mandatory variables for which information must be provided for a site to remain in the study. These mandatory variables (needed to monitor the treatment cascade) included the following: (1) VL, (2) date of visit, (3) age, (4) weight, (5) height, (6) ICD-10 and CPT codes, (7) sex, (8) race, and (9) ethnicity. For the most part, the sites were able to provide information regarding the required data. The use of EHR data is effective in assessing the patterns of completed appointments. However, in most cases, these data are insufficient for identifying patterns of missed appointments because such misses are not captured in the EHR system. Direct electronic download may not be possible in all situations; however, our data management team was able to work with the sites to develop a successful plan for data abstraction. Sites with good access to data management resources can work more efficiently for CM purposes. However, we do not know the IT resources of the study sites. Many clinic site personnel shared with the study investigators that they were not sure who to contact for help or how much help they could expect from their IT service group. Clinical staff members at many sites have little day-to-day contact with IT data specialists. This is an important issue that should be part of the selection process when looking for site partners for clinical studies that plan to use EHR data. Study planners should determine the feasibility of additional funding for organizations in need of additional IT or data management resources because these needs are not always obvious at the planning stage.

A number of barriers to EHR use and lessons learned as part of the CM study have come to light. First, the required variables that are *visible* to clinicians on the EHR user interface may not be readily available for electronic download. A number of important variables are part of the narrative text or are simply not recorded as structured data. VL, height, and weight are examples of information contained within clinic notes or PDF files of the results of tests performed off-site by a vendor and only available as scanned reports. An HIV surveillance study found that differences in estimated care engagement and viral suppression between data sources revealed incomplete laboratory reporting and that patients received care from

multiple providers [14]. Such findings highlight the potential unavailability of information pertinent to treatment CM and make monitoring *dashboard* construction infeasible. Some data require *hand extraction*, and sites cannot easily find the data. Patient height is often not recorded, which makes it difficult to define important measures, such as overweight, obesity, or BMI. Laboratory data extracts may lack important definitions of *normal*. Undetectable VL is especially difficult to standardize in a common data model because the laboratory definition varies according to the type of test used. Some important characteristics of the youth population infected with HIV were not recorded. Sexual partner preference or sexual orientation is not routinely documented in clinics. Sex is sometimes provided as gender and sometimes as biological sex. Missing data are common, and there are few explanations for missing data, but our comparison of data from 2016 and 2017 indicates that variables with missing values in 1 year tend to be within a normal range if present subsequently, so we suspect that they are most likely missing at random. This means that current statistical approaches for dealing with missing data may not be good choices for use in EHR data studies. In addition, there may be a discrepancy between the information provided during a consultation and that reported in the EHR [15], and vital information regarding participation is not captured or readily accessible. Much important information in an EHR for youth infected with HIV is located in unstructured data such as physician, nurse, or social worker notes. Neither data formatting nor hand cleaning will solve this lack of structured data. What may be needed is text recognition software and natural language processing approaches. However, these methods are costly and pose problems with regard to deidentifying data.

The study findings indicate that a substantial disease burden is present in this very young population infected with HIV. However, EHR data can be systematically obtained from multiple clinical sites and used to meaningfully capture the CDC's continuum of care measures. In addition, this study used standard cost values attached to CPT codes to estimate the cost per visit. This approach delineates the differences in prices between sites and proves the internal and external validity of cost estimates. To the best of our knowledge, this is the first EHR study to use this approach.

As previously stated, to fully benefit from advances in HIV treatment, youth must actively engage in each step of the treatment cascade. Although EHRs sufficiently capture pathology and many other aspects of health, obtaining meaningful indicators of health and treatment outcomes regarding patient activity measures of the care continuum (eg, keeping appointments and taking ART medications as prescribed) proved more difficult. Among other recommendations, Newman-Griffis et al [16] suggested specific actions to improve the capture and analysis of activity and participation information throughout the continuum of care, including (1) making activity and participation annotation standards and data sets available to the broader research community and (2) establishing standards for how and when to document activity and participation status during clinical encounters. A data-driven approach leveraging current techniques in health informatics to extract information about function, particularly activity and participation, is needed [16,17].

Conclusions

The work performed as part of the CM study has greatly advanced our understanding of the strengths and weaknesses of using EHR data to monitor the treatment cascade in youth infected with HIV. The analysis of the data from the first year of the study indicates that EHR data can be extracted from diverse sites and converted into analyzable data sets capable of monitoring important variables in the HIV treatment cascade. However, the success of any such effort will depend entirely on a solid collaboration between investigators and staff at the sites and the study team responsible for the cleaning and standardization of the data. The support of clinical investigators at the site has been essential for the success of the project, and the study would not have been possible without the extraordinary level of commitment and willingness to overcome obstacles exhibited by the clinical site staff. The work effort was much greater than expected for the CM study team. However, it appears that the careful programming work performed to transform the 2016 data is paying off because the 2017 data have been downloaded, and early cleaning efforts indicate that much of the work conducted for 2016 is usable for the 2017 data download. This is encouraging and indicates that *up-front* work on a standard data model pays off in terms of efficiency in subsequent years. This study provides pilot data on the use of EHRs to determine who and when youth living with HIV/AIDS disengage from the cascade and a broad, nonintrusive, and efficient way of assessing whether SIU interventions improve cascade outcomes. We conclude that although the use of EHR data for treatment CM for youth with HIV is labor-intensive and not ideal for some measures, it works for much of what we need to know about monitoring retention in care. Thus, it has the potential to become an essential tool for measuring the achievement of the goal of improving access to quality care for youth infected with HIV in the United States.

Future Directions

The longitudinal design of this study will allow for the calculation of cascade measures (ART prescription, viral suppression, and retention in care) throughout the study time fame of 2016 to 2021. In addition, advanced analytic procedures will be used to model care retention based on both patient-related and clinical characteristics, resulting in the creation of patient phenotypes for youth living with HIV/AIDS. Creation of the phenotypes will facilitate the identification of relevant predictors associated with dropout at any stage of the cascade and will be used to estimate the cost per quality-adjusted life year expected from cascade outcomes. As part of the identification of the larger cost-of-illness burden of cascade lapses for youth living with HIV/AIDS, we will use the EHR phenotypes and archival data from Medicaid or privately insured populations to model the extent of cascade interruptions present in other practice settings. The data will be combined with the individual cost weights to estimate the variations in the economic burden that cascade disruptions for youth living with HIV/AIDS place on US communities.

With the development of phenotypes, we will be able to extend our study findings to identify lapses in the treatment cascade for youth living with HIV/AIDS using large national databases. This process will permit the enumeration of these patient phenotypes nationwide and the description of the related annual economic costs of care. This will enable us to identify meaningful variations between communities that can then serve as the basis for targeted interventions.

Acknowledgments

This study was supported by the NIH Adolescent Medicine Trials Network for HIV/AIDS Interventions (ATN 154) as part of the FSU/CUNY Scale It Up Program (U19HD089875; multiple principal investigators: SN and Jeffrey Parsons). Abstract

Background: The ability for patients to directly view their radiology images through secure electronic portals is rare in the American health care system. We previously surveyed patients within our health system and found that a large majority wanted to view their own radiology images online, and we have since implemented this new feature.

Objective: We aim to understand patient experiences, opinions, and actions taken after viewing their own radiology images online.

Methods: We emailed a web-based survey to patients who recently viewed their radiology images via our electronic patient portal.

Results: We sent 1825 surveys to patients and received 299 responses (response rate 16.4%). Patients reported a favorable experience (258/299, 86.3% agree) viewing their radiology images online. Patients found value in reading their radiology reports (288/299, 96.3% agree) and viewing their images (267/299, 89.3% agree). Overall, patients felt that accessing and viewing their radiology images online increased their understanding of their medical condition (258/299, 82.9%), made them feel more in control and reassured (237/299, 79.2% and 220/299, 73.6%, respectively), and increased levels of trust (214/299, 71.6%). Only 6.4% (19/299) of the patients indicated concerns with finding errors, 6.4% (19/299) felt that viewing their images online made them worry more, and 7% (21/299) felt confused when viewing their images online. Of patients who viewed their images online, 45.2% (135/299) took no action with their images, 32.8% (98/299) saved a copy for their records, 25.4% (76/299) shared them with their doctor, and 14.7% (44/299) shared them with another doctor for a second opinion. A total of 9 patients (3%) shared their radiology images on Facebook, Instagram, or both, primarily to inform family and friends. Approximately 10.4% (31/299) of the patients had questions about their radiology images after viewing them online, with the majority (20/31, 65%) seeking out a doctor, and far fewer (5/31, 16%) choosing to ask a family member about their images. Finally, respondents viewed their images online using 1 or more devices, including computers, smartphones, tablets, or a combination of these devices. Approximately 26.7% (103/385) of the responses noted technical difficulties, with the highest incidence rate occurring with smartphones.

Conclusions: We report the first known survey results from patients who viewed their own radiology images through a web-based portal. Patients reported high levels of satisfaction and increased levels of trust, autonomy, reassurance, and medical understanding. Only a small minority of patients expressed anxiety or confusion. We suggest that patient access to radiology images, such as patient access to radiology reports, is highly desired by patients and is operationally practical. Other health care institutions should consider offering patients access to their radiology images online in the pursuit of information transparency.

KEYWORDS

personal health records; patient-accessible electronic health records; online radiology image viewing; imaging informatics; patient portals; electronic health records; digital health; mobile phone

Introduction

Hospital systems and providers (health care professionals) around the country have increasingly implemented web-based patient portals, which allow patients to directly access portions of their electronic health record data, including laboratory test results, radiology reports, and pathology reports [1-3]. This new and unprecedented transparency between patients and their health information has been spurred forward by the information-blocking provision of the 21st Century Cures Act, which requires patients to be granted immediate access to clinical information entered into the electronic health record, including radiology reports [4]. The expansion of patient health information availability and obtainability has led to improvements in communication between patients and their providers as well as increased patient-centered care [4-6]. Until recently, however, patients were only able to read their radiology reports and could not view their personal radiographic images themselves. Health systems that have integrated image viewing portals into the patient accessible electronic record have documented up to >7-fold increases in the numbers of patients viewing their images, indicating a strong patient interest in the ability to view images [7]. Such interest has been corroborated by surveys demonstrating patient interest in viewing their radiology images and patient perception that there are potential benefits from doing so [8-10], but they have never before been surveyed about their experiences after viewing their own images though a web-based patient portal.

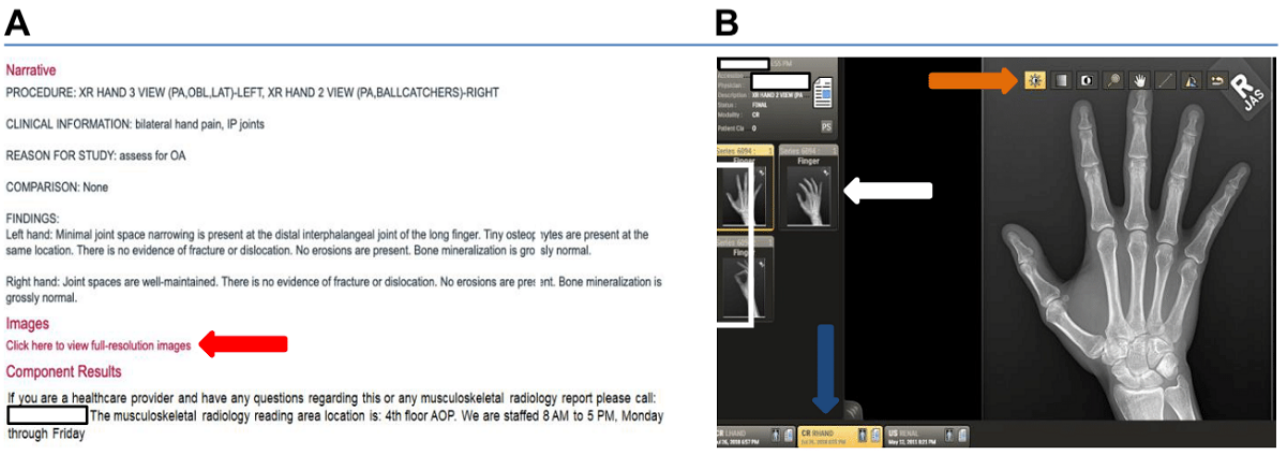
In August 2018, UCHealth launched direct patient viewing of personal radiology images through its My Health Connection (MHC) web-based portal. Prior to the release of this feature, we conducted an independent preintervention survey aimed at better understanding patient attitudes toward viewing their radiology images online. A majority of the surveyed patients felt that the increased transparency far outweighed the associated risks [10]. Following the successful launch of online patient radiology image viewing at UCHealth through the MHC patient portal, we asked patients about their experiences interacting with this new feature. In this report, we present the results of the first known survey of patients who have viewed their own radiology images online.

Methods

Imaging Viewing Implementation

Patients are able to view their images using our MHC patient portal. The MHC patient portal is available for patients to access both on desktop computers using a browser, as well as through tablets and mobile devices using a dedicated application. Upon viewing their report, they are able to click a link to load their images into a viewer originally designed for providers to view images remotely. They can then interact with these images via a series of tools/buttons on touch screen devices and mouse/keyboard on desktop/laptop computers as shown in Figure 1. All radiology imaging modalities are available for review through the portal, including radiography, computed tomography, magnetic resonance, ultrasound, fluoroscopy, and other images obtained during interventional procedures. Images are available immediately as soon as they are uploaded to our radiology picture and archiving communication provider and are not held pending review and released by the care team/doctor.

Figure 1. (A) Shows a sample musculoskeletal radiology report accessible to the patient via the My Health Connection web-based portal with a clickable link to view the associated images (red arrow). (B) Shows the imaging viewer with tabs for navigating all available images (white arrow) and studies (blue arrow), as well as modifying tool buttons (orange arrow) that provide patients with the ability to interact with their images. AOP: Anschutz Outpatient Pavilion; CR: conventional radiography; IP: interphalangeal; LAT: lateral; OA: osteoarthritis: OBL: oblique; PA: posterior-anterior; US: ultrasound; XR: x-ray.



Survey Design and Ethics Approval

This postintervention survey was designed to evaluate patient attitudes about viewing their own radiology images online, and a copy of the full survey is available in Multimedia Appendix 1. This survey had the support of the Chief Medical Officer of our health system and was reviewed by the Colorado Multiple Institutional Review Board (protocol #20-2593) who determined in an expedited review that the survey met ethics clearance guidelines, was deemed "quality improvement," and did not require full review. The survey instrument can be found in Multimedia Appendix 1.

Target Population

We included patients who had undergone radiology imaging and had viewed their images online via the MHC portal. The sample includes patients who underwent imaging both as inpatients and as outpatients.

Recruitment

The surveyed patients were identified by querying our radiology picture and archiving communication provider for the most recent patients who viewed their radiology images within the web-based MHC portal over a 5-day period at the time of our study. There were 1998 patients from this list who could be matched to email addresses in our electronic health record. These patients were emailed a link to the survey. The initial recruitment email garnered 185 responses and was followed by 1 reminder notification 2 days later, after which an additional 114 responses were received.

Statistical Analysis

Survey questions included both open- and closed-ended responses. After reading through all responses, open-ended responses were coded manually, sorting each response into a bucket. Buckets were developed by determining which themes came up most frequently. To ensure that we did not lose any information or make assumptions over implied importance, 1 response could be coded into multiple thematic buckets if multiple themes were present in the comment. For example, "I had to try to bring up the images multiple times before I could successfully bring up the images. It was also hard to navigate between images" was coded as both "Navigation issues" and "Required multiple refreshes/attempts to work." Closed-ended responses were rated on a Likert-like scale. Likert scores were employed to report the survey results as percentages and were reflected as Top 2 Box scores aggregating scores of 4 or 5 from the 5-point scale. All statistical analyses were performed using Q Research Software Version 5.4.5.0 (Displayr).

Results

Target Population

Of the 1998 recruitment emails sent, 173 emails were returned to the sender and 1825 were successfully delivered. We received 299 complete responses, yielding a response rate of 16.4%. This response rate is within the expected range based on previous work completed in our health system. Approximately 69.2% (207/299) were female, 28.7% (86/299) were male, 1.3% (4/299) preferred not to answer, and 0.7% (2/299) identified with another gender. This gender demographic breakdown is in line with what is to be expected from an unweighted convenience sample, and as seen in Table 1, compares favorably with the percentage of patients in our institution who have undergone radiologic imaging. The majority of the respondents were aged 55 years or older (175/299, 58.5%). Regarding education levels, 28.4% (85/299) of the respondents held a bachelor's degree, 23.1% (69/299) held a master's degree, 14.8% (44/299) had some college, and 1% (3/299) did not complete high school. The majority of patients (271/299, 90.6%) had their radiology images taken as part of a clinic or outpatient radiology appointment, while far fewer were taken during an inpatient admission (18/299, 6%).

Table 1. Demographics of the patients.

Characteristic	Study population (N=299), n (%)	UCHealth imaging studies (N=650,843), n (%)
Age (years)		
18-24	4 (1.3)	36,236 (5.6)
25-34	31 (10.4)	79,274 (12.2)
35-44	40 (13.3)	88,348 (13.6)
45-54	49 (16.4)	95,413 (14.7)
55-64	81 (27.1)	127,049 (19.5)
65+	94 (31.4)	224,523 (34.5)
Female sex[a]	207 (69.2)	178,000 (64)

[a]Sex is reported for UCHealth data, as gender identity data were incomplete. The total number of imaging studies in female UCHealth patients was 278,000.

Survey Results

When patients were asked on the postimplementation survey on a scale of 1 to 5 (1=poor, 5=excellent) about their overall experience viewing their radiology images in MHC, 86.3% (258/299) rated it favorably by the Top 2 Box score. Patients were asked to rate the value of viewing their radiology report and images online on a scale of 1 to 5 (1=not at all valuable, 5=extremely valuable), with the results shown in Table 2.

Table 2. Patient responses to the question, "Please rate the value of viewing each of the following within your web-based patient portal" (N=299).

Response	Agreement with statement, scored on a 5-point scale		
	Not valuable (bottom 2), n (%)	Neutral (middle 3), n (%)	Valuable (top 2), n (%)
Report	3 (0.7)	5 (1.7)	288 (96.3)
Images	8 (2.7)	22 (7.4)	267 (89.3)

Of the 299 respondents, 96.3% (288/299) of the patients rated viewing their radiology REPORT as valuable by the Top 2 Box score. Simultaneously, 89.3% (267/299) of the respondents rated viewing their IMAGES as valuable by Top 2 Box score. Surveyed patients rated their level of agreement with various statements regarding online viewing of their images as shown in Table 3. Approximately 82.9% (248/299) of the patients agreed that viewing radiology images would help "better understand my medical condition," 79.2% (237/299) agreed that viewing their images made them "feel more in control" of their health care, 63.2% (189/299) agreed that viewing their radiology images online allowed them to "better follow their doctor's recommendations," and 73.6% (220/299) "felt reassured" that their doctor was doing the right thing. Moreover, 71.6% (214/299) of the patients agreed that viewing images online increased levels of trust. Lastly, 6.4% (19/299) of the patients indicated concerns with finding errors, 6.4% (19/299) felt that viewing their images online made them worried, and 7% (21/299) felt confused when viewing their images online. A total of 174 patients (58.2%) had questions about their radiology images after viewing them; 137 (45.8%) patients discussed their questions with their referring doctor, 14 (4.7%) patients discussed their questions with the radiologist, 23 (7.7%) patients had questions but did not ask anyone, and 30 (10%) patients asked someone else but did not specify who. We asked patients how they used their web-based images and with whom they wanted to discuss their images. As summarized in Table 4, 25.4% (76/299) reported sharing their images with their doctor and 14.7% (44/299) shared them with other doctors for a potential second opinion. Approximately 32.8% (98/299) saved a copy for their records, and 3% (9/299) shared them on social media.

Table 3. Distribution of agreement with statements regarding online viewing of images (N=299).

Statement: Viewing my radiology images online caused me to…	Agreement with statement, scored on a 5-point scale		
	Disagree (bottom 2), n (%)	Neutral (middle 3), n (%)	Agree (top 2), n (%)
...better understand my medical condition.	19 (6.4)	32 (10.7)	248 (82.9)
...feel more in control.	10 (3.3)	52 (17.4)	237 (79.3)
...feel reassured.	19 (6.4)	60 (20.1)	220 (73.6)
...trust my doctors more.	18 (6)	67 (22.4)	214 (71.6)
...better follow recommendations.	28 (9.4)	82 (27.4)	189 (63.2)
...feel confused/have a lot of questions.	229 (76.6)	49 (16.4)	21 (7)
...worry more.	250 (83.6)	30 (10)	19 (6.4)
...find errors in my radiology reports.	239 (79.9)	41 (13.7)	19 (6.4)

Table 4. Patient responses to the question, "Which of the following have you done with your radiology images? Select all that apply" (N=299).

Response	Patients, n (%)
Save a copy for my records	98 (32.8)
Share them with my primary care doctor if they don't have them already	76 (25.4)
Share them with other doctors for a potential second opinion	44 (14.7)
Other (please specify)	31 (10.4)
Share them on social media	9 (3)
None of the above	135 (45.2)

Of the 9 patients who shared their images on social media, their images were posted on Facebook or Instagram, with 2 patients posting on both platforms. In response to asking why they posted their images to social media, the vast majority (8/9, 89%) stated they intended to inform their friends, family, or both. One respondent shared ultrasound images of their pregnancy, and 1 respondent did not answer this open-ended question. Additionally, 45.1% (135/299) of the respondents reported taking no action with their images and 10.4% (31/299) indicated that they did something else with their images but provided no specifics on this. Tables 5 and 6 reveal the breakdown of the electronic devices used by patients to view their images online as well as the technical difficulties experienced, respectively.

Table 5. Patient responses to the question, "Which type of device(s) did you use to view your images? Select all that apply" (N=299).[a]

Response	Patients, n (%)
Desktop/laptop computer	172 (57.5)
Smartphone	154 (51.5)
Tablet/iPad	59 (19.7)

[a]The percentage of each device user sums to greater than 100% because each patient was able to select more than one type of viewing device.

Table 6. Technical issues expressed by the patients in response to the open-ended statement, "Did you experience any technical issues with viewing your radiology images?" (N=103).

Concern	Patients, n (%)
Trouble viewing (image did not load, froze, server down, etc)	43 (40.2)
Navigation issues	25 (24.3)
Required multiple refreshes/attempts to work	15 (14.6)
Phone-specific issue	7 (6.8)
Browser-specific issue	4 (3.9)
Tablet/iPad-specific issue	3 (2.9)
None reported	6 (5.8)

We had 299 patients respond to the survey, but some patients indicated that they used more than one type of device to view their images, which resulted in 385 data points that included patients who used either just a single device or multiple devices. Approximately 44.6% (172/385) of the patients viewed their images on a desktop or laptop computer, with 22.1% (38/172) of the users reporting technical difficulties. About 40% (154/385) of the respondents viewed their images on their smartphone, with 33.1% (51/154) of the users reporting technical difficulties. Approximately 15.3% (59/385) of the respondents used a tablet to view their images, with 24% (14/59) of the users reporting technical difficulties. The total percentage of computer, smartphone, and tablet users sums to greater than 100% because patients commonly view their images on more than one device and could select more than one type of viewing device in our survey. Lastly, we asked patients a series of open-ended questions to better understand their experiences (ie, questions 6, 11-13, and 15 available in Multimedia Appendix 1). We received 231 open-ended responses regarding the question of perceived benefits of viewing radiology images online. Of these respondents, 41.9% (97/231) stated that online viewing of radiological images increased their understanding of their medical issue and 18.6% (43/231) reported access to the images being beneficial for seeing, saving, and sharing their images with family or their doctor. Patients were also asked about their concerns regarding viewing radiology images online, to which we received 197 open-ended responses; 28 of these respondents (14.2%) stated that online viewing of their radiology images caused them confusion, 14 (7.1%) reported feeling that they had no one with whom they could discuss their questions, and 128 (64.9%) respondents reported no concerns with viewing their actual images. Table 7 illustrates representative patient quotations from open-ended questions 6, 12, and 13. Sample responses to question 6 are listed under "General Reactions," sample responses to question 12 are listed under "Benefits," and sample responses to question 13 are listed under "Concerns."

Table 7. Representative patient responses.

Response type	Quote 1 examples	Quote 2 examples
General reaction	*…This is an excellent feature that assists me as a patient in making my healthcare decisions.*	*…The report is more important to me than the images. I really have no idea what I'm looking at with the images.*
Benefits	*…A sense of involvement in my treatment and health. Usually you never get to see your images, so it felt empowering.*	*…I was able to ask my doctor more informed questions when we spoke. As a result, I felt I had fewer unresolved questions later, and worried less.*
Concerns	*…I would like access the report at the same time I get access to the images. Seeing the images without the results is not an effective way to share the information.*	*…I did not have a professional available to explain the results. I had to wait for my appointment with my oncologist.*

Discussion

Principal Findings

As anticipated from our prior work, a majority (258/299, 86.3%) of the postintervention respondents had a favorable experience of viewing their radiology images online [10]. Additionally, the majority of the respondents reported finding high levels of value in viewing both their radiology reports and images online. The perceived value patients experienced viewing their reports and radiology images was higher than that anticipated by the responses in our prior survey, perhaps suggesting that patients may underestimate the value of having access to these until they have the opportunity to do so. This highlights the importance of patient accessibility to their personal health information. For example, 1 patient stated, "I like to be informed on what's going on and this is the best way to do it, where I can see the X-ray or CT scan and then listen to their follow-up on it, which helps me learn about my illness." Other patients reported feeling "empowered," while one stated that viewing their images "made me feel more involved/in control of my injury. 'A picture is worth a thousand words' comes to mind."

It has been theorized that patient fears related to confidentiality, lack of awareness of patient portals, and negative experiences when first accessing portals, as well as numerous socioeconomic factors related to education, limited internet access, and being members of certain racial minorities can lead to significant skepticism regarding patient portals and results in reduced use of these tools [11-14]. Although our study is not designed to assess the myriad of factors that may cause patients to be reticent to view their images online, in all categories regarding patient concerns, postimplementation patient concerns were even lower than those anticipated from our prior work [10]. We suspect that the universally lower rates of adverse experiences reported by our respondents in this study compared to what was anticipated could be a result of assumption-making or insufficient preliminary understanding about the proposed implementation. Our postintervention survey by design samples only those patients who have used and are familiar with the portal. Actually using and being familiar with the portal itself and how it functions may allay wariness or other concerns that a patient may have anticipated before actually being able to utilize such functionality. Nevertheless, there remains ample opportunity to address concerns raised by patients, thus improving overall access and patient experience. Potential solutions include better instructional material on how to access these images on the various desktop, tablet, and mobile platforms, the ability to demo the image viewer to allow patients to practice using them and gain familiarity with their use before using them to access their own images in a higher stress environment, and perhaps target these interventions at specific patient groups more likely to experience such issues (the older adults and certain socioeconomic populations).

Over half of the patients (174/299, 58.2%) reported having questions about their images after viewing them. Although most of these patients discussed their questions with their referring doctor, 7.7% (23/299) of the patients did not ask anyone about their questions. Those that did not ask anyone about their questions indicated a myriad of reasons for this, including "not knowing who to ask," feeling that the "doctor did not have time to answer questions during their visit," that they felt "embarrassed" or did not want to "bother" anyone, or simply that they decided to "wait to ask questions at their next appointment." For those patients who may not know where to direct their questions, possible solutions include an in-application chat-style box, question form, and an easily accessible contact list of providers involved in that patient's care, such as providing contact information of the radiologist at the bottom of every report so that patients can easily contact the radiologist with questions [15].

A significant concern cited by up to 14.2% (28/197) of the respondents was confusion brought upon by viewing the images themselves. Perhaps this confusion is not at all surprising as radiology images are quite complex, and the verbiage used in the dictated reports describing these images are tailored for medical professionals rather than for helping patients understand their images themselves. One possible intervention that may help to reduce this confusion would be to provide reports that are more patient-friendly, either utilizing simplified language that can be understood by patients without medical backgrounds or providing patient-friendly explanations/definitions and diagrams directly within the patient report to allow patients to better understand the reports and their corresponding images [16]. Moreover, some reporting systems allow for hyperlinks within reports that can bring patients to the specific image being discussed, which can help patients correlate between the findings described on the reports and the corresponding images. Additional visual aids such as normal comparisons may be of use and was specifically suggested by 1 respondent who stated "it would be nice to see what a normal image would look like against mine so I can see what's different."

Between a quarter and a third of the patients reported technical difficulties with viewing their images online using their electronic device, with the highest incidence rate for those using smartphones. Many patients reported issues with loading and navigating their images. One patient stated that "enlarging or reducing images is difficult. Tools are not user-friendly for nonmedical people." Another said that image viewing "works more easily on iPad or computer." One explanation for these experiences is that no substantial modifications were made to the provider image-viewer to aid in functionality when it was adapted for patient use. Specifically, no explanations are provided within the image viewer tool as to what individual buttons mean. Although some tools such as a magnifying glass may be self-explanatory to patients, other tools such as Window/Level buttons etc are far less intuitive and are likely to easily confuse patients. Additionally, the image viewer tool is optimized for desktop/browser-based interactions, but a significant proportion of our patients accessed these images via touch screen mobile devices, which make interaction with the image-viewer tool more difficult. A number of potential solutions for these problems should be considered. An in-application help feature explaining the function of buttons within the tool may be of benefit to improve the experience. Additional optimization of image viewing tools for mobile devices/tablets will also make the image viewing experience

far easier. Health care systems should continue investing in their information technology infrastructure and upgrading image-viewing platforms to meet the needs of their patients.

It is notable that patients in our study reported significant lower rates of saving copies of images for their records (98/299, 32.8%), sharing their images with their primary care physician (76/299, 25.4%), or sharing their images with other providers (44/299, 14.7%) than anticipated from our prior work. In fact, 45.2% (135/299) of our survey respondents reported doing nothing with their images, as opposed to only 5.7% of anticipating the same in our prior work [10]. Although this could be due to a multitude of different factors, a significant factor is likely that in our image viewer, no modifications were made to increase the ease of saving and sharing images from their device. Additionally, technical difficulties experienced by patients, especially on mobile devices, likely made such image sharing far more difficult than originally anticipated.

A small percentage of the patients (9/299, 3%) posted their radiology images to social media platforms, that is, Facebook and Instagram. Patients who engaged with social media did so primarily to inform and reassure their friends and family. One patient reported sharing their images "for my family only to keep them better informed, to answer their questions and to reassure them." Another patient expressly used the platforms to share pregnancy ultrasound images: "Seeing prenatal ultrasounds was fun for family members who couldn't be at appointments because of COVID. I also love reviewing the images to see our baby grow."

Limitations

We have refrained from a detailed direct comparison of the results of this study survey to our work prior to the implementation of the image viewer portal owing to differences in the populations sampled. Our prior work sampled members of the UCHealth Insights community, many of whom are patients at UCHealth, but includes other health care decision makers in the community as well. Patients were a sample limited to MHC portal users, as this is the only way to survey patients who had viewed their radiology images. As such, only general comparisons to prior work are discussed here. Although our survey demonstrated a largely favorable experience with viewing their images online, the literature on patient satisfaction surveys does show that the most satisfied patients are more likely to participate in surveys than the dissatisfied, and this tendency produces a positive bias in favorability scores. Additionally, the response rate for our survey is 16.4% (299/1825), which while within the expected range for email survey responses based on previous work in our health system and within the lower end of range of reported response rates in the literature still leads to the possibility that dissatisfied patients may have not responded, and we cannot infer bias or motivation to reply in our analysis [17,18]. Our respondents come from a single center, and the age/sex of the respondents (online image viewers) do not perfectly reflect the age/sex of the patients in our health system in general. Our surveyed patients were selected by sampling those who had most recently accessed their images online over a 5-day period of the study. Given the anonymous nature of the survey, we are unable to consider the severity of patient illness or the cognitive impairment of the survey respondents and cannot assess how these factors may impact survey results. Lastly, as a quality improvement project, our findings are not intended to be generalizable.

Future Directions

As more health care systems move to making online viewing of radiology images available to their patients, our understanding of the associated benefits and risks will continue to grow. Although our respondents largely indicated favorable experiences with viewing their radiology images on MHC, future investigations should determine the reproducibility of our findings in more diverse population groups. A small but significant set of concerns were raised in terms of patient anxiety and worries caused by viewing radiology images before seeing the associated report or being able to discuss the results with a health care provider. Institutions that offer patients the ability to view their radiology images online should consider ways of mitigating these concerns during the implementation of these novel solutions. We also noticed a lower rate of utilization of images (saving copies for their records, sharing with primary care physician and other providers) than anticipated. Further insight into this surprising result is warranted, as it highlights a potential target for improvement.

Additionally, future investigations focusing on user interface, technical improvements, and additional features desired by patients could help to improve the overall patient experience interacting with their web-based portal and image-viewing platform. Although our survey focused on the patient perspective, we believe that a comprehensive understanding of the impact of online radiology image viewing requires the consideration of the provider perspective as well. In the experience of our radiology leaders and clinician leaders, surprisingly few concerns have been raised in the past 2 years. By seeking out both patient and provider attitudes, we would be able to optimize the experience for both.

Conclusions

To our knowledge, this is the first report to describe patients' experience in viewing their radiology images through a web-based patient portal. Patients expressed a high level of satisfaction and a low incidence of negative experiences. Patients who viewed their radiology images reported increasing trust, autonomy, reassurance, and medical understanding, with few expressing concerns such as anxiety or confusion. From these results, we see opportunities to further improve the patient experience with online image viewing. Overall, our experience and that of our patients has been positive with rare concerns. We suggest that patient access to radiology images, such as patient access to radiology reports, is highly desired by patients and is operationally practical. Other health care institutions should consider offering radiology images online in the pursuit of information transparency.

Abstract

Background: Computerized cognitive behavioral therapies (cCBTs) have been developed to deliver efficient, evidence-based treatment for depression and other mental health conditions. Beating the Blues (BtB) is one of the most empirically supported cCBTs for depression. The previous trial of BtB with veterans included regular guidance by health care personnel, which increased the complexity and cost of the intervention.

Objective: This study, conducted by researchers at a Veterans Affairs Medical Center, aims to test the acceptability and feasibility of unguided cCBT for depression among US military veterans.

Methods: To examine the acceptability of BtB delivered without additional peer or other mental health care provider support, a before-and-after trial was conducted among United States (US) military veterans experiencing mild to moderate depressive symptoms. The feasibility of the study design for a future efficacy trial was also evaluated.

Results: In total, 49 veterans completed preintervention assessments and received access to BtB, and 29 participants completed all postintervention assessments. The predetermined acceptability criterion for the intervention was met. Although the predetermined feasibility criteria regarding screening eligibility rate, number of BtB modules completed, and completion of a posttreatment assessment were not met, the results were comparable with those of other cCBT studies.

Conclusions: This is the first study among US military veterans to demonstrate support for the implementation of cCBT for depression without the assistance of a mental health professional or a peer support specialist, suggesting that stand-alone computer-aided interventions may be viable. Ideas for improving feasibility in future trials based on this study are discussed.

Introduction

Background

Depressive disorders are among the most common mental health conditions associated with high morbidity [1]. Compared with the general population, US military veterans are at an increased risk of depression [2]. Approximately 1 in 3 veterans visiting primary care clinics has some symptoms of depression, 1 in 5 has serious symptoms that indicate the need for further evaluation, and 1 in 9 requires psychotherapy or antidepressant treatment for major depression [3].

Although depressive disorders are common and undertreated conditions [4-6], there are effective treatments, including cognitive behavioral therapy (CBT) and pharmacotherapy [7]. Research supports the notion that patients generally prefer psychological therapy to medication [8,9]. However, there is a critical need for trained mental health professionals to treat depressive disorders among individuals in the US, including the US veterans [10]. Although CBT training programs are available for providers within the Department of Veterans Affairs (VA), additional factors can limit individuals' ability to engage in traditional face-to-face therapy, including the resources required to travel to the clinic for repeated appointments, which may not be available at the most convenient time [11]. Alternative methods have been developed to address limitations inherent to traditionally delivered psychotherapy and facilitate efficient, evidence-based, and appropriate treatment [12]. An alternative method for providing evidence-based psychotherapy to a larger population is the use of computer-aided therapies.

In the past 40 years, efficacious computerized cognitive behavioral therapies (cCBTs) have been developed to treat depression and other mental health conditions. Most cCBT programs can be accessed using the internet (eg, from an individual's home or a public library) and are highly interactive (eg, audio, video, and animations) [13]. cCBTs have the potential to address some accessibility concerns related to mental health care, as they can be administered at home during times that are most convenient for the patient, thereby reducing barriers to care, including those posed by geography, transportation costs, travel time, and childcare. Because cCBTs generally require less provider time, they can also be cost-effective alternatives to traditional face-to-face psychotherapy.

Meta-analyses have found that cCBT for depression and anxiety disorders is similarly effective to traditional face-to-face CBT in reducing symptoms of depression and anxiety [14-16]. Posttreatment satisfaction with cCBT in the general population has also been studied [17,18] and is similar to that of face-to-face therapies [19,20]. Patients receiving cCBT reported being as satisfied as those receiving CBT from a clinician [21] and more satisfied than those receiving treatment as usual [22,23]. These findings suggest that cCBT is a viable alternative for treating common mental health symptoms.

One of the most empirically supported cCBTs for depression is Beating the Blues (BtB), an 8-session, self-administered, and interactive cCBT program (see the *Methods* section). Although BtB is self-administered, the program offers a provider portal to track patient progress and facilitate health care provider or peer support to encourage treatment engagement. Participation in the BtB program has been associated with reductions in mild to moderate symptoms of depression and anxiety [24-26], and it has been recommended as the gold standard for treating mild to moderate symptoms of depression in primary care contexts [13,16,27]. In randomized controlled trials, BtB has also been established as a cost-effective intervention [16,28]. In addition, BtB has demonstrated effectiveness in addressing depression in older adults [29].

A recent study has demonstrated the acceptability and feasibility of BtB with peer support for treating mild to moderate symptoms of depression in veterans receiving primary care or outpatient mental health services [30]. However, because the study intervention included an additional component of weekly interactions with a veteran peer support specialist, it is unclear whether the effects observed were associated with the BtB program, the peer support specialist, or the combination.

Some studies have shown that veterans respond differently to evidence-based psychotherapies, including CBT for depression [31]. In terms of variables associated with treatment response, including psychiatric comorbidity and lack of stable housing, Veterans receiving health care from the VA differ from other US cohorts [32]. For example, comorbid posttraumatic stress disorder, which is more common in veterans than civilians, may reduce the effectiveness of depression treatments [31].

Objectives

This study aims to examine the acceptability and feasibility of delivering BtB without additional peer or mental health care provider support among veterans receiving care at a Veterans Affairs Medical Center (VAMC). Acceptability refers to the suitability of an intervention from the perspective of participants [33]. Feasibility refers to the goodness of fit between an intervention and the system in which it is disseminated. Aligned with the guidance provided by Areán and Kraemer [34], our feasibility assessment focused on the ease of implementation of study design elements, which were participant recruitment, enrollment, and retention. Before commencing the study, a set of a priori criteria (see the *Acceptability and Feasibility Criteria and Analysis* subsection in the *Methods* section) was established to measure the acceptability and feasibility per best practices in pilot study designs [35].

Methods

Design

All participants were allocated to receive the BtB intervention following a before-and-after trial design [36]. This study was approved by the Colorado Multiple Institutional Review Board and the local VA Research and Development Committee. A Health Insurance Portability and Accountability Act waiver was granted for the entire study, as all procedures were completed remotely (over the phone with the participant or on the web via a survey link). Data collection occurred between September 2019 and February 2020. After a research team member read

the consent information sheet to the potential participants, verbal consent was obtained. Participants could also download a copy of the consent form via the Research Electronic Data Capture (REDCap; Vanderbilt University) [37] platform, a web-based portal for participants to complete self-report study measures. Following verbal consent, the interviewer conducted a telephone eligibility screening. If the participant was eligible for the study, the interviewer ended the telephone conversation and sent a link to a web-based survey of preintervention (baseline) measures to be completed on the REDCap platform. After completing the preintervention measures, participants were provided a link to register for and access the BtB web-based intervention. All the BtB content, including an introductory session and 8 content modules, could be completed autonomously via an internet browser interface without facilitation by a health care provider, peer, or study staff. Although the core content of BtB can be completed in as few as 8 weeks, participants were given access to the program for 12 weeks. After completing 8 modules or at the end of the 12 weeks, participants were emailed a second link to complete postintervention assessments via REDCap. All participants were compensated for completing the pre- and postintervention surveys.

Participants

Initially, veteran participants were recruited exclusively via referral from a Primary Care and Mental Health Integration (PC-MHI) psychologist. PC-MHI psychologists are embedded in VA Patient Aligned Care Teams within primary care clinics to provide brief mental health assessments, referrals, and interventions. The study team received 45 referrals from the PC-MHI psychologist, and 29 veterans consented to participate in the study. Of the 29 veterans, 18 (62%) did not complete any BtB modules, 4 (14%) were lost to follow-up, and 7 (24%) completed postintervention surveys. Because the study did not meet its targets for recruitment, enrollment, and data collection, the study team implemented a new recruitment strategy that involved identifying potential participants using electronic medical records (EMRs). This paper does not report data from participants recruited via PC-MHI psychologist referral because they might systematically differ from those recruited using EMRs. In addition, we may use the EMR recruitment method in future clinical trials based on this feasibility and acceptability study.

For recruitment using EMRs, potential participants were identified from the VA Corporate Data Warehouse. The records were electronically searched for veterans (1) eligible to receive care at a particular VAMC between August 2017 and July 2019 who (2) were administered the Patient Health Questionnaire-9 (PHQ-9), a brief self-report measure of depression and (3) received a total score between 5 and 15 points, which indicates the presence of mild to moderate symptoms of depression [38]. Considering previous studies supporting the efficacy of cCBT in the treatment of depression and the statistical relationship between depression and suicidal behavior among veterans [39], we chose to recruit veterans based on symptoms of depression instead of other symptomatology. Veterans meeting these criteria were sent a letter inviting them to participate in the study. The letter briefly described the study and instructed interested veterans to call a research team member to be screened for eligibility.

During the telephone screening, potential participants self-reported whether they met the following inclusion criteria: (1) being a US military veteran aged between 18 and 89 years; (2) having a score of 5 to 15 on a verbally administered PHQ-9, which determined whether the veteran currently endorsed mild to moderate depressive symptoms [38]; (3) able to write, read, and speak English; and (4) having reliable access to the internet. The following exclusion criteria were also assessed: (1) inability to complete the assessment sessions or participate in the intervention because of visual or hearing impairment, severe psychiatric symptoms (eg, active psychosis or imminent suicide risk), or severe cognitive impairment; (2) membership in a vulnerable population (eg, pregnant women and prisoners); and (3) self-reported current participation in another mental health intervention study. The telephone-administered PHQ-9 was only used for screening purposes; another PHQ-9 was administered electronically via REDCap along with the other preintervention assessments to collect the data used in the study analyses.

Measures

The measures administered during pre- and postintervention are shown in Multimedia Appendix 1; Table S1.

Client Satisfaction Questionnaire

The Client Satisfaction Questionnaire (CSQ) [40] is an 8-item questionnaire used to assess participants' satisfaction with an intervention. Scores range from 8 to 32, with higher scores indicating greater satisfaction. A score of 24 or higher indicates that the average item rating was in the *mostly satisfied* or better range. The CSQ has good reliability and validity and has been frequently used to evaluate mental health care [41]. The CSQ was administered during the postintervention assessment and was a measure of acceptability.

Generalized Anxiety Disorder Inventory-7

The Generalized Anxiety Disorder Inventory-7 (GAD-7) [41] is a 7-item self-report measure that assesses symptoms related to generalized anxiety disorder. Participants respond to items using a 4-point Likert scale ranging from 0 to 3 (*not at all* to *nearly every day*, respectively). Participants endorse the items based on how they felt in the last 2 weeks. Higher scores reflect greater symptoms of generalized anxiety. The GAD-7 has demonstrated good reliability and validity [41]. As our trial was specifically designed to examine BtB acceptability and feasibility and not as an efficacy trial (eg, it did not include a control condition), only baseline GAD-7 scores are reported in this paper.

Internet Evaluation and Utility Questionnaire

The Internet Evaluation and Utility Questionnaire (IEUQ) [42] is a 13-item measure that examines the participants' experiences of a web-based intervention. The IEUQ was adapted for this study to refer specifically to BtB. The constructs measured included items on ease of use, convenience, engagement, enjoyment, layout, privacy, and overall satisfaction. The IEUQ was administered to gather further information on the

participants' impressions of the aspects of the intervention that were relevant to its acceptability (eg, convenience). Participants responded to items on a 5-point Likert scale from 0 (*not at all*) to 4 (*very*) or rated them as *not applicable*. Previous research indicates that the IEUQ has adequate reliability [42,43].

Internet Impact and Effectiveness Questionnaire

The Internet Impact and Effectiveness Questionnaire (IIEQ) [42] is a 20-item instrument that measures individuals' perceptions of the effectiveness of a web-based intervention. The perceived impact is measured in terms of helpfulness, knowledge gains, treatment effectiveness for self and others, long-term effectiveness, quality of life, mood, physical activity, family and peer relationships, social activity, school or work attendance and performance, treatment implementation, goal orientation, confidence in the ability to manage conditions, relapse prevention, and service reduction. The perceived or actual effectiveness of the intervention is likely to influence patients' perceptions of acceptability [44]. This measure was adapted for this study to refer specifically to BtB. Participants responded to items using a 5-point Likert scale ranging from 0 (*not at all*) to 4 (*very*). There was also a *not applicable* option. Adequate psychometric properties have been demonstrated previously [42,43].

PHQ-9 Scores

The PHQ-9 is a 9-item measure that assesses symptoms of depression. Participants respond to items using a 4-point Likert scale ranging from 0 to 3 (*not at all* to *nearly every day*, respectively), endorsing them based on how they felt in the last 2 weeks. Higher scores reflect greater symptoms of depression. The PHQ-9 has demonstrated good psychometric properties [38]. Similar to the GAD-7, only baseline PHQ-9 scores are reported in this paper.

Reasons for Termination–Adapted

The reasons for termination (RFT) scale [45] assesses 10 common reasons why patients terminate therapy and the impact these reasons have on termination. Thus, the RFT scale gathers information about the elements of a therapy that reduce its acceptability. If a participant completed between 1 and 7 modules of the BtB treatment within 12 weeks of the initial log-in to the BtB treatment website (ie, began but did not finish the therapy within the allotted time), this measure was included with the postintervention measures collected via a REDCap survey link.

Intervention

BtB is a computerized cognitive behavioral intervention program aimed at reducing depressive and anxiety symptoms [23]. BtB was designed explicitly to implement the standard CBT model of depression and anxiety and include the therapeutic elements that make up traditional CBT psychotherapy (eg, thought records [46]). The web-based intervention consisted of a 15-minute introductory session followed by 8 interactive modules, usually taken weekly. Each weekly module lasted approximately 50 minutes, with homework projects to complete between the modules (eg, problem diaries, thought records, and behavioral experiments).

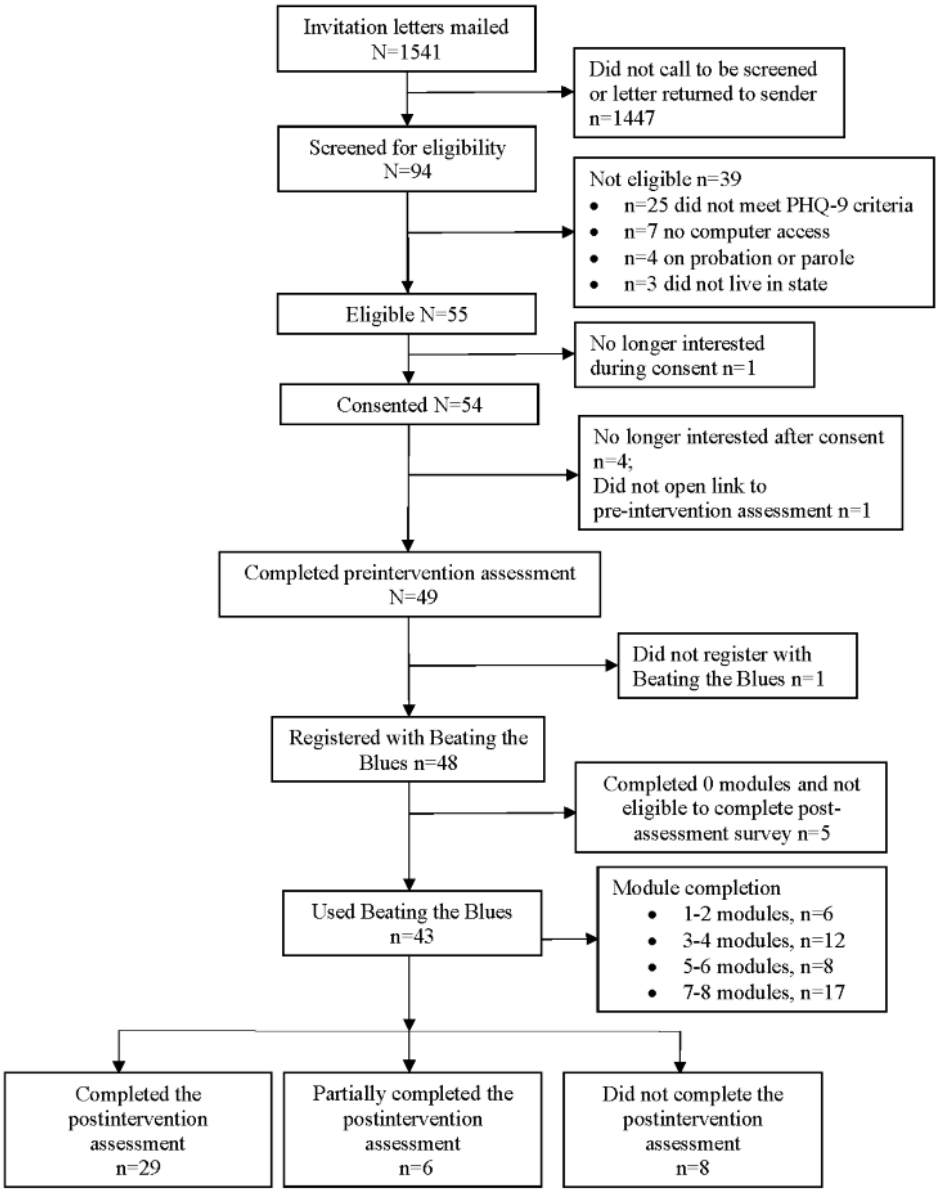
Acceptability and Feasibility Criteria and Analysis

The a priori criterion for assessing the acceptability of the intervention was that ≥70% of the participants had a score of ≥24 on the CSQ. A score of ≥24 was selected as the cutoff because it indicates that the average item rating was in the *mostly satisfied* or better range. Additional acceptability data were collected from the IIEQ, IEUQ, and RFT. The a priori criteria for assessing the feasibility of the study were (1) ≥70% of potential participants would meet the eligibility criteria assessed during the telephone screening, (2) ≥70% of those found eligible would consent to participate in the study, (3) ≥60% of those who completed the preintervention survey would complete all the intervention modules, and (4) ≥75% of those who registered for BtB and completed at least one module would complete the postintervention survey measures.

Study Procedures

Study recruitment, enrollment, and data collection were conducted at multiple time points (Figure 1).

Figure 1. Enrollment flow diagram. PHQ-9: Patient Health Questionnaire-9.



Results

Baseline Demographics

Of the 54 veterans recruited via EMRs who consented to participate in the study, 49 (91%) used the emailed link to complete the baseline assessment measures. The sample was predominantly male (43/49, 88%) and White (37/49, 76%). At baseline, most participants reported moderate depression (ie, a PHQ-9 score in the moderate depression range of 10-14) and mild anxiety (ie, a GAD-7 score in the mild anxiety score range of 5-9). Further details regarding demographic characteristics are shown in Table 1.

Acceptability

The CSQ was used to examine whether participants found the BtB intervention acceptable, which was operationalized as a CSQ score of ≥24. Among the 35 participants who completed the CSQ, 26 (74%; 95% CI 57%-88%) received a score of ≥24, which met the a priori criterion of ≥70% (CSQ mean 25.2, SD 4.8).

Acceptability data were also collected using the IEUQ, IIEQ, and RFT. The responses to the IEUQ are presented in Table 2. On the IEUQ, many participants reported liking BtB and being satisfied with the intervention. Data from the IEUQ suggested that BtB was *mostly* or *very easy* to use (23/30, 77%) and generally kept participants' attention. On the IEUQ, most of the participants (21/30, 70%) found that the internet was a *mostly* or *very good* method for delivering CBT. In addition, participants (18/30, 60%) reported they were *mostly* or *very likely* to come back to BtB if depression difficulties continued or returned.

Responses to the IIEQ regarding the perceived effectiveness of BtB are shown in Table 3. On the IIEQ, most participants reported that BtB *somewhat* or *mostly* improved depressive symptoms (18/29, 62%), quality of life (15/29, 51%), and mood (15/29, 51%). Participants felt they *somewhat* or *mostly* gained more knowledge while using BtB (21/29, 72%), and they were *somewhat* or *mostly* prepared to handle depressive symptoms in the future (16/29, 55%). In addition, they were *mostly* or *very likely* to recommend BtB to others with similar problems (20/29, 69%).

Although many participants found the intervention acceptable, some did not complete all the 8 modules of the intervention (Figure 1). The RFT questionnaire was administered to participants who completed between 1 and 7 modules (Table 4). Some participants reported that the barriers to completing

all modules included practical problems (3/14, 21%), time constraints (5/14, 36%), and medical reasons (4/14, 29%). None of the participants who completed the RFT reported that they chose to stop the intervention because they were dissatisfied or wanted a different intervention.

Other reasons that led to ending participation	6 (43)	6 (43)	2 (14)

[a]BtB: Beating the Blues.

Feasibility

Of the 94 veterans identified via EMRs and screened, 59% (55/94) were eligible for the study, which did not meet the a priori feasibility criterion of ≥70%. Of those eligible, 98% (54/55) consented to participate in the study (Figure 1), meeting the a priori feasibility criterion of ≥70%, and 49 (91%) of them used the emailed link to complete the preintervention assessments. A participant did not register with the BtB program after completing the preintervention assessment, leaving 48 participants in the study. Of these, 33% (16/48) completed all 8 BtB modules, which did not meet the a priori feasibility criterion of ≥60%. Among the other registered participants, 19% (9/48) completed 5 to 7 modules, 38% (18/48) completed 1 to 4 modules, and 10% (5/48) did not complete any module after registering for BtB. Participants were not eligible to complete the postintervention survey if they did not register with BtB and complete at least one module. Of the 43 participants who completed at least one BtB module, 67% (29/43) completed all postintervention measures, which did not meet the a priori criterion of ≥75%, and 6 (14%) individuals partially completed the postintervention survey, meaning that 81% (35/43) of participants completed at least part of it. Of note, based on demographics and preintervention measures, participants who completed this survey did not differ significantly from those who did not (Multimedia Appendix 1; Table S2).

Discussion

Principal Findings

The results of this pilot study indicate that the a priori acceptability criterion for the intervention was met. Veterans generally found BtB helpful and easy to use. Most of the veterans who completed the postintervention assessment reported that they were able to complete the tasks associated with the intervention, that they found the intervention helpful, and that they would recommend it to other veterans with similar problems. The observed module completion rate was similar to the rates found with other unguided cCBT interventions [47] and with BtB in non-Veterans [48]. The completion rate was also similar to that found in a previous study of a peer-supported implementation of BtB in veterans [30]. Among the veterans who completed the RFT measure, the most common reasons for treatment discontinuation were related to external factors (eg, time constraints). None of the veterans reported discontinuing because of dissatisfaction with the treatment.

Concerning feasibility, three of four a priori criteria were not satisfied. We believe that a reason for this outcome is that, in retrospect, the criteria selected before the pilot study were overly conservative. In this study, participant recruitment via EMRs occurred rapidly (within 2 months), which did not allow for larger modifications to aspects of the design (eg, the retention plan) while the study was being conducted. However, in line with the advice of Thabane et al [35], conducting this pilot study has suggested several modifications to the study design that we will implement in future iterations of this research protocol.

One of the initial feasibility criteria was that ≥70% of veterans referred to the study would meet the secondary screening criteria, which included current mild to moderate depressive symptoms. As depression is a waxing and waning condition [49], it is unsurprising that many veterans' symptoms improved or worsened between the initial administration of the PHQ-9 recorded in the EMR and when they were screened for this study. Furthermore, undertaking this pilot trial suggested that only modest experimenter and participant efforts were required to conduct the telephone screening to confirm the presence of current mild to moderate symptoms of depression. Given these considerations, we concluded that the 59% eligibility rate among veterans who received a telephone screening was more than sufficient to demonstrate the feasibility of enrolling this population in future larger efficacy trials. Additional feasibility-related modifications of the study protocol to increase the percentage of veterans with eligible PHQ-9 scores at phone screening (eg, requiring a more recent PHQ-9 administration in the EMR) would not be required.

Another a priori feasibility criterion was that ≥60% of veterans would complete all the 8 modules associated with the treatment. In retrospect, both the percentage of veterans required to complete the modules and the number of modules required by this criterion were overly conservative. Furthermore, we believe that easily implemented changes to the protocol (described below) may further increase the mean number of modules completed. Regarding the number of modules required, a more appropriate number might have been derived from the previous study of BtB in veterans [30], which found that those who completed 5 or more modules of BtB showed statistically significant improvements in symptoms. In our sample, 52% (25/48) of veterans completed 5 or more modules, compared with only 33% (16/48) who completed all 8 modules. Although a higher percentage of veterans met the 5 or more module completion rate criteria, the fact that this 52% completion rate is still less than the 60% rate that we targeted suggests that we should consider modifications to the study protocol to increase the proportion of veterans who complete at least five modules. Of relevance to identifying potentially useful protocol modifications, a previous study found that simple weekly email reminders to complete web-based psychotherapy modules increased the mean number of modules completed by 50% (from 3.7 modules to 5.5 modules) [50]. Researchers have obtained further increases in the efficacy of such reminder emails by adjusting their content (eg, sending emails that inform the user of new content rather than simply reminding them to complete a session) and timing (eg, emailing users after 2 weeks of absence rather than longer periods) [51]. In future iterations of this protocol, we will implement such email reminders to improve the mean number of modules completed. It should be noted that only 40% of veterans completed at least five modules in the previous trial of BtB that used peer support specialists to facilitate the completion of BtB modules [30] compared with 52% (25/48) in our unfacilitated trial, suggesting that the greater investment of resources required to include peer support specialists in the intervention may not necessarily increase the average number of modules completed by participants.

Regarding the criterion for the proportion of participants who needed to complete the required number of modules, we believe that setting this criterion to ≥60% of participants was also too conservative. A core advantage of BtB (and other cCBT interventions) is that it requires less time and resources to be administered to an individual, both from the perspective of veterans and the health care system. Therefore, whereas traditionally implemented treatments might indeed require a low noncompletion rate to justify their research or clinical use, a low-intensity intervention such as BtB probably may not. To reiterate, we believe that the study protocol should be modified to increase the mean number of modules completed. However, we also conclude that a lower minimum completion rate might have been a more useful feasibility criterion given the low veteran and provider burden associated with BtB.

The final a priori feasibility criterion that was not met required that ≥75% of veterans complete the postintervention assessment. In reflecting upon our pilot study, we believe that some small alternations to the experimental design could have improved the observed postintervention survey completion rate of 67%. Previous studies on methods to increase participant retention and assessment completion suggest that using one or more of the following strategies might have increased the rates of postintervention survey completion: a telephone follow-up to the assessment invitation; shortened versions of questionnaires where possible; and, reminders to nonrespondents [52]. We also note that the literature on methods to improve participant retention is growing, and efforts to systematically identify efficacious retention strategies are underway [53].

To our knowledge, this study is the first to demonstrate that a substantial percentage of veterans can complete BtB without the assistance of a mental health professional or peer support specialist [30]. This is important because one of the main virtues of cCBT interventions is the possibility of providing evidence-based CBT interventions to a larger number of individuals [54]. A strength of our study was its broad eligibility and few exclusion criteria, which allowed us to recruit a veteran sample that was relatively representative of the broader population of veterans to whom a BtB intervention might be provided in regular clinical practice (eg, veterans receiving care at a VAMC and reporting mild to moderate symptoms of depression).

Limitations

Our study has several important limitations. First, the relatively small number of veteran participants who were women, non-White, or Hispanic did not represent the entire US veteran population [55] and limited the ability to demonstrate the acceptability of BtB in these important populations. However, other studies have generally shown that cCBT interventions, including BtB, have similar acceptability among women and members of minority groups [56]. Second, veterans with more severe depression (scores >15 on the PHQ-9) were excluded from our study, limiting our ability to draw conclusions regarding the feasibility of the design and acceptability of the intervention among veterans with more severe symptoms of depression. However, this exclusion criterion is consistent with the practice of health care systems where cCBT has already been successfully implemented (eg, in the United Kingdom [57]). In these systems, cCBT (and other less resource-intensive interventions) are initially provided to a larger population of individuals with mild to moderate depression symptoms, whereas a smaller population of high-acuity patients receive more resource-intensive interventions, such as in-person psychotherapy [58]. Finally, 17% (8/48) of the participants who registered with BtB did not complete the postassessment surveys. It is possible that their responses to the CSQ would have suggested that they did not find the intervention acceptable.

Future Research and Conclusions

These findings suggest that further studies on cCBT interventions for treating depressive symptoms in veterans are warranted. Furthermore, the results suggest that unguided implementation of such interventions (ie, those that do not include regular interactions with a health care provider) may be a viable treatment delivery modality, at least for a significant proportion of veterans. Future research is needed to further develop cCBT interventions for veterans. Specifically, research is needed to establish the relative efficacy of cCBTs compared

with standard face-to-face therapy among veterans, as well as with other treatment modalities that improve access to evidence-based psychotherapy for depression (eg, group-therapy delivery formats). Future research could also investigate the differences between veterans who may benefit from cCBTs on their own and those for whom additional support (eg, contact with peer support specialists) could help with successful therapy completion [58]. Finally, future research is required to empirically establish which veterans are most likely to benefit from cCBT interventions and which require other treatment modalities.

Abstract

With thousands of mobile health (mHealth) solutions on the market, patients and health care providers struggle to identify which solution to use and prescribe. The lack of evidence-based mHealth solutions may be because of limited research on intervention development and the continued use of traditional research methods for mHealth evaluation. The Multiphase Optimization Strategy (MOST) is a framework that aids in developing interventions that produce the best-expected outcomes (ie, effectiveness), given constraints imposed on affordability, scalability, and efficiency (also known as achieving intervention EASE). The *preparation phase* of the MOST highlights the importance of formative intervention development—a stage often overlooked and rarely published. The aim of the preparation phase of the MOST is to identify candidate intervention components, create a conceptual model, and define the optimization objective. Although the MOST sets these 3 targets, no guidance is provided on how to conduct quality research within the preparation phase and what specific steps can be taken to identify potential intervention components, develop the conceptual model, and achieve intervention EASE with the implementation context in mind. To advance the applicability of the MOST within the field of implementation science, this study provides an account of the methods used to develop an mHealth intervention using the MOST. Specifically, we provide an example of how to achieve the goals of the preparation phase by outlining the formative development of an mHealth-prompting intervention within a diabetes prevention program. In addition, recommendations are proposed for future researchers to consider when conducting formative research on mHealth interventions with implementation in mind. Given its considerable reach, mHealth has the potential to positively affect public health by decreasing implementation costs and improving accessibility. The MOST is well-suited for the efficient development and optimization of mHealth interventions. By using an implementation-focused lens and outlining the steps in developing an mHealth intervention using the preparation phase of the MOST, this study may guide future intervention developers toward maximizing the impact of mHealth outside academia.

Introduction

Background

Without effective, affordable, scalable, and efficient interventions to prevent or delay the onset of type 2 diabetes (T2D), >1 billion people will have or be at risk of developing diabetes by 2045, with an estimated annual global health expenditure of US $845 billion [1]. The efficacy of dietary and physical activity behavior change programs on T2D incidence has been shown in several large-scale randomized trials [2-5]. Specifically, these diabetes prevention programs (DPPs) have resulted in reductions in T2D incidence by 28% to 58%. That said, the protective effects of these behavior changes are largest during intensive DPPs, and the relative risk reduction tends to wane over time [6]. This is likely because of the decreased adherence to dietary and physical activity recommendations. For example, the Finnish DPP found that those who engaged in more physical activity during the 4-year follow-up saw larger reductions in T2D risk; however, 38% of participants in the behaviour change intervention group and 54% of participants in the control group did not meet the physical activity recommendations of 150 minutes of moderate to vigorous physical activity during this time [7].

Although the results from DPPs are promising, there is potential for time- and cost-efficient maintenance interventions to improve adherence to long-term behavior changes. Given the wide availability and accepted use of mobile technologies in daily life, mobile health (*mHealth*; defined as health services that are delivered by mobile devices) offers the potential to improve DPP service delivery and patient outcomes by providing the opportunity for patients to leverage the technologies they are already using to learn about their conditions, monitor their health-related behaviors and outcomes, and actively participate in their own health care [8]. Despite this promise, the rapidly evolving landscape of health technologies has resulted in a dearth of evidence-based mHealth interventions used in clinical practice [9]. Furthermore, mHealth tool and service design are often driven by the technology sector (not the health care industry), which prioritizes the rapid development of technologies to reduce time to market, often at the cost of the rigorous development and evaluation processes associated with traditional medical device and intervention design [9,10].

The challenge of developing and translating effective and scalable mHealth interventions into practice to improve public health, preventive medicine, and health communication has been well documented [11,12]. In fact, it has been noted that research findings can take up to 17 years to be integrated into clinical practice [13]. Even more disheartening is the fact that 50% of clinical innovations never reach widespread clinical use [14], and 80% of medical research dollars do not make a public health impact and result in *research waste* [15].

At this pace, technological advances will perpetually outpace research. Furthermore, when technologies are designed for research purposes without clinical implementation in mind, they may need significant modifications to be applicable for use in practice, resulting in increased cost and time—barriers that hinder the delivery of potentially meaningful mHealth programs to those in need [16]. Establishing the effectiveness of an mHealth innovation is insufficient to ensure its uptake in routine practice [17]. The question then remains: how can rigorous, evidence-based mHealth interventions be developed for clinical practice in a time-sensitive manner?

A potential method is to use methodological frameworks to aid in navigating the process from mHealth development to its implementation. This paper provides an example and recommendations for how the *Multiphase Optimization Strategy* (MOST) can be used to develop mHealth interventions and how the implementation context can drive decision-making throughout. Implementation science focuses not on the impact of an mHealth innovation but rather on the factors that influence the adoption of that innovation into routine use [17]. Implementation science has been defined as "the scientific study of methods to promote the systematic uptake of research findings and other evidence-based practice into routine practice and, hence, to improve the quality and effectiveness of health services" [18]. By using the MOST and integrating an implementation-focused lens early in formative mHealth development, mHealth interventions can be developed in a way that will ensure that they are not only effective but also immediately scalable [19].

The MOST Framework

Overview

mHealth interventions are generally a combination of intervention components packaged together and offered to participants (eg, a weight-loss intervention delivered via a mobile phone app that includes diet logging, push notifications providing feedback on the foods eaten, and additional video conferencing with a dietitian to develop and refine a meal plan). Although traditional behavioral trial designs (eg, randomized controlled trials [RCTs]) can provide evidence of whether an mHealth intervention package is better than a control, such designs cannot determine which components contribute most to an outcome and the presence of potentially inert components resulting in inefficient mHealth interventions with unnecessary or possibly detrimental components. The MOST provides a structured, 3-phase, engineering-inspired framework in which intervention development and optimization precede an RCT (or other methods of evaluation). A potential use of the MOST within mHealth is the ability to develop resource-efficient mHealth interventions that include only active components delivered at an optimal dose. Using this strategy, interventions can be developed so that they are not only effective but also efficient, economical, and scalable—all attributes that are necessary for the development of mHealth interventions with implementation in mind. The 3 phases of the MOST include *preparation*, *optimization*, and *evaluation*. The aim of the preparation phase of the MOST is to identify candidate intervention components, create a conceptual model mapping target behaviors to outcomes, and define the optimization objective. Next, optimization trials are conducted to identify the *optimized* intervention, given certain implementation constraints. Finally, optimization may be followed by an evaluation phase, in which the optimized intervention package is evaluated (often in an RCT). This study focuses on the

preparation phase of the MOST. For more information pertaining to the optimization and evaluation phases see Collins [20].

Preparation Phase

Intervention components are defined as any feature that can be manipulated for study by turning it on or off or setting them to be high or low [20] and can include program content (eg, behavior change techniques [BCTs]), fidelity components (eg, provision of additional education to those moderating group chats within an mHealth app to ensure consistent tone and language across all moderators), engagement components (eg, providing badges and rewards to encourage adherence), and delivery components (eg, timing and frequency of contact with a participant).

The *conceptual model* outlines how candidate components are expected to theoretically influence short- and long-term outcomes of interest. Without this forethought, intervention components may be chosen as "it sounded like a good idea at the time," which can limit the utility of an intervention. By creating a conceptual model that identifies the proposed mechanisms of action, the MOST encourages well-thought-out mHealth interventions that can be built on and generalized beyond a single program of research.

The *optimization objective* describes how intervention EASE will be achieved by balancing an intervention's *Effectiveness* against its *Affordability*, *Scalability*, and *Efficiency*. By considering implementation constraints at the onset, the MOST has the potential to create digital interventions that expedite the translation of evidence-based mHealth innovations into clinical practice, thereby maximizing their impact on public health [21].

There is growing interest in applying the preparation phase of the MOST in implementation science [19] and digital behavior change interventions [21], and recent guidelines have been published to ensure transparent and consistent reporting within the preparation phase [22]. Although the MOST outlines these 3 targets within the preparation phase (ie, identification of intervention components and the optimization objective and creation of the conceptual model), little guidance is provided on *how* to conduct quality research within the preparation phase of the MOST, what steps should be taken to decide on what technologies should be used in the intervention, and how to systematically identify potential intervention components, develop the conceptual model, and achieve intervention EASE with the implementation context in mind. This paper provides an example of this by outlining the formative development of an mHealth-prompting intervention to be used within the Small Steps for Big Changes (SSBC) DPP with the aim of improving long-term behavior change adherence.

The SSBC Program

SSBC is an evidence-based, brief diet and exercise counseling program that aims to reduce individuals' risk of developing T2D [23]. SSBC comprises two phases: (1) training and (2) follow-up. The training phase includes 6 one-on-one dietary and exercise counseling sessions and supervised exercise sessions facilitated by a YMCA coach over a span of 3 to 4 weeks. The follow-up phase includes check-ins and measurements for months following program completion. Participants are asked to continue using the strategies they learned in the program to engage in diet and exercise behaviors without any continued coaching support.

The SSBC program has been shown to improve both cardiorespiratory fitness and cardiometabolic risk factors in a university laboratory-based study [23] and has been successfully transitioned from the laboratory into the community [24]. In the laboratory-based randomized trial, accelerometer-measured physical activity significantly increased after program completion when compared with that of baseline measures [23]. Effectiveness data for the community-based program on behavior change outcomes were evaluated using self-report measures 6 months after program completion and showed continued participant engagement in diet and exercise behaviors [24].

Participants in both the laboratory-based and community-based trials, which were conducted in Kelowna, British Columbia, Canada (the province's third-largest metropolitan area, with an approximate population of 152,000) [25], were provided with mHealth platforms in which they were asked to continue to self-monitor their exercise behaviors during both the training and follow-up phases. In the laboratory-based trial, participants were asked to digitally self-monitor daily whether they exercised, took a day off (participants were prescribed 4 days off per week), or did not exercise (if they exceeded their number of days off) on an mHealth platform that is no longer available (Motivation Engine). During the laboratory-based trial, participants were provided with additional BCTs, including mHealth *prompts* (BCT 7.1) sent via push notifications and *rewards* (BCT 10.6), for continued self-monitoring. In the community-based trial, participants self-monitored their activity on a different mHealth platform (HealthWatch360), in which they were asked to log only the days in which they exercised. On this platform, no additional BCTs were used to encourage continued engagement.

Following completion of SSBC, a focus group was conducted to allow SSBC participants to share the challenges they faced while making diet and physical activity changes after the intensive SSBC training phase [26]. Key recommendations from this work include the creation of platforms to communicate information about prediabetes and receive ongoing support from their coaches. Further qualitative work (4 semistructured interviews; before and after training and at 3 and 12 months after completion of the training phase) found that a key facilitator of maintaining long-term behavior changes was the use of mHealth technologies [27]. As such, this study aimed to assess the utility of mHealth prompts within SSBC and develop an mHealth-prompting intervention to provide continued support to clients in their behavior change journey.

Recommendations to Develop mHealth-Prompting Interventions Using the Preparation Phase of the MOST

Overview

The following sections present a high-level overview of the steps taken to develop an mHealth-prompting intervention to be implemented within the follow-up phase of SSBC, situated

within the preparation phase of the MOST. The intended focus of this paper is on the *process of decision-making* involved in choosing possible components and component levels and the development of content within an mHealth-prompting intervention and not the *outcome* of this research. This work was written in accordance with the MOST PREP-REP (Preparation Reporting) checklist by Landoll et al [22] (Multimedia Appendix 1).

On the basis of lessons learned through these steps, coupled with key design considerations posited within the *Person-Based Approach* [28], *agile innovation* [29], and *user-centered design* [10], recommendations are provided for future mHealth developers to promote implementation considerations throughout the preparation phase of the MOST. Specifically, recommendations drawn from these 3 development strategies include a focus on end users throughout, integration of existing research or rapid intervention prototyping, and iterative design and testing [10,28,29]. This presents a single use case of the preparation phase of the MOST; as such, these recommendations may not be generalizable to all applications of the MOST.

Step 1: Select Appropriate mHealth Technology

Recommendation

Although mHealth is wide reaching, the uptake and availability of certain technologies are not equal across all populations. Therefore, researchers *must* consider the contextual factors of the target population before deciding which mHealth technologies will be used or developed to promote feasible implementation [28]. The target population should encompass all potential stakeholders (ie, those using the technology both directly or indirectly) and contextual factors derived from the physical environment or clinical workflow in which the technology is to be implemented [16]. For example, if a researcher develops an mHealth intervention that is inaccessible to the target population in the real-world context but then provides the technology to research participants to prove its efficacy, this mHealth intervention is only effective within the sphere of academia. Such research findings may still have implications in policy (eg, informing health care coverage to include novel technologies) but are unlikely to be translated quickly into practice to improve public health [17].

SSBC Example

As SSBC begins to scale up across Canada, mHealth technologies provide an opportunity to improve long-term behavior change adherence while providing participants with continued support from program providers in an accessible manner. Although much of the mHealth research and development has focused on smartphones and associated apps, such technologies are less likely to reach rural Canadian populations (ie, Canadians at increased risk for developing T2D) [30]. However, cellular phone ownership and SMS text messaging rates are increasing, with 99.7% of Canadians covered by mobile phone networks [30]. To date, SSBC has been implemented within Kelowna, a metropolitan area. However, as SSBC expands to more rural communities, mHealth prompts sent via SMS text messaging have the capacity to reach and engage with the largest number of potential SSBC participants compared with the mHealth prompts sent via push notifications (through an mHealth platform) in the laboratory-based trial.

Step 2: Assess Potential Impact of mHealth Technology Within the Target Context

Recommendation

Before investing resources in developing an mHealth intervention, researchers should first evaluate the intervention's potential to influence behaviors within a given context [16]. Common pitfalls in formative development include spending too much or too little time on this phase [16]. The use of existing data, conducting research using methods that prioritize speed and simplicity (eg, rapid prototyping and innovation sprints), conducting or consulting reviews of the literature, and conducting qualitative research with the target end users can aid in the evaluation of the potential utility of a given technology for the population of interest [29]. Furthermore, agile innovation suggests that creating a clear termination and evaluation plan a priori may avoid continuing to invest resources in an intervention that does not suit the intended users or target context [16].

SSBC Example: Secondary Analysis

To identify the potential utility of mHealth prompts sent via SMS text messaging as SSBC expands to more rural areas, exploratory analyses were conducted to identify how long participants self-reported that they exercised on their respective mHealth platforms during the laboratory-based trial (when they received mHealth prompts sent via push notifications) and community-based trial (when they received no additional BCTs to increase engagement) [31]. We found that 83% of participants in the laboratory-based trial (ie, those who received prompts) self-reported exercise on their mHealth platform for an average of 82 days, whereas only 34% of participants in the community-based trial (those who did not receive prompts) self-reported exercise on their mHealth platform for an average of 43 days.

Following this, a more in-depth analysis of the laboratory-based trial was conducted to determine the acute impact a prompt may have on self-monitoring (ie, any day in which they logged *yes*, *no*, or *day off*) and self-reported exercise (ie, only the days in which they logged that they completed exercise) in the week following compared with the week preceding a prompt [32]. Self-monitoring and self-reported exercise data from the mHealth platform were averaged over 1, 3, 5, and 7 days before and after a prompt for the first and second half of the 12-month follow-up phase and were compared using *t* tests. The impact of the prompt was strongest in the first half of the year, with no significant differences found in the second half of the year. In the first half of the year, self-monitoring significantly increased in the 3 days following a prompt ($P<.001$; $d=0.60$), and self-reported exercise significantly increased in the 3 ($P<.001$; $d=0.37$), 5 ($P=.04$; $d=0.14$), and 7 days ($P=.02$; $d=0.15$) following a prompt.

Together, these secondary analyses provide preliminary evidence that mHealth prompts *may* be useful within the SSBC context, and more comprehensive development of an mHealth-prompting

(to be sent in the future via SMS text messaging to improve scalability) intervention is warranted.

SSBC Example: Consultation of Previous Literature

Once the potential utility of an mHealth-prompting intervention was identified, a scoping review was conducted to identify how existing DPPs develop mHealth-prompting interventions [33]. The results from this review highlight that mHealth prompts are typically delivered via SMS text messaging, followed by push notifications, and that they are generally well-received by participants. However, both the development of prompt content (ie, what BCTs are used and how theory influenced content) and delivery of prompts (eg, frequency, timing, and duration of prompting interventions) are often underreported, highlighting the need for structured development and rigorous evaluation of mHealth-prompting interventions before deployment.

In addition to conducting our own review, previous reviews assessing SMS text messaging interventions were also consulted. To date, many reviews have assessed the impact of SMS text messaging on health behavior change interventions [34-41], and meta-analyses have consistently shown that SMS text messaging interventions have a significant effect on hemoglobin A_{1c} among individuals with diabetes [39,40,42], weight loss [36,37], and physical activity [38,43]. It is widely accepted that behavior change interventions *should* be developed using theory, past evidence, and formative research [20,44] and that sufficient intervention detail be reported to allow for replication [45,46]. However, many SMS text messaging interventions lack rigorous development and thorough reporting, thereby limiting their utility in future intervention development and implementation [47].

In addition to how SMS text messaging interventions are developed, the description of theoretical mechanisms within message content and reporting of delivery characteristics (eg, timing and frequency) are largely unspecified in the literature [48]. With respect to SMS text messaging delivery, the evaluation of weight management SMS text messaging interventions by Skinner et al [36] included subgroup analyses examining intervention duration (<6 months vs 6 months vs 12 months), message frequency (daily vs weekly or biweekly vs personalized), and 1- versus 2-way messaging and found no significant subgroup differences. The authors noted that poor intervention descriptions within publications may have affected their ability to accurately code aspects of intervention delivery. Although a trend was noted that less frequent messaging (weekly or biweekly) was associated with greater reductions in weight (mean −2.88 kg, 95% CI −4.56 to −1.21 kg) than for daily messages (mean −1.56 kg, 95% CI −2.26 to −0.86 kg), the authors concluded that the mechanisms of action by which SMS text messaging programs lead to these effects remain largely unclear, and further investigation into message delivery and content features is warranted. This is mirrored by other reviews that note the heterogeneity in message timing, frequency, and duration within the existing literature and call for future research to determine the optimal message dose for health behavior change [35,49].

Step 3: Select Potential Intervention Components

Recommendation

The selection of intervention components should be performed early in the development process to identify different component levels. Component levels include the different doses of an intervention component one wishes to test (eg, high or low dose or turning a component on or off). By selecting components early, adequate time may be invested in preparatory development work to select appropriate component levels and consider how they will be tested. The detection of key intervention components should be based on theory, evidence, and end users [28,50,51].

Steps 1 and 2 may help to clarify intervention components that are either (1) based on existing evidence or (2) currently under researched and may be studied to move the field forward. In this way, evidence-based intervention components may be incorporated into the intervention package, and where evidence for a potential intervention component does not yet exist, researchers are able to further study the mHealth intervention component of interest (eg, if there is no existing evidence on how the frequency of intervention contact may influence a target population, but previous theory or evidence suggests that it should influence their behaviors, inclusion of that delivery component can allow a new line of evidence to be built for the target population).

The integration of previous research evidence and theory can provide insight into what intervention components have been previously identified as having the potential to be effective; however, unless these studies were conducted with the population of interest, they are unlikely to provide guidance on which intervention components are most important or can be best implemented within a given context [28]. To ground mHealth development within the implementation context, the Person-Based Approach suggests engaging in in-depth qualitative research [28]. Understanding user perspectives and accommodating their priorities within the candidate intervention components can aid in maximizing the acceptability and uptake of interventions when they are at the implementation stage [28].

SSBC Example

Based on qualitative work profiling SSBC participants, participants wanted continued support from their coach and additional information regarding prediabetes after the completion of the training phase, and they found mHealth technologies to be facilitators for maintaining their long-term behavior change [26,27]. From the results of the scoping review, the intervention components to be tested in the SSBC MOST optimization trial included SMS text messaging content and delivery components (ie, timing and frequency of prompt delivery) [33]. By understanding what message content SSBC participants would like to see (and the underlying theoretical mechanisms) and by optimizing SMS text messaging delivery to best facilitate behavior change, this research may reduce intervention costs and promote user engagement, ultimately reducing T2D risk.

Step 4: Place Constraints on mHealth Development to Improve Affordability, Scalability, and Efficiency

Recommendation

The MOST recommends that interventions be developed and optimized to meet resource-related implementation considerations (eg, constraints on personnel time, costs, or complexity of the selected technology). Typically, interventions are developed without considering affordability or the ability to be implemented as designed, which results in considerable research funds and time devoted to establishing efficacious interventions that are not practical in the real-world context [52]. By accounting for implementation constraints at the onset, the MOST aims to achieve intervention EASE by balancing the effectiveness of an intervention against relevant implementation constraints on affordability (eg, can be developed and delivered within certain budgetary constraints), scalability (eg, can be implemented with high fidelity), and efficiency (eg, contains only *active* intervention components).

By considering potential end users when designing mHealth content, researchers can tailor development and delivery based on the intended implementation context, thereby improving translation into practice [10]. Specifically, these constraints can help balance the intervention *EASE* while developing a specific optimization objective. Intervention optimization objectives can be broad (eg, achieving the best outcomes for the lowest price) or specific (eg, improving physical activity by a minimum of 15 minutes per day while keeping the overall intervention cost <US $300), and the level of specificity will depend on the constraints outlined at the onset and the requirements and resources of potential end users.

SSBC Example

When developing the SMS text messaging intervention, constraints were placed on the messages themselves, and the platform that was chosen to deliver the messages. The optimization objective was defined as identifying the SMS text messaging intervention that increases physical activity adherence most during the SSBC follow-up phase, given the identified constraints.

Text Messaging Constraints

Before message development, the following message constraints were put in place to improve the reach and scalability of the current intervention: messages must be written so that they can be sent as automated, 1-way messages (to reduce the burden on SSBC coaches), and they must be <160 characters long (to ensure they fit into a single SMS text message for individuals without a smartphone). These decisions were made so that the development process used in the current program of research could be adapted for any behavior change scientist or health care professional who may not have the resources necessary to create or invest in mHealth platforms that use advanced decision-making algorithms to provide just-in-time adaptive SMS text messaging interventions.

Text Messaging Platform Constraints

To reduce the person-hours required for sending messages and allow for fidelity assessment in future research, the following constraints were identified when selecting the SMS text messaging platform for use in this research program. The platform must be able to schedule and queue messages with rolling start dates; allow for variable timing, content, and frequency within scheduled messages; provide analytics such as audit logs of messages sent, declined, or undeliverable; and provide opt-out reports for participants requesting to unsubscribe from receiving messages.

Step 5: Develop mHealth Content

Recommendation

To improve the implementation of evidence-based mHealth research in real-world contexts, it has been suggested that intervention content should be developed (1) using a dynamic and iterative process including end users, (2) based on existing research evidence and theory, and (3) with the implementation context in mind (eg, clinical workflows) [28,53]. The integration of specific theoretical frameworks such as the Behaviour Change Wheel (BCW) has been suggested to systematically identify candidate intervention components and develop theory-based mHealth content that is underpinned by specific mechanisms of action (note that the use of such theoretical frameworks can also be helpful when developing a conceptual model) [21]. The BCW is a synthesis of 33 behavior change theories that collate the barriers and facilitators needed to change a target behavior.

SSBC Example

The development and refinement of SMS text messaging content for SSBC were split into 3 parts: identification of BCTs, message development, and message evaluation and refinement.

Identification of BCTs

To determine which BCTs were already in use within the SSBC program, 2 coders trained in BCT identification assessed all SSBC program materials and standard operating procedures [54] using the systematically developed taxonomy of BCTs (BCT Taxonomy version 1) [55]. BCTs are the building blocks of an intervention and are defined as the smallest *content components* within an intervention. Depending on the granularity in which a researcher wishes to assess the intervention components, BCTs can be toggled on or off for a more rigorous assessment during the optimization phase of the MOST.

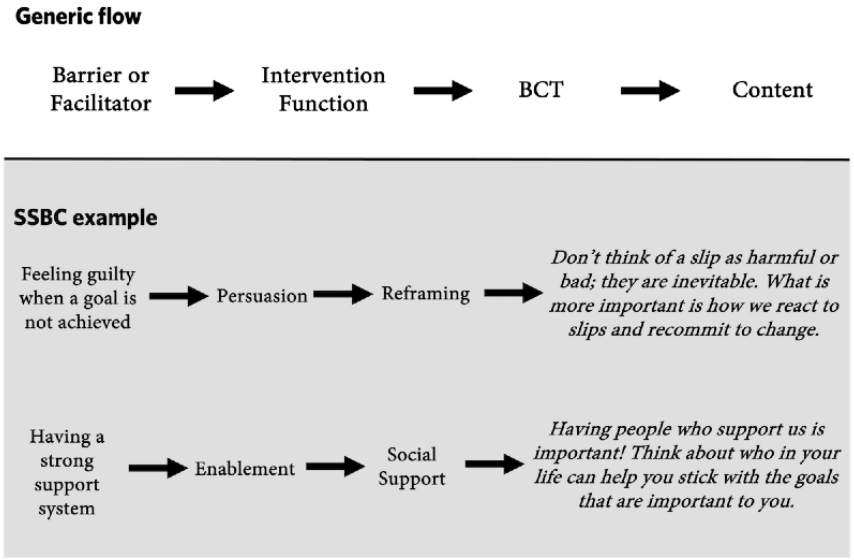
Message Development

The BCW [56] was used to develop a bank of messages [57] linking the relevant BCTs previously identified with theoretical mechanisms by which the messages should influence behaviors. Previous qualitative research profiling SSBC participant journeys in the year following the program [27] was used to identify barriers to and facilitators of maintaining dietary and physical activity behaviors after program completion. These barriers and facilitators were then linked to intended intervention functions (eg, education, persuasion, and enablement) and previously identified BCTs to formulate a bank of 124 theory-based messages based on participant-identified barriers and facilitators (Figure 1). Decisions on which intervention functions and BCTs to use in the messages were guided by the *APEASE criteria*, which may aid in achieving intervention EASE. APEASE represents affordability, practicability,

effectiveness, acceptability, side effects/safety, and equity [56]. By critically appraising each intervention function and potential BCT using the APEASE criteria, only those components likely to elicit changes that are also likely to be implemented in the given context may be included in the development of mHealth content.

Messages were written to target diet or physical activity behaviors or provide more general motivation and education; this was done by tailoring content to target client–identified barriers or facilitators toward improving client confidence in their ability to maintain the diet and physical activity changes made during the SSBC training phase.

Figure 1. Theoretical content development using the Behavior Change Wheel. BCT: behavior change technique; SSBC: Small Steps for Big Change.



Message Evaluation and Refinement

After development using the BCW, key knowledge users (SSBC coaches and past SSBC clients) evaluated the messages on their readability, relevance, and utility for individuals at risk of developing T2D [58]. Overall, messages were rated highly by both coaches and participants (receiving an average score of 13.77 out of a possible 15). General motivational messages (eg, "Your first plan will not work 100% of the time. Continue to change your goals until you find what works best for you!") were generally scored among the highest compared with targeted behavioral messages (eg, "Think about where, when and how you'll get your exercise in today!"). In addition, while evaluating messages, participants were asked if they were to send or receive messages similar to those they evaluated, how many they would like to send or receive weekly, and for how many months. SSBC coaches reported that they would like to send an average of 3 messages per week (mode 3, range 1-5) for 5 months (mode 1, range 1-12), and past SSBC clients reported that they would want to receive an average of 3 messages per week (mode 2, range 2-5) for 7 months (mode 12, range 2-12).

Step 6: Identify Intervention Component Levels

Recommendation

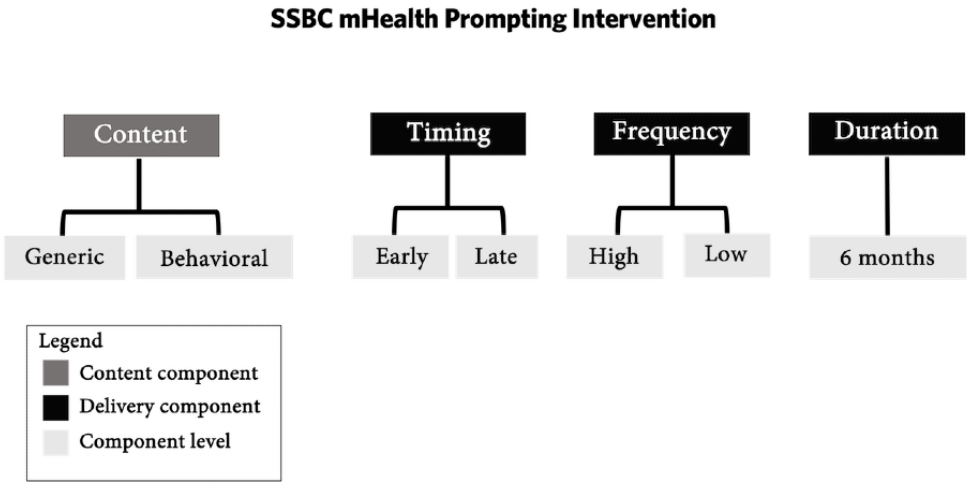
Where previous experimental evidence exists, as identified in the review of existing literature (step 2), it should be used to inform intervention component levels, warranting further testing. If no experimental evidence exists for different component levels or the objective is to further the science of mHealth development and evaluation, different components or component levels may be chosen. At this stage, intervention developers should begin to think about the study design for future intervention optimization trials; these can include factorial, sequential multiple assignment randomized trials (SMART) and microrandomized trials to name a few. The design of the optimization trial is driven by the research questions and available resources. When conducting a factorial experiment, the most efficient way (and the one recommended by the MOST) is to stick with 2 levels for each component (eg, on or off or high or low dose). Once the MOST optimization trial design has been decided, researchers can consider the candidate intervention component levels to be tested. Component levels can be as broad or as specific as needed and often depend on the nature of the intervention and research questions.

SSBC Example

Overview

Our previously identified intervention components included *prompt content* and *message delivery* (ie, duration, timing, and frequency; Figure 2). As this intervention is intended to be implemented by SSBC coaches and potentially other health care practitioners, a factorial experiment with 2 levels for each component was chosen. Although it is likely that the *optimal* (in terms of effectiveness) prompting frequency may change over time and be specific to the client receiving the prompts (thus lending itself better to a SMART or microrandomized trial), health care and public health services are unlikely to have the resources available to tailor prompting delivery to each individual client, making a standard delivery frequency more likely to be implemented into practice.

Figure 2. Intervention components and component levels. mHealth: mobile health; SSBC: Small Steps for Big Change.



Prompt Content

As each message was carefully curated and linked to specific BCTs, it would theoretically be possible to test different BCT categories or compare those messages that include one versus multiple BCTs; however, based on participant feedback in the evaluation and refinement survey, we will test 2 levels in our future optimization trial: general and targeted behavior content.

Message Delivery

Based on secondary analyses showing that prompts were most effective in the first 6 months following the SSBC training phase, coupled with diabetes prevention coaches and past SSBC clients wanting to receive messages for approximately 6 months, we decided not to include another level for this component, thereby defaulting the intervention *duration* to 6 months for all participants. In addition, our review highlighted that prompt *timing* is grossly underreported in diabetes prevention programming; thus, we chose to set the delivery component to *early* or *late* in the day. To identify a specific timing, participant preferences for timing (morning, afternoon, or evening) are being solicited in an ongoing feasibility study (further discussed in the following sections) [59].

For prompt *frequency*, our previous research (ie, secondary analyses assessing the acute impact of a prompt and message evaluation survey) [31,32] suggests that more frequent messages (eg, 6 or 7 per day) are burdensome and are therefore unlikely to positively affect the target behaviors. In addition, none of the past SSBC clients reported wanting only a single message within a week. On the basis of the paucity of data on optimal prompting frequency coupled with these secondary analyses and participant preferences, a frequency between 2 and 5 messages per week is suggested to optimally affect self-monitoring and self-reported exercise. Therefore, we chose to make the weekly prompt frequency a *high* or *low* dose. Again, the specific dose will be identified after the completion of the ongoing feasibility study.

Step 7: Develop a Conceptual Model

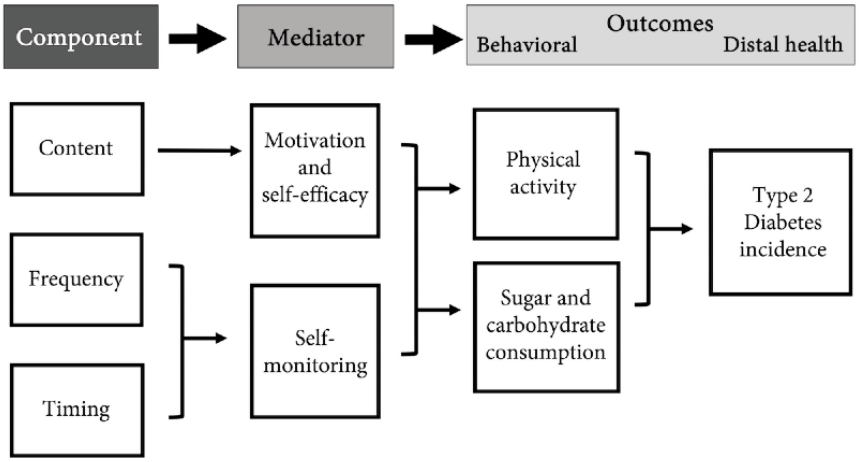
Recommendation

Creating a conceptual model to link intervention components to their theoretical mediators and expected outcomes may improve the ability of an intervention package to be effectively adapted to different contexts or settings [60]. Developing a conceptual model within the preparation phase of the MOST can be completed using a number of potential theories. As pinpointing a specific theory that fits one's needs can be overwhelming, the use of a theoretical framework such as the BCW can aid mHealth researchers in developing a conceptual framework based on theoretical constructs [21].

SSBC Example

Based on the identified intervention components of prompt content and message delivery (timing and frequency), a conceptual model was created (Figure 3) to outline how these components are anticipated to influence target behaviors (dietary and physical activity behavior change adherence). Although each individual message is made up of different BCTs targeting different barriers and facilitators, the content generally aims to increase an individual's motivation and self-efficacy to adhere to the diet- and exercise-related behavior changes made during the SSBC training phase. From our secondary analyses, it appears that the prompting dose may influence a participant's behaviors by encouraging them to continue to self-monitor their behaviors.

Figure 3. Conceptual model.



Step 8: Run a Feasibility Study

Recommendation

Before the optimization phase, Collins et al [20] suggest conducting a feasibility study to establish whether each candidate component and component level can be feasibly implemented as intended. Feasibility studies are a common step in the process of developing and translating social science and public health interventions. Conducting a feasibility study can provide necessary information on participant recruitment, intervention acceptability, and the feasibility of administering an intervention as intended. This information may be used to aid in the decision to (or not to) conduct a fully powered optimization and efficacy trial. Furthermore, this may ensure that resources are not wasted in conducting an optimization trial if the intervention itself cannot be delivered as intended [61]. The primary aim of a feasibility study should be to inform the feasibility or acceptability of an intervention and identify modifications that need to be included within the intervention before a large-scale trial. As feasibility studies are not fully powered trials, conducting inferential statistical tests is discouraged, as *P* values rely on sample size [61]. If a researcher needs to make decisions about the inclusion or exclusion of an intervention component or component level, they should identify a priori how they intend to use the feasibility study data to inform this decision making. It is recommended that participant acceptability and preferences be used instead of *P* values in addition to effect sizes (which are less reliant on sample size).

SSBC Example

To test the feasibility and acceptability of the message delivery platform before optimization, a feasibility study is currently being conducted [59]. In addition to general intervention feasibility (ie, can it be delivered as intended), this study aims to assess participant preferences regarding message timing and frequency to further refine intervention levels. The feasibility study will result in a final set of mHealth-prompting delivery characteristics for further testing in the second phase of the MOST, using a factorial experiment.

Discussion

Given their considerable reach, mHealth interventions have the potential to positively affect public health by decreasing implementation costs and improving accessibility. The impact can be maximized through rigorous development followed by optimization to ensure that candidate mHealth interventions meet the real-world contexts they seek to serve. Transparent reporting should also be prioritized to promote replicability and use beyond the intended scope, where applicable. In addition, these steps may promote intervention packages that are cost-efficient and effective without including unnecessary or potentially detrimental intervention components that could reduce the overall potency of the intervention. The MOST provides an example of a framework suitable for such development. The MOST follows 3 phases to identify components, pinpoint optimal delivery, and evaluate the efficacy of a final intervention package.

This paper provides an example of how the MOST was used to develop an mHealth-prompting intervention for the SSBC program situated within the preparation phase of the MOST. In addition, although this paper may serve as a guide for future mHealth researchers to develop mHealth interventions using the MOST, some of these steps (or the order in which they have been presented) may not be applicable for all mHealth development. Consequently, researchers should adjust their approaches to meet their own contextual needs. Despite the applicability of each individual step, mHealth development using the MOST should consider integrating concepts from agile innovation, the Person-Based Approach, and user-centered design to improve the likelihood that their mHealth development is grounded in the context of those who will be using the intervention and therefore is more likely to be integrated into routine clinical practice following evaluation [10,28,29].

Abstract

Background: Prior to the wider adoption of digital health technologies during the COVID-19 pandemic, applications of virtual care were largely limited to specialist visits and remote care using telehealth (phone or video) applications. Data sharing approaches using tethered patient portals were mostly built around hospitals and larger care systems. These portals offer opportunities for improved communication, but despite a belief that care has improved, they have so far shown few outcome improvements beyond medication adherence. Less is known about use of virtual care and related tools in the outpatient context and particularly in rural community contexts.

Objective: This study aims to reflect on the opportunities and barriers for sustainable virtual care through an example of a digitally enabled rural micropractice, which has provided 10%-15% virtual care since 2016 and 70% virtual care since March 2020.

Methods: Three focus groups, 1 with providers (physician and medical office manager) and 2 with a total of 8 patients from a rural micropractice in British Columbia, were conducted in November 2020 and December 2020. Virtual care delivery was explored through the topics of communication approach, mixing virtual and in-person care, the practice team's journey in developing these approaches, and provider and patient satisfaction with the care model. Interviews were transcribed, checked for accuracy against recordings, and thematically analyzed.

Results: Both patients and providers reported ease of communication and high satisfaction. Either could initiate communication, and patients found the ability to share health information asynchronously through the portal allowed time to reflect and prepare their thoughts. Patients were highly engaged and reported feeling empowered and true partners in their health care, although they noted limited care coordination with specialists. The mix of virtual and in-person visits was highly regarded by patients and providers, and patients reported feeling safe and cared for 24/7, although both expressed concern about work spilling into the provider's home life. The physician worried about missed diagnoses with virtual care. With respect to establishing the micropractice, solutions took about 5 years to optimize, with providers noting a learning curve requiring technical support for both themselves and their patients and a willingness to respond to patient feedback to identify the best solutions. Despite a mature virtual practice, patients reported deferred care due to COVID-19.

Conclusions: The micropractice's hybrid care model encouraged patients to be true partners in their care and resulted in high patient engagement and satisfaction; yet, success may rely on the patient population being willing to engage and being comfortable with technology. Barriers lie in gaps in care coordination and provider fear that signs or symptoms more evident with an in-person exam could be missed. Even in this setting, deferral of care in light of COVID-19 was present, and opportunities to address care gaps should be sought.

Introduction

Background

Virtual care represents any nondirect synchronous or asynchronous interaction between patients or members of their circle of care, using any form of communication or information technology. Virtual care encompasses a range of health care activities enabled by technology, including telehealth (the term commonly used for the delivery of care through video or telephone conferencing with a care provider) [1]. Before wider adoption of digital health technologies during the early phases of the COVID-19 pandemic, applications of virtual care were mostly in the form of virtual walk-in clinics using tools enabling communication between health care providers for specialist visits or for phone or video visits between providers and patients in remote settings [2]. These applications were primarily focused on diagnosis, prevention, and public health [3]. However, the COVID-19 pandemic prompted widespread emergency adoption of virtual care models that were haphazardly implemented, with the primary aim of reducing infection risk but also conserving resources including personal protective equipment [4].

Virtual Care Opportunities

Patient engagement has not traditionally been a focus of virtual care applications [3]. While there is no strong evidence that educating health care providers in patient self-management approaches will actually improve outcomes [5], patient empowerment appears to improve medication adherence, and patient engagement may lead to better mental and physical health outcomes [6]. Virtual care tools include interconnected personal health records and tethered patient portals, videoconferencing solutions, remote patient monitoring, and wearable technologies for such things as electronic collection of patient-generated data and delivery of patient education; they allow patients and family members to advocate for their needs, including health and wellness and preventative care services. These tools enhance the potential for participation and bidirectional communication, both asynchronously and synchronously, between patients and providers; hence, they offer a mechanism to increase patient engagement and empowerment [7-9]. While there are limited data supporting change in patient health outcomes, a meta-analysis of patient portals tethered to hospital electronic medical records (EMR) found that patient portals improved patient safety, medication adherence, patient-provider communication, and patient engagement, and both patients and providers believed that portals improved patient care [10]. Less is known about best practices for outpatient and community use of virtual care technologies. Although patient portals are becoming more common, only 20% of Canadians say they have accessed their health information through a blend of channels (mostly lab results and not primary care records) [11-13], and availability and use are far from equitable, leading one author to suggest that the digital divide may be yet another social determinant of health [14]. However, a hybrid approach, combining virtual care with a more traditional in-person approach, might enhance access opportunities.

Access to care has traditionally been a challenge in the Canadian rural setting [15]. The COVID-19 pandemic highlighted the opportunities offered by telehealth and virtual care [16], notwithstanding their current limitations. Given the likelihood that virtual care is here to stay, preparing for transition to long-term sustainable implementations should leverage experiences from stakeholders, both before and during the COVID-19 pandemic. This presents an opportunity for the health system to plan, for providers to learn from their peers in identifying the optimal balance between in-person care and virtual care, and for patients to benefit from advanced digital tools and improved access and patient empowerment.

Micropractice Care Approach

Since the early 21st century, the micropractice model of health care has appeared in the United States, Eastern Mediterranean, and Canada. A clinical microsystem approach advocates for constant communication between health care providers and their patients to understand mutual expectations about care and appreciate the patient's needs and clinician's concerns [17]; it does so by focusing on 6 aims of quality improvement: patient safety, clinical care effectiveness, patient focus, timeliness of care delivery, efficiency in care delivery, and equity of access to care [18]. Micropractices, as a patient-focused, quality-assurance, and data-driven care model, may be an efficient and cost-effective model for primary care delivery that allows health care providers to spend more time with their patients and leverage new technologies and approaches of care more easily than regular (larger) practices [19,20]. In a recent systematic review looking at whether clinical microsystems work, only 3 of the 35 papers included in the review targeted primary care [17]. However, the foci of these studies were highly specific to either a chronic condition [21] or to team effectiveness and care coordination activities [22,23], and neither focused on the patient and provider as a core unit of analysis nor a virtual micropractice delivery model in a rural setting.

Study Aim

The aim of this paper was to explore the opportunities and barriers for sustainable patient-centered virtual care through an example of a rural micropractice, which has provided 10%-15% virtual care since 2016 and 70% virtual care since March 2020. The clinic, as a single-physician, virtually enabled practice pre-COVID-19, offered an opportunity for the researchers to explore a unique model of care during a public health disaster and for community-based providers to learn about digital enablement from the experience of patients and providers in a micropractice.

Methods

Location

This qualitative descriptive study targeted a micropractice as part of a larger mixed methods study examining data sharing and personal health records among rural primary care practices in British Columbia, a province in western Canada. The practice is located in a small rural community with a population of about 11,000 people and was identified as a valuable exemplar in its application of digital health technology deserving of further exploration.

Ethical Approval

Ethical approval was granted by the joint review boards of the University of British Columbia Clinical Research Ethics Board (H19-00958; principal investigator, KLR) and the Interior Health Research Ethics Board. This article follows the Consolidated Criteria for Reporting Qualitative Health Research (COREQ) [24].

Participant Recruitment

The providers of the micropractice were approached to participate through an email invitation from our team's digital health liaison. The micropractice providers then sent a broadcast email advertising the study to all portal-registered patients over the age of 18 years. Interested patients contacted the research assistant who obtained informed consent. Patients received a CAD $25 (US $19.93) gift certificate for their participation, and the physician and clinic manager or medical office assistant (MOA) was remunerated commensurate with provincial guidelines for payment of health professionals participating in research.

Data Collection

A focus group was conducted in November 2020 with the physician and the clinic manager or MOA from the micropractice. Questions asked providers about types of data shared, platforms and tools used for data sharing both pre- and postpandemic, value and trust in patient-generated data, and use of patient-generated data in care decisions. Two focus groups of 4 patients each were conducted in December 2020 following informed consent and completion of a brief survey including demographic information, health status, and use of technology. Focus groups lasted approximately 1 hour and were guided by a semistructured interview guide with questions about types of data or health information shared with their providers; who initiated sharing; problems encountered with electronic data sharing; current and preferred data sharing features, functions, and processes; value of data sharing and sense of partnership with provider; and communication changes since the pandemic. Focus group participants were encouraged to not only address the researcher's questions but also build constructively on the comments made by other participants.

One experienced team member facilitated each focus group (MG, KLR), with at least 2 other research team members present in each group, to cofacilitate as needed. Each focus group was held on Zoom videoconferencing software (Zoom Video Communications, San Jose, CA). All sessions were audio-recorded, with nonmoderating team members taking notes and asking questions to probe for follow-up details or clarification by relaying them to the focus group moderator via a chat function.

Data Analysis

Interviews were transcribed automatically using NVivo Transcription (QSR International, Melbourne, Australia), checked for accuracy against the recordings by a research team member, and thematically analyzed [25]. Initial coding was completed according to a priori categories (eg, electronic communication, selection of tools or platforms, and satisfaction). Through team discussion and consensus, a final schema was generated, with themes emerging from the data, to capture (1) learning and evolving the micropractice model, (2) communicating meaningfully, (3) partnering in care, and (4) transition to (increased) virtual care during the COVID-19 pandemic.

Results

Participant Characteristics

Eight patients participated in 2 patient focus groups. All (8/8) were Caucasian, most (6/8) were female, median age was 60.5 (IQR 35-76) years, most (6/8) were college or university graduates, and participants had a wide range of incomes. Median distance from the micropractice was 3 (range 1-10) km. These patients had also sought health care from a median of 2 (range 0-6) specialists, but only 2 of the 8 patients had required a hospital admission in the past year. Two participants reported poor health, and 5 patients considered themselves in good or excellent health. All used technology at least some of the time, with 7 considering themselves a regular or frequent user. In addition, the 2 providers of the micropractice clinical team, a physician and the clinic manager or MOA who own the micropractice, participated in a separate provider focus group; due to the small sample size, their characteristics are not described here. The micropractice has a panel of approximately 700 patients; most have access to the electronic tools utilized by the micropractice (only 19 patients do not).

Themes

Four themes emerged to describe patients' and providers' experiences with the micropractice. These included learning and evolving the micropractice model, communicating meaningfully, partnering in care, and transitioning seamlessly to an increased virtual care model during the pandemic. The Results section is organized around these 4 themes.

Learning and Evolving the Micropractice Model

Both patients and health care providers acknowledged the need for learning to operate in a technology-enabled virtual care model. Providers described a learning curve for both themselves and their patients. For themselves, it was learning over time, through trial and error in using different systems, what constituted the optimal technology and electronic systems to support their practice. The micropractice providers use Med Access EMR (Telus Health, Montreal, Canada) and have been using a virtual attendant, text messaging, and phone-based appointments (RingCentral, Belmont, CA) with online booking (Veribook, Toronto, Canada) since March 2016. They have used videoconferencing visits since 2017 and used RingCentral (RingCentral, Belmont, CA) until mid-2019. They also have a website that explains how the practice works (eg, restricted phone hours but 24/7 messaging). In mid-2019, they centralized and integrated the virtual care options with their EMR, adding a tethered patient portal (Pomelo Health, Montreal, Canada) for videoconferencing visits, secure messaging, appointment booking and reminders, completion of some forms, and broadcast messaging and information sharing; email is only used as a last resort. Patient communication is supported and, in part, triaged by the medical office manager and ultimately addressed by the physician when needed.

Providers described how important it was for clinic personnel to be very comfortable with technology, to have an open mind to ride the learning curve, and to not resort to going back to "what we know" and how they practiced using these digital tools before making them available to their patients. Providers also set up tools and guidance for patients on using digital tools (eg, video appointments) on their clinic website, including FAQs. If needed, the clinic manager provided tool education before appointments, and providers educated patients to appropriate appointment types (eg, virtual vs in-person) to best support their use. Additionally, providers learned about what was optimal through patients' feedback. Some changes to the practice model were prompted by patient feedback, including negatively perceived online reviews:

> *Because of that feedback, we decided to change things around with the schedule and the paperwork. So now it looks like I'm more available, even though I'm still working the same hours. [...] We do take the feedback seriously.*

It was also noted that some patients may have left the practice as this care model did not suit them. While this practice is located in a small city, access to high-speed internet was not identified as a problem by the providers, who noted that fewer than 3% of their patients were without internet access. Similarly, patients also noted that internet access was not a concern for them.

Providers learned to be proactive and anticipate future challenges and difficulties so they could plan accordingly to remediate them or reduce their negative impact. For example, providers began letting patients know in advance when the clinic would be closed for vacations, and patients spoke of valuing this mass communication to keep them informed and be able to do their own planning. Additionally, providers highlighted the importance of maintaining strong boundaries between personal and work life. Finally, providers highlighted that it was essential to have health care team autonomy and proper compensation for the implementation and delivery of virtual care to make this model sustainable.

The patients in our focus groups speculated that patients likely self-selected for this virtual care model, based on familiarity with technology and a willingness to take an active role in their care. Finally, several patients offered suggestions for improving the technology, for example, to accommodate the visually and hearing impaired (eg, running text beneath a picture) and incorporating additional patient data into clinical care such as step counter (pedometer) results. One patient suggested that use of a dialog box or personal diary between him and the physician might help him decide when a visit is necessary or to avoid putting off needed care. Another patient suggested additional reminders for things like preventive care.

Communicating Meaningfully

Communication was at the heart of patients' and providers' experiences with the micropractice; both described various facets of the communication that characterized their micropractice experience. These included the nature of the communication as promoting dialogue, enhancing data sharing, and including family.

Promoting Dialogue

Unique to this practice was the fluid bilateral dialogue that was both synchronous (eg, virtual visits) and asynchronous (eg, email, secure text, appointment booking) that patients found engaging and empowering. One advantage highlighted by both health care providers and patients was that there were no set rules nor conventions about who would initiate a conversation. Sometimes the patient would begin the exchange, and, with the portal, they were not confined to office hours, such as sending pictures of something painful or making appointments in the middle of the night:

> *The technology is so helpful—it's...all online, and you can book at 2:00 AM—you don't have to wait to call to talk to a receptionist.*

At other times, the practice providers would reach out with reminders, follow up on results of tests, or ask patients to schedule an in-person appointment. Patients did not comment on preferences in communication mode, other than preferring the security of the portal compared with email.

The ability to have more of a dialogue-based communication approach made these patients feel more empowered in their care due to the ability to ask questions and send pictures, compared with a physician-driven exchange:

> *I had booked an in-person appointment for a lump that came up in my back. I was very concerned about that, and so I just added that in the comments because the appointment was so far away. And then I very quickly got a response that was like, we want to talk to you sooner.*
>
> *I got an infected foot, and I wasn't quite sure what it was, but I didn't know how the heck she was going to*

> *decide whether I needed to come in or not unless I took a picture of it.*

Patients who liked the asynchronous communication approach described the time it gave them to rephrase their response, rethink their request, and remember answers instead of having to respond on the spot, as when communicating synchronously. Furthermore, one patient noted that there were things that were more easily expressed in writing rather than face-to-face, such as embarrassing conditions or symptoms:

> *It comes out a lot easier, and I can say more through a message. And then, by the time I get to the face to face, like the embarrassment is all gone.*

In contrast, other participants found a relative lack of ease and candor in the virtual setting.

Patients had reasonable expectations for response times, understanding that they would not get a reply on the weekend but expecting text messages to have a slightly shorter response time than portal messages. Patients were oftentimes surprised to get written responses outside regular office hours:

> *I've gotten replies and emails back like in the middle of the night because she's just kind of up and whatever and she never stops working* [...]
>
> *If there's some sense of urgency, it's not as if she hangs up the computer at 5 o'clock in the afternoon. There tends to be responses at interesting times. So, we feel very safe and comfortable about that.*

Despite the value of dialogue for both patients and providers, there was acknowledgement of the impact on providers. Providers acknowledged that it caused a slight blurring of work and home life for them, but the text messaging system, or the "text line," akin to an office phone line, protected their personal phone number from the patient. Further, patients expressed worry about burdening their physician too much.

Enhancing Data Sharing

The integrated, multimodal system and patient portal allowed for communication of a range of types of patient-generated data. Such data included general intake questionnaires (eg, before a pap smear, COVID-19 screening before a visit, new mother, or new patient intake forms), clinical screening tools (eg, Patient Health Questionnaire-9, Generalized Anxiety Questionnaire-7, chronic pain questionnaires, or attention deficit hyperactivity disorder assessment forms), documentation of patient-recorded measurements (eg, blood pressure, heart rates, daily weights, or blood glucose readings), any clinical notes (eg, lab work, investigations, or consults) that the patient might have, pictures from skin lesions, applications for patient benefits, and any appropriate consents (eg, for treatment, requesting medical records, sharing medical information with a caregiver). Health care providers felt that their relationship with their patients allowed them to trust patient-provided information in all but few cases, such as patients with memory limitations or those seeking specific benefits (eg, in disability applications):

> *If I have an elderly patient with dementia, I'm not going to be asking [that] from that patient—maybe I'm going to be asking their caregiver instead. For the most part, the data that I'm collecting, I feel comfortable trusting it because I know the patient is capable of giving me good information or giving me the right data.*

The clinic manager or MOA was responsible for checking the portal and downloading information into the EMR.

Patients and providers found it challenging that platforms for data sharing did not transfer to other care providers to allow for better care coordination. For example, 1 patient noted:

> *I would love to see more data sharing and more integration. I would love to be able to book an appointment with my specialist the same way but [this particular specialist] doesn't offer eHealth appointments. It would be amazing if it was all integrated; [clinicians would realize] that I haven't had imaging done in a while.*

This might lead to timelier receipt of results:

> *If those results were available online instead of being mailed to my house [...] when moving around for school, I would not have gotten them months later.*

The physician reported frustration over lack of system integration with other providers, resulting in delayed receipt of consult reports from specialists. This caused both patient frustration and resulted in a delayed implementation of specialist recommendations:

> *Many times, we need to go out of our way and "fish" for them so we can get back to the patients with a plan and update their medical records.*

Patients were uniformly positive about this new care delivery system. One patient noted that other health care providers were "way behind" in offering virtual access to care:

> *The way in which I approach my access to the health care system changed before COVID. I'm noticing that other physicians are way behind—my specialist does not have the same ability to provide me care that they had before the pandemic. They aren't up to speed with how to do this electronically...so I can get better care by following up with* [the micropractice provider]

Inclusion of the Family

Patients appreciated that the virtual care approach enabled family members to be involved more easily. This included granting access to information and communication to local family members, children, or carers, but the system also allowed involvement of family members outside the province to participate in their care:

> *What's been fascinating about this approach is that my separated spouse in Ontario can participate as well as I can. And that's been incredibly helpful [...]; it provides a level of foundation, a solidity, that I'm not sure we would have had, had there not been this micropractice.*

Health care providers illustrated an example in which a very complex patient, who required point-of-care testing, was able to make use of the virtual care technology to receive optimal

care with the help of a (distant) family member; this would have been very difficult in a traditional office-based practice setting.

Partnering in Care

Unique to this practice is patients' and providers' shared sense of a partnership and patients feeling empowered to take ownership of their care. Both patients and health care providers liked the micropractice care model:

> *You know, you get your full time with them, and they're on time, and I think I feel more heard than when I was in the clinic.*
>
> *They are simply an amazing team, the two of them.*

Health care providers felt they provided very patient-centered care, recognizing that patients enjoyed this access to their provider and generally did not abuse it, but they also missed some separation of work from home life due to the 24/7 messaging.

Overall, patients felt that there was a true partnership, and health care providers valued their opinions, whether the appointment was conducted in-person or virtually, with the clinician offering them opportunities to make informed choices. Patients unanimously agreed that this practice approach empowered them and forced them to take greater ownership of their own care:

> *I have a couple of chronic conditions that I kind of monitor bloodwork for. And I look after myself, and I can do a lot of that kind of self-monitoring. [...] I have the same access to my bloodwork as my physician, so we can both look at it at the same time. I really appreciate that, and it makes me take more responsibility and feel empowered and not helpless.*

Seamless Transition to (Increased) Virtual Care During the COVID-19 Pandemic

Prior to the pandemic, virtual care was used for a substantial portion of patient visits at the micropractice. Prepandemic use eased the care disruption and confusion that occurred with the pandemic shift to a predominant virtual model of care. Patients recognized that virtual care was often the only way they could seek care during the pandemic and acknowledged the benefit of prior familiarity with virtual care (eg, for some mental health concerns). One patient said:

> *Had we had not been transitioning to this style of medical care when the pandemic hit, I think it would have been way crazy, a lot clumsier, and a lot harder.*

Providers similarly lauded being able to seamlessly respond to the virtual shift in care due to the pandemic:

> *I knew these stories from colleagues having to close the clinics because at the beginning of the pandemic, you couldn't see patients, but we never stopped. We had a video conference. [...] And even though patients were not using it much before, now was the opportunity to really push it and get it to what we envision at some point. And now it's probably past that. [...] We had texting. We had messaging. We have it all in play.*

Both patients and providers expressed concerns about not having in-person visits. The health care providers suggested that they sometimes feared not getting the whole picture and missing problems during virtual visits:

> *Missing like, for example, checking the blood pressure of my patients when they come or maybe looking at moles or maybe listening to hearts. I have found things when they come for some other unrelated issues [...] now that I'm not seeing them that often, how many things am I missing?*

These concerns were echoed in patients' concerns that virtual visits provided fewer opportunities than face-to-face meetings to discuss other issues. These concerns were accentuated during the pandemic. Several patients noted deferring needed care during the pandemic such as follow-up blood tests, with 1 patient mentioning being selective about what to visit the doctor for and not being comfortable in a crowded clinic for minor problems, noting how helpful it was having a virtual care format; 1 patient noted:

> *I don't want to go into the lab. I don't want to wait in a line up at the hospital for anything. If I go there and I see a bunch of people, I come home. I just don't go. [...] having your doctor appointments electronically, amazing, I never have to have that fear of, you know, waiting in a waiting room full of people.*

Patients appreciated not having to spend time sitting in waiting rooms or travelling to a speciality clinic that offers virtual visits, which could be substantial in remote settings (eg, 1 hour to 1.5 hours each way); 1 patient noted:

> *Reflecting on my previous experience with an in-person clinic, I have had to wait over an hour, and when you're already taking an hour off of work to go to an appointment, to then have to take 2 hours off of work. [...] I've missed several appointments where I've waited as long as I can* [and then left]

Discussion

Principal Findings

This study suggests that the micropractice care approach can enable patients to be true partners in their care and have more meaningful communication with their providers. Patients who participated in this study were highly engaged in their care, felt safe, and were able to initiate care when needed. These patients liked the asynchronous communication encouraged by this practice model as it allows both immediacy and having time to formulate their thoughts. Providers in the study were proud of delivering very patient-centered care, although they acknowledged that it caused a slight blurring of work and home life. Having a virtual care system in place proved advantageous during the pandemic, although patients reported some deferral of care, which must be addressed as the pandemic eases. The care model, however, likely depends on self-selected patients who are technology-capable and are willing to initiate communication through the portal. Identified challenges of this virtually enabled care model includes providers' fears of missing symptoms and indicators that they may have otherwise noticed

during an in-person visit and the time and effort needed to train both patients and providers in the use of digital technology.

Learning and Evolving the Micropractice Model

Micropractices may allow health care providers to spend more time with their patients and can leverage new technologies and approaches to care more easily than regular (larger) practices [19,20]. Other reported advantages are increased provider satisfaction with their work, including being able to spend more time with their family, but which may come with reduced scope of practice [26]. In contrast, in this work, both health care provider and patients expressed concerns regarding work-life balance for their provider team. In addition, the micropractice team noted that it takes time to find the right systems and there is a digital health learning curve for both patients and providers (eg, requiring technical support). While not identified as an issue in this study, the chasm between those who have internet access to technologies and the digital literacy to work them and those who don't may to lead to disparities and inequities and warrants further research [27].

Historically, micropractice patients report excellent continuity of care, delivered with high efficiency and low barriers to access, yet their value for enabling patients to manage their care remains less clear [28]. A systematic review of 35 studies evaluating clinical microsystems, of which 18 described general practice clinics, found that implementation of these care models helped develop a patient-centered approach; promoted interdisciplinarity and quality improvement skills; and increased clinical efficiency, patient safety, and patient and clinician satisfaction [17]. A recent UK-based qualitative study of general practitioners practicing in micropractice settings found that, while this care model increased clinician satisfaction, quality improvement efforts focused more on administrative or process metrics than health outcome-focused metrics, and, as such, the value of this approach in improving patient outcomes remains unclear [29].

Communicating Meaningfully

Care coordination is a challenge in health care due in part to communication barriers between primary care providers and specialists; this was no different for the micropractice providers and their patients who participated in our study. Care coordination strategies may improve health outcomes after hospital discharge [30]; for example, using technology to deliver discharge information was the preferred method for both health care providers and patients [31]. While awaiting province-wide integrated EMRs that allow data sharing, suggestions for improving care coordination include use of smartphone apps [32], patient portals as a communication tool for care coordination [33], and developing middleware solutions for transferring data from personal health records to EMRs [34].

Virtual 2-way patient-provider communication was a valued component of the micropractice we studied, which highlighted the dialogical nature of communication between patients and health care providers who are not constrained by traditional office-hour conventions. This contrasts with concerns raised previously by physicians about the obligation of communicating beyond normal working hours [35] and reflects the patient-centric ethos of the micropractice. The ability of the providers in this study to make themselves more available while working the same number of hours through use of multiple communication modalities allowed patients to share their data and questions at times that were relevant to them (ie, when they were experiencing concerns). The timeliness of the responses contrasts with the long patient waiting times typical of traditional primary care providers [36,37].

Partnering in Care

Personal health records may increase health-protective behaviors and facilitate a more patient-focused health partnership and social care system [38]; yet, evidence indicates that uptake of patient portals and personal health records is low [39,40]. The majority of studies, however, used patient portals as a supplement to in-person visits, making the portal seem more peripheral to care and potentially discouraging its use. In the micropractice we studied, portal use was patients' primary mode for accessing care and interacting with their providers; this appeared to facilitate high patient engagement, a behavior also observed in patients in rural New Zealand [41]. Supporting this idea, authors of a systematic review reported patients' interest in using portals for patient-clinician communication as one of the areas with strongest evidence [42]. Recommendations for patient-provider partnerships in care and to build lasting digitally enabled care models include the use of low-threshold technologies, security and privacy regulations, reimbursement and liability policies, training and awareness of the technology's limitations, and not completely replacing the role of in-person medicine [9].

Seamless Transition to (Increased) Virtual Care During the COVID-19 Pandemic

Although the decision for scheduling mostly virtual visits during the pandemic was made by the micropractice team, patients expressed great satisfaction with the virtual care received, in part because they were already familiar with virtual visits and also likely due to their underlying relationship with, and trust in, the micropractice team. A survey of 420 patients attending virtual visits before the pandemic found that over 80% of patients agreed or strongly agreed that their virtual visit was as good as an in-person visit by a clinician [43]. While having a prior relationship with their virtual visit clinician was associated with less comfort and ease with virtual technology [43], here the opposite was found, possibly due to enhanced digital data sharing experienced by micropractice patients. Patients expressed hopes that such health data sharing systems would increase ownership in their care, improve timeliness and efficiency of care delivery, increase care personalization, and lead to safer care [44].

The fear about missed diagnoses during virtual care expressed by the micropractice physicians was also seen in a recent media review, in which health care providers worried that less frequent care, or more impersonal virtual care, might worsen health outcomes [45]. Missed diagnoses during virtual care have not been widely reported; in contrast, a report of tele-ophthalmology during the COVID-19 pandemic indicated appropriate triage and what appeared to be reasonable patient safety, with only

1.5% of virtual visits resulting in an in-person visit within 1 day or 5.4% in a visit within 2 weeks [46].

Despite the value of virtual care, the micropractice team in this study expressed concern that care had been missed. This is consistent with evidence of deferral of primary care in the United States, Canada, and the Netherlands during the COVID-19 pandemic, including concerns about missed referrals and routine care, increasing risk for morbidity and mortality [47,48]. As the acute phase of the COVID-19 pandemic subsides, this issue may resolve; however, health care providers may need to strategize ways to address this issue for future emergencies [49] and plan for catching up on preventive activities such as immunizations [50,51] and cancer screening [52,53].

Limitations

In this study, we focused on only 1 micropractice and its patients and health care providers, which limits transferability of the results, including the potential to adapt its success to other practices. There is also the possibility of selection bias, whereby those more enthusiastic about the virtual care approach volunteered to participate in focus groups. Yet, this in-depth exploration provides unique insights that might be lost by pooling results with other practices that adopted virtual care during the pandemic. Another limitation might be that the health care providers owned the micropractice; however, the providers were not involved in the study design, collection of patient data, nor the analysis of results. Additionally, they might be more invested in its success and be willing to tolerate hardships more than if they had been employees. As such, additional insights from micropractices that are not owner-operated may be useful to inform the feasibility and utility of larger-scale implementation.

Future Work

Additional study is needed regarding implementation of digital solutions in primary care practices with respect to different stages of practice and technology readiness for implementation, number of features added separately or together, and the influence on patient outcomes and team-based care. A comparison of the experiences of patients and health care providers in this rural micropractice with rural practices that only adopted virtual care as a response to the COVID-19 pandemic might be insightful to identify additional barriers and opportunities for long-term sustainable implementation of virtual and technologically enhanced care.

Conclusions

Using focus groups of health care providers and patients of a virtually enabled micropractice, we identified that opportunities of this hybrid care model lie in patients being true partners in their care. This can result in high patient engagement and satisfaction. Yet, the virtual care model needs to take account of less technology-engaged or technology-comfortable patients. Barriers lie in gaps in coordination of care with other practices that are less technology-enabled and provider fear that signs or symptoms more evident with an in-person examination could be missed. Finally, even in this setting, deferral of care occurred during the COVID-19 pandemic, and opportunities to address care gaps, including prevention, should be sought.

Acknowledgments

This work was supported by a BC SUPPORT Unit Data Science and Health Informatics (DaSHI) Methods Cluster project grant (Award number: DaSHI – 003; PI: KLR). MG holds a Michael Smith Health Research BC scholar award. The authors wish to extend thanks to all the patient and provider participants who shared their insights during the study, their collaborating partner, the Kootenay Boundary Division of Family Practice, Dr Leanne Currie for her help with data collection, and Nicholas West for editorial assistance.

Authors' Contributions

All authors contributed to the study design. All authors contributed to the collection of data, and MG, KLR, LB, and MAS analyzed the data. MG drafted the manuscript. All authors critically revised and approved the manuscript for publication.

Conflicts of Interest

PRE and LSH own the Kootenay Micro Practice, Nelson, BC.

Abstract

Background: Successful best practice implementation is influenced by access to peer support and knowledge exchange. The Toronto Stroke Networks Virtual Community of Practice, a secure social media platform, is a knowledge translation tool supporting dissemination and adoption of stroke best practices for interprofessional stroke stakeholders.

Objective: The aim of this study is to evaluate the use of a virtual community of practice (VCoP) in supporting regional stroke care best practice implementation in an urban context.

Methods: A mixed methods approach was used. Qualitative data were collected through focus groups and interviews with stroke care provider members of the VCoP working in acute and rehabilitation settings. Thematic analysis was completed, and the Wenger Value Creation Model and developmental evaluation were used to reflect practice change. Quantitative data were collected and analyzed using website analytics on VCoP use.

Results: A year after implementation, the VCoP had 379 members. Analysis of web analytics data and transcripts from focus groups and interviews conducted with 26 VCoP members indicated that the VCoP provided immediate value in supporting user networking, community activities, and interactions. Skill acquisition and changes in perspective acquired through discussion and project work on the VCoP were valued by members, with potential value for supporting practice change. Learning about new stroke best practices through the VCoP was a starting point for individuals and teams to contemplate change.

Conclusions: These findings suggest that the VCoP supports the early stages of practice change and stroke best practice implementation. Future research should examine how VCoPs can support higher levels of value creation for implementing stroke best practices.

Introduction

Background

In Canada, stroke care is guided by the *Canadian Stroke Best Practice Recommendations* [1], a resource for health professionals to bridge the gap between scientific knowledge and clinical practices in stroke care. Best practice guidelines are effective in increasing the performance of care processes identified as best practices and in improving patient outcomes [2]. Although best practices can support the consistent delivery of evidence-based care throughout a health system, the implementation of best practices can be challenging because of environmental barriers including organizational constraints, resource allocation, and social and clinical norms that vary among professions, organizations, and regions [3]. To address the challenge of implementing best practices in diverse contexts, a variety of approaches to tailor programs to meet the needs of regional settings and target groups have been developed [3]. Implementation success is influenced by individual factors such as educational interests and motivation [4]. Social factors, such as communication within a social network, accessibility of local opinion leaders, and availability of knowledge exchange with peers, also influence the success of initiatives aiming to achieve practice change in health care [5-8].

Communities of practice (CoPs) are groups of people "sharing a concern, a set of problems, or a passion about a topic, and who deepen their knowledge and expertise in this area by interacting on an ongoing basis" [9,10]. CoPs are knowledge translation (KT) tools that have the potential to support the implementation of practice change initiatives by addressing the communication and social network factors affecting implementation success. Research on CoPs shows that they can contribute to best practice implementation in a variety of health care contexts, including stroke care [11-14]. Virtual CoPs (VCoPs) are a type of CoP that combines the value of traditional face-to-face CoPs in supporting peer-facilitated learning with the value of social media networks to overcome geographical and temporal boundaries to knowledge sharing and continuing education in health care [15]. VCoPs have typically provided a closed, virtual group environment to share knowledge, address professional isolation, network, foster peer collaboration and mentorship, and improve clinical practice through KT [15].

Rationale

VCoPs are a potentially valuable tool for supporting the implementation of stroke care best practices, as they provide a mechanism to share knowledge among stakeholders across geographical and organizational boundaries. VCoPs also provide a virtual space for care providers from different disciplines to connect. VCoPs provide stakeholders with a platform to share strategies and outcomes of best practice implementation initiatives in different contexts, allowing them to leverage learning from others to make the process of quality improvement more efficient.

The Toronto Stroke Networks (TSNs) work collaboratively with stakeholders to implement high-quality stroke care and have an established education and KT infrastructure grounded in the *Knowledge to Action* (KTA) Framework [16]. Following TSNs stakeholder meetings with clinicians, researchers, managers, and system leaders across 17 regional acute and rehabilitation organizations, the TSNs established a stroke-specific VCoP to support the system-wide implementation of stroke best practices [17]. VCoP membership is largely constituted by regional stroke care providers in a large urban setting; however, there are also members from outside this region. As an ongoing KT initiative, the TSNs VCoP supports stroke best practice implementation by providing discussion forums, organizing working groups, housing a directory of local stroke care stakeholders, and curating a central repository of stroke care resources. In addition to housing passive resources (eg, educational and implementation resources for stroke best practices and members directory), the VCoP was designed to support active engagement and interaction among members through discussion groups and forums. Members may join any open public groups based on specific topics (eg, mood and cognition), in which multiple discussion forums may be housed about different subtopics (eg, depression screening as a subtopic of mood and cognition). Members have the capability to start new discussion threads within a forum or respond to existing threads by posting. Posts can include plain text responses, links, or uploaded resource documents. Documents can also be uploaded to groups as a general resource not associated with a specific post. Members may also request the creation of private groups, which have the same functionality as public groups, but require members to submit a request to join them.

The aim of this study is to evaluate the use of the TSNs VCoP by members and the value created in supporting regional dissemination and implementation of stroke care best practices using a mixed methods approach. This study adds to the small existing body of literature on the use and value of VCoPs to support best practice implementation in health care contexts.

Methods

Overview

A mixed methods approach was used in this study to evaluate the TSNs VCoP using both quantitative data on site use and qualitative data on value created through the use of the VCoP. Developmental evaluation [18,19] and the Wenger Value Creation Model [10] were used as foundations to inform the development of the evaluation framework for the VCoP.

Evaluation Framework

Developmental evaluation seeks to enhance the "understanding [of] the activities of a program operating in dynamic, novel environments with complex interactions" [18] by asking evaluative questions and gathering data to inform ongoing decision-making. Developmental evaluation poses a useful approach for assessing the value and impact of CoPs for supporting best practice implementation because of the complex, social nature of CoPs as an educational strategy. For VCoPs, developmental evaluation is an appropriate approach for assessing the challenge of tailoring implementation for varying contexts identified by individual VCoP members, teams, organizations, and the region.

Although developmental evaluation provides a structured method of assessment, the Wenger Value Creation Model [9] provides a complementary conceptual framework for contextualizing the results of this evaluation. The Wenger Value Creation Model [9] consists of five cycles: cycle 1, *Immediate Value—Activities and Interactions*; cycle 2, *Potential Value—Knowledge Capital*; cycle 3, *Applied Value—Changes in Practice*; cycle 4, *Realized Value—Performance Improvement*; and cycle 5, *Reframing Value—Redefining Success*. The Wenger Value Creation Model [9] supports the evaluation of CoPs by assigning value to the processes and outputs of a network that result in learning enabled by community involvement and networking [10]. The use of this model requires the integration of quantitative indicators and qualitative themes to build a picture of how a CoP creates value for its members [10]. To support data analysis, a framework based on developmental evaluation [18,19] and the Wenger Value Creation Cycles [9,10] was constructed by the authors (MD, EL, and SQ; Table 1).

Data Collection

Data on VCoP use were collected 1 year after implementation of the VCoP by 2 university students supervised by a member of the TSNs team (JF), including quantitative, aggregate web analytics data (eg, number of members and number of site visits), quantitative user-level data (eg, number of discussion posts), and qualitative user-level data (eg, questions asked in discussion forums and replies to discussion posts). Quantitative data were collected manually from the VCoP and using Google Analytics. Qualitative user-level data were collected manually from the VCoP and did not contain any identifying characteristics of users.

VCoP members were contacted with a request to participate in a focus group or semistructured interview via email and through the VCoP by a member of the TSNs team (JF). Semistructured interviews and focus groups were conducted by a member of the TSNs team (JF) with support from 2 university students following an interview guide with prompts based on the Wenger Value Creation Model [9,10]. Interviews and focus groups were audio recorded and transcribed.

Data Analysis

To analyze the data collected using web analytics, descriptive analysis of quantitative data on VCoP use was completed using Microsoft Excel (version 2015, Microsoft) to determine the total numbers of page visits, posts, VCoP members, and other indicators of VCoP engagement within 1 year following implementation. Narratives from VCoP discussion forums were analyzed using the analysis framework for this study based on the Wenger Value Creation Model [9,10] (Table 1).

To analyze the data collected from interviews and focus groups with VCoP members, transcripts from audio recordings of interviews and focus groups were generated and analyzed using thematic analysis [20]. Although an interview guide based on the Wenger Value Creation Model [9,10] was used, the analysis was inductive, in that themes developed in the analysis were based on what emerged from discussions in interviews and focus groups, not a predetermined thematic or coding structure.

The analysis was conducted individually by two university students and two authors (MD and EL) with expertise in KT. Manual coding of transcripts was performed to create frameworks by each individual. Subsequently, individual coding frameworks were compared manually to reach a consensus and develop a preliminary coding framework. This framework was then applied in recoding the transcripts. The resulting themes were collectively reviewed for validation through consensus. The trustworthiness of the findings was supported by review and validation of themes by authors who did not participate in the interviews and focus groups (MD and EL). An audit trail of coding changes was created to document the process of analysis and ensure consistency between coders.

Quantitative and qualitative data from web analytics and interviews and focus groups with participants were integrated using the evaluation framework developed for this study (Table 1) to identify broader themes of value creation stories generated from VCoP use.

Ethics Approval

Ethical review and approval for this study were provided by the Sunnybrook Health Sciences Centre Research Ethics Board before the collection of data (approval number 123-2013). Quantitative data on VCoP use were anonymous, and qualitative user-level data were anonymized and deidentified at the time of collection. Informed consent to participate in interviews and focus groups was provided by VCoP members interested in participating in the study. Any identifying details presented in interviews were omitted from transcripts.

Table 1. VCoP[a] evaluation framework using the Wenger Value Creation Cycles.

Cycle and cycle indicator	Quantitative data (web analytics)	Qualitative data (interviews and narratives from VCoP)
Cycle 1: Immediate Value—Activities and Interactions		
Level of participation	Number of threads, total number of members, number of members in a group, number of members in discussion forums, and number of discussion forums	Questions or statements related to joining a discussion forum
Quality of interaction	Frequency of responses to inquiries, frequency of citing one's own experience, post length (words), number of debates or differing points of view, and number of suggestions made to a problem	Questions or statements about a clinical issue and sharing of a case example
Networking	Number of group memberships	Question or statement about a need that can be met by the expertise of another member and request connection with a member's particular knowledge
Collaboration	Number of joint projects and timeliness of responses	Question or statement about a collaborative project and statement about length of time a member waited for response to a question
Cycle 2: Potential Value—Knowledge Capital		
Skills acquired	Number of documents	Question or statement about a document on the VCoP that was used or shared with colleagues
Change in perspective	—[b]	Statements indicating a shift in understanding or opinion
Confidence building	—	Questions or statements indicating disagreement or challenging posts of other members
Cycle 3: Applied Value—Changes in Practice		
Implementation of advice, solutions, and insights	—	Questions or statements about successes or challenges related to applying new learning from the VCoP
Use of social connections	—	Questions or statements about networking with other VCoP members
Cycle 4: Realized Value—Performance Improvement		
Personal performance	—	Statements about personal goals
Organizational performance	—	Statements about organizational goals or accomplishments
Organizational reputation	—	Statements about organizational performance relative to other benchmarks (eg, Ministry of Health and Long-Term Care and Health Quality Ontario)
Cycle 5: Reframing Value—Redefining Success		
Community aspirations	—	Questions or statements that indicate new purpose for the VCoP or improvements and/or additions to the community
Relationships with stakeholders	—	Questions or statements about relationship building or with others external to the VCoP (eg, patients or other organizations)

[a]VCoP: virtual community of practice.

[b]No quantitative data identified.

Results

Overview

A year after implementation, 379 members had joined the VCoP from 22 organizations in the TSNs representing several professional backgrounds: nursing, occupational therapy, physical therapy, speech-language pathology, medicine, academic research, and other health system stakeholders. Of these 379 members, 26 (6.9%) provided informed consent and participated in 14 interviews and 2 focus groups. Participants included nurses, occupational therapists (OTs), physicians, physiotherapists (PTs), and speech-language pathologists (S-LPs) from 4 rehabilitation and 8 acute care organizations. Overall, 19 participants provided data for number of years in practice, with the mean number of years practicing being 15.6 (SD 8.7; range 2-29.5) years.

Quantitative Results

The data collected from the VCoP through web analytics reflecting cycles 1 and 2 of the evaluation framework are summarized in Table 2.

Table 2. Quantitative data summary.

Qualitative Themes

The subjective value of the VCoP and use patterns were collected using interviews and focus groups with VCoP members. Through a qualitative thematic analysis of interview and focus group transcripts, the research team identified 5 themes discussed in the next sections.

Theme 1: Effective Networking

Participants noted that a primary function of the VCoP is to provide a more effective platform for contacting individuals and building networks within and across disciplines. This enhanced connectivity was primarily achieved through the use of the VCoP as a mechanism to find members' organizational contact information and directly message them through this platform. Participants noted that they leveraged the VCoP network to assist colleagues who were not VCoP members, suggesting the spread of VCoP value beyond the immediate member network:

> *...I helped a colleague here who needed to contact somebody...and you know, through the VCoP I knew exactly who she needed to contact. I got her number through the member directory.* [Participant 17, OT]

> *What is meaningful to me is directly messaging other members, I can network with people in the same discipline.* [Participant 2, S-LP]

Theme 2: Value for Project-Based Work

Participants also discussed how they leveraged the VCoP to support collaborations within and between professions on ongoing stroke projects. Members also used the VCoP to collaborate with individuals on posters for conferences, which contributed to knowledge transfer outside the VCoP:

> *We've been using [the] VCoP for the development of posters...to share ideas & information about the process, and then post the actual creation of posters on VCoP...that was our only means of communication at that point...I was able to liaise with different [colleagues] about different practice concerns...the two posters I worked on.* [Participant 10, OT]

This project-based collaboration on the VCoP was noted to provide additional educational opportunities. For example, individuals not directly involved in he projects benefited from observing the collaborative process in public groups, leading to the development of conference posters. In addition, VCoP members identified that conducting project-based work on the VCoP led to the development of practice resources:

> *I have learned things from reviewing the other posters that I haven't been involved in because I was part of the online group and saw what was posted.* [Participant 6, nurse]

> *[The] VCoP was the means of communication for a group project...afterwards, I created additional assessment checklists...and shared it with my team.* [Participant 19, OT]

Theme 3: Resource Sharing Supports Application of Knowledge to Practice

Participants identified that access to up-to-date information and resource sharing improved with VCoP use. The VCoP was noted as beneficial for identifying topic-specific resources more easily and providing a central location for resources. This increased accessibility saved members' time that would otherwise have been spent searching for these resources:

> *Now with the VCOP, I will not have to go back to my desk to refer to the assessment checklist as it is all online now.* [Participant 16, nurse]

> *I printed the triage tool that someone uploaded to the VCoP and gave it to new people on my team for reference.* [Participant 17, PT]

VCoP members also noted that these resources had an impact beyond their immediate use. Resource sharing on the VCoP provided a catalyst for in-person knowledge sharing about best practices across institutions. Although a direct link to changes in practice was not identified, participants noted that VCoP resources started discussion about changes in practice that could lead to future changes:

> *I shared information with a group that sparked discussion about [specialized] assessments, the comparison between hospitals prompted discussions here with our [professional group] about whether we should change our ways of doing things.* [Participant 13, OT]

Theme 4: Enhancing Understanding of Stroke Best Practices and Stroke Care Priorities

Participants identified that the VCoP helped them understand the broader picture of stroke best practices within their region beyond their disciplinary boundaries. Participants noted that the VCoP helped them access information to support learning about stroke Quality-Based Procedures (QBPs) [21], which are stroke care procedures associated with improved outcomes and reduced financial cost to the health care system:

> *Looking up the information about the QBP is very helpful to get someone new to understand how it impacts the [stroke] program...it gives them a leverage point of how they can advocate for the stroke patients.* [Participant 17, PT]

Multiple participants noted that the information shared on the VCoP went beyond what was available from other web-based sources and was more regionally relevant. Learning about activities and concerns outside one's practice was made possible through a diverse membership on the VCoP from across professions, sectors, and organizations within the region:

> *So if you really want to find out what's happening across the stroke community, you have that opportunity more at your fingertips than what you did before.* [Participant 8, PT]

> *It's information that you're not going to necessarily find on the internet because it's about current practice.* [Participant 12, OT]

> *I have a better awareness of the best practices and what the bigger picture is. When you work in one area (e.g. rehab) you don't really have a big sense of what was going on in acute care, what they were looking at for outpatient services, community service...being a part of the community and through looking at some of the resources.* [Participant 8, PT]

Theme 5: Barriers to Use

Although themes of benefits were identified, challenges with accessing resources were also recognized as barriers to VCoP use. Members noted that the navigation path to certain resources was too long, making them difficult to find. Frustration over inability to find resources and time spent searching for them was noted as a deterrent to future use:

> *If it takes less time to find it, right, it's like you're spending like 10 minutes and you're like, "Okay, I'm not going to do this again," right?* [Participant 2, S-LP]

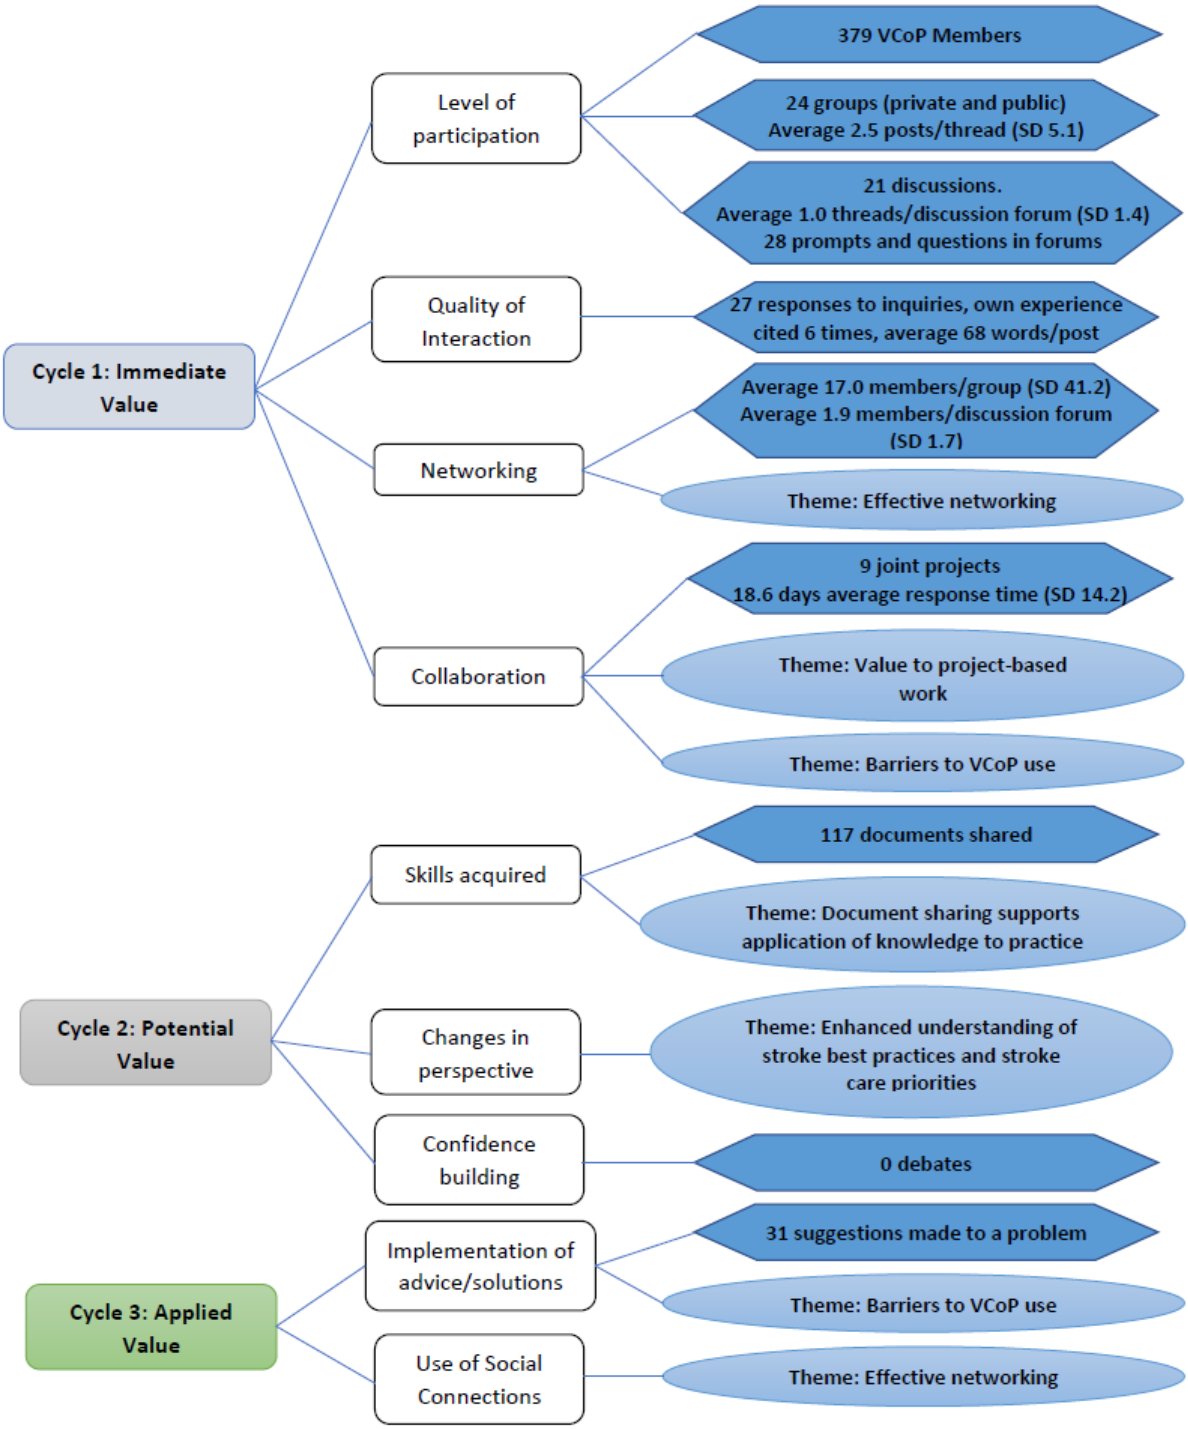
Email notifications were suggested as a strategy to increase engagement in preferred topics and previous discussions in which individuals had participated. This suggested that improvement may decrease the time spent searching the site for information and challenges with navigation:

> *...if there was a new tag or a new thing, something pops up into my e-mail, to, kind of, go answer it...what about an option to receive updates via email, or notifications based on individuals' interests?* [Participant 9, physician]

Integrating Quantitative Data and Qualitative Themes

The results from both quantitative and qualitative analyses were applied to the evaluation framework. These results provide evidence for value creation associated with VCoP reflective of cycles 1 to 3 of the Wenger Value Creation Model (Immediate Value, Potential Value, and Applied Value, respectively; Figure 1).

Figure 1. Mapping of quantitative data and qualitative themes to an evaluation framework reflecting the Wenger Value Creation Model (cycles 1-3). VCoP: virtual community of practice.



Discussion

Principal Findings

The results of this evaluation strongly support the creation of *Immediate Value—Activities and Interactions* (cycle 1) and *Potential Value—Knowledge Capital* (cycle 2), with some evidence provided for creation of value in *Applied Value* (cycle 3) in a VCoP to support stroke best practice implementation [9]. Support for the creation of immediate value in activities and interactions is evidenced by value creation stories identified in this study that described networking, collaboration, and acquiring skills and perspectives through document sharing as meaningful forms of VCoP use for members. Several groups and discussion forums were created during the evaluation period, providing a platform for networking and collaboration. Evidence supporting the creation of value in knowledge capital was evidenced by the number of resources shared by VCoP members during the evaluation period and participants' narratives about using resources from the VCoP to initiate conversations with

their teams about best practice change. Participants frequently cited this as a starting point for team discussions and questioning of current practice that could lead to practice change. The number of responses to inquiries and suggestions made by members demonstrates the responsiveness of the community to one another.

Although evidence for value creation reflective of cycle 3 was weaker than that of cycles 1 and 2 in this study, some narratives and data on the number of projects, number of resources shared, and number of solutions to problems offered by members support the initial steps toward best practice implementation. Several VCoP member narratives described sharing of resources as helping individuals and teams make progress toward changes in practice. For example, VCoP members interacting in a group (cycle 1) supported the generation of knowledge capital such as an educational poster (cycle 2). In the process, members learned from each other and brought information back to their teams, prompting discussions about practice changes (cycle 3).

Evidence of the value created by a VCoP to support stroke best practice implementation in this study aligns with existing KT frameworks that identify the importance of increasing awareness of best practices and identifying practice gaps. For example, the KTA Framework [16] outlines the importance of becoming aware of best practices before determining the gaps, which, in this study, was achieved through interactions between VCoP members and collaboration to create new knowledge products addressing identified gaps. In another framework, Pronovost et al [22] described a collaborative model for integrating theory into practice that engages staff in understanding the current best practice gap and the potential negative consequences of the gap. The KTA Framework [16] and the Wenger Value Creation Model [9] both identify the need to build awareness and prompt collaborative thinking about practice gaps as foundations for successful implementation, which aligns with what was observed in this evaluation.

This evaluation found few instances of members sharing their experiences or debating issues, suggesting that this community is still in the process of building social capital. Social capital is created in social networks [23] through relationship formation and is supported by mutual confidence and trust [24,25]. Members may be hesitant to challenge others or share experiences that could be perceived as organizational or personal shortcomings in a web-based forum such as a VCoP. Previous research has suggested that developing social capital requires more time [26]. This may also explain why this study found evidence for the creation of value in cycles 1 to 3 but less evidence of value created in cycles 4 and 5. It is possible that a data collection period of 1 year may have been too brief, for this growing community, to capture VCoP value in cycles 4 and 5. As the VCoP builds and becomes more deeply integrated into the TSNs' initiatives, more evidence for cycles 4 and 5 may emerge. Research should continue to evaluate mature VCoPs, as this technology is increasingly being adopted to support KT and interprofessional collaboration.

The patterns of and reflections on VCoP use identified in this study may pose challenges to value creation on the VCoP. Web analytics data indicated slow response times for users to address questions posed by others on the VCoP and instances of as few as 2 individuals having web-based exchanges in some discussion forums, whereas other forums had extensive resource sharing. Slower response times and inconsistent engagement across different discussion forums could challenge value creation on the VCoP by discouraging members from posing questions if they do not think they will receive a timely response or any response at all. Although some VCoP members identified that the VCoP saved them time in the long run when it came to finding resources, others, as supported by previous literature [15,27], also identified the amount of time required to navigate the VCoP as a potential challenge to use. A shorter click path required to access sections of the site, active facilitation of the VCoP (eg, prompting responses and connecting members to answer each other's questions), and more notifications for personally relevant site activity, as suggested by participants, may lead to a greater number of responses and sharing of experiences.

The self-selection of VCoP members to participate in the focus groups and interviews, rather than random sampling, creates a potential sampling bias that could impact the generalizability or transferability of this work to different regional contexts or KT applications. Additional insights provided by less active members could improve understanding of VCoP value, as active members outweighed nonactive members participating in focus groups and interviews.

Participants included health care providers in acute and rehabilitation hospital settings, which represents VCoP membership demographics at the time of data collection. Membership has since expanded to include more VCoP members from nonhospital settings. Although the VCoP has an interprofessional membership, most participants in focus groups and interviews were allied health professionals. A more diverse group of participants may affect the value expressed by VCoP members for health professions involved in stroke care.

In addition, this study was conducted to evaluate a regional best practice implementation tool. Study participation included users in a large metropolitan area. Although there are existing face-to-face opportunities to build social capital in this region, challenges for stroke care providers to access these opportunities exist (eg, taking time away from care provision to commute to in-person events) [28]. This feedback from stakeholders prompted the development of the TSNs VCoP as a virtual KT resource. Previous research has shown that VCoPs are an effective tool for addressing geographical boundaries to collaboration among health care providers [15]. Some studies have suggested that individuals in more rural areas, where stroke teams are more isolated, may be more motivated to engage in alternate ways to learn and decrease isolation [29,30]. This virtual KT resource was developed to address geographical challenges to in-person engagement in an urban setting; however, they are potentially relevant to both urban and rural settings. Future research should compare the value of VCoPs as a tool for KT in different regional contexts.

Conclusions

Through a developmental evaluation approach, the value of a VCoP in supporting the initial phases of stroke best practice

implementation was demonstrated in this study. Members reported enhanced networking, more efficient identification of resources, and enhanced collaboration on joint projects to build and maintain professional relationships. VCoP use contributed to a broader understanding of the stroke continuum of care and a better understanding of the priorities in stroke care that supported individuals and teams to contemplate best practice change. Future VCoP design changes to improve functionality and user experience were suggested to increase collaboration and the quality of engagement. The evaluation framework used in this study will continue to be used to collect evidence of the value created by the TSNs VCoP as an ongoing KT initiative. The use of a VCoP in other care networks and regions should be investigated to gauge the potential value of this educational strategy for health professionals working with other populations seeking to enhance best practice implementation.

Abstract

Background: Knee osteoarthritis (KOA) is the most common joint disorder in the United States and a leading cause of disability. Depression and obesity are highly comorbid with KOA and accelerate knee degeneration and disability through biopsychosocial mechanisms. Mind-body physical activity programs can engage biological, mechanical, and psychological mechanisms to improve outcomes in KOA, but such programs are not currently available.

Objective: This mixed methods study aims to adapt a mind-body activity program for the unique needs of patients with KOA, depression, and obesity (GetActive-OA) delivered via live video.

Methods: Participants were adults (aged ≥45 years) from rural Kentucky with obesity (BMI≥30 kg/m^2), idiopathic KOA with mild to moderate radiographic changes, and elevated depressive symptoms (9-item Patient Health Questionnaire ≥10) recruited from 2 orthopedic centers. In phase 1, we developed GetActive-OA and the study protocol using qualitative focus group feedback from the study population (N=9; 2 focus groups, 90 minutes) and multidisciplinary expertise from clinical psychologists and orthopedic researchers. In phase 2, we explored the initial feasibility, credibility, and acceptability of GetActive-OA, live video delivery, and study procedures via an open pilot with exit interviews (N=5; 1 group). This research was guided by National Institutes of Health (NIH) model stage IA.

Results: Phase 1 qualitative analyses revealed nuanced information about challenges with coping and increasing activity, high interest in a mind-body activity program, program participation facilitators (flexibility with technology) and barriers (amotivation and forgetfulness), and perceived challenges with data collection procedures (blood and urine samples and homework). Phase 2 quantitative analyses showed that GetActive-OA met most a priori feasibility markers: acceptability (80%), expectancy (100%), credibility (100%), clinician adherence (90%), homework adherence (80%), questionnaire data collection (100%), program satisfaction (100%), and safety (100%). Adherence to ActiGraph wear (80% baseline, 20% posttest) and collection of blood samples (60%) were low. Participation in GetActive-OA was associated with signals of improvements in general coping (Cohen *d*=2.41), pain catastrophizing (Cohen *d*=1.24), depression (Cohen *d*=0.88), anxiety (Cohen *d*=0.78), self-efficacy (Cohen *d*=0.73), pain (Cohen *d*=0.39), and KOA symptoms (Cohen *d*=0.36). Qualitative exit interviews confirmed quantitative findings and provided valuable information to optimize the program and protocol.

Conclusions: Patients with KOA, depression, and obesity from rural Kentucky were interested in a live video mind-body activity program. GetActive-OA shows promise; however, the program and protocol require further NIH stage I refinement before formal efficacy testing (NIH model stage II).

Introduction

Background

Symptomatic knee osteoarthritis (KOA) is the most common joint disorder in the United States and is projected to affect >67 million Americans by 2030 [1,2]. Approximately one-third of patients with KOA experience rapid progression of cartilage degradation, knee pain, and disability [3], leading to greater health care use [4,5]. Depression and obesity, which are highly comorbid among patients with KOA [6-8], place individuals at a greater risk for these poor outcomes.

Depression, obesity, and KOA exacerbate one another through biopsychosocial pathways. Specifically, these conditions share a common pathophysiology [9-11] that involves a cycle of increased proinflammatory cytokine interleukin 1-beta (IL-1β) and Toll-like receptor 4 (TLR4) [3,12,13] activity, which, in turn, leads to inflammation-induced knee cartilage degradation [14]. KOA, depression, and obesity also exacerbate one another though a *disability spiral* that involves reduced physical activity [15], more pain, low mood, higher weight, and further knee cartilage degradation [16]. Current treatments (eg, medications, injections, and knee arthroscopy) are costly [17] and have limited efficacy [18], likely because they do not address the aforementioned biopsychosocial pathways that reinforce knee cartilage degradation, disability, and obesity. Novel treatments are needed to target the biopsychosocial processes involved in the KOA, depression, and obesity comorbidity.

Physical activity can improve depression, obesity, KOA pain, and cartilage breakdown [19]; however, uptake and adherence are challenging [20,21]. Indeed, there are barriers to engaging in physical activity in this population, including pain intensity, misinterpretation of pain signals as threats, and programs that are too challenging or incompatible with patients' lives [22-25].

Walking is a promising, safe, and patient-preferred method for improving physical function in populations with chronic pain, particularly when it is gradually and strategically increased (ie, quota-based pacing regardless of symptoms) [22,26-32]. In addition, mind-body programs, which incorporate a range of complementary practices (eg, meditation, relaxation, breathing, and body movement) [33], can decrease depression, obesity, and pain in osteoarthritis (OA) [34-36], which are additional barriers to engagement in activity in this population. Combining mindfulness with walking is promising for improving mood and coping with KOA [35], and trials of this approach are ongoing (eg, NCT03064139). Multimodal programs that teach a variety of mind-body, walking, cognitive behavioral, and resiliency skills are needed to address depression, obesity, and pain as barriers to physical activity in OA and to target the biopsychosocial pathways of this comorbidity [37-42].

We have previously developed a multimodal, evidence-based program [43-46] for adults with chronic pain (GetActive) that combines mind-body skills with walking. GetActive has demonstrated high feasibility, acceptability, and satisfaction as well as statistically significant improvement in pain and physical and emotional function outcomes when delivered in person to adults with chronic pain [28,32]. Adapting this program for live video delivery would be an attractive option for patients with this comorbidity, including those living in rural areas. Depression, pain, and stigma associated with obesity can make weekly travel for clinic appointments challenging. Furthermore, live video delivery bypasses several barriers to care, including the lack of skilled providers in remote areas, missed work, and the burden of travel (cost and reliance on family and friends). This is particularly relevant for our patients in Kentucky with this comorbidity, who are underserved and prefer telehealth as a treatment modality. GetActive may be a solution to the problem of comorbid KOA, depression, and obesity, but it requires adaptations.

Objectives

Here, we followed the National Institutes of Health (NIH) stage model [47] and conducted a mixed methods study aimed at adapting the original GetActive program for live video delivery and meeting the unique needs of patients with KOA, depression, and obesity (GetActive-OA) from rural Kentucky (NIH stage IA). In phase 1, we developed the live video GetActive-OA program and protocol through qualitative feedback from patient focus groups and multidisciplinary experts. In phase 2, we explored the initial feasibility, credibility, and acceptability of the program and preliminary signals of improvement in pain, multimodal physical function, emotional function, coping, and KOA biomarker outcomes. Individual exit interviews were then conducted to assist in further optimizing the programs and methodology before conducting a subsequent efficacy trial (NIH stage II).

Methods

Overview

Our methodology followed our previously published study protocol [48]. A total of 7 physicians at the University of Kentucky (UK) Healthcare Hip & Knee Center and the UK Healthcare Orthopedic & Sports Medicine Center referred eligible patients with mild to moderate KOA, using standard diagnostic criteria, during regularly scheduled office visits. The

standard diagnostic criteria included clinical examination, patient-reported symptoms or functional limitations, and radiographic assessments. We also circulated an institutional review board–approved study flyer at the UK, Massachusetts General Hospital (MGH), and patient advocate groups such as the Arthritis Foundation.

Ethics Approval

The institutional review boards at the UK and MGH approved all study procedures (approval number 53457 for the focus groups [Phase I] and 62256 for the open pilot [Phase II]).

Participant Recruitment and Enrollment

Our eligibility criteria are consistent with those of other clinical trials in KOA or mind-body interventions [43,47]. The inclusion criteria were as follows: (1) obesity (BMI ≥30 kg/m^2), (2) idiopathic KOA [49] with mild to moderate radiographic changes (Kellgren or Lawrence grade 2 or 3 [50]) or Knee Injury and Osteoarthritis Outcome Scores (KOOSs) consistent with KOA [51], (3) elevated depressive symptoms with a 9-item Patient Health Questionnaire (PHQ-9) score ≥10 [52,53], (4) aged ≥45 years [54,55], (5) history of concurrent psychotropics for <2 weeks before initiation of treatment or on stable doses for >6 weeks, (6) access to an internet-enabled computer or smartphone, (7) willingness to comply with the study protocol and assessments, and (8) physician's clearance to participate. We selected the PHQ-9 because it is widely used and validated as a screener in health care settings [56], including orthopedic clinics [57], and for patients with KOA [58]. Given the tendency to underreport emotional symptoms of depression in our rural population, particularly among men, the PHQ-9 is also more likely to detect physical manifestations of depression that overlap with KOA (eg, slow movement and sleep disturbance).

The exclusion criteria were as follows: (1) any disorder requiring the use of systemic corticosteroids; (2) rheumatoid arthritis; (3) history of cancer within 5 years of screening; (4) inability to walk or use of a wheelchair; (5) previous surgical fixation of a femur or tibia fracture; (6) taking high doses of opioid pain medication (>50 mg of morphine equivalent per day); (7) diagnosis of a medical illness expected to worsen in the next 6 months (eg, malignancy); (8) active suicidal ideation or past-year psychiatric hospitalization; (9) non-English speaking; (10) lifetime history of schizophrenia, bipolar disorder, or other psychotic disorder; (11) current substance abuse or dependence (or a history within the past 6 months); (12) practice of yoga or meditation or other mind-body techniques once per week >45 minutes within the last 3 months; and (13) engagement in regular moderate or vigorous physical exercise for >30 minutes daily.

To reduce the travel burden for participants in rural Kentucky, we enrolled and collected baseline data (self-report questionnaires, blood draws, and urine samples) during the patient's office visit with their referring physician whenever possible. After providing verbal consent, potential participants met with a trained research coordinator for study screening. Eligible participants provided written informed consent and Health Insurance Portability and Accountability Act authorization owing to the sensitive data collected. Trained clinical psychologists from MGH conducted the focus group and open pilot sessions via secure Health Insurance Portability and Accountability Act–compliant Zoom. After enrollment, the research coordinator either assisted participants with installing the Zoom app on their smartphone or emailed participants the Zoom installation instructions. The research coordinator also emailed the invitation link and appointment reminders to participants, offered Zoom test calls, and was available to solve technical difficulties in real time during the focus group and open pilot sessions.

Phase 1: Development of GetActive-OA

The goal of phase 1 is to identify the treatment needs and preferences of patients with comorbid KOA, depression, and obesity from rural Kentucky via focus groups.

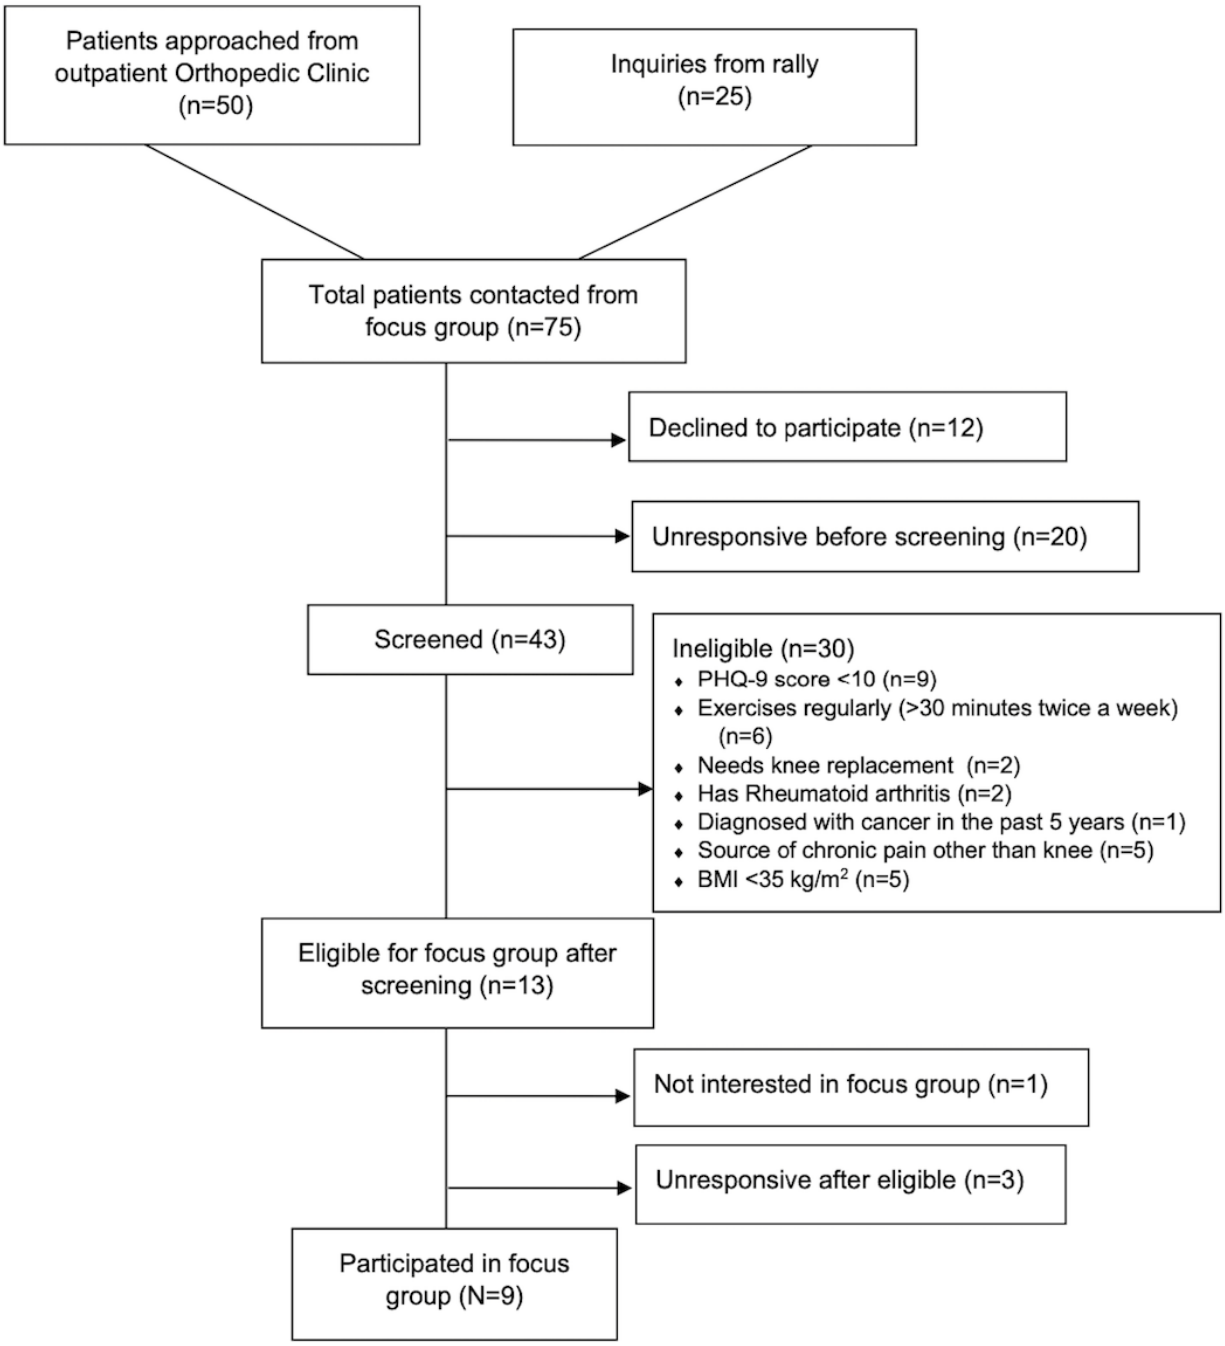
Focus Group Procedures

Figure 1 depicts participant flow in phase 1.

Enrolled participants completed a one-time 90-minute focus group (N=9; a total of 4 groups). Clinical health psychologists with expertise in heterogeneous pain conditions and qualitative methods moderated the focus groups via Zoom. Our interdisciplinary team developed a semistructured qualitative interview guide to elicit feedback on the following a priori set themes: (1) experiences living with comorbid KOA, depression, and obesity (challenges, causes, and connections between conditions); (2) patients' previous experiences with medical and complementary treatments; (3) perceptions of increasing walking; (4) perceptions of the GetActive-OA program, including barriers to program adherence (challenges with live-video delivery, group participation, homework completion); and (5) perceptions of data collection procedures (self-report assessments, ActiGraph, and blood and urine tests). The research coordinator transcribed the audio recordings of the focus groups.

We used rapid assessment procedures to analyze the focus group data, consistent with established qualitative frameworks [59-61]. Rapid assessment is a valid alternative to in-depth qualitative methods and is ideal for delivering timely results to guide multiple phases of intervention development [62,63]. We used rapid assessment to identify actionable suggestions to modify the GetActive-OA program and the study procedures for the phase 2 open pilot. First, the researchers created neutral domains that corresponded to each of the a priori set interview themes. Next, the moderators (RAM and JG) created a summary template to take notes during focus groups and reflexively summarize the main ideas directly afterward. The summary template was piloted with 1 focus group and modified, as necessary. The senior authors (CAJ and AMV) conducted a secondary review of the summaries to ensure consistency. In addition, the study team held regular meetings to collaboratively discuss any discrepancies in the summaries until a consensus was reached. Finally, we consolidated the summaries with a matrix to compare the focus groups, identified common themes, and reported the results in the next section [64].

Figure 1. Participant flow for the focus groups (phase 1). PHQ-9: 9-item Patient Health Questionnaire.



Focus Group Results

Multimedia Appendix 1 reports detailed qualitative results by semistructured interview topic.

Theme 1: Experiences Living With Comorbid KOA, Depression, and Obesity

Participants attributed KOA, depression, and obesity to significant challenges across the domains of physical, emotional, and social functioning. Participants identified physical discomfort, pain flare-ups, and swelling as the primary sources of disability. Some participants were worried about deteriorating knee health, and a participant expressed further concerns that OA would negatively affect other parts of their body. Participants endorsed a variety of depressive symptoms, including low mood, amotivation, and feelings of hopelessness. Because of these emotional challenges, they described feeling socially isolated, lonely, stigmatized, embarrassed, and having low self-esteem. Most participants were knowledgeable about the range of psychological (eg, sedentary and dietary habits and life stressors) and biological factors (eg, heredity and aging) that contribute to KOA, depression, and obesity. However, some participants were unable to identify risk factors or endorsed misconceptions about KOA, such as activity causing knee flare-ups or being "too active" when young.

Participants described the co-occurrence of KOA, depression, and obesity as a "vicious cycle" of worsening disability. Many participants believed that depression led to unhealthy eating habits, subsequent weight gain, and knee pain. Other participants

explained that KOA or pain flare-ups made it harder to move, resulting in weight gain and depression. Participants reported noticing themselves withdrawing from both physical and social activities and becoming more depressed over time. They reported frustration and discouragement by the lack of available or effective treatments.

Theme 2: Previous Experiences With Medical and Complementary Treatments

All participants reported a history of 1 or more medical treatments for KOA and knee pain including injections, surgery, pain medication, and steroids. The medical treatments were described as providing mixed results. Some participants reported that they had short-term relief, but the benefits wore off and they experienced negative side effects. Some participants were informed that they were ineligible for surgery because of their weight. One person reported having a *botched surgery*. Similarly, many participants reported prescriptions for antidepressant medication with modest benefit and negative side effects (eg, *brain fog*). Participants felt that their physicians commonly focused on 1 comorbidity and did not view them as a whole person.

Participants were knowledgeable about nonpharmacological interventions for pain (eg, physical therapy and mind-body activities) and depression (eg, psychotherapy and self-care) and weight loss interventions (eg, weight loss programs, personal trainers, and dietitians). Participants endorsed high interest and motivation in these approaches, as evidenced by initial lifestyle changes and help-seeking behaviors (eg, contacting physicians for referrals, removing junk food from pantry, and purchasing walking shoes). However, participants reported struggling to follow through because of lack of time, poor planning, distractibility, negative coping strategies (eg, withdrawal and avoidance, and overeating *comfort foods*), weather, and lack of insurance.

Theme 3: Perceptions of Increasing Walking

Overall, participants shared positive views of a program that encourages increased walking. Most identified walking as their preferred and primary source of physical activity. Some participants expressed an interest in walking more, whereas others reported that they already walk a lot for work. Participants recognized a bidirectional relationship between increasing walking and healthy eating or losing weight, which motivates them to continue positive habits (*building momentum*).

Participants identified several personal facilitators for walking, including setting gradual and feasible goals, pacing, creating reinforcements, and prioritization. Participants valued encouragement from others or having a *walking buddy*. Several participants used technology to promote walking, such as listening to music or using guided smartphone apps. Warm weather and having access to safe places to walk and exercise equipment were identified as environmental facilitators of physical activity.

Participants acknowledged several personal barriers to walking, including fear of further pain or injury, lack of motivation, procrastination, and time. A participant expressed concerns that walking is unsafe for patients with KOA and preferred to use a stationary bike. Several participants also identified a lack of access to safe walking areas (eg, few sidewalks and uneven surfaces) and COVID-19 restrictions as environmental barriers to walking. A participant noted that after overcoming these initial barriers, they were typically able to sustain their momentum and continue walking.

Theme 4: Perceptions of the GetActive-OA Intervention Components

Participants expressed a high interest in a program that combines increased walking with mind-body skills. Many participants agreed with the program's rationale for addressing the 3 comorbidities. They believed that the mind-body skills would help them overcome the barriers to walking and healthy eating identified in theme 3. Participants also liked that the program did not include medication. Many participants noted the importance of balancing intervention components targeting KOA, obesity, and depression in every session. To reduce stigma surrounding obesity and depression, participants recommended the use of sensitive language in the treatment manuals and that the study clinicians speak about these issues in positive ways ("do not force dietary information"). Some participants expressed a fear of increasing walking because of the possibility of falling. Few participants had previous mind-body experience and were unsure if mindfulness would help but were open to trying it. Participants explained that reassurance from trusted sources, including medical clearance from their physicians or patient testimonials, would reduce their ambivalence about walking and mind-body skills.

With respect to format and delivery, participants were in support of participating in a live video group setting. Participants shared positive impressions of Zoom during the focus group, including that it was feasible, they enjoyed learning the features, and it enabled flexible attendance. Many participants were familiar with live video to stay connected with friends and family during the COVID-19 pandemic. Barriers to attending a live video group program included a lack of privacy at home, scheduling conflicts, and internet connectivity. Participants also noted several factors that would facilitate participation, such as support from the group and clinicians, regular reminders for walking and attendance, calendar appointments, and easy access to readings and program materials.

Participants also agreed that 5 to 10 minutes of home practice per day was feasible and constructive. They believed that home practice could encourage them to track progress in their walking goals and mind-body practice. Participants reported that a smartphone log would be easier and faster than paper and pencil. A participant noted that they might need assistance with using the smartphone log. Additional barriers to home practice include distractions, low motivation, forgetfulness, and schedule conflicts. A combination of reinforcements, such as reminders to log their home practice, check-ins from clinicians, and identifying family support, could prevent nonadherence.

Theme 5: Perceptions of Data Collection Procedures

There were no major concerns regarding the biological data collection of blood and urine samples. A few participants noted previous experience with phlebotomists who had difficulty locating a vein for blood collection. Several participants noted

the inconvenience of traveling to the clinic, including long commutes, transportation costs, and difficulty finding parking. Nevertheless, participants confirmed that the biological data collection could not deter them from participating. Participants recommended combining the biological data collection with physician appointments to reduce this burden. Many participants also expressed an interest in receiving the results to learn about their inflammation levels and other markers of knee health.

Similarly, most participants had no concerns about ActiGraph or self-report assessments. Participants expressed a preference for a small, unobtrusive, and well-fitting device. A participant was concerned about privacy and wanted more information on whether ActiGraph could track the geographical location. Several participants had experience with self-reports for research or medical appointments and preferred to complete them via a web-based survey. A participant noted the importance of explaining the purpose of the self-report assessments so that they "don't feel like an exam."

Phase 2: Preliminary Feasibility of the GetActive-OA Program

Overview

The goal of phase 2 is to conduct an open pilot study of the newly developed GetActive-OA with individual exit interviews to explore preliminary credibility, acceptability, satisfaction with treatment, feasibility of recruitment, instruments, biological data collection, and adherence to homework (exercise and mind-body skills). Here, we describe modifications to the GetActive-OA program and the phase 2 procedures informed by our phase 1 qualitative focus group results. Our published protocol [48] contains remaining details of procedures that were not influenced by the focus groups, including clinician adherence, depression severity and suicide risk assessment, and the GetActive-OA makeup session.

GetActive-OA Program and Procedures

Table 1 presents the program outline and skills for each session.

GetActive-OA also provides educational information on the biopsychosocial interactions among KOA, depression, and obesity that comprise a population-specific *disability spiral*. Participants learn that inflammation is the biological tie among the 3 conditions and physical activity is a modifiable factor that can decrease inflammation, improve the biology and function of the knee, and decrease both depression and obesity [7-9,16,38-40,65-67]. GetActive-OA teaches 5 core skills that target the comorbidities: (1) setting weekly activity goals that are personally meaningful (eg, walking with kids instead of forcing a gym workout); (2) quota-based pacing to gradually and safely increase activity that is noncontingent on pain (eg, walking for 15 minutes twice per day); (3) mind-body skills to elicit relaxation and cultivate mindfulness (eg, deep breathing and mindfulness meditation) and minimize negative reactivity to pain and reduce activity avoidance; (4) cognitive behavioral skills (eg, behavioral activation and adaptive thinking) to challenge pain-specific cognitions such as catastrophizing and fear avoidance that interfere with program goals; and (5) resiliency skills including self-compassion, gratitude, acceptance, and social support to enhance coping, given that discouragement is common in this population.

We also added several novel components based on the focus group results. First, we added patient-friendly educational information on the interconnectedness of KOA, depression, and obesity (eg, reduced activity can exacerbate pain and disability). Second, participants were encouraged to apply mindfulness to facilitate healthy eating and dietary changes (eg, noticing hunger or fullness urges and mindful eating). Third, our multidisciplinary team reviewed all skills for patient-sensitive language and to reduce stigma. Fourth, we provided all participants with a stationary peddler. This was intended to serve as an alternative to walking for participants with concerns about starting a walking program or with limited access to sidewalks in rural Kentucky. It may also address other environmental barriers to walking, such as bad weather, as identified in the focus groups or participants who live in neighborhoods with high crime rates.

Finally, given the positive impressions of technology and to reach patients in rural areas, we optimized the program and study procedures for live video delivery. We have successfully adapted mind-body programs for live video similar populations with chronic pain [45,68]. We considered other approaches to live video, such as asynchronous web platforms, but decided against it because telehealth delivery is preferred by this population and fostering peer contact can directly target stigma and isolation common in this comorbidity. To offset the weaknesses of live video groups (eg, scheduling), we created a website that contains program materials and audio recordings of mind-body skills that participants can access at any time.

A clinical psychologist from MGH led the 8 weekly GetActive-OA group sessions (90 minutes) via Zoom with the support of a clinical psychology fellow. The first session of GetActive-OA oriented participants to program expectations for participation. In each weekly session, the study clinician introduced the core GetActive-OA skills and problem-solved adherence issues. Participants' home practice involved daily walking or stationary pedaling according to their activity goal, daily mind-body skills (5-10 minutes, via clinician-guided audio recordings available on the program website), and logging in the GetActive-OA manual at least three examples of gratitude. Participants who achieved their activity goal from the previous week were encouraged to increase their goal by 10% to 20%, according to the guidelines for quota-based pacing [69]. Participants also logged their mindfulness minutes and skills practiced each day using a smartphone log. The research coordinator sent reminders (via SMS text messaging, phone call, or email based on participant preference) to remind participants of the homework and sessions.

Table 1. GetActive-OA session overview informed by the focus group results.

Topic	GetActive-OA skills
1. Break the disability spiral by exercising	Myths about pain, disability spiral, and quota-based pacing
2. Smart ways to exercise more	Exercising with enjoyment, self-compassion and gratitude, and diaphragmatic breathing
3. Mindfulness	Mindfulness, mindful breathing, body scan, and mindful moments
4. Everyday mindfulness	Leaning into difficulty, mindfulness of pain, mindful exercising, and noticing the benefits of exercising
5. The benefits and barriers to exercise	Mindful eating, overcoming barriers to exercising, stop and breathe, reflect, and choose
6. Coping with negative thoughts	Negative automatic thoughts, changing our perspective, and acceptance
7. Strengthening social support	Social support and the disability cycle, effective communication, social walking, and loving kindness
8. Staying on track and maintaining your progress	The powerful self; working with pain, your emotional well-being, and unhealthy weight; and resiliency plan

Measures

Feasibility Markers

We evaluated a priori appropriateness, acceptability, feasibility, and fidelity based on established benchmarks, consistent with our prior feasibility pilot studies [31,32,70] and protocol for GetActive-OA [48].

- Program credibility and expectancy were determined by the percentage of participants with Credibility and Expectancy Questionnaire–6 [71] scores above the scale's midpoint.
- Program satisfaction was determined by the percentage of participants with Client Satisfaction Questionnaire–3 [72] scores above the scale's midpoint.
- Feasibility of recruitment was determined by the percentage of patients who agreed to participate from the total patients approached.
- Program acceptability was determined by the percentage of patients who attended at least six of the eight of the GetActive-OA sessions.
- Adherence to ActiGraph wGT3X-BTLink was determined by the percentage of participants with valid accelerometer data for at least five of seven days for a minimum of 10 hours per day during the baseline and postintervention testing.
- Adherence to the home practice was determined by the percentage of participants who completed mind-body and walking skills at least four of seven days or one of these skills at least five of seven days.
- Feasibility of assessments was determined by the percentage of participants with no missing outcome data.
- Study clinician adherence was determined by the percentage of content delivered based on an independent audit of audio recordings and progress notes for all sessions by the senior authors.
- We assessed program safety based on the absence of adverse events (eg, swelling soreness and stiffness) and stable medication use reported to the study staff.

Quantitative Assessments

Our assessments aligned with the Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials, Osteoarthritis Research Society International, and Outcome Measures in Rheumatology recommendations [73,74]; our conceptual model [48]; and recommendations for feasibility trials [75,76]. In addition, 1 week before and after the GetActive-OA program, participants traveled to the UK to receive their ActiGraph activity monitor (model wGT3X-BTLink) and collect biological data. Participants completed the self-report assessments on the web via REDCap (Research Electronic Data Capture; Vanderbilt University).

The Numerical Rating Scale (NRS) [77] assessed pain intensity at rest and with activity on an 11-point scale. Higher scores indicated greater severity of pain (0, no pain; 10, worst pain). The minimum clinically important difference (MCID) for the NRS was 1 [78].

The KOOS [79] assessed KOA-specific pain (9 items), KOA symptoms (7 items), activities of daily living (17 items), sport and recreation function (5 items), and knee-related quality of life (4 items). Items were scored on a scale from none (0) to extreme (4) or never (0) to always (4). Subscale scores were transformed to a scale of 0 to 100, with lower scores indicating more severe knee problems. Of the 5 subscales, 4 (80%) were used in this study's analyses, as the Sport and Recreation Score was not applicable to this population, and MCIDs for the 4 subscales were as follows: pain=9.3, symptoms=8.4, activities of daily living=9.0, and quality of life=10.3 [80].

The ActiGraph wGT3X-BTLink accelerometer assessed the average step count over a 7-day period at the baseline and postintervention time points. Our published protocol contains full details of the accelerometer procedures [48]. Participants had to wear ActiGraph on their nondominant wrist for a minimum of 10 hours per day for a minimum of 5 days for their data to be considered valid during the baseline and postintervention testing [32,48]. Participants did not wear the ActiGraph wGT3X-BTLink during the program and did not have access to their step count data, as the device itself does not have a display screen. We opted to use the *blinded* ActiGraph so that any change in physical activity would not be confounded by the feedback provided by the device. We processed the accelerometer data using the ActiLife software [81] according to established guidelines [82-84]. The MCID

for the accelerometer was 800 steps/day, which is consistent with that used in other clinical populations [85].

The Physical Activity Scale for Individuals With Physical Disabilities (PASIPD) [86] assessed self-report of disability on a 13-item scale. Lower total scores, calculated based on the average hours per day and metabolic equivalent values, indicated higher disability across leisure, household, and work-related activities. The MCID for the PASIPD is not available.

The Patient-Reported Outcomes Measurement Information System (PROMIS) Anxiety (v1.08a) and PROMIS Depression (v1.08b) [87] both assessed emotional functioning on separate 8-item scales. Participants were asked about the frequency of their anxiety and depression symptoms (1, never; 5, always). Higher *T* scores indicated greater severity of anxiety and depression. The MCID was 4.28 for the PROMIS Anxiety and 5.19 for the PROMIS Depression [88].

The Pain Catastrophizing Scale (PCS) [33] assessed hopelessness, helplessness, and negative rumination about pain on a 13-item scale. Higher scores (range 0-52) indicated greater pain catastrophizing (0, not at all; 4, all the time). An MCID was not available for the PCS.

The Arthritis Self-Efficacy Scale (ASES) [89,90] assessed arthritis-specific self-efficacy on a 20-item scale. The ASES contains pain (5 items), function (9 items), and other symptoms (6 items) that are scored on a scale from very uncertain (1) to very certain (10). Scores ranged from 1 to 10, with higher average scores indicating greater arthritis-specific self-efficacy. The MCID for the ASES was not available.

The Measure of Current Status–Part A (MOCS-A) [91] assessed general coping skills on a 13-item scale. Participants rated their ability to use relaxation, awareness of tension, ability to express needs, confidence in coping, and assertiveness skills on a scale from 0 (I cannot do this at all) to 4 (I can do this extremely well). Higher total scores (range 0-52) indicated greater use of coping skills. An MCID was not available for the MOCS-A.

The Modified Patient Global Impression of Change (MPGIC) [92] assessed patients' perception of improvement using the scale from 1 (very much improved) to 7 (very much worse) on 5 questions related to the following: pain, level of physical activity, physical function, emotional function, and resiliency.

We assessed KOA biomarkers of cartilage breakdown and systemic inflammation. Urinary CTXII (Urine Cartilaps, CTX-II; Immunodiangostic Systems Inc) was used to assess cartilage degradation, which was normalized to creatinine levels to account for differences in hydration [93] (Parameter Creatinine Assay; R&D Systems Inc). Enzyme-linked immunosorbent assays were used to assess the proinflammatory cytokines IL-1β and interleukin 6 (IL-6; Proinflammatory Multiplex 1; Meso Scale Diagnostics) as well as TLR4 (Invitrogen Human TLR4, Life Technologies Corporation). The selected biomarkers have been shown to predict inferior clinical outcomes and cartilage thinning [93,94] and are responsive to changes over a 3-month follow-up [95-97]. Our published protocol contains full details of the biological data collection [48].

Quantitative Analysis

This open pilot study was designed in accordance with the NIH stage model intervention development pilot studies to explore feasibility and *not* to test efficacy [47,98,99]. We reported the frequency and percentage of each a priori benchmark set in our previously published protocol [46]. We rated each benchmark as *good* if the criteria were met in at least ≥80% (4/5) of the open pilot study participants. The benchmarks allowed us to evaluate readiness for a subsequent efficacy trial and determine whether further modifications to GetActive-OA and study procedures are needed. Exploratory analysis for each quantitative measure included descriptive statistics, baseline and postintervention comparisons using paired 2-tailed *t* tests, and Cohen *d* effect sizes (0.20, small; 0.50, medium; and 0.80, large; [100]) to cautiously explore preliminary before and after improvement associated with participation in GetActive-OA.

Exit Interviews

We conducted group exit interviews via Zoom using the same rapid assessment procedures as in phase 1. Our goal is to gather impressions about the GetActive-OA adaptations and technology enhancements. We performed rapid assessment procedures on the exit interview transcripts to identify actionable suggestions to optimize GetActive-OA for the subsequent randomized controlled trial (RCT) [59]. Integrating the qualitative exit interviews with the quantitative results also allowed us to corroborate the feasibility markers, contextualize the findings at both the group and individual participant levels, and begin to understand *why* changes in outcomes may have occurred [101].

Results

Participants and Feasibility Markers

Figure 2 shows the flow diagram, and Table 2 reports the demographics of the open pilot study participants.

GetActive-OA had *good* feasibility on nearly all of the a priori benchmarks (Table 3) [31,32,48,70].

Of the 10 patients who were approached, 9 (90%) were eligible after screening. Of these 10 participants, 6 (60%) were enrolled after 4 (40%) declined to participate owing to disinterest in the study and lack of time (*poor feasibility of recruitment*). All but one of the enrolled participants, who was removed because of neurological symptoms that were not present at the time of enrollment, completed baseline testing and started the open pilot. The sample was majority White, non-Hispanic, women, married, and fully employed. More than half of the participants were prescribed psychotropic medication for depression or anxiety (3/5, 60%) and had bilateral KOA (3/5, 60%).

GetActive-OA was viewed as highly credible, and participants expected their knee health to improve during the program (5/5, 100% above the Credibility and Expectancy Questionnaire–6 scale midpoint, *good program credibility and expectancy*). Of the 5 participants, 4 (80%) attended at least six GetActive-OA sessions (*good program acceptability*), and 4 (80%) completed the smartphone homework logs (*good adherence to homework*). The study clinicians delivered 90% of the manual content (*good*

study clinician adherence). Participants completed all self-report measures at the baseline and postintervention assessment time points (no missing data, ie, *good feasibility of quantitative measures*). At baseline, of the 5 participants, 4 (80%) met the adherence benchmark of a minimum of 10 hours of ActiGraph wear time for a minimum of 5 days (*good ActiGraph adherence*). However, of the 5 participants, only 1 (20%) met this benchmark at the postintervention time point, with 1 (20%) patient not meeting the minimum wear time for even 1 day (*poor ActiGraph adherence*). All participants were highly satisfied with the program (5/5, 100% above the Client Satisfaction Questionnaire–3 scale midpoint, *good satisfaction*). No adverse events were reported (*good program safety*).

Figure 2. Participant flow for the live video open pilot study (phase 2). OA: osteoarthritis.

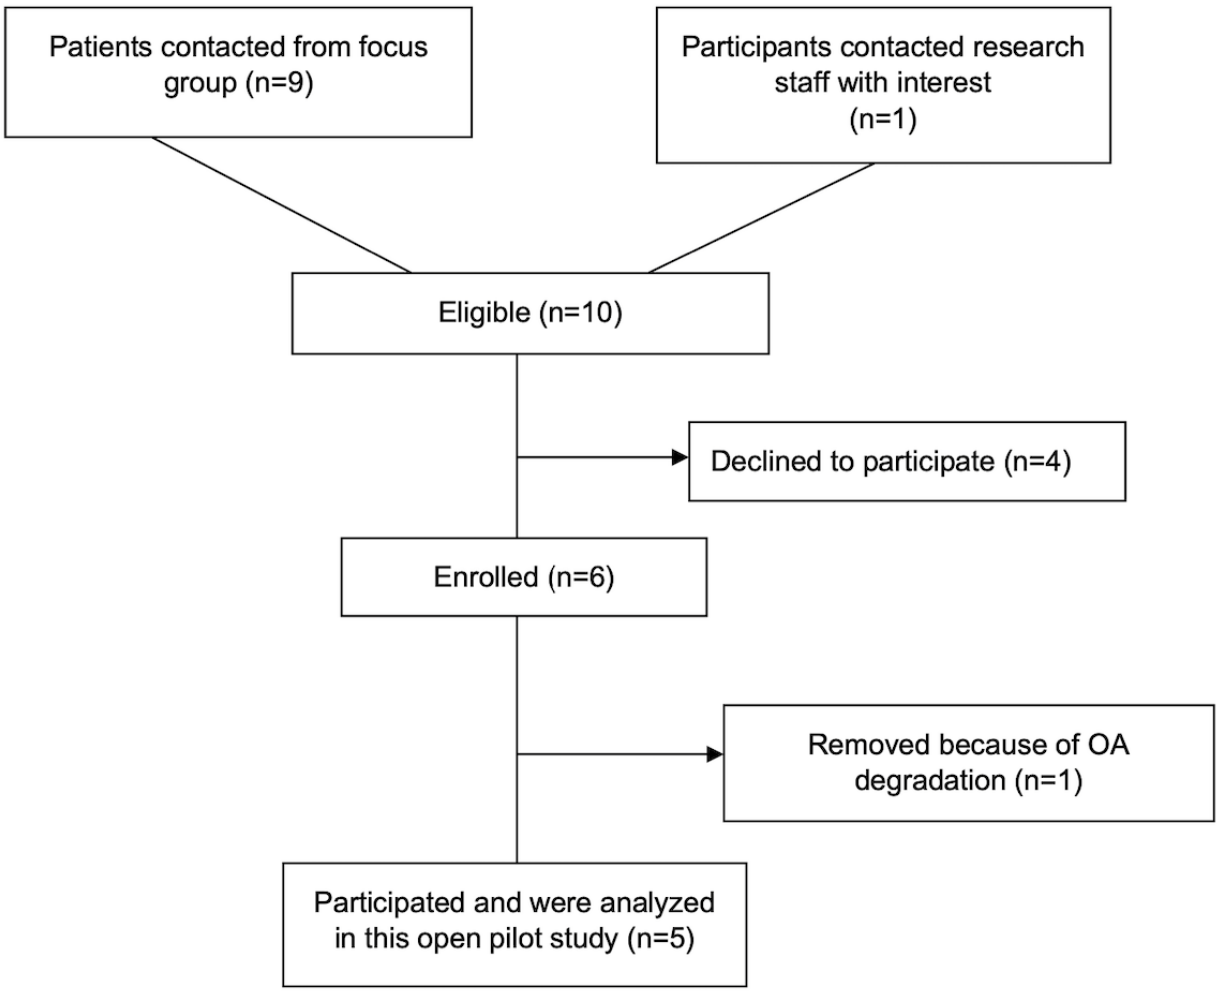


Table 2. Demographics and clinical characteristics of open pilot study participants (N=5).

Characteristics	Value
Age (years), mean (SD; range)	53.2 (6.64; 49-65)
BMI (kg/m^2), mean (SD; range)	39.8 (6.68; 32.6-50.8)
Sex, n (%)	
Male	0 (0)
Female	5 (100)
Ethnicity, n (%)	
Hispanic or Latinx	1 (20)
Not Hispanic or Latinx	4 (80)
Race, n (%)	
White	4 (80)
African American	1 (20)
Marital status, n (%)	
Single, never married	1 (20)
Widowed	1 (20)
Married	3 (60)
Education, n (%)	
Completed high school or GED[a]	2 (40)
Associate's degree	2 (40)
Some college	1 (20)
Employment, n (%)	
Employed full-time	3 (60)
Homemaker	1 (20)
On disability	1 (20)
OA[b] symmetry, n (%)	
Bilateral	3 (60)

No	2 (40)
Opioid medication, n (%)	
Yes	1 (20)
No	4 (80)

[a]GED: graduate equivalency degree.

[b]OA: osteoarthritis.

Table 3. A priori feasibility markers.

Marker	Criteria
Feasibility of recruitment	Of 10 eligible patients, 6 (60%) successfully contacted agreed to participate (poor)
Program acceptability	Of 5 participants, 4 (80%) attended ≥63% (≥5/8) of group or make-up sessions (good)
Credibility and expectancy	Of 5 participants, 5 (100%) scored above the scale midpoint for expectancy (good), and 5 (100%) scored above the scale midpoint for credibility (good)
Study clinician adherence	The study clinicians delivered 90% of the manual content across the 8 sessions (good)
Feasibility of quantitative measures	Of 5 participants, 5 (100%) were not fully missing questionnaires on quantitative measures at baseline (good), and 5 (100%) were not fully missing questionnaires on quantitative measures at the postintervention time point (good)
Adherence to homework	Of 5 participants, 4 (80%) completed mind-body and walking skills at least four of seven days or one of these skills at least five of seven days (good)
Adherence to ActiGraph	Of 5 participants, 4 (80%) who received ActiGraph at baseline wore it for ≥5 of 7 days (good), and 1 (20%) who received ActiGraph at the postintervention time point wore it for 5 of 7 days (poor)
Client satisfaction	Of 5 participants, 5 (100%) scored above the scale midpoint (good)
Program safety and adverse events	0 adverse events

Quantitative Outcomes

Table 4 reports the results for the quantitative outcomes.

Baseline ActiGraph step count varied widely (mean 8832, SD 4083; range 5548-16,410). Participants endorsed moderate to high levels of pain intensity (mean 7.0, SD 1.5) [102]. The levels of pain catastrophizing were higher than the norms for chronic pain samples (mean 39, SD 12.5). Participants had more severe knee problems than previous samples with OA across all KOOS measures [103]. Participants reported elevated levels (PROMIS+1 SD) of both depression (mean 60.6, SD 7.5) and anxiety (mean 60.8, SD 9.0).

As a group, participants exhibited small to moderate improvements in KOA pain, KOA symptoms, and KOA physical function on the KOOS. Participants reported large improvements in general coping on the MOCS-A, arthritis self-efficacy on the ASES, and reductions in pain catastrophizing on the PCS. Participants also showed large reductions in depression and anxiety on the PROMIS. Changes in KOA-related quality of life on the KOOS, pain intensity on the NRS, and disability on the PASIPD were minimal. Among the 4 patients with pre- and posttest ActiGraph data, there was a small decrease in the average step count. The 1 participant who met the adherence benchmark at the postintervention time point increased by 310 steps. Only 1 participant reported that their emotional functioning had improved on the MPGIC. Participants did not report improvements on the remaining MPGIC items: pain, physical function, and resiliency.

Table 4. Quantitative outcomes.

Measure	Baseline, mean (SD)	Postintervention, mean (SD)	Mean difference from the paired sample *t* test (2-tailed)	*P* value	Cohen *d*
KOOS[a] pain	33.6 (5.5)	38.0 (14.9)	4.4	.36	0.39

[a]KOOS: Knee Injury and Osteoarthritis Outcome Score.

[b]ADL: activity of daily living.

[c]QOL: quality of life.

[d]NRS: Numerical Rating Scale.

[e]PASIPD: Physical Activity Scale for Persons With Physical Disability.

[f]PROMIS: Patient-Reported Outcomes Measurement Information System.

[g]PCS: Pain Catastrophizing Scale.

[h]ASES: Arthritis Self-Efficacy Scale.

[i]MOCS-A: Measures of Current Status–Part A.

[j]ActiGraph step count, which is the weekly average of the valid days (≥10 hours).

[k]IL-6: interleukin-6.

[l]TLR4: Toll-like receptor 4.

[m]CTX-II: Urine Cartilaps (Immunodiangostic Systems Inc).

Biomarker Analyses

Urine samples were successfully collected from all patients at both pre- and posttest time points, and CTX-II and creatinine values were above the lower limits of detection for all samples. CTX-II, expressed as nanogram per millimole creatinine, moderately increased. Whereas urine samples were successfully collected, only 60% (6/10) of the total possible blood draws were successful because of low vein patency, thereby prohibiting meaningful analysis of pre- to posttest changes. From the available samples, all TLR4 and IL-6 values were above the lower limits of detection; however, 67% (4/6) of the samples had IL-1β levels below the limits of detection.

Exit Interview Analysis

Participants shared positive overall impressions of the program, including the group setting, mind-body and activity skills, and home practice logs. Participants were more engaged with the program website than with the physical treatment manual. Almost all participants enjoyed the group setting. Several participants noted that the group normalized the challenges of living with KOA, unhealthy weight, and a low mood. The weekly meetings also increased motivation and accountability for their goals. Zoom was well liked, accessible, and feasible for everyone. Some emphasized the need to foster connections among group members (eg, exchange helpful information) to overcome the tendency for remote participation to be impersonal. There was some disagreement about program length; many reported that the 8 weeks and 90-minute sessions were too long, whereas a few were satisfied with these commitments. Other barriers to participation included previous commitments, life events, and health concerns. Reminders and individualized support from the study staff were helpful for staying engaged with the program.

Many reported improvements in their physical activity, pain-specific cognitions, and mood associated with the program components. Most notably, all participants highlighted mind-body skills as their favorite aspect of the program. Participants enjoyed the in-session mindfulness exercises and reported using mind-body skills outside of the session, with recordings on the program website. Participants described the mindfulness exercises as helpful when experiencing high levels of pain and for altering pain-specific cognitions (eg, use of deep breathing at night to dull throbbing sensations in the lower limbs, to manage pain, and to lessen rumination on pain experiences). Participants also reported positive impressions of the activity skills and that they increased their activity with pacing, individualized goal setting, and linking exercise to personally meaningful activities. A participant noticed that combining mind-body and activity skills, such as mindful walking, made gradual increases in activity safer. However, a few participants struggled to implement activity skills, citing lack of time and the ability to structure activity blocks into their daily routine.

Participants had mixed experiences of gratitude and self-compassion. Many participants acknowledged that these skills did not reduce self-criticism and self-doubt, which are both common in pain and depression. However, a participant noted that self-compassion resonated and helped them "break the spiral" of disability. Some participants believed that the healthy eating skills were helpful in changing dietary choices, whereas others believed that the information was redundant. Finally, adaptive thinking skills were generally not impactful on participants. Many did not recall these skills or implement them. However, a participant noted that adaptive thinking helped change their relationship with pain in a positive way.

Discussion

Principal Findings

Depression and obesity are highly comorbid with KOA, can accelerate knee degeneration, and share a common pathophysiology involving systemic inflammation and proinflammatory cytokines. Mind-body interventions targeting depressive symptoms, physical activity, and pain-related coping may promote healthy physical and emotional functioning and improve KOA biomarkers in these patients. We adapted a mind-body and activity program for live video delivery tailored to patients with this comorbidity (GetActive-OA). This study assessed the program's initial feasibility, credibility, and acceptability, as well as preliminary signals of improvement in pain, multimodal physical function, emotional function, coping, and KOA biomarker outcomes. Consistent with the early stages of the NIH model of intervention development, this study was not powered or intended to evaluate program efficacy. Rather, it aims to refine study procedures (eg, screening, recruitment, and assessment), identify participants' perceptions of the study or intervention (eg, acceptability, credibility, and barriers and facilitators to participation), and iteratively refine the program in preparation for a resource-intensive, fully powered RCT.

The phase 1 focus groups revealed the unique challenges, limitations of previous medical treatments, interest and expected benefits of a mind-body activity program for KOA, barriers and facilitators to participation, and minor concerns about data collection (eg, travel to clinics and blood draws). These findings provided important information about the unique needs of patients with KOA, depression, and obesity, which we used to tailor GetActive-OA and study procedures to reduce reported barriers to adherence (eg, group-based intervention for accountability, structured goal setting, teaching skills to tolerate increased walking or lifestyle changes, and regular reminders for walking or home practice) and increasing walking (eg, address misconceptions that walking is harmful for individuals with KOA). On the basis of these findings, clinicians and researchers working with this population should consider assessing functioning across physical, emotional, and social domains. Focus group participants openly described experiences of stigma and highlighted the importance of patient-provider relationships. To build trust and encourage participation in treatment and studies, clinicians and researchers should take the time to understand participants' underlying challenges and validate their efforts before introducing possible changes to weight, exercise, or depression.

The benchmarks for the phase 2 open pilot study indicated that the GetActive-OA program and study procedures met the criteria on nearly all a priori benchmarks for feasibility, acceptability, expectancy, and satisfaction. The exit interview findings complemented our feasibility marker results, as participants had favorable views of the live video delivery, group structure, and mind-body and activity skills. The group identified several external barriers to participation, which, coupled with concerns about the time commitment (100% of declined enrollments), suggest a need to shorten the program to optimize feasibility. The subsequent RCT will increase program reinforcements to further increase adherence, such as individualized support from study staff, recordings on the program website, and reminders for attendance and home practice. We plan to de-emphasize the skills that either participants did not use (adaptive thinking) or did not meaningfully reduce negative thoughts and emotions related to pain and depression. To improve the healthy eating component, we will streamline dietary education to bolster in-session meditation exercises (eg, mindful eating and urge surfing), with a focus on modifying their relationship with eating.

The phase 2 quantitative results offer preliminary evidence that GetActive-OA is sensitive to population-specific needs and that the measures are sensitive to changes in key outcomes [98,99]. We observed small to moderate improvements in KOA-related pain, KOA symptoms, and physical functioning and large improvements in general coping, arthritis self-efficacy, pain catastrophizing, depression, and anxiety on the quantitative outcomes. We observed minimal changes in quality of life, pain intensity, and disability, perhaps because of the high KOA severity endorsed by participants. During the exit interviews, some participants reported that their walking *increased* with the help of mind-body skills (eg, mindful walking) and linking walking to personally meaningful activities. This aligns with support from the literature that deep breathing and mindfulness can facilitate physical activity goals and decrease depression, obesity, and pain in individuals with OA [34-36]. Given this pattern of results, the lack of perceived improvement on the

MPGIC was surprising. Negative perceptions on the MPGIC may be due to several factors, such as unrealistically high initial expectations for improvement, realization of the effort required to develop healthier habits during the program, and regret about how much they engaged with the program. In the subsequent RCT, study staff and clinicians will help participants set more realistic goals for the program based on their ability levels and interests. It will also provide an opportunity to further explore the correlations between perceptions of improvement and KOA outcomes in a larger sample.

In addition to changes in self-reported knee function and psychosocial factors, pre- and posttest changes in biological markers were also observed, including large improvements in the inflammatory marker IL-6 and small improvements in TLR4. IL-1β values were often below the limits of detection, suggesting that this biomarker might not be viable for assessing systemic changes in the fully powered RCT. In contrast, we observed large increases in biomarkers of cartilage breakdown (CTX-II). Although increased CTX-II levels have predicted subsequent KOA progression [93], it remains unclear whether CTX-II acutely increases as a direct result of increased physical activity. Increasing physical activity may trigger a short-term increase in cartilage turnover; however, this may be offset by attendant cartilage synthesis. As such, the subsequent RCT will assess the relative ratio of cartilage catabolism and synthesis by measuring CTX-II as well as CS846, which is a biomarker of cartilage synthesis [104].

Limitations

Our study has several limitations. First, although we successfully recruited a complex medical population in underserved rural areas with limited access to quality care, our sample comprised exclusively women. This may have been due to several factors, including the risk of sampling bias in small samples, higher prevalence of both KOA and depression among women than among men in the United States, and stigma surrounding depression and other mental health problems [1,105]. Only patients who reported depressive symptoms and were willing to learn skills to better manage these symptoms in a group setting were included in this study. The data suggest that men and individuals from rural areas have higher levels of internalized mental health or depression stigma (ie, the tendency to agree with and internalize negative stereotypes that apply to oneself) [106,107] and thus may have been unwilling to participate. When screening and enrolling patients for the subsequent RCT, we will focus on normalizing stress and negative thoughts or emotions when living with KOA and obesity for men, specifically, while also avoiding terms such as *psychological disorder* or *major depression* to minimize stigma and increase acceptability for all patients.

Although GetActive-OA and study procedures met most of the a priori feasibility benchmarks, poor adherence to ActiGraph and blood collection at the postintervention time point hindered the interpretability of signals of improvement and should be addressed for the subsequent RCT. All participants wore the ActiGraph at baseline, but only 1 participant logged sufficient valid wear time at the postintervention time point to analyze pre- and posttest changes. Although we assessed familiarity with technology during the focus groups, we did not formally assess the technology profile of individual participants, which limits insight into specific factors that influenced adherence with either the live video aspects of the intervention delivery or activity monitoring performed at the pre- and posttest phases. Informal feedback collected by the study clinicians and research coordinators suggests low participant buy-in with ActiGraph. We will boost ActiGraph adherence for the subsequent RCT through improved incentive structures (eg, structuring compensation in proportion to the number of days and hours of wear time), explaining the purpose of the devices (eg, establishing a step count baseline for individualized quota-based pacing), and clarifying misconceptions raised during the focus groups (eg, no location tracking). We will also consider technological strategies to increase adherence, such as notification on wearable devices that they are not being worn and visualizing or gamifying step count data. In addition, owing to 4 unsuccessful blood draws, only 1 participant had both baseline and postintervention data. This was likely due to two factors: (1) a trained clinical research coordinator who completed a phlebotomy course collected blood specimens at baseline rather than expert phlebotomists and (2) consistent with the focus group results, blood draws can be more challenging in patients with obesity [108]. For the subsequent RCT, we will ensure that trained phlebotomists collect all blood samples to reduce participant burden and prevent missing data.

Conclusions

This study depicts the development and preliminary feasibility of the first mind-body and activity program (GetActive-OA) for patients with KOA, depression, and obesity—prevalent and challenging-to-treat comorbidities for which effective treatment is lacking. Participants' needs, preferences, and responses to the initial program yielded valuable suggestions for clinicians and researchers seeking to better support this patient population and integrate mind-body and activity interventions as complementary approaches for KOA, depression, and obesity. On the basis of our mixed methods results, we will refine the program to increase feasibility for participants (6 sessions, 45 minutes) and more comprehensively target all 3 comorbidities (renamed as *GetHealthy-OA*). The next phase will involve a live video pilot RCT (N=60 participants) of the GetHealthy-OA program with a time- and attention-matched health enhancement control (Health Enhancement Program) [68,109]. The study will yield critical information on how participants might engage differently with the intervention and control, as well as definitive information on feasibility, acceptability, and signal of improvement in the intervention before investment of resources in a fully powered efficacy trial.

Acknowledgments

This study was funded by a clinical trial grant awarded to CAJ and AMV by the National Center for Complementary and Integrative Health (R34 AT010370-01A1). JG's contribution was made possible through National Center for Complementary and Integrative Health grant 1K23AT010653-01A1. This project was supported by the National Institutes of Health National Center for Advancing Translational Sciences through grant UL1TR001998. The sponsors were not involved in the review or approval of this manuscript for publication. The authors would like to thank Sarah Hopkins for coleading the GetActive-OA intervention and Jennifer Wang and Megan Edwards for their tireless efforts in enrollment and data collection. The authors would also like to thank Jason Kim and the Arthritis Foundation for supporting this project by circulating information about the study through their peer-to-peer patient network.

Abstract

Background: Information and communication technology (ICT) use may enhance social work practice and continuous professional development. Under the Hong Kong Jockey Club SMART Family-Link Project, we developed an innovative web-based training, learning, and sharing platform (i-TLS) to support not only ICT and other learning needs of Hong Kong social workers but also their practice.

Objective: We developed i-TLS with 3 major components (i-Training, i-Learning, and i-Sharing) and assessed its acceptability and impact on facilitating ICT use in family services.

Methods: We described the i-TLS development based on a 4-phase model and evaluated i-TLS using the platform database, Google Analytics, a self-administered survey, and individual phone interviews 1 year after launching.

Results: i-TLS was launched in 12 nongovernmental organizations on July 1, 2019. The COVID-19 outbreak in December 2019 limited face-to-face services, which galvanized digital transformation in social work practice. By July 31, 2020, 313 social workers had registered with i-TLS. Approximately 79.6% (249/313) of users accessed i-TLS at least once in the past 28 days, averaging 3.2 (SD 1.35) platform visits per day and viewing 4.8 (SD 1.42) pages per visit. i-Training provided 41 mini-modules on applying ICT to family services, with 730 enrollments. Approximately 70% (511/730) of users completed the mini-modules and obtained digital mini-certificates. i-Learning provided 112 items of learning resources centered on ICT use in family services, with nearly 4000 page views. i-Sharing had 25 discussion threads with 59 posts. Approximately 53.7% (168/313) of users completed the 1-year evaluation survey, including 7.1% (12/168) who were phone interviewed. The mean i-TLS satisfaction score (out of 10) increased from light (4.99, SD 1.54) to occasional (6.15, SD 1.34) and frequent (6.31, SD 2.29) users. Frequent users showed higher scores (out of 10) than light users for an increase in knowledge (5.84, SD 1.34 vs 4.09, SD 1.74; $P<.001$), self-efficacy (5.23, SD 1.92 vs 3.96, SD 1.77; $P=.02$), and knowledge application (6.46, SD 1.33 vs 1.91, SD 1.40; $P<.001$). Interviewees reported increased ICT use in services and considered i-TLS an acceptable and supportive tool for learning and practice, especially during the pandemic.

Conclusions: i-TLS is acceptable to social workers and enhances their learning and use of ICT in family services. This was achieved through access to self-directed and collaborative learning and sharing of experiences within their practice. Further research on enhancing web-based platforms is needed to expand participation and capacity building among social workers and other health and social care professionals.

Introduction

Background

Widespread use of information and communication technology (ICT) has revolutionized human communications and the way social work practitioners and clients connect [1]. This has fueled the demand for ICT use in social work practice to improve service delivery and benefit society [2]. Social workers can choose from a wide range of ICT service delivery options, such as web-based counseling, self-help web-based interventions, social networking, email, and SMS text messaging [3], that have enhanced their availability and interaction with individual clients and specific groups and achieved better intervention outcomes [4,5].

Traditional face-to-face training with a fixed schedule and venue has restricted its reach and social workers' opportunities of learning. Skill and knowledge exchanges are limited and often confined to colleagues within the same center or organization. Before the COVID-19 pandemic, despite the potential benefits of ICT use, many social workers were hesitant to adopt ICT at work [6]. This may relate to the importance of in-person relationships in social work or the constraints on resources and knowledge in digital practice. Limited digital competence may hinder social workers from realizing the potential of ICT to support their practice. With limited exposure to a technology-rich environment, it will be more difficult for social workers to integrate technology into service effectively [4,7]. This in-person learning approach is essential but not sufficient as a method to meet the needs of the fast-growing digital practice.

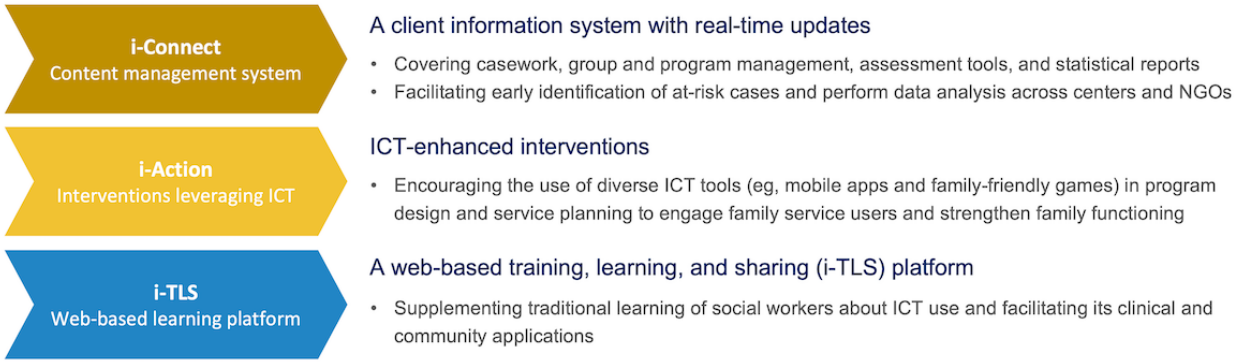
Conducting traditional teaching or on-site training can be challenging in certain situations, such as a pandemic [8,9]. The COVID-19 pandemic has significantly changed the context of ICT use in social work practice and learning. Owing to the unprecedented suspension of all nonessential in-person services, social workers are forced to rely on ICTs for most practice and communication with clients. Without preparation, an emerging and instant difficulty for social workers is how to transit and effectively use ICT to maintain service [10,11]. This urgent situation necessitates social workers to adopt more asynchronous and shared approaches to learning. They need a space where they can quickly access updated information and share a body of knowledge, tools, and ideas and learn from each other about how to improve web-based services and outcomes. During these challenging times, a web-based learning platform can offer timely support in providing essential learning resources at social workers' fingertips and leveraging technology to create a learning community that can benefit practice in the long term. Our search of PubMed and Social Care Online, using keywords such as *social work* and *online learning* or *digital learning* or *learning platform*, up to July 27, 2021, found only 1 study [12] on creating a platform for social work clinical practice in a health care setting; however, none were found on the development and evaluation of a web-based platform for social workers to learn about ICT use in family services.

The Hong Kong Jockey Club SMART Family-Link Project, funded by The Hong Kong Jockey Club Charities Trust since 2018, is a collaboration between the School of Public Health and the Technology-Enriched Learning Initiative of the University of Hong Kong (HKU) and 26 Integrated Family Service Centers and Integrated Services Centers operated by 12 nongovernmental organizations (NGOs) in Hong Kong. The goal of the project is to develop an advanced family service delivery system through the cost-effective use of ICT to support and enhance service delivery so as to promote family health, functioning, and well-being. Before this project, ICT use was minimal across the family service centers [13].

Apart from public education to promote family well-being by the HKU project team, the project includes design and development in close collaboration with all Integrated Family Service Centers or Integrated Services Centers of an i-Connect system and an i-Action component for promoting the use of ICT in preventive family service delivery. The i-Connect system includes a client information system, casework, group and program management, assessment tools, and statistical reports. It helps to reduce administrative work, facilitate the early identification of at-risk cases, and perform data analysis across centers and NGOs. i-Action promotes the use of ICT in program design and planning in services by cocreating a wide range of ICT tools with NGO partners. The tools include e-message portals, mobile apps, and family-friendly games to engage target families and further enhance service reach. As part of the project, an innovative web-based training, learning, and sharing platform (i-TLS) was developed, in parallel, to supplement the traditional learning of social workers regarding ICT use and facilitate its clinical and community applications. It is a multicomponent and web-based platform comprising social work and ICT-specific information covering tips and training in applying ICT to family services from counseling, program design, and implementation to evaluation.

The i-Connect system was launched in May 2020, and i-Action had its first ICT-enhanced program implemented in early July 2018. Throughout the implementation process, i-TLS provided additional training support and important information tied to i-Connect and i-Action. A summary of the project components—i-Connect, i-Action, and i-TLS—is presented in Figure 1, and the interface of the i-TLS components is presented in Multimedia Appendix 1.

Figure 1. Overview of the three project components (i-Connect, i-Action, and i-TLS). ICT: information and communication technology; NGO: nongovernmental organization.



Objectives

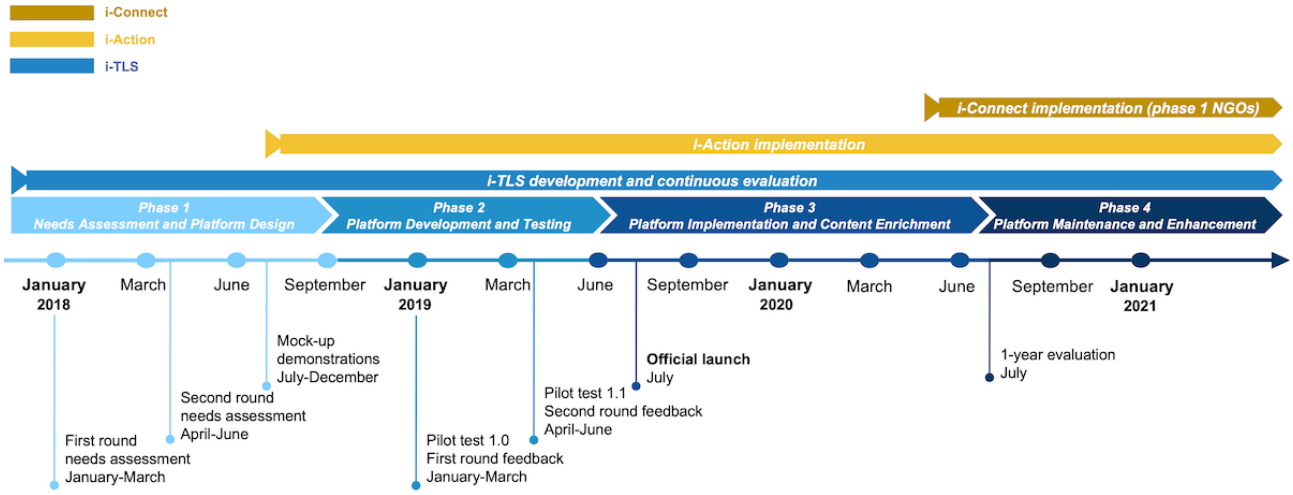
More than a website for information sharing, i-TLS encourages the collective wisdom of large groups of social workers to address the challenging conditions of the COVID-19 pandemic and facilitate ICT-enhanced services. Users are expected to improve their knowledge and skills in using digital tools in ways that benefit the values of the social work profession, enhancing service quality, efficiency, and experience. The aim of this paper is to provide an overview of the i-TLS design and development for social workers to learn about ICT use in family services and evaluate its acceptability and impact in its first year using both quantitative and qualitative methods.

Methods

i-TLS Design and Development

By integrating the principles of asynchronous and collaborative learning, i-TLS was developed based on a 4-phase model with a continuous evaluation that spanned the 4 phases. Figure 2 shows the development of i-TLS and the other 2 project components.

Figure 2. The development of the innovative web-based training, learning, and sharing platform (i-TLS) in 4 phases and the other 2 project components. NGO: nongovernmental organization.

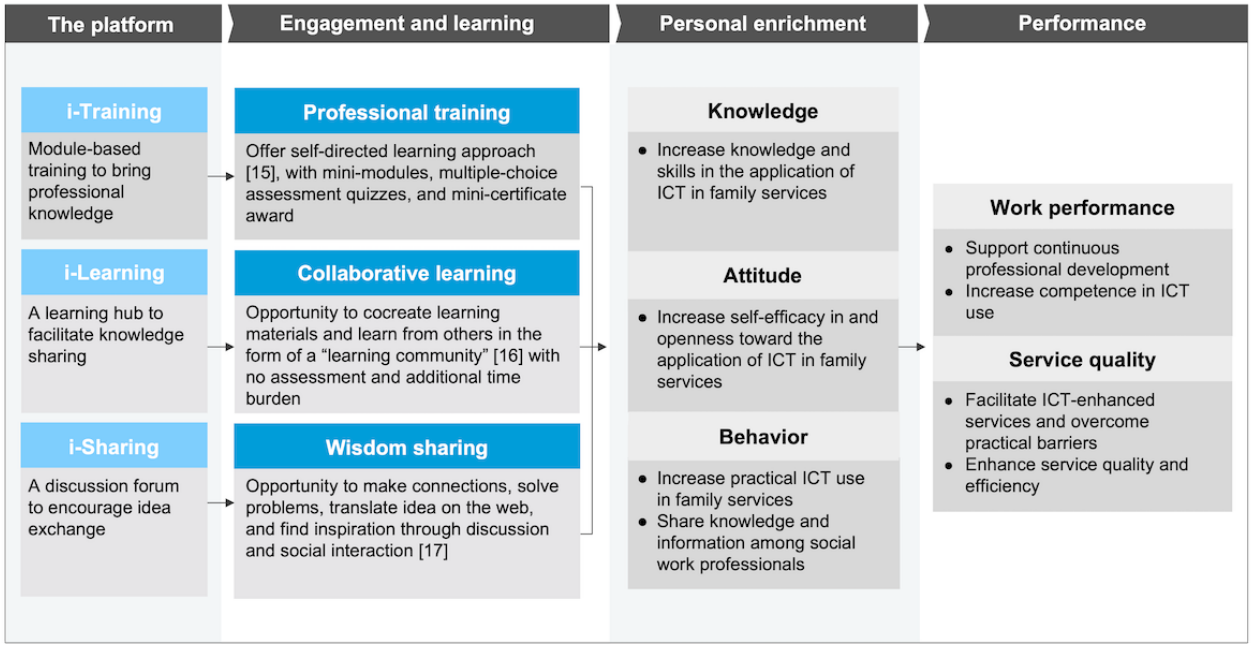


Phase 1: Needs Assessment and Platform Design

Overview

From January 2018 to June 2018, 16 face-to-face focus groups were conducted with 12 NGO partners to understand their learning needs, attitudes, and barriers to ICT use. Some of them participated twice as they have different centers across service boundaries. Overall, 108 social workers, including 28 (25.9%) supervisors and 80 (74.1%) frontline workers, participated. Approximately 61.1% (66/108) of them were women, and the median number of participants per group was 5 (range 3-21). Qualitative methodologies are optimal when the researcher wants to examine participants' views and experiences [14]. Semistructured interviews with open questions allow for flexibility and the discovery of more in-depth information that is important to participants and researchers. The information was analyzed to help design the i-TLS content and format. The design of the individual components (i-Training, i-Learning, and i-Sharing) and their theoretical backgrounds are shown in Figure 3 [15-17].

Figure 3. Overview of the innovative web-based training, learning, and sharing platform (i-TLS) components [15-17]. ICT: information and communication technology.



i-Training

i-Training adopts a self-directed learning approach [15], which includes self-monitoring and self-evaluation mini-modules designed by a multidisciplinary team of health, ICT, and social work professionals for materials that are considered to be most important, including 4 categories: data privacy and system security, ICT use in practice, program evaluation and ICT tools. On the basis of the concept of cognitive load theory [18-20], the contents were designed as mini-modules with multiple-choice assessment quizzes that can be completed in approximately 15 minutes to prevent information overload. It has been suggested that minimizing the extraneous load enables more working memory resources to be available that facilitate learning [20,21]. Social workers who completed a mini-module with a score of ≥50% in a quiz were awarded a digital mini-certificate. They could re-enroll or retake the module anytime.

i-Learning

i-Learning is a learning hub with no assessment. It adopts a flexible and collaborative approach that encourages social workers from different centers to join a colearning circle with less time burden than traditional methods. Social workers cocreated learning materials and tip packs, including sharing of successes and lessons learned in ICT-enhanced practice, with the HKU project team and shared any resources that are useful for social services. The contents are shareable, practical, and high-yield educational, benefiting social workers in the form of communities of practice through sharing their common concerns, learning from each other's experiences and growing in their practice [16]. We aim to support such communities of practices to enhance social workers' training and services that are frequently absent in the bustling clinical learning environment.

i-Sharing

i-Sharing is a sharing and discussion forum through which social workers can interact and exchange ideas on topics related to their professional interests or project information. They can also post questions, remarks, and comments on the training and learning resources to support ICT use in social services and professional development in social services and professional development. Through this process, users have the opportunity to make connections, solve problems, and find inspiration from others, which are crucial factors in learning [17]. Their feedback also guided us in platform improvements and planning.

Phase 2: Platform Development and Testing

We consolidated the learning content and multimedia tools. A series of digital learning resources with videos, graphics, and quizzes was created for a mock-up. Showing a video can provide easier understanding than a text description of complex ideas or procedures [22], whereas these diverse formats of web-based learning materials with quizzes may increase users' engagement in web-based learning use. Every feature of the platform was tested with all participating users in 2 pilot tests from January 2019 to June 2019 to ensure the usability of the platform and identify key challenges.

Phase 3: Platform Implementation and Content Enrichment

On the basis of the users' feedback, we conducted a thorough review of the platform and made the necessary adjustments before implementation. i-TLS was officially launched for all supervisors and frontline workers of 12 NGO partners on July 1, 2019. In parallel, we continued to enrich the learning content and facilitate cocreation with NGO partners. A series of training and learning resources, such as practical tips, prototypes, manuals, and video tutorials, was uploaded to i-Training and i-Learning on a regular basis.

Phase 4: Platform Maintenance and Enhancement

To enhance the users' experience, we worked with web developers to conduct platform maintenance. All information from the continuous evaluation was analyzed and incorporated into a new platform design to enhance navigation, display, layout, and user engagement.

Continuous Evaluation

As the HKU project team interacted with the NGO partners, their feedback and needs emerged through both formal inquiries and informal conversations. Collective platform use and activity data were reported to stakeholders each month to evaluate the development and progress of the platform. Approximately 1 year after launching i-TLS, we used the platform database, Google Analytics, a self-administered anonymous survey questionnaire, and individual phone interviews to assess its acceptability and impact in facilitating social workers' learning and ICT-enhanced family services.

Process Evaluation

Acceptability: Use

We assessed acceptability based on the number of registered and active users, platform use, and reactions to the platform. Registered users were those who were registered with i-TLS during the evaluation period (from July 1, 2019, to July 31, 2020). Active users were those who accessed i-TLS at least once in the past 28 days. Platform use included frequency of use and platform activity. Frequency of use was assessed using Google Analytics data on the duration and number of pages per visit and the following survey item: "In the past 3 months, to what extent did you use the platform?" Responses were given on an 11-point Likert scale ranging from *0=never* to *10=every day* and were analyzed as light users (score of 0-3), occasional users (score of 4-5), and frequent users (score of 6-10). Platform activity was directly assessed using the platform database on the number of mini-module completions and discussion posts, as well as Google Analytics data on the number of page views.

Acceptability: Reaction to Platform

The users' reactions to i-TLS were assessed using 2 survey items and phone interviews to cover their overall satisfaction with i-TLS and their likelihood of recommending it to others. Survey respondents were asked, "In general, how satisfied have you been with i-TLS?" and "How likely will you recommend the platform to other colleagues?" Responses were given from *0=very dissatisfied* to *10=very satisfied* using a dichotomous scale—*yes* and *no*—respectively.

Outcome Evaluation

Impact on Learning

We assessed the impact of i-TLS on learning and behavior. Learning was assessed using 2 survey items: "To what extent did you gain knowledge of applying ICT to family services?" and "To what extent did you feel confident in applying ICT to family services?" Responses ranged from *0=not at all* to *10=very highly increased*.

Impact on Behavior

We assessed the impact of i-TLS on learning using 2 items on the frequency of knowledge application and sharing: "In the past 3 months, how often did you apply the acquired knowledge to family services?" and "In the past 3 months, how often did you share the content of the platform to your colleagues in family services?" Responses ranged from *0=not at all* to *10=every day*.

We also conducted semistructured individual phone interviews with both supervisors and frontline workers to explore the usefulness of i-TLS for learning and practice and the practical barriers to ICT use in service.

Ethics Approval

Ethical approval was granted by the Institutional Review Board of HKU and Hospital Authority Hong Kong West Cluster (UW19-449) on July 11, 2019. This study was also registered at the National Institutes of Health (NCT04034420) on July 29, 2019. All participants provided web-based written informed consent at the beginning of the study.

Data Collection

From July 2020 to August 2020, we invited all 313 users (n=23, 7.3% supervisors and n=290, 92.7% frontline workers) to complete a self-administered anonymous survey questionnaire via email. A total of 168 users (n=18, 10.7% supervisors and n=150, 89.3% frontline workers) responded to our survey, and the 12 users (n=3, 25% supervisors and n=9, 75% frontline workers) who indicated willingness were randomly selected to participate in individual phone interviews from August 2020 to September 2020. The first author (MTMS) conducted and recorded all interviews, each lasting approximately 10 to 20 minutes with a mean of 15 minutes.

Data Analysis

Quantitative analyses were performed using SPSS Statistics (version 25.0; IBM Corp). One-way ANOVA followed by post hoc tests was used to compare the means between subgroups (light users, occasional users, and frequent users). All significance tests were 2-sided, with $P<.05$ indicating statistical significance. Effect size (Cohen *d*) was calculated with values of 0.2, 0.5, and 0.8 indicating small, medium, and large effects, respectively [23].

Phone interview data were analyzed using NVivo (version 12; QSR International) and thematic analysis [24]. Thematic analysis is a method of analyzing qualitative data that provides a rich account of the data collected [24]. In this study, it was used as a realist method to report the experiences of users. Transcripts were coded by the first author (MTMS) and a research assistant of the project, with guidance from an experienced researcher (AYKL). Themes were coded deductively based on the outcome assessment at the manifest level to provide personal insights and practical examples for social work professionals and researchers. Coding was conducted systematically, and the identified themes were reviewed and refined continually to ensure that they reflected the original meaning of the data set.

The consistency of an independent coder attributing themes is often used as a method of checking the reliability in qualitative methods [25]. Coding was conducted systematically, and the identified themes were reviewed by the experience researcher (AYKL) and refined continually to ensure that they reflected the original meaning of the data set. In total, 2 independent researchers were given the codebooks and interview excerpts and asked to code the excerpts using the themes to check the reliability of the themes.

Results

Survey Respondent Characteristics

Table 1 shows that 72% (121/168) of respondents were women, 49.4% (83/168) were aged 30 to 39 years, and 84.5% (142/168) had a degree or higher education. Approximately 89.3% (150/168) were frontline workers, and 52.4% (88/168) had at least 9 years of social work experience. Approximately 59.5% (100/168) had registered with the platform for <1 year.

Table 1. Characteristics of the survey respondents (N=168).

Characteristic	Survey respondents, n (%)
Sex	
Male	47 (28)
Female	121 (72)
Age group (years)	
18-29	43 (25.6)
30-39	83 (49.4)
40-49	31 (18.5)
≥50	11 (6.5)
Education level	
Diploma, subdegree, or below	26 (15.5)
Degree or above	142 (84.5)
Post	
Frontline worker	150 (89.3)
Supervisor	18 (10.7)
Social work experience (years)	
0-2	35 (20.8)
3-8	45 (26.8)
9-15	88 (52.4)
Registration duration (years)	
<1	100 (59.5)
≥1	68 (40.5)

Overview of Qualitative Themes

The phone interview data provided a deeper understanding of user views and experiences using i-TLS and ICT in social services. Textbox 1 shows the 5 key subthemes that emerged from our data analysis.

Textbox 1. Overview of qualitative themes.

Themes and subthemes

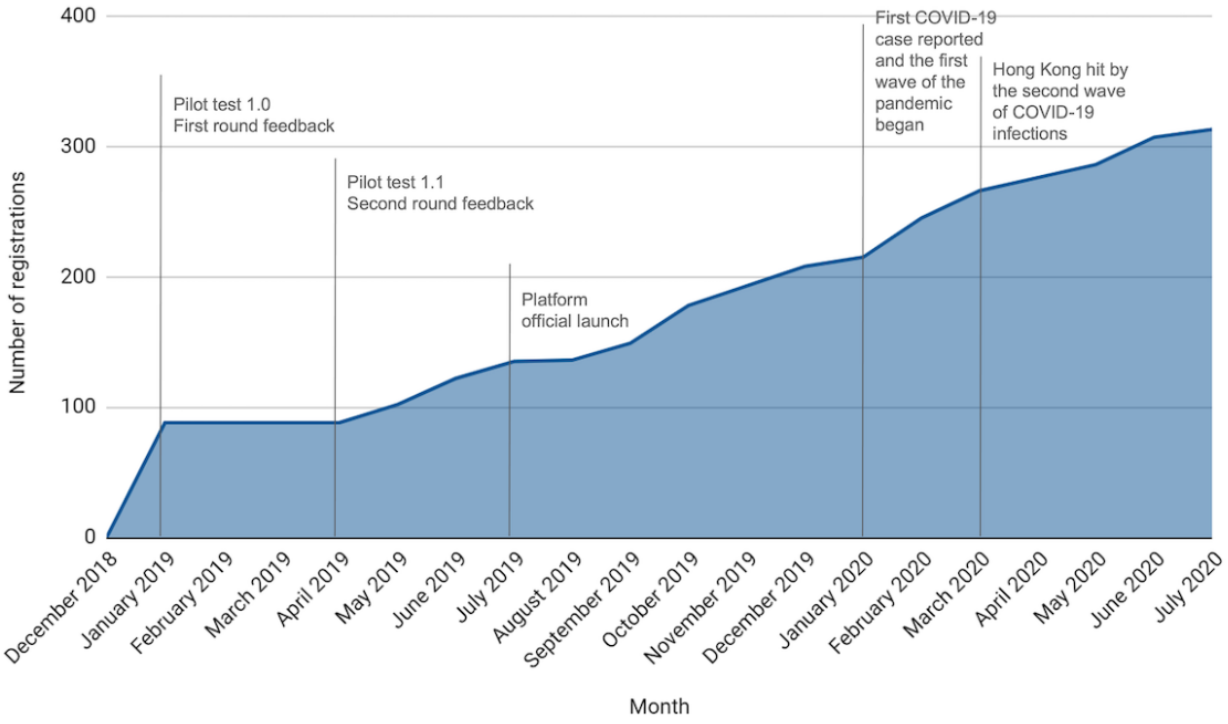
- Reactions to innovative web-based training, learning, and sharing platform
  - Enabled access to self-directed learning and resources
- Impact on learning
  - Enhanced memorization and application of information and communication technology (ICT) in services
  - Facilitated knowledge transfer through collaborative learning
- Impact on behavior
  - Increased openness and ICT use
  - Barriers to effective ICT-enhanced practice

Acceptability

Registered and Active Users

Figure 4 shows that i-TLS was launched to 135 initial users on July 1, 2019. The number of users has substantially grown thereafter. During the first wave of the COVID-19 pandemic, the number of users rose from 215 in January 2020 to 245 (14%) in February 2020. By July 31, 2020, 313 users (n=23, 7.3% supervisors and n=290, 92.7% frontline workers) from 12 NGO partners had registered. Six NGO partners reached a 100% registration rate the registration rates of the remaining 6 NGO partners ranged from 5.2% to 57.1% by July 31, 2020. Although the number of users doubled in a year, Google Analytics showed that 79.6% (249/313) of the users were active in the past 28 days during the evaluation period.

Figure 4. Registration trend since the platform pilot launch as of July 31, 2020.



Platform Use

Overview

The average duration of the visits was 4.3 minutes. The average number of visits per user per day was 3.2, and the average number of pages per visit was 4.8. Of the 168 survey respondents, 76 (45.2%) were light users, 79 (47%) were occasional users, and 13 (7.7%) were frequent users. On the basis of the platform database and Google Analytics data, the most commonly visited resources across i-Training, i-Learning, and i-Sharing were related to ICT use in practice.

i-Training

A total of 41 mini-modules in 4 categories were created and uploaded to i-Training from July 1, 2019, to July 31, 2020. Table 2 shows a total of 730 enrollments in the mini-modules, with 70% (511/730) awarded digital mini-certificates. Training on data privacy and system security had the highest average number of enrollments, with 71.5% (271/379) completion.

Within each of the 4 categories, mini-modules *Data Best Practice*, *The Application of E-messaging Intervention in Services*, *The BACK* Model, and *i-Connect System—Group/Program Enrolment* were the most popular, with 90.9% (50/55), 80% (28/35), 78% (18/23), and 75% (6/8) completed, respectively.

Table 2. Number of enrollments in and completions of the 41 mini-modules in i-Training.

Category	Minimodules (N=41), n (%)	Enrollments (N=730), n (%)	Enrollments per mini-module, mean (SD)	Completions[a] (N=511), n (%)	Completions[a], mean (SD)	Completion rate (%)
Data privacy and system security	13 (32.3)	379 (51.9)	29.2 (13.1)	271 (53)	20.8 (13)	71.5
ICT[b] use in practice	5 (12.2)	127 (17.4)	25.4 (18)	94 (18.4)	18.8 (16)	74
Program evaluation	3 (6.8)	72 (9.9)	24.0 (1)	54 (10.6)	18.0 (0.5)	75
ICT tools	20 (49.4)	152 (20.8)	7.6 (4.9)	92 (18)	4.6 (3)	60.5

[a]Including all who completed the post–mini-module quizzes with an overall score of ≥50% and were awarded mini-certificates.

[b]ICT: information and communication technology.

i-Learning

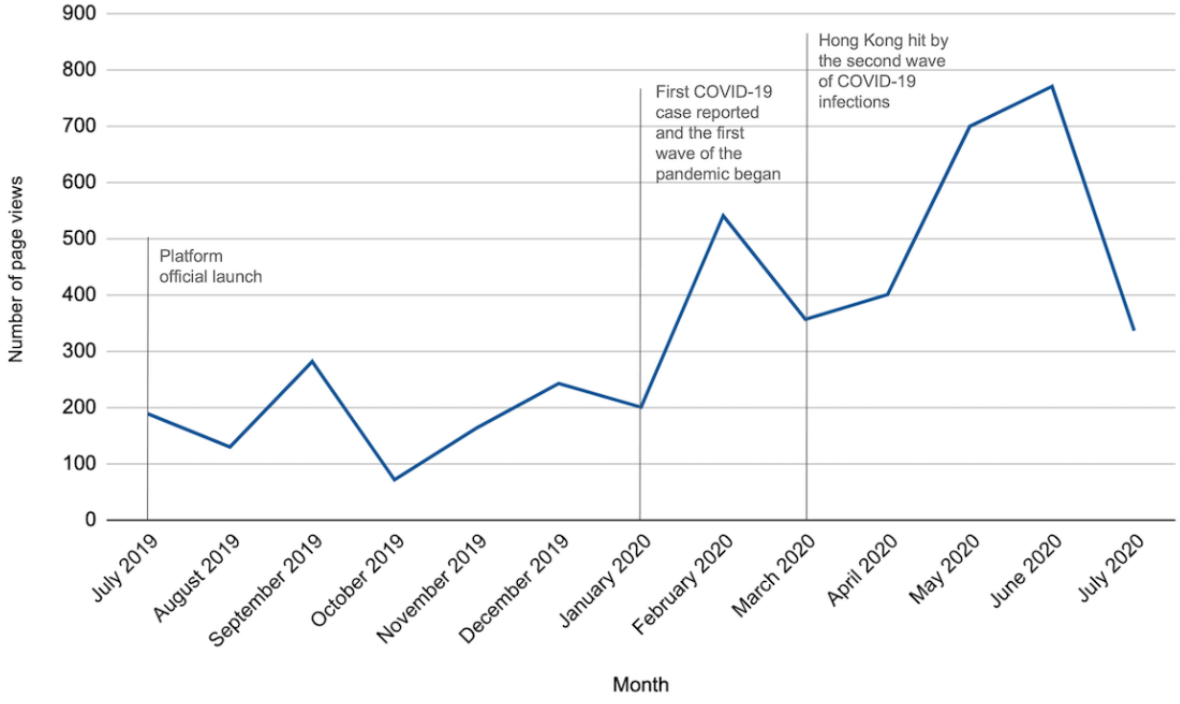
A total of 112 items of learning resources were created and uploaded to i-Learning from July 1, 2019, to July 31, 2020, with 4388 page views recorded from Google Analytics. Table 3 shows that the item with the highest average number of page views was experience sharing of ICT use in practice, followed by ICT tools and games. Figure 5 shows the number of page views by month for the period from July 1, 2019, to July 31, 2020. The number of page views maintained steadily between 100 and 300 in the first 6 months but increased sharply from 201 in January 2020 to 541 following the first COVID-19 case reported. The number of page views slightly dropped in March 2020 but rebounded and surged to 771 in June 2020 after the second wave of the COVID-19 pandemic hit in mid-March.

Table 3. Number of items and page views in i-Learning.

Category	Items (N=112), n (%)	Page views (N=4388), n (%)	Page views per item, mean (SD)
Experience sharing of ICT[a] use in practice	8 (7.13)	696 (15.86)	87.0 (27.7)
ICT tools and games	54 (48.18)	3116 (71.01)	57.7 (18.9)
Professional practice	50 (44.64)	576 (13.13)	11.5 (5.7)

[a]ICT: information and communication technology.

Figure 5. Number of page views in i-Learning by month from July 1, 2019, to July 31, 2020.



i-Sharing

A total of 25 discussion threads with 59 posts, including all the replies and follow-up comments, were posted in the i-Sharing forum from July 1, 2019, to July 31, 2020. Approximately 75% (9/12) of NGOs created at least one post, with a median of 2.5 posts. Table 4 shows which ICT tools and their uses had the highest average number of posts per thread, followed by project information.

Table 5 summarizes the number of activities in i-Training, i-Learning, and i-Sharing, as well as the number of project target deliverables. The number of activities of each platform component exceeded the targets by 190% to 3224%.

Table 4. Number of discussion threads and posts in the i-Sharing forum.

Category	Threads (N=25), n (%)	Posts (N=59), n (%)	Posts per thread in each category, mean (SD)
ICT[a] tools and use	8 (32)	41 (70)	5.1 (2.30)
Project information	8 (32)	9 (15)	1.1 (0.35)
Professional practice	9 (36)	9 (15)	1.0 (0)

[a]ICT: information and communication technology.

Table 5. Target deliverables and output activities for i-Training, i-Learning, and i-Sharing.

Component	Target deliverables, N	Output activities, N	Target (%)
i-Training (module completions)	141	511	362.4
i-Learning (page views)	132	4388	3324.2
i-Sharing (posts)	31	59	190.3

Reactions to i-TLS

Satisfaction with i-TLS on a scale of 0 to 10 showed a median of 5 (IQR 5-7). Table 6 shows a significant difference in satisfaction according to the frequency of use (P<.001). Frequent and occasional users showed significantly higher satisfaction than light users, with moderate to large effect sizes (Cohen d=0.68-0.80). However, we found no differences between frequent and occasional users. In addition, 74.4% (125/168) of respondents would recommend i-TLS to their colleagues.

In individual phone interviews, the respondents reported that the typical busy schedule of family services made it difficult for them to find resources and learn. i-TLS helped overcome barriers in traditional face-to-face settings, in particular during the COVID-19 pandemic when almost all communication with others shifted to the web. Social workers highlighted the benefits of web-based learning with increased access to resources and reach to colleagues, which provided a good way of continuing development and maintaining service:

> *I think it is good because it's accessible to us when we need the resources. It is much easier on a web-based platform, where I could learn anywhere at any time...As you know, we always have a busy schedule in service. With i-TLS, we can revisit the webinars or other resources at our convenience.* [Frontline worker, male, 7-8 years of experience]

> *Training and learning that are related to ICT are really rare in social work...except your project. So I think it is quite nice to have many different ICT resources available on a web-based platform. You know, the COVID-19 situation has forced us to adapt to online learning and service.* [Supervisor, male, 9-15 years of experience]

> *Family services are very busy...especially when the pandemic doesn't always allow us to meet face-to-face. It is hard for us to keep everyone updated and teach colleagues how to use ICT tools for program activities as we seldom meet each other. The platform allows us to learn and read through the training resources at our own pace.* [Frontline worker, female, 7-8 years of experience]

Table 6. Survey respondents' satisfaction with i-TLS and change in knowledge, self-efficacy, and behaviors in applying information and communication technology in family services (N=168).

Variable	Platform users[a], mean (SD)			Platform users[b], Cohen *d*			Platform users[c], *P* value		
	Light users (n=76)	Occasional users (n=79)	Frequent users (n=13)	Occasional vs light users	Frequent vs light users	Frequent vs occasional users	Occasional vs light users	Frequent vs light users	Frequent vs occasional users
Reactions to i-TLS[d,e]									
Satisfaction	4.99 (1.54)	6.15 (1.34)	6.31 (2.29)	0.80	0.68	0.09	<.001	.01	.94

[a]*P* value for differences between innovative web-based training, learning, and sharing platform users (3 groups) <.001 in all cases.

[b]Effect size (Cohen *d*): small=0.20, medium=0.50, and large=0.80.

[c]*P* value for the difference between innovative web-based training, learning, and sharing platform users (2 groups).

[d]i-TLS: innovative web-based training, learning, and sharing platform.

[e]11-point Likert scale ranging from 0 to 10 (0=very dissatisfied, 3=dissatisfied, 5=half, 7=satisfied, and 10=very satisfied).

[f]11-point Likert scale ranging from 0 to 10 (0=not at all, 3=slightly increased, 5=moderately increased, 7=highly increased, and 10=very highly increased).

[g]11-point Likert scale ranging from 0 to 10 (0=not at all, 3=seldom, 5=sometimes, 7=almost every day, and 10=every day).

Impact

Impact on Learning

Table 6 shows significant differences in the change in knowledge and self-efficacy in applying ICT to family services according to the frequency of use (*P*<.001). Frequent and occasional users showed a significantly greater increase in knowledge and self-efficacy than light users, with moderate to large effect sizes (Cohen *d*=0.69-1.13). However, we found no differences between frequent and occasional users.

In individual phone interviews, respondents appreciated that the learning resources were easy to understand, which facilitated memorization and application in their daily practice. The web-based shared resources were easy to retrieve and helped reinforce their ICT skills in program implementation:

> *Many of our services are changing from offline to online now. Those video tutorials on ICT tools really help us a lot, as our colleagues are not active ICT users and do not know how to use them. The videos teach us step-by-step and we know how to use Zoom and other tools to conduct online programs now.* [Frontline worker, female, 9-15 years of experience]

> *The recommended ICT tools and other resources on the platform are informative and easy to use. They help strengthen our ICT skills and stimulate ideas in online program implementation. They also help us maintain online services during the pandemic.* [Frontline worker, male, 3 years of experience]

> *The game demonstration videos helped remind me of things I had done and learned from other NGO partners during the project launch. Sometimes, I might have forgotten and am not sure how it [the game] works, so it is nice to have that documentation...I will follow the steps and do it again in my program.* [Frontline worker, male, 9-15 years of experience]

Respondents also believed that i-TLS facilitated knowledge transfer within their professional practice. They especially enjoyed learning from the experiences of workers from other centers. Sharing information in i-TLS boosted their confidence and was highly applicable to their service, which benefited everyone by filling the gaps between knowledge and practice. It also built an environment of colearning:

> *I guess it [i-TLS] is like a learning hub...we are learning together. We have more confidence in applying ICT after reading others' experience sharing. Their sharing provides us concrete ways of implementation, which also helps stimulate new ideas in practice. It is nice to learn from others.* [Frontline worker, male, 5-6 years of experience]

> *We like something practical...my colleagues and I like skimming through the examples of the program plans and designs from other workers. They are very good ideas for reference. It helps facilitate our*

> *learning through knowing how to do it in practice.* [Frontline worker, female, 7-8 years of experience]
>
> *Many social workers from other family centers shared their experiences in applying ICT to engage vulnerable families. I learned a lot of practical skills from their experiences and was able to apply them to my work.* [Frontline worker, male, 1 year of experience]

Impact on Behavior

Table 6 shows significant differences in applying and sharing knowledge according to the frequency of use (P<.001). Frequent and occasional users showed a significantly greater increase in applying and sharing the acquired knowledge in family services than light users, with large effect sizes (Cohen d=1.79-3.33). Frequent users also showed a significantly greater increase in applying the acquired knowledge to family services than occasional users, with a large effect size (Cohen d=1.55). However, we found no differences between frequent and occasional users in knowledge sharing.

In individual phone interviews, respondents had mixed views on whether ICT tools should be used or how they should be supported in family services. In general, respondents felt that ICT offered many benefits, and they saw the potential use of ICT in family services after knowing more about ICT and its related resources. They became more open to ICT and increased ICT use in family services:

> *It was challenging to my colleagues when it started, especially to those who were not active ICT users...But we see the advantages of them and more of our colleagues are using ICT in service now. The materials on the platform are good sources for us to start off.* [Supervisor, female, 9-15 years of experience]
>
> *I see my colleagues changing their attitude toward ICT use after using the platform. In the past, they were very reluctant to apply ICT tools. Most of them preferred face-to-face as their usual practice. However, they are more willing to incorporate ICT tools into their program now. They also take the initiative to explore the ICT tools on i-TLS and use more ICT in their program.* [Frontline worker, male, 2 years of experience]

However, a few respondents were not very positive. Some remained hesitant about adopting ICT in family services. They reported that barriers included the absence of human quality and emotional bonding during counseling. How to navigate the electronic environment to effectively apply learning to an in-person practice setting remains a challenge to some social workers:

> *Counseling is somewhat relational that involves human interactions and emotional bonding while ICT is more informative...I think counseling cannot be replaced by ICT completely. We need to think about how to flexibly incorporate ICT into this ever-changing environment and to facilitate current service.* [Supervisor, male, 9-15 years of experience]
>
> *ICT might be useful, but it does not play a large role in motivating service users and enhancing the counseling process. Face-to-face interaction is still a priority in our service, especially in casework.* [Frontline worker, female, 1 year of experience]

Service users' ability to use ICT could also affect social workers' attitudes and use of ICT tools during program activities. Indeed, as the respondents reported, not all service users were information technology–literate and had access to electronic devices, which was essential for ICT use. Therefore, social workers usually preferred adopting simple or usual ways in their practice to meet the needs of service users:

> *So...the way things work usually for our service users is very much sort of pen and paper. The outcomes can be very different from using a laptop or smartphone for many of our service users. We need to think carefully about what devices or ICT tools suit our service users...we usually go back to the basics or stick to the old practice.* [Frontline worker, male, 3 years of experience]

Discussion

Principal Findings

We have reported the development and evaluation of a web-based platform aimed at supporting social workers' learning during the early stage of digital transformation in social work family practice. The results provided insights into the acceptability and impact of an innovative learning platform with 3 different components and learning approaches. Overall, we enrolled 313 social workers, with around 80% (249/313) of active users at 13 months. The demographic characteristics of the respondents revealed similar trends to those in the statistics report from the Hong Kong Social Workers Registration Board [26]. Although the pandemic might have led to more ICT use and targets being exceeded, the continuous increase in the number of users and platform activity showed that the platform was acceptable and useful in its first year but with room for further improvements and increase in use. Users were satisfied with the platform, and more frequent users showed increased knowledge, self-efficacy, and use of ICT in services compared with light users. Through focus groups and individual phone interviews, we found nuances in motivation and behavior change, which gave us a better understanding of how this platform influenced the learning of social workers and their clinical practice.

Users in this study were positive about the potential use of i-TLS in supporting continuous learning. They felt that i-TLS could increase accessibility to learning in a way that might not be possible in traditional face-to-face settings. Some admitted that they felt unease in finding time for learning amid the busy professional duties and time pressures they faced in clinical settings. These findings support previous assertions by clinicians and researchers that the asynchronous and hybrid nature of web-based learning allows for more learning opportunities [12] and provides more access to a wide range of information independent of space and time [27]. These findings are also consistent with a British sample of social workers in a

web-based learning pilot study [28], who also felt that web-based platforms could increase flexibility and autonomy for learning.

Importantly, our data suggest that i-TLS could increase support by reaching more social workers across centers at the point of need, particularly during the outbreak of COVID-19. Given the primary face-to-face nature of social work practice, keeping social workers engaged in such a digital environment is challenging. However, the rapid transformation and need for digitalization in this specific situation necessitated the use of web-based learning and new communication modes to maintain the quality of professional development and service delivery. Training on data best practices and video tutorials on web-based communication tools and creative platforms such as Zoom videoconference, YouTube, and Prezi have become the most popular materials among social workers. Social workers across centers were more willing to use and share information over time as they learned more about the platform's capabilities. Before launching i-TLS, the exchange of information, ideas, and knowledge on ICT use across centers was limited, with little peer collaboration. Although books [29,30] and social work professional bodies such as the National Association of Social Workers and the Association of Social Work Boards [31] have recommended ways of ICT use and set new standards regarding social workers' ability to use ICT in practice earlier, factors such as limited access to ICT-related training and resources mean that many social workers and service users may not be able to receive timely access to the support they need during this difficult time. It is expected that the demand for and use of web-based learning will continue to increase.

We found that frequent users showed a higher score in knowledge and self-efficacy than light users. Users expressed that i-TLS encouraged collaborative learning through sharing of knowledge and experiences in the sense of a learning community. The adopted collaborative learning approach created a peer-to-peer environment that could benefit users' learning through learning from others [32]. As such, knowledge acquisition occurred not only via self-experiences but also indirectly through the experiences of others. Successful presentations with applause and appreciation by peers created a sense of success and positive feeling regarding their learning experiences, which boosted the self-efficacy of both presenters and attendees. According to the self-efficacy theory [33,34], one's self-efficacy increases not only through positive personal experiences but also by seeing others succeed. There has been an increasing awareness and understanding of learning from others within higher education [35,36] and various professions that require clinical practice [32,37,38]. However, this learning approach has not been well-described in the social work learning literature. The cocreating feature of our i-TLS, which fosters the sharing of knowledge and experiences, was identified as a strength by the users.

Despite concerns about human interaction and some practical barriers inherent in ICT tools, the attitude of the participating social workers toward the use of ICT in practice was largely positive and much more open after using i-TLS, especially under the challenges of social distancing measures amid the pandemic. We found that frequent users, who showed higher perceived knowledge and self-efficacy, used ICT in services more frequently. However, some social workers remained hesitant to fully embrace technology and expressed concerns about its practical use, especially in traditional in-person services such as counseling, although they were aware of the benefits of incorporating ICT into their practice. Considering the principles of social work ethics, which value the central importance of human relationships [39], social workers may see ICT as only a supplementary tool and less important. Therefore, those who emphasize the development of in-person relationships may remain struggling to incorporate ICT into practice to maintain emotional bonding with clients.

By contrast, this suggests that the perception of users toward ICT is also a key factor influencing the adoption of ICT. These findings are largely supported by the theory of planned behavior, with one's belief, perceived behavioral control, and intention predicting a behavior [40]. A review of ICT use in Norwegian social work practice [41] also suggested that the perception of new ICT solutions may affect how far and well they spread and evolve according to the diffusion of innovation theory by Roger [42]. Knowing the benefits and understanding alone does not ensure widespread adoption; rather, it requires changes in the values, beliefs, and needs of the adopter. The reluctance of some social workers to use ICT suggests that the information currently available does not adequately address their concerns. With the increasing demand for web-based services and the propensity to seek help on the web [43], it is essential for social workers to master ICT practices from scheduling appointments to program implementation, therapeutic discussions, and counseling. To enhance social workers' professional development, experienced practitioners in the field indeed play an important role in wisdom sharing and providing a clearer understanding of building effective web-based relationships. Their sharing may help lay the foundation for this new trend in using ICT to achieve the desired values of social work. Future educators and researchers should put more effort into ensuring that the ICT training content promotes both professional and technical improvement and enhancement of services.

Limitations

This was the first evaluation of i-TLS approximately 1 year after its official launch [13]. Our study had some limitations. The survey sample size and response rate were not great. This is similar to those reported in the literature [44], which showed a relatively lower participation rate of social workers on a learning and sharing platform than other service providers across care centers. Owing to the busy schedule in family services, especially challenges from the pandemic, many social workers were not able to set aside the time to use the platform or complete the survey questionnaire. In addition, the culture of some agencies relied on the coordinator to collate information, which further limited social workers' self-learning and individual access to the platform. Before the SMART Family-Link Project, most participating social workers were in the same form of training or work environment with very limited exposure to ICT in their centers. i-TLS was their first web-based learning platform, and some would be slow to join and adopt it. Moreover, we did not have objective data on knowledge and behaviors, and self-reported data might be subject to social

desirability bias. Objective assessments in future research are warranted. Consequently, our results might not be generalizable to all social workers and other social welfare services. Nevertheless, these limitations should not detract from our findings, which suggest that the participating social workers were eventually well-versed in the benefits of and barriers to ICT use in family services.

Recommendations

The feedback from i-TLS users revealed some important elements that researchers and technical developers need to consider when developing web-based learning platforms, whereas the results of this evaluation also underscored the need for further enhancement of the platform to help social workers learn. Additional promotion and engagement are required to further increase the use and ensure that social workers receive sufficient support to access web-based resources. Attempts are continuously being made to improve the i-TLS platform's layout and functionality. A revamped version of i-TLS was officially launched on June 28, 2021, and access to the site can be provided upon request. From the results of this study, literature reviews, and social work feedback, we propose several recommendations (Textbox 2).

Textbox 2. Recommendations for the development of web-based learning platforms.

Recommendations for the web-based learning format

- The accessibility, convenience, and simplicity that came from the platform and digital resources were valued.
- Videos, including animations, module recordings, and demonstration clips, were the preferred types of e-learning resources among participating social workers, which should be considered in future web-based learning design in social work curricula.
- Various formats of web-based learning and their combinations, including videos, animated clips, text documents, or links to external web-based resources, as opposed to a single delivery mode, may address a diversity of needs and increase the users' engagement. Further research on the effectiveness of using web-based learning and training by integrating various formats of learning is needed.
- More graphics, animated text documents, and illustrations should be provided to increase user engagement and adherence. As suggested by Keller and Suzuki [45] in a motivation model of instructional design, the learning process begins by providing knowledge and information using multimedia such as animation videos, text, and illustrations to gain and sustain attention.

Recommendations for professional development

- Training and resources that facilitated applicability in services bridged the gaps between knowledge and practice, which were perceived as important to social workers' professional development.
- Sharing of experiences supported social workers' learning process and created valuable content that maximized their experiential learning.
- Documentation of procedures helped memorization and reinforced social workers' skills in practice.
- The learning together environment provided a potential means by which social workers could be inspired and then generate more creative ideas that benefited their services. A cocreating nature was identified as a strength by users.
- A diverse collection of learning items should be included to fit the needs of social workers with various backgrounds and interests to increase learning engagement.
- Key leaders in social work and health-related fields sharing valuable resources and feedback may play an essential role in social workers' professional development. Leaders are expected to play active roles in initiating chat topics and sharing valuable insights, which could draw social workers' attention and facilitate more sharing and participation on the platform.

Conclusions

We have shown that the newly developed learning platform for family service social workers is acceptable and effective, as reflected in the substantial growth in platform use and increased knowledge, self-efficacy, and ICT use in family services. Social workers identified some key elements through which i-TLS was perceived to optimize their learning, including enabling access to promote self-directed and collaborative learning and encouraging sharing of experiences within their practice. i-TLS can foster unique collaborations across boundaries by allowing social workers from different service centers to interact and share equally in a colearning environment without time and space constraints. Our results should be a useful reference for researchers, health and social care professionals, and administrators considering developing a web-based learning platform for continuous professional development. Further research on the development and enhancement of web-based platforms to promote and expand the participation and capacity building of social workers and other related professionals is warranted.

Acknowledgments

The authors would like to thank Alice Wan, Ka Yan Ip, and Hilary Pui Yee Ho for their guidance and contributions to the development of innovative web-based training, learning, and sharing platform. The authors also thank Tai On Kwok, Yiu Lun Wong, Chor Pun Tang, and Esther Sze Tsai Lee at the Technology-Enriched Learning Initiative and Hoi Wa Wong at the School

of Public Health for developing the innovative web-based training, learning, and sharing platform initial build. This study was funded by The Hong Kong Jockey Club Charities Trust.

Conflicts of Interest

None declared.

Abstract

Background: We report the use of an electronic tool, Eir (Eir Solutions AS, Norway), for symptom registration at home after knee arthroplasty. This electronic tool was used in a randomized controlled trial (RCT) comparing 3 different analgesic regimens with respect to postoperative pain and side effects.

Objective: The aim of this substudy was to investigate this electronic tool for symptom registrations at home with respect to usability (ie, how easy it was to use) and feasibility (ie, how well the tool served its purpose).

Methods: To assess the tool's usability, all participants were invited to fill out the 10-item System Usability Scale (SUS) after using the tool for 8 days. To assess feasibility, data regarding the participants' ability to use the tool with or without assistance or reminders were collected qualitatively on a daily basis during the study period.

Results: A total of 134 patients completed the RCT. Data concerning feasibility of the web-based tool were collected from all 134 patients. The SUS was completed by 119 of the 134 patients; 70.2% (94/134) of the patients managed to use the tool at home without any technical support. All technical challenges were related to the login procedure or internet access. The mean SUS score was 89.6 (median 92.5; range 22.5-100).

Conclusions: This study showed high feasibility and high usability of the Eir web tool. The received reports gave the necessary information needed for both research data and clinical follow-up.

Trial Registration: ClinicalTrials.gov NCT02604446; https://www.clinicaltrials.gov/ct2/show/NCT02604446

Introduction

Background

Length of hospital stay (LOS) after hip and knee arthroplasty is shorter with modern fast-track surgery [1]. Therefore, symptoms and complications previously observed and treated in the hospital will now occur at home. These include risks for respiratory depression caused by opioid analgesics and infectious complications. Tools for active communication with the patients after early discharge from the hospital will be important to avoid or address these problems.

Benefits of communication via the internet using tablets and smartphones for postoperative follow-up after surgery have been reported by previous research [2-5]. Modern technology can provide detailed postoperative surveillance data at home [2], guide patients in postoperative pain management [3], provide detailed data on postoperative pain development and opioid use [4], and measure recovery of activity level after total joint arthroplasties [5]. Several advantages of using electronic tools for patient-recorded outcomes have been identified, such as fast and direct communication between patient and health personnel, higher data quality and response rates, easier storage of data, easier access to data for both patients and health personnel, access to real-time patient data for health care personnel, and easier connection of different sources of data [6]. Challenges when using electronic tools can be software failure when used at home or user errors, or the tool can be inconvenient and tiresome to use for the patients over time. These factors can lead to missing data [2,3,5]. Electronic tools should be user-friendly and understandable for the patients, and they should be able to obtain the information needed for clinical follow-up. Evaluations of electronic tools related to specific patient populations must highlight these features and should be done before implementing a tool in routine use.

Objectives

We report the use of an electronic tool, Eir (Eir Solutions AS, Norway), for symptom registration at home after knee arthroplasty. This electronic tool was used in a randomized trial [7] comparing 3 different analgesic regimens with respect to postoperative pain and side effects. An electronic tool for symptom registration was initiated to closely monitor the patient's course at home over the succeeding postoperative week. The aim of this substudy was to investigate this electronic tool for symptom registration at home with respect to usability (ie, how easy it was to use) and feasibility (ie, how well the tool served its purpose).

Methods

Study Design

The study was conducted and is reported according to the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist (Multimedia Appendix 1). In a randomized, double-blinded, placebo-controlled study comparing 3 different postoperative analgesic regimens [7], we used a web-based tool, Eir, for registration of patient-reported outcomes and medication [8,9] to evaluate the effect of the pain management and to assess side effects. The web-based tool was used by all patients regardless of intervention arm. We present the results for the full sample regardless of which intervention arm they were allocated to in the randomized controlled trial (RCT), as we did not expect the different postoperative analgesic regimens to influence the patients' ability to use the tool. The patients registered pain levels, medication use, and side effects for the first 8 days after surgery. Two of the postoperative regimens included the use of opioids: oxycodone 10 mg twice daily or tapentadol 50 mg twice daily. All 3 groups had access to immediate-release oxycodone 5 mg as rescue medication for pain. Other sedative medications were not given as a part of the study interventions. Assessment of the tool's usability and feasibility was an integrated part of the trial. To assess the tool's usability, all participants were invited to fill out the 10-item System Usability Scale (SUS) after using the tool for 8 days. To assess feasibility, data regarding the participants' ability to use the tool with or without assistance or reminders were collected qualitatively on a daily basis during the study period.

Patients and Setting

The study was a single-center, prospective, randomized, double-blinded trial carried out in a university hospital setting from November 26, 2015, to November 7, 2018. Patients scheduled for surgery with total knee arthroplasty (TKA) between 18 years and 80 years of age were considered for inclusion in the study. Exclusion criteria were cognitive impairment, inability to read or speak Norwegian, lack of a cell phone or wireless Wi-Fi connection at home, or use of drugs or medical conditions that conflicted with one or more of the study drugs or any of the multimodal basal pain medications given in the study. The trial was completed by 134 patients [7].

The Web-Based Application

Eir is an electronic symptom assessment tool developed by the European Palliative Care Research Centre at the Norwegian University of Science and Technology and St. Olavs Hospital, Trondheim University Hospital for use in cancer care. A separate patient module was designed for patient-reported postoperative symptom assessment and medication registration after fast-track knee arthroplasty. It consisted of measurements of pain and side effects and detailed registration on use of analgesic drugs (Multimedia Appendix 2).

Procedures

Patient-reported data concerning effect and side effects of the pain treatment were registered daily for 8 days by use of Eir on a tablet and transferred wirelessly to the Eir database. The patients used Eir either on their personal tablet or on a tablet supplied by the study (Apple iPad Mini 2, 16 GB). The patients were introduced to the application and the tablet after surgery when awake and after mobilization. All patients were supervised for 2 electronic self-reports while hospitalized, to check that the system was working and that the patient was able to comply with the procedure. To be able to use Eir on tablets at home, the patient had to log on to a wireless Wi-Fi connection, use the correct password to log in, and answer 15 questions regarding use of study drug and other analgesics, pain intensity,

and side effects of analgesics (Multimedia Appendix 2). Pain intensity and side effects were all measured on an 11-point numeric rating scale, from 0 to 10 (Figure 1).

All patients were instructed to self-report on the tablet each day before noon. A reminder was sent by the main author as an SMS if no registrations were received within the agreed time. The patient received a second reminder as a phone call if there were no registrations after the SMS reminder. The patient`s closest relative was contacted if none of these communication methods succeeded. All patients received a paper version of the tablet questions for back-up in case of technical failure.

Figure 1. Picture of the application in use with English text (Norwegian text was used in the study).

Data Collection Instruments

For each patient, the completeness of data, use of reminders, potential user problems, solution to problems, and phone calls were registered for feasibility assessment. Usability was measured by use of the 10-item SUS, which is designed to measure the subjective usability of websites and software [10,11]. The SUS gives a score ranging from 0 to 100, with higher scores meaning better usability. A paper version of the SUS questionnaire was given to the participants on the day of discharge from the hospital, and the participants were instructed to complete the form 8 days after surgery. All patients received a reminder about the SUS form as an SMS and returned the questionnaire by mail.

Two weeks after the operation, all patients were interviewed by telephone as a follow-up, and a global satisfaction score on the pain treatment was registered. The patients were given the opportunity to comment on any part of the treatment and follow-up after the operation.

The participants were grouped into 5 levels of technical skills, or tech groups. The 5 different groups were made by the first author (TR), based on the level of intervention needed to retrieve data (Table 1). The patients' skill levels were compared with the registered data on side effects, drug consumption, age, and gender to assess if such factors could explain the difference in feasibility.

Table 1. Classification of the tech groups.

Tech group	Level of technical skills
1	No intervention was needed.
2	1-2 reminders were provided, but no technical support was needed.
3	Technical support was provided 1 time.
4	Technical support was provided several times.
5	Not able to use the application at all, all data were collected by paper forms.

Statistical Methods

Descriptive statistics were reported as mean (SD) or median and 25th and 75th percentiles, as appropriate, according to the distribution of variables. The distribution of feasibility categories was reported as multinomial probabilities with exact 95% CIs. Correlation between feasibility and SUS and between feasibility and other clinical characteristics (eg, age, gender, type, and amount of drug received) was calculated using the Kendall nonparametric correlation coefficient and plotted appropriately. Correlation between feasibility and use of a personal tablet as opposed to those who borrowed a tablet from the hospital was calculated using the Mann-Whitney *U* test.

Ethics

The study was approved by the Regional committee for Medical and Health Research Ethics (2015/209/Rek-Midt) and the Norwegian Medicines Agency (15/01581-13) and registered at clinicaltrials.gov (NCT02604446) on November 13, 2015. The study was conducted in compliance with the Declaration of Helsinki and Good Clinical Practice. Written informed consent was obtained from all participants before inclusion.

Results

Patients

A total of 134 patients (61 men and 73 women) between the ages of 32 years and 78 years completed the RCT. Data were collected from all 134 patients concerning feasibility of the web-based tool. The SUS was completed by 119 of the 134 patients.

Evaluation Outcomes

The mean SUS score was 89.6 (median 92.5; range 22.5-100). This score corresponds to an A+ in a scoring system given by Sauro [12].

Most of the patients (94/134, 70.2%) managed to use Eir without any technical support (Table 2). Patient-reported data were provided by 68 patients for the defined period of 8 days without any intervention (tech group 1); 26 patients received 1 to 2 reminders but did not need any technical support (tech group 2); 24 patients received simple technical support once, typically on their first attempt to answer after hospital discharge (tech group 3); 10 patients received technical support several times (tech group 4); and 6 patients did not use the application system at home at all (tech group 5). For this tech group, all data after hospitalization were collected from the paper version.

In tech group 5, 1 patient was transferred to ward home for blood transfusion and never managed to connect to the internet, 1 patient could not find the password for his home network, and 1 patient was sent home without a tablet. These 3 patients did not complete the SUS. The last 3 patients in tech group 5 did not use the tablet at home and gave a SUS score based on their use of the application while hospitalized, their scores being 50, 62.5, and 85.

Of the 134 patients, 49 (37%) used their own tablet with the application installed, while 85 of 134 (63%) patients borrowed a study tablet in the registration period at home.

Patient demographics, study drug, level of self-reported side effects, and mean SUS score for each tech group related to their technical skill level is displayed in Table 2.

Figure 2 shows the relationship between tech group and SUS. We observed a significant negative correlation between technical performance (feasibility) and the patient´s evaluation of the electronic tool’s usability (SUS score; correlation coefficient –0.18; P=.02). The 6 patients who were not able to use or not interested in using the tablet for self-registration (tech group 5) had a significantly higher age than the rest of the patients (P=.004). We found a correlation between feasibility and use of personal tablet (P=.04) as opposed to those who borrowed a tablet from the hospital. We observed no gender differences related to technical skills (P=.16). There were no significant associations between the patients' technical skills and the use of study drug (placebo versus the opioid groups: tapentadol and oxycodone).

The total amount of reports possible was 1072 both at hospital and home. At home, the maximal total number of reports was 642, of which 631 (98.3%) was delivered. The patients delivered 450 of 631 reports (71.3%) at home without technical support.

Table 2. Patient demographics, study drug, level of self-reported side effects, and mean System Usability Scale (SUS) score for each tech group.

Characteristics	Tech group 1 (n=68): no intervention	Tech group 2 (n=26): 1-2 simple reminders	Tech group 3 (n=24): technical support once	Tech group 4 (n=10): support on multiple occasions	Tech group 5 (n=6): unable to use
Proportion of the total sample (95% CI)	0.51 (0.39-0.62)	0.19 (0.12-0.30)	0.18 (0.10-0.27)	0.07 (0.03-0.15)	0.05 (0.01-0.11)

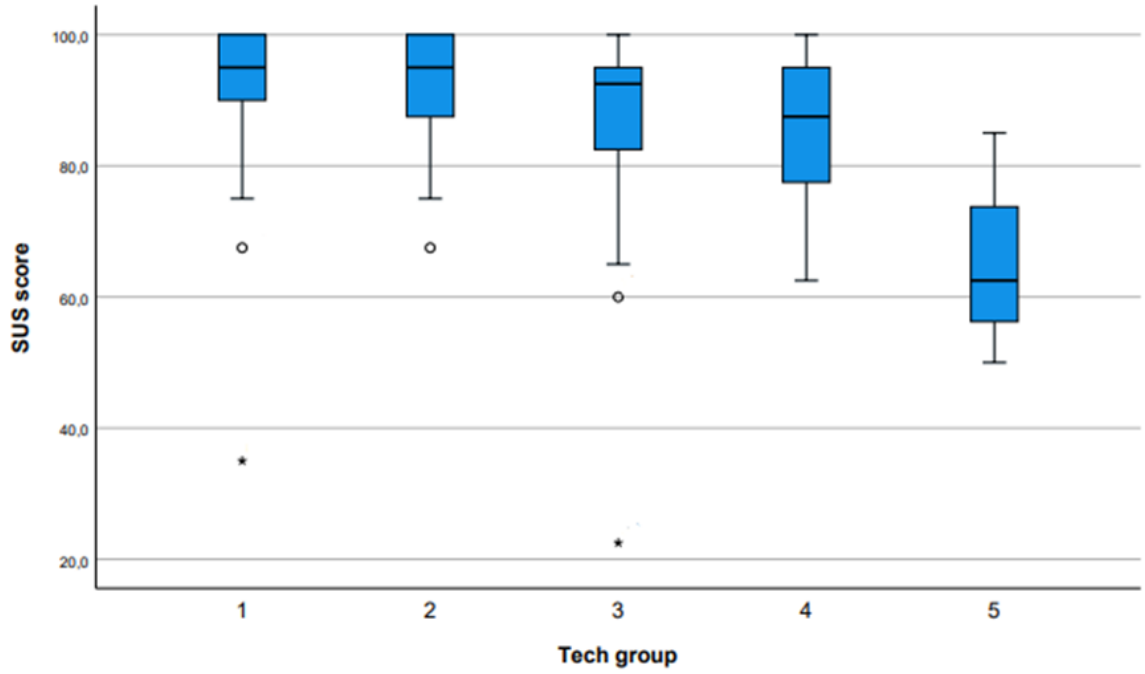
[a]LOS: length of hospital stay.

[b]SUS: System Usability Scale.

[c]Measured on a 0-10 numeric rating scale (0=best, 10=worst).

Figure 2. The relationship between tech group and System Usability Scale (SUS) score.



Discussion

Principal Findings

This study showed high feasibility and high usability of the Eir web tool. A large majority (94/134, 70.2%) of the patients managed to use the tool at home without any technical support. All technical challenges were related to the login procedure or internet access. The received reports gave the necessary information needed for both research data and clinical follow-up.

Almost 90% (119/134, 88.8%) of the patients completed the SUS to evaluate the usability of the electronic tool. Missing reports were evenly distributed between all technical skill groups. We found a clear correlation between the SUS score and feasibility of the tool (ie, the level of technical support given). In the tech groups with higher need of technical support, there was also a higher fraction of patients not having their own tablet, and those not able to complete the reports were older. This implies that the differences in feasibility and usability score between the tech groups are more related to technical experience and skills, rather than effects of the original study intervention or factors explained by the tool itself. The total score for usability was high and more than 80 in groups 1 to 4.

Comparison With Prior Work

The electronic tool evaluated in this study has previously been tested among patient groups with cancer treated in hospital [8,9]. This is the first time the tool was evaluated for unassisted symptom registration at home. There are a few studies on electronic symptom assessment at home after surgery [2-5], indicating that electronic postoperative follow-up at home might be an emerging field. Previous studies for electronic follow-up have obtained different information. Chevallier et al [2] evaluated 29 patients using a home assessment tool after ambulatory surgery and measured pain, nausea, vomiting, comfort, oxygen saturation, heart rate, and blood pressure. Pombo et al [3] used an electronic tool for pain registration with 32 patients, which generated treatment recommendations for the patients after ambulatory surgery. Hajewski et al [4] used automated mobile messaging to gather detailed data on pain development and opioid utilization in 29 patients after periacetabular osteotomy. Lyman et al [5] used a smartphone application to measure step counts and patient-recorded outcome measures, including pain scores, with 267 patients after TKA and total hip arthroplasty (THA) surgery. These 4 studies had patients with mean ages of 47, 48, 22, and 61 years, respectively, while the mean age in our study was 61.5 years.

The technological tools and patient populations differ in these previous studies. The study by Chevallier et al [2] was a pilot study testing advanced monitoring equipment at home. The electronic tools provided 62% (2038/3248) of the expected data items compared with 82% (2656/3248) from a paper back-up. The major reason for missing data was software malfunction. The percentage of missing data in the study by Pombo et al [3] was 29.6%. They used an electronic pain diary based on periodic alarms to recommend pain treatment. The major reason for missing data was that the participant did not hear the alarm or it occurred at an inconvenient time. Hajewski et al [4] reported missing or incomplete data for 16% of the patients but stated no reason. In the study by Lyman et al [5], 6 months of follow-up was completed by 65% of THA patients and 68% of TKA patients. Reasons for noncompletion included time commitment, phone battery, app issues, and health complications. In our study, missing data were considerably less. We received 631 of 642 reports and hence, had only 1.7% (11/631) missing data. We used the tool to gather information in a drug study and had to assist 30% of the patients to avoid loss of data. The fraction of missing data is approximately the same in these studies, but with different causes. In our study, it was more important to gather all data regarding the effect of

the different drugs than to let the patients use the electronic tool without assistance.

Use in Research

The original trial [7] used this tool to obtain data for pain research. The pain data from the Eir database provide a detailed diary with daily pain scores with an exact time stamp and is a promising tool for pain research in the early postoperative period after early admission to home. Electronic assessment at home provides unbiased data from the patients and may be more reliable as the patients are not influenced by the investigators. As for other surgeries, the LOS after arthroplasty has been reduced in recent years, and in our study, the mean LOS was 2.1 days. This advocates for closer evaluation of symptoms at home.

Limitations

There is no consensus in previous studies evaluating electronic tools on how to measure feasibility. The need for technical assistance has been defined differently between studies. Our intention was to describe the variation, and we found that a division into 5 tech groups was informative, as it elaborates the variation between the tech groups with regard to need for support. This symptom assessment system requires a well-developed technological infrastructure, which is present in Norway and many developed countries but not in all countries. It also demands a population that is familiar with use of technology. The study population is not necessarily representative of all patients operated with TKA since patients with cognitive impairment, an age older than 80 years, and inability to read or speak Norwegian were excluded from this study. For a home electronic registration of symptoms to be of use for patients, it must also be connected to an organization that monitors the patients' responses and, if needed, intervenes.

Conclusions

In this study, we evaluated an electronic symptom assessment tool that most patients used without technical support. The tool's usability was scored as high, and it seems as if the differences in feasibility and usability scores were more related to technical experience and skill rather than the tool itself or the clinical intervention in this study. An electronic tool that is easy to use for patients and does not require technical support can provide adequate follow-up for patients in the early postoperative period at home.

Abstract

Background: Half of women begin pregnancy above the healthy weight range, increasing the risk of complications and adversely affecting the lifelong health of their babies. Maternal obesity remains the strongest risk factor for offspring obesity across childhood, adolescence, and adulthood. Previous research suggests that women should be encouraged to be within a healthy weight range before conception to improve health outcomes.

Objective: We outlined the intervention planning and design process to develop an evidence-informed eHealth intervention to promote weight management. The intervention, based on psychological theories and behavior change techniques, has been developed for women affected by overweight or obesity who intend to become pregnant. The *Begin Better* web application is part of an integrated program being evaluated in a clinical trial to assess if weight management *before* pregnancy can influence clinical outcomes for mothers and babies.

Methods: Our intervention development process was guided by intervention mapping and person-based methods. This study documents steps 2 to 4 of a 6-step iterative intervention mapping approach informed by the Information-Motivation-Behavioral Skills model and the findings of a previous interview study. We defined behavior change objectives for each of the Information-Motivation-Behavioral Skills behavioral determinants as well as theory-based behavior change techniques and practical strategies. We also used persuasive system design principles to assist in translating these strategies into a digital environment.

Results: The resultant intervention comprises nutritional and physical activity content along with psychological strategies, which are notably absent from mainstream weight management programs. Strategies to increase motivation, garner social support, and promote self-care are integral to maintaining engagement with the intervention, which aims to improve lifestyle behaviors and enhance well-being. Important elements include tracking mechanisms for percentage progress toward goals to enable feedback on behaviors and outcomes; in-application messages of praise on entry of goals or habits; and strategies to prompt habit formation and action planning via small, easily achievable steps toward positive change.

Conclusions: Design decisions and processes for idea generation about intervention content, format, and delivery are often not reported. In this study, we respond to this gap in the literature and outline a process that is potentially transferable to the development of other interventions.

Introduction

Background

Women who begin pregnancy above the healthy weight range (BMI ≥25.0 kg/m^2) can experience a range of complications such as gestational diabetes mellitus, pre-eclampsia, premature birth, and stillbirth and have a higher risk of fetal malformations [1]. In addition, babies born to women above the healthy weight range are more likely to be born with high birth weight and experience a range of health conditions—including obesity—across childhood and into adulthood [2]. The resulting costs to the health system and society are considerable [3]. Previous research suggests that being within the healthy weight range should be encouraged before pregnancy to improve outcomes [1]. Although clinical weight management interventions can be rigorous, they are often time- and resource-intensive. Interactive communication technology in the form of an eHealth application offers a low-cost, high-reach, and potentially scalable solution. Such technologies also seek to engage the intended population group—women of childbearing age—with a product that is enjoyable to use and effective in promoting behavior change.

This paper outlines the intervention planning approach used to develop the *Begin Better* eHealth intervention. The web application is part of a multicomponent intervention that is being evaluated via a clinical trial to establish whether weight management *before* pregnancy can influence clinical outcomes for women and their babies. Although theories often describe what is required to prompt healthy behaviors, they rarely describe *how* intervention techniques induce these changes [4,5]. In addition, design decisions and idea generation about intervention content, format, and delivery are often not discussed within frameworks or reported widely [6]. Researchers also acknowledge that scientific knowledge is too often valued over the practical and social wisdom of experience-based contextual knowledge [6]. Furthermore, it is thought that a person-based approach is crucial in determining which intervention design features will be most acceptable and effective for a particular population and context [7,8].

Intervention mapping (IM) is a method used to devise health promotion programs that enable effective decision-making at each development step [9]. The planning process integrates theory and empirical findings with the collection and use of new data to develop interventions [9]. IM has been used successfully across programs for diabetes prevention and weight control, chronic disease self-management, and complex behavioral interventions for diet and physical activity [10].

It is widely recognized that selecting appropriate behavior change techniques (BCTs) can greatly enhance the effectiveness of interventions [11]. A recent meta-analysis of 46 postpartum weight management interventions found that the most successful behavioral strategies for decreased energy intake were *problem-solving*, *goal-setting*, *reviewing goals*, *feedback on behavior*, *self-monitoring of behavior*, *behavioral substitution*, and *credible source* [12]—all predominantly related to self-regulation. Some evidence exists that including a greater number of BCTs predicts greater behavior change in some contexts [13], whereas this association was not found elsewhere [12]. Meta-analyses have found greater effects when *self-monitoring* was combined with other self-regulation techniques such as explicit *goal-setting*, *feedback on goal progress*, and *action planning* [14-16]. A weight loss randomized controlled trial (RCT) found that *action planning* had the highest "usefulness" rating of all self-regulation intervention components, with daily action plans noted as being particularly effective [15]. However, much of the existing research is not specific to preconception women. Several studies related to maintenance of behavior change [17,18], including our previous work [19], have also emphasized the need for ongoing positive motivational support and encouragement—a common barrier to long-term adherence.

Interventions that provide a person-centered and autonomy-supportive communication style such as those based on self-determination theory and motivational interviewing are associated with long-term efficacy [20]. Despite this, motivational interviewing remains challenging to implement in a web-based environment [21]. Although behavior change interventions with a theoretical background are more effective than those that are not theory-informed, translation difficulties mean that theory does not underpin many developed interventions [22]. In addition, theory-based interventions are often poorly reported, making replication or adaptation difficult. It is often unclear how the BCTs have been implemented or which ones are most effective in promoting positive change [5] as techniques are rarely implemented in isolation.

Researchers have suggested that one of the most important ways to improve health care is through the use of persuasion [23]. Persuasive design uses interactive technology to change users' attitudes, behavior, or both [24]. A systematic review of 81 web-based interventions found that higher levels of interaction significantly predicted greater adherence [23]. In addition, a large-scale study of 568 participants investigated the perceived effectiveness of various individual strategies in motivating behavior change [25]. *Suggestion* was perceived as the most persuasive as it increases confidence for change, followed by *praise*, *self-monitoring*, and *reminder* [25].

Our Research Objective

Our primary objective is to plan, design, and develop a behavior change web application as part of a multicomponent intervention—the *Begin Better* trial for preconception weight management. Although the application also includes general preconception care information, nutrition and physical activity sections, and a recipe database, this study is primarily concerned with the *Mind* modules of the application. We outline the application of methods adapted from IM [9] and person-based approaches [7] to develop an evidence-informed eHealth intervention to promote weight management. The intervention, based on psychological theories and BCTs, has been developed for women affected by overweight or obesity who intend to become pregnant. Begin Better is part of an integrated program being evaluated in a clinical trial to assess whether weight management *before* pregnancy can influence clinical outcomes for mothers and babies. Participants will, at least initially, also have access to face-to-face sessions with a health coach to

complement the strategies used in the application and build on the personalized and collaborative approach to aid motivation.

Although intervention effects can often diminish over time or when support ends, the intent of the Begin Better program is a lifestyle change that women can sustain in the long term. Contrary to the *initiation* of change, theories of behavior change and weight loss *maintenance* focus on strategies such as sustained motivation, self-regulation, psychological and physical resources, habit formation, and environmental and social influences [17,26]. These reflect how health changes can be maintained over time and in different contexts. At least one sustained motivator, which may include enjoyment, satisfaction with outcomes, self-determination, or a sense of alignment with values or beliefs, is required to maintain the new behavior [17]. This aspect is especially salient as our previous interview study found that all participants had made previous attempts to lose weight but could not maintain the changes in the long term [19]. We intend to build motivation, skills, and self-efficacy so women can make sustainable lifestyle changes.

Methods

Overview

We aim to systematically describe the adapted IM and person-based process and the evidence-informed and practical strategies used to develop the *Begin Better* intervention. Begin Better targets cognitive restructuring around weight management, stress reduction, physical activity, and healthy eating behaviors. A person-based approach was used in initial interviews with 23 target women [19] to ground the design in an in-depth understanding of users' beliefs and psychosocial contexts. This process is particularly relevant in increasing engagement with digital interventions [7] and complements the theory- and evidence-based approaches to intervention development.

IM Approach

We used the 6-step IM protocol for behavior change interventions as a basis for our intervention planning [9]. Although it is an iterative process, this study reports on steps 2 to 4. Step 1 (needs assessment) occurred via the previous qualitative interview study with 23 women aged 23 to 48 years who were above the healthy weight range and wanted to make lifestyle changes [19]. Exploring the women's emotional and social contexts, knowledge, motivations, skills, and self-efficacy in changing health behavior, this qualitative study identified the personal determinants of change that drove the intervention development and enabled the production of a logic model.

Step 2 involved defining the intervention objectives for each of the behavioral determinants. Change objectives were drafted by the first author (JS) informed by the barriers, facilitators, and needs identified in the interview study, and a consensus was reached with other authors (DT and MO). In a person-based approach, these reflect the psychosocial characteristics and context of the intended users.

In step 3, BCTs and practical strategies were identified to address the objectives based on appropriate theory and evidence. The selection of BCTs was based on what has been deemed effective within each construct domain [27] and what is known to be effective in previous studies in similar contexts [12]. Change methods were operationalized to meet the parameters for effectiveness set out in the IM behavior change tables [9], where crossover occurs with BCTs [28] used in the intervention. Examples include *goal-setting*, whereby the women are prompted to set challenging but achievable goals. Similarly, *providing cues* enables the women to have the autonomy to select their own cues for healthier habits. Brainstorming and lateral thinking were used to consider practical strategies that were engaging and met the objectives of the intervention while still addressing the parameters. Where parameters were undefined, we used discretion to apply assumptions for effectiveness given the situation and context. Persuasive principles were also chosen to assist in translating design features for greater user engagement, enjoyment, and effectiveness [29].

Step 4 comprised refining the program structure and producing content. A multidisciplinary team comprising academic researchers, clinical and health psychologists, dietitians, designers, computer scientists, web developers, and women in the target population were consulted to develop the intervention. The first author (JS) completed the planned content outlines for the *Mind* modules and developed draft content along with annotated mock-ups of interactive components. A stepped approach of psychological skill building was adopted throughout the 5 modules, with plans integrated for effective delivery within the constraints of the medium.

Mind module content and interactive components were reviewed by an obstetrician (JD), clinical and health psychologists (DT and MO), a midwife, a dietitian, a nutritionist and health behavior researcher, academic researchers (AD), and clinical psychologists not associated with the project to ensure clinical accuracy and comprehension. Feedback was provided regarding simplifying some psychological concepts for our target audience and further use of metaphors to explain difficult or unfamiliar ideas. Minor grammatical edits were also made. The web programmer reviewed the overall structure and interactive elements to ensure that they were feasible to build into the application within the constraints of the medium. Drafts were reviewed and discussed with all authors, and agreement was reached on final content.

Videos and podcasts were recorded and edited by members of the research team with skills in this area. A PhD-qualified registered nutritionist and health behavior researcher—who is not an author of this paper—presented all videos and podcasts to eliminate bias in the evaluation process. The web programmer integrated the interactive tasks at key points within each video aligned with the appropriate session of the module.

Informal pilot testing of various components provided direction for the final interface. A total of 9 women in the target age group provided feedback on branding and design options for the look and feel of the application. General feedback was that the fun and relaxed designs depicting warmth and care were favored over the more clinical representations of health—in part because of the highly stigmatizing nature of being overweight in clinical settings.

Various sources of knowledge are often valued differently and can change across the development process [6]. Design decisions were driven primarily by the new interview data from the target group, with theory and empirical evidence, and informal pilot-testing providing secondary sources of guidance. Although all sources of knowledge were valuable, the stakeholder views allowed us to tailor the content to the personal determinants of our target population and to suit the context of their lives. These were women in a busy phase of life, time-poor, and often with competing work and child-rearing demands. Some belonged to lower socioeconomic groups, with limited access to information and resources. Many had also tried unsuccessfully to lose weight previously, so we knew that they required a less prescriptive approach to weight management with flexible options that could be maintained in the longer term. Some of the women struggled with comorbidities that could be improved with lifestyle changes. Many in this life phase also told us that their partners or children created barriers to healthier habits, so strategies that included partners for support were prioritized given that the intent was to conceive a child.

The intervention content and structure were also informed by published theories and evidence to enhance effectiveness. Learnings from previous complex intervention development projects also guided decision-making [6,30,31]. In addition, consideration was given to developing an eHealth solution that would be feasible to develop and deliver within time, resource, and funding constraints.

Finally, steps 5 and 6 involve planning the implementation, delivery, and evaluation. Although these stages are not reported in this paper, considerations for implementation begin with the initial needs assessment and continue throughout all steps. Change methods and practical strategies were carefully selected to support implementation. Forward planning included ensuring that all aspects of delivery satisfied the change objectives and implementation outcomes and could be easily tracked in evaluation studies. Planning also established that the intervention could be readily adapted following feedback or scaled up for future use if proven effective through RCT.

The iterative process means that steps are often not cycled through in a systematic linear manner; instead, it was necessary to readdress aspects of previous steps and refine the program to ensure that intervention strategies were feasible. An example is that we scaled back personalization aspects as developing a complex level of tailored content was not achievable within the resources available—therefore, BCT methods, persuasive system design (PSD), and practical strategies were revised accordingly.

Information-Motivation-Behavioral Skills Model

We used the Information-Motivation-Behavioral Skills model [32] for the interview study that informed the planning process. This allowed us to address any knowledge, motivation, and skill deficits of the target population. The model's simple structure allows for the easy translation of constructs into intervention components. It provides a framework for defining intervention objectives and candidate change techniques that may be key to the effectiveness of the final program [11]. The model has been well-tested in changing health behaviors and is highly applicable to weight management [33].

BCTs Used

The BCTs we used in the intervention were classified and described using the Behavior Change Technique Taxonomy [28], consisting of 93 techniques clustered across 16 categories (Multimedia Appendix 1 [28]).

PSD Model Principles

We used the PSD framework [34] to develop the eHealth intervention's technology elements, features, and interactivity to increase participant engagement and adherence. The framework proposes persuasive principles across 4 categories: primary task support (supporting users to perform the intended tasks), dialogue support (providing feedback that directs users toward healthier behaviors), system credibility support (supporting the development of trustworthy systems), and social support (motivating users through social influence; Multimedia Appendix 2 [34]). We chose this framework for the design principles' particular relevance to well-being, nutrition, and physical activity given their success in these areas [29].

Ethics Approval

The interview study that informed the planning process was approved by the Women's and Children's Health Network (HREC/19/WCHN/108) and the University of Adelaide Human Research Ethics Committee (33863).

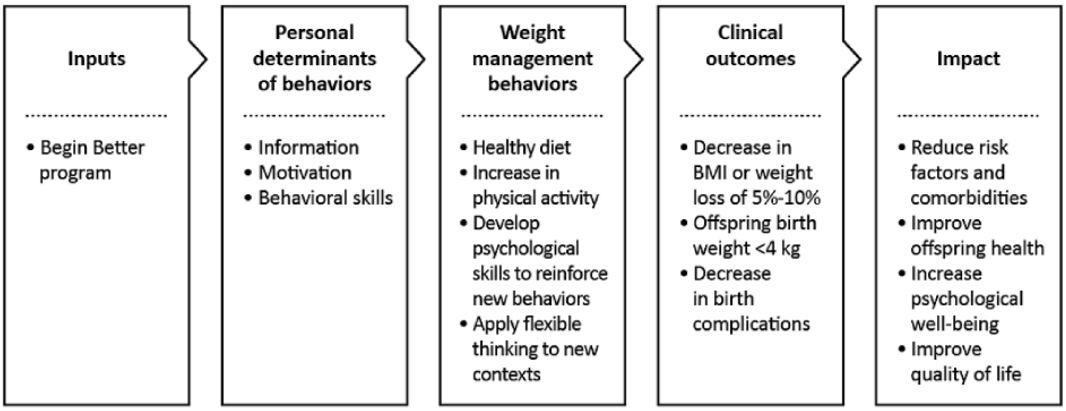
Results

Overview

Compared with the reductionist philosophy often used in weight management programs, the Begin Better intervention uses a holistic approach informed by the biopsychosocial model [35], which considers the biological, psychological, and socioenvironmental factors integral to health behavior change. A logic model of the intervention based on the personal determinants of the Information-Motivation-Behavioral Skills model; the desired weight management behaviors; clinical outcomes for the program; and the health, social, and emotional impact is shown in Figure 1. Multimedia Appendix 3 describes the change objectives, BCTs, PSD principles, and practical strategies used throughout the intervention aligned with each of the determinants.

Some of the more important techniques supported by strong evidence of effectiveness and with relevance to our context are described below, with the BCTs and PSD principles highlighted in italics.

Figure 1. Logic model of the Begin Better intervention.



BCTs Used

BCTs are used throughout the eHealth intervention. Techniques known to be the most effective, such as *goal-setting* and *self-monitoring*, are used early in the intervention. Women are guided to set goals that align with their values and encouraged to set a weight goal and several whole-person goals related to health, social, or mental well-being. Self-monitoring of weight and whole-person goals occurs within the application, with the ability to add, review, or update goals and habits as they are achieved or maintained to build self-efficacy for change. Bar charts that track percentage progress toward goals and a graph showing the overall trend line enable timely *feedback on behavior* and *outcomes* to increase motivation. Users are also encouraged to consider health benefits and measures of success beyond just the number on the scale.

One of the more effective BCTs is providing *information about health consequences*. Interviews with target women demonstrated that knowledge of the impacts of their weight status on themselves and their babies was alarmingly low. By highlighting the benefits of a healthy lifestyle before pregnancy in a nonjudgmental and supportive tone, we hope to provide women with added motivation. The language used was conversational rather than clinical, using terms such as *benefits of weight management* rather than noting the *risks*. Similarly, women are encouraged to consider the benefits of a healthy lifestyle beyond just weight management, with *information about emotional consequences* and *information about social and environmental consequences* provided. This was done via an animated sequence that highlighted the benefits not just for their babies but also for themselves—including psychosocial benefits such as more energy, positive mood changes, and being a role model for others.

The intervention also includes aspects of *nudge* theory, whereby small, simple *micronudges* are used to initiate healthy change rather than complex or restrictive regimes. For example, *restructuring the physical environment* prompts small changes in the women's choice architecture (eg, placing healthy food within easy eyeshot and reach, keeping sneakers by the front door as a reminder to take a walk, or preloading a meditation app that is visible each time the phone is used). These strategies make healthier choices easier to make.

Research also indicates that habits are important drivers of behavior [36], especially healthy eating and physical activity. *Habit formation* is promoted through ideas and inspiration to implement new healthy habits into women's daily routines. These techniques can influence behavioral flexibility and have been effective in clinical trials [37,38]. As noted previously, effective interventions need to focus on prompting action rather than merely providing motivation [4,5]. *Action planning* is an important aspect of the intervention; women will create and upload habit action plans to the application.

Social support and encouragement remain important motivators as many women in our previous interview study reported that interpersonal challenges had affected their motivation toward lifestyle change [19]. An opt-in *buddy system* is offered, whereby participants are paired with another woman in the program to reciprocate motivation and encouragement. Some women in the interview study noted the motivation and satisfaction they would garner from helping a peer along their journey to health [19]. Buddies may also function as accountability partners who check in and keep each other accountable to their goals and problem solve issues together. Women's attention is also drawn to *identification of self as role model* for those around them. Strategies are promoted to encourage healthy change across their entire family.

Other BCTs important for mental well-being and self-efficacy, such as *problem-solving* and relapse prevention, are also used as strategies to maintain motivation and increase psychological flexibility. *Repetition and substitution*, including *habit formation*, are considered integral to behavior change. Women are encouraged to integrate microhabits into their daily routine—small changes they can repeatedly implement until they become automatic. Substitution ideas are also offered for less healthy foods and behaviors.

PSD Model Principles

Our intervention incorporates the following PSD techniques. *Tunneling* guides users through the process of behavior change without overwhelming them. Key *Mind* modules, unlocked at fortnightly intervals, include various psychological techniques to create a healthier lifestyle. These are aligned with key *Nutrition* modules to deliver a cohesive program with a natural progression of skill building. Some nutrition and physical

activity content is also free-roam so that the application provides information and engaging content at all times. Topics include how to read food labels, portion control, practical tips for simple meals, and reducing sedentary time.

In-application alerts are provided to motivate and draw attention to modules as they are unlocked. For example, if women do not upload their weight for a week, *reminders* prompt a weigh-in for self-monitoring. *Praise* is offered when goals are uploaded and action plans are set with in-application messages such as "Great work with the values. Let's discuss them at our next catch-up" and "It feels great to have plans in place! Now for the benefits to flow!" Women are also prompted to reflect on their progress.

Reduction is a key technique used to simplify complex behaviors into manageable tasks that women can easily integrate into their lives. Women in our interview study cited complexity and lack of flexibility as reasons why previous weight management programs were unsustainable [19]. *Suggestion* is also used, with ideas and inspiration for small daily changes that can be made to promote healthier behaviors. A database of easy, fast, dietitian-approved recipes is also included to reduce the cognitive load associated with making daily food decisions.

Dialogue support strategies such as *Suggestion* are integrated, providing ideas and inspiration to help women reach their goals. In response to short, interactive questionnaires about areas that users find particularly challenging, feedback provides encouragement and tips for overcoming these barriers.

The intervention integrates aspects of acceptance and commitment therapy and cognitive behavioral therapy. These approaches are more often used in face-to-face therapy and have only recently been introduced in eHealth interventions for weight management. The psychology component of the intervention is delivered via video and podcast in 5 modules, with therapeutic techniques and interactive content outlined in detail in a subsequent study. Intervention features and strategies may continue to evolve as the Begin Better intervention uses an adaptive design approach [39] that allows for ongoing improvements to the application following user feedback.

Discussion

Principal Findings

In this paper, we systematically report the planning process for a complex, evidence-informed eHealth intervention for preconception health in women above the healthy weight range. We integrated research evidence with BCTs and persuasive technologies that map directly onto behavioral determinants, an approach that is underused and underreported [5]. Incorporating the views of women from a previous study [19] and those of research and professional stakeholders was a valuable addition, allowing for more targeted decision-making about intervention design.

Although traditional weight management programs promote dietary and physical activity changes, the Begin Better intervention also addresses the complex psychological processes that underlie health behaviors. It is widely acknowledged that many of our lifestyle behaviors are governed by automatic responses to contextual cues in our environment—both with food and socially [40]. As humans, we have inherent cognitive limitations in this area [40], often using emotional—rather than logical or rational—decision-making, which can lead to poorer choices. These factors can override individual motivation and intention and have been cited as a reason why many behavior change interventions show only modest effect sizes [41]. We hope that the techniques and engagement strategies used in the Begin Better intervention can address some of these factors.

Our intervention integrates therapeutic approaches that are not often used for health behavior change to assist users in creating the psychological flexibility required to sustain these changes in the long term [42] and within different contexts. Alongside behavior change, the intervention aims to induce cognitive change [43] that may predict the achievement of personal health goals and the maintenance of lifestyle changes.

Some key learning points from various knowledge sources were especially salient in translating theory into an environment for users that would be acceptable, enjoyable to use, and effective. One of the main priorities was the need for simplicity that permeated each step of the planning and development process. This need came through very strongly from interviews and was addressed by keeping behavior changes small, achievable, and flexible for the women to build self-efficacy and motivation for change. Similarly, the interface itself was simplified to 3 key areas that the women would access the most (Nutrition, Mind, and Body). Previous research has also found that users dislike applications that require too much user input [18]. Although greater levels of interactivity predict greater engagement and behavior change [5], these aspects needed to be kept as simple and user-friendly as possible. It was particularly challenging to adapt face-to-face therapy techniques or activities that are often *pen and paper* tasks to a web-based environment. Strategies needed to be chosen and implemented carefully to maintain clarity and ease.

Although not all aspects of step 5—planning, delivery, and implementation—have been explicitly detailed in this paper, an understanding of the factors that influence the wider implementation, scaling, and maintenance of an intervention is crucial for selecting intervention components [44]. The process is highly iterative and context-dependent. In addition, challenges exist in engaging women in preconception planning beyond the current RCT project. At a later stage, undertaking step 6 of the IM protocol—the evaluation plan—will confirm whether the processes undertaken through the development of the intervention have been effective [44].

The outcomes of the Begin Better program are currently being evaluated via an ongoing RCT of 870 women. To be eligible, women will be above the healthy weight range (BMI ≥25 kg/m^2), intending to become pregnant, and willing to postpone conception for the 6 months of the trial. Women in the intervention group consult with a midwife and dietitian at trial entry, gain access to the full intervention within the Begin Better application, and receive fortnightly individual health coaching sessions. Women in the control group consult with a midwife at trial entry and receive standard preconception care advice

within the Begin Better application. At the time of writing, recruitment has commenced with approximately 100 women randomized. Women will complete questionnaires assessing food intake, physical activity, emotional health, and well-being (Depression, Anxiety, and Stress Scale–21) [45] and health-related quality of life (Short Form–12) [46] along with a measure of readiness to change at trial entry and upon completion of the 6-month program. Future research is required to test acceptability and engagement and the relationships between module completion, weight goals, and psychosocial outcomes. Plans are underway to examine the impact of the emotional and affective components of the program, including the mechanistic processes of cognitive change, using scales of stages of change, cognitive flexibility, cognitive fusion, and committed action.

Strengths and Limitations

Many behavior change interventions are designed with a *one-size-fits-all* approach that fails to account for individual differences [41]. Although the Begin Better application allows for individual values, goals, and habit action plans, personalization may be further integrated in future design iterations. Additional personalization may include motivational SMS text messages tailored to the participants' individual goals, habits, and coaching sessions.

The need for a pragmatic approach guided our planning methods. The IM protocol involves a highly prescribed, time- and resource-intensive process that could not be implemented in its entirety for this project. Its application can be complicated, as noted by other researchers [10], and consideration of the resources available within the time frames of funding opportunities drove the decision to simplify the process and adapt it to our needs. It is also recommended by experts that intervention developers apply individual approaches in a flexible manner to fit their individual problem and context [31].

Although the intervention evaluation is ongoing, the content was reviewed by specialists in obstetrics, clinical and health psychology, nutrition and dietetics, exercise physiology, and computer science. In addition, potential users reviewed other aspects of the intervention, such as look and feel, and commented on the design decisions, providing insights into how participants may perceive the intervention. However, we did not extensively pilot-test the *live* application with target populations because of time and resource constraints, so new feedback was not collected or integrated.

Conclusions

The use of an adapted IM process and person-based methods provided us with a clear and tailored approach to developing the Begin Better intervention. In this study, we address a gap in the literature about detailing underlying program mechanisms and outline a process that is potentially transferable to developing other interventions.

Acknowledgments

JS was funded by an Australian Federal Government Research Training Program PhD Scholarship. JD was supported by a National Health and Medical Research Council Practitioner Fellowship (APP1078980). The Begin Better study is funded by the Medical Research Future fund (MRFF1199789).

The authors would like to sincerely thank the women who participated in the initial interviews that informed this study for their generosity in sharing their thoughts and experiences with us. Many thanks also to peers, researchers, and clinicians who generously reviewed and pilot-tested various components of the application and provided constructive feedback.

Authors' Contributions

JS made substantial contributions to study conceptualization and design, including methodology, and drafted the manuscript. MO and DT contributed to study conceptualization and design, methodology, supervision, and manuscript editing. JD, CS, and AD also contributed to study conceptualization. All authors reviewed and commented on the manuscript and approved its final version.

Abstract

Background: Atrial fibrillation is commonly associated with obesity. Observational studies have shown that weight loss is associated with improved prognosis and a decrease in atrial fibrillation frequency and severity. However, despite these benefits, nonadherence to lifestyle programs is common.

Objective: In this study, we evaluated adherence to and feasibility of a multidisciplinary lifestyle program focusing on behavior change in patients with atrial fibrillation and obesity.

Methods: Patients with atrial fibrillation and obesity participated in a 1-year goal-oriented cardiac rehabilitation program. After baseline assessment, the first 3 months included a cardiac rehabilitation intervention with 4 fixed modules: lifestyle counseling (with an advanced nurse practitioner), exercise training, dietary consultation, and psychosocial therapy; relaxation sessions were an additional optional treatment module. An advanced nurse practitioner monitored the personal lifestyle of each individual patient, with assessments and consultations at 3 months (ie, immediately after the intervention) and at the end of the year (ie, 9 months after the intervention). At each timepoint, level of physical activity, personal goals and progress, atrial fibrillation symptoms and frequency (Atrial Fibrillation Severity Scale), psychosocial stress (Generalized Anxiety Disorder–7), and depression (Patient Health Questionnaire–9) were assessed. The primary endpoints were adherence (defined as the number of visits attended as percentage of the number of planned visits) and completion rates of the cardiac rehabilitation intervention (defined as performing at least of 80% of the prescribed sessions). In addition, we performed an exploratory analysis of effects of the cardiac rehabilitation program on weight and atrial fibrillation symptom frequency and severity.

Results: Patients with atrial fibrillation and obesity (male: n=8; female: n=2; age: mean 57.2 years, SD 9.0; baseline weight: mean 107.2 kg, SD 11.8; baseline BMI: mean 32.4 kg/m2, SD 3.5) were recruited. Of the 10 participants, 8 participants completed the 3-month cardiac rehabilitation intervention, and 2 participants did not complete the cardiac rehabilitation intervention (both because of personal issues). Adherence to the fixed treatment modules was 95% (mean 3.8 sessions attended out of mean 4 planned) for lifestyle counseling, 86% (mean 15.2 sessions attended out of mean 17.6 planned) for physiotherapy sessions, 88% (mean 3.7 sessions attended out of mean 4.1 planned) for dietician consultations, and 60% (mean 0.6 sessions attended out of mean 1.0 planned) for psychosocial therapy; 70% of participants (7/10) were referred to the optional relaxation sessions, for which adherence was 86% (mean 2 sessions attended out of mean 2.4 planned). The frequency of atrial fibrillation symptoms was reduced immediately after the intervention (before: mean 35.6, SD 3.8; after: mean 31.2, SD 3.3), and this was sustained at 12 months (mean 24.8, SD 3.2). The severity of atrial fibrillation complaints immediately after the intervention (mean 20.0, SD 3.7) and at 12 months (mean 9.3, SD 3.6) were comparable to that at baseline (mean 16.6, SD 3.3).

Conclusions: A 1-year multidisciplinary lifestyle program for obese patients with atrial fibrillation was found to be feasible, with high adherence and completion rates. Exploratory analysis revealed a sustained reduction in atrial fibrillation symptoms; however, these results remain to be confirmed in large-scale studies.

KEYWORDS

cardiac rehabilitation; atrial fibrillation; obesity; participation; completion; adherence; lifestyle

Introduction

Worldwide, atrial fibrillation is the most common sustained cardiac arrhythmia in adults [1]. It has been estimated that 17.9 million people will suffer this condition in Europe by 2060 [2]. The prevalence of atrial fibrillation also increases with the presence of traditional cardiovascular disease risk factors including diabetes, obesity, and hypertension [3]. Importantly, several longitudinal studies [4,5] have demonstrated the association between obesity and cardiac dysrhythmias with increased risk of atrial fibrillation. Moreover, patients with obesity often have a higher burden and faster progression of atrial fibrillation symptoms compared with patients having a normal weight. Not surprisingly, sustainable weight loss is, therefore, associated with a decrease in atrial fibrillation symptoms [6]. Lifestyle modification, including education, psychosocial support, dietary counseling, and physical training, are effective strategies to achieve weight loss in order to reduce atrial fibrillation symptoms and improve quality of life [7]. European Society of Cardiology guidelines [8] for the management of atrial fibrillation recommend lifestyle modification to achieve weight reduction for obese patients with atrial fibrillation; however, in practice, the effects of traditional lifestyle modification programs are often not maintained in the long-term because regular cardiac rehabilitation programs, which focus on restoring the physical condition, improving lifestyle, and providing psychological support throughout, do not sufficiently focus on behavior change [9]. In addition, only a small proportion of patients with atrial fibrillation are included in cardiac rehabilitation programs, despite proven clinical benefits [10,11]. Low participation rates are caused by suboptimal referral by medical professionals. In addition, participation in cardiac rehabilitation programs for patients with atrial fibrillation is not reimbursed by health insurance in the Netherlands. Although at the start of cardiac rehabilitation, more than 80% of patients are overweight and more than 50% have metabolic syndrome [12], most cardiac rehabilitation programs do not contain a program specifically aimed at weight loss [12,13]. In addition, most efforts to change health behaviors have had limited success due to dropout and declines in adherence [14]. Therefore, addressing barriers that influence adherence, such as a lack of personalization or tailoring of the program to a specific disease is key for improving the effectiveness of lifestyle modification programs [15,16].

In this study, we aimed to investigate the adherence and feasibility of a lifestyle program for overweight atrial fibrillation patients specifically designed to improve long-term adherence by focusing on improving self-management and sustainable behavior change.

Methods

Study Design

We conducted a feasibility study; the results of this study will be used to optimize the intervention, specifically targeted to long-term behavior change, in an associated parallel multicenter open-label randomized controlled trial (Optimal Cardiac Rehabilitation XL; Netherlands Trial Register NL5589) that will evaluate the cost-effectiveness of a multidisciplinary cardiac rehabilitation program in obese patients with atrial fibrillation and coronary artery disease.

Ethics

The study protocol was reviewed and approved by the medical research ethics committee of Máxima Medical Center. All participants were informed about the goals of the study, and all participants provided written informed consent.

Participants

Patients with atrial fibrillation who presented at the cardiac rehabilitation unit (Centre Flow, Máxima Medical Center in Veldhoven/Eindhoven) in 2016 and 2017 were eligible for participation. Patients with atrial fibrillation and obesity were referred by the cardiologist, and subsequently, invited for an intake assessment with an advanced nurse practitioner. All participants were screened for trainability and practical possibilities. To personalize the lifestyle intervention, participants were counseled to formulate personal lifestyle goals based on SMART (Specific, Measurable, Achievable, Realistic and relevant, and Timed [17]), for a 1-year lifestyle program consisting of physical training, nutrition guidance, lifestyle counseling, and psychosocial therapy, with relaxation therapy as optional additional treatment module.

For this study, we chose a sample of 10 participants, rather than using a calculation-based sample size because the goal of this study was not to evaluate clinical effectiveness but to evaluate the feasibility of the intervention in this specific patient population.

Inclusion and Exclusion Criteria

Patients with symptomatic atrial fibrillation and a BMI higher or equal to 29 kg/m^2 were asked to participate in the study. Exclusion criteria were progressive symptoms of heart failure, myocardial ischemia during exercise testing (ST depression ≥2 mm), sinus tachycardia at rest with a frequency greater than 110 bpm or atrial fibrillation greater than 100 bpm at rest, and severe cognitive impairment (memory, attention, concentration and psychiatric disorders).

Intervention

An individual program was created with the patient, based on their exercise capacity and personal goals. To improve exercise capacity, aerobic training was included, as well as strength training. Training frequency, training duration, training intensity, length of the work and rest intervals, and dosage training were used as variables to determine prescribed aerobic and strength training. The first 6 weeks of the intervention consisted of 2 training sessions per week, and the 6 weeks thereafter consisted of training sessions once per week. Blood pressure and heart rate were checked before, during, and after sessions. Training sessions (total duration: 60 minutes) consisted of aerobic training (treadmill or bicycle ergometer; a build-up time of 2 weeks at 40% to 50% of maximum rate of oxygen consumption was recommended) and strength training. For each strength training exercise (seated leg press, chest press, biceps curls, triceps curls, core muscle exercises, low-dose hip abductor-adductor exercise, and low row back exercise), 2 sets were performed with 1 to 2 minute breaks in-between, and each set consisted of 12 repetitions. In addition to the exercise program, all participants received an individual intake assessment with a dietician and a psychologist. If indicated (ie, depending on care need), treatments were planned with the dietician or psychologist. Finally, participants were offered an optional relaxation module, which consisted of breathing exercise and body awareness relaxation techniques aimed at teaching participants to create more moments for rest and to cope better with stress.

At the end of the 3-month intervention and at the end of the year, participant progress was evaluated with the advanced nurse practitioner, and personal goals were adjusted (participants were coached on active lifestyle and personal goals). Participants were instructed to continue to pursue these goals in their home environment. We used behavior change techniques such as goal setting, action planning, motivational interviewing, information about healthy lifestyle and reviewing outcome goals.

Main Outcomes and Measures

The primary endpoints of the study were percentage of participants who completed the intervention and adherence to the treatment modules (percentage of visits attended out of those planned). Secondary endpoints included body weight, atrial fibrillation frequency and severity, exercise capacity, anxiety, and depression. The frequency and symptom severity of atrial fibrillation were assessed with the Atrial Fibrillation Severity Scale, which is a validated questionnaire [18] that combines measures of frequency and patient-perceived severity. Exercise capacity was measured using the 6-minute walking test. The 6-minute walking test was performed in a 25-meter-long corridor at a speed of the participants' preference with the instruction to cover the greatest possible distance during 6 minutes without running. The 1-repetition maximum, a measure of muscle strength, was defined as the maximum weight that could be pushed or lifted once. Anxiety and depression complaints were assessed using validated questionnaires (Patient Health Questionnaire–9 [19] and Generalized Anxiety Disorder–7 [20]). Weight and height were measured at all follow-up visits, and BMI was calculated. Secondary outcome measures were assessed at baseline, at 3 months (ie, immediately after the intervention), and at 12 months.

Statistical Analysis

Program completion and adherence to the treatment modules and changes in secondary endpoints (body weight and Atrial Fibrillation Severity Scale score) were analyzed by calculating descriptive statistics.

Results

A total of 10 participants participated in the feasibility study. The majority of participants were male (male: n=8; female: n=2; age: mean 57.2 years, SD 9.0; baseline weight: mean 107.2 kg, SD 11.8; baseline BMI: mean 32.4 kg/m^2, SD 3.5). Two participants did not complete their cardiac rehabilitation programs due to personal problems.

Of the 10 participants, 8 participants completed all 4 appointments with the advanced nurse practitioner to monitor their lifestyle (mean 3.8, SD 0.42 appointments attended per participant); 2 participants canceled their last appointment, resulting in an adherence of 95% (mean 3.8 sessions attended out of mean 4 planned). All participants were referred to the exercise training program sessions, for which adherence was 86% (mean 15.2 sessions attended out of mean 17.6 planned); 9 participants were referred to a dietician (1 patient had already received dietetic treatment in a referring hospital), for which adherence was 88% (mean 3.7 sessions attended out of mean 4.1 planned); and all participants were referred to a medical psychologist, for which adherence was 60% (mean 0.6 sessions attended out of mean 1.0 planned). Of the 10 participants, 9 participants were referred to, of whom 7 participants participated in, relaxation sessions for which adherence to the relaxation sessions was 86% (mean 2 sessions attended out of mean 2.4 planned).

After the initial 3-month cardiac rehabilitation period, weight decreased from mean 107.2 kg (SD 11.8) to mean 102.5 kg (SD 13.7), and there was weight loss at 12 months compared with baseline (Table 1). The frequency of atrial fibrillation symptoms was reduced immediately after the intervention (before: mean 35.6, SD 3.8; after: mean 31.2, SD 3.3), and this was sustained at 12 months (mean 24.8, SD 3.2). Severity of atrial fibrillation complaints immediately after the intervention (mean 20.0, SD 3.7) and at 12 months (mean 9.3, SD 3.6) were comparable with that at baseline (mean 16.6, SD 3.3). Depression and anxiety scores immediately after the intervention were comparable with those at baseline. The distance walked on the 6-minute walking test was higher after the intervention (before: mean 538.9, SD 70.6 meters; after: mean 595.3, SD 72.8 meters) and at 12 months (mean 600.8, SD 94.0). Quadriceps strength (1-repetition maximum) showed an increase immediately after rehabilitation (before: mean 179.5, SD 49.3 kg; after: mean 245.3, SD 63.7 kg) and at 12 months (mean 259.7, SD 52.7 kg). The 1-repetition maximums for biceps (before: mean 22.1, SD 8.9 kg; after: mean 25.6, SD 6.0 kg) and triceps (before: mean 27.1, SD 9.7 kg; after: mean 35.6, SD 6.8 kg) also showed increases in strength immediately after cardiac rehabilitation, and at 1 year,

remained higher (biceps: mean 29.8, SD 3.4, triceps: mean 39.6, SD 2.5) than those at baseline.

Table 1. Outcome measures at baseline, at 3 months (immediately after the cardiac rehabilitation intervention), and at 12 months (follow-up).

	Baseline, mean (SD)	Postintervention (at 3 months), mean (SD)	Follow-up (at 12 months), mean (SD)
Weight (kg)	107.2 (11.8)	102.5 (13.7)	105.1 (16.1)
Atrial Fibrillation Severity Scale			
Atrial fibrillation frequency	35.6 (3.8)	31.2 (3.3)	24.8 (3.2)
Atrial fibrillation severity	20.0 (3.7)	16.6 (3.3)	9.3 (3.6)
6-Minute walking test (m)	538.9 (70.6)	595.3 (72.8)	600.8 (94.0)
Patient Health Questionnaire–9	6.8 (4.3)	4.6 (4.3)	—[a]
Generalized Anxiety Disorder–7	4.4 (5.3)	2.7 (2.9)	—
1-Repetition maximum			
Quadriceps (kg)	179.5 (49.3)	245.3 (63.7)	259.7 (52.7)
Biceps (kg)	22.1 (8.9)	25.6 (6.0)	29.8 (3.4)
Triceps (kg)	27.1 (9.7)	35.6 (6.8)	39.6 (2.5)

[a]No data.

Discussion

General

This study shows that a multidisciplinary lifestyle program focused on sustainable behavior change in individuals who are overweight with atrial fibrillation is feasible with high completion rates (8/10 participants, 80%) and high adherence to the treatment modules (60% to 95%). Although exploratory analysis revealed sustained improvements in both the frequency and the severity of the atrial fibrillation symptoms and modest weight reduction, these results need to be confirmed in large-scale randomized controlled trials.

To the best of our knowledge, this is the first study to evaluate cardiac rehabilitation adherence specifically in obese patients with symptomatic atrial fibrillation. One study [21] showed that 81.3% of general patients referred for cardiac rehabilitation attended at least one-half of the sessions; however, nearly half of the patients did not follow any dietary recommendations or did not increase their physical activity levels, and in another, the dropout rate (24% [22]) was comparable to that in our study (20%). However, whereas participation in exercise training was high (90% [22]), participation in other modules (25% for dietary counseling, 9% for relaxation therapy, 9% for psychological therapy [22]) was substantially lower than those in our study. Data on adherence to the planned sessions were lacking [22].

The relatively high completion and adherence rates in our study may be explained by the design of the intervention. First, the intervention was designed to be a nurse-coordinated multidisciplinary intervention, rather than one that focused on exercise training or dietary counseling only, which is in line with the notion that holistic care models targeting are most effective for behavior change [23]. Second, counseling on expectations and individualized goal setting constituted an important part of the intervention. In fact, a previous study [24] showed that unrealistic expectations form an important barrier to lifestyle behavior change [24]. Also, it is well recognized that goal setting is an effective way of achieving behavior change [24,17]. Third, the high adherence rates may be explained by the fact that we used motivational interviewing, which is a communication skill set to help facilitate change and adherence to health behaviors. In fact, Pack et al [25] showed that continual, purposeful, and planned quality improvement efforts significantly increased patient participation in cardiac rehabilitation—motivational interviewing was an important strategy in achieving this.

Our exploratory analysis revealed that cardiac rehabilitation resulted in sustained reductions in the frequency and severity of atrial fibrillation symptoms. However, in contrast with other studies [6,26,27] that have shown that weight loss has beneficial effects on atrial fibrillation symptoms, the reduction in symptoms in our study was not associated with weight loss, suggesting that other physiological mechanisms, such as improvement of traditional cardiovascular risk factors and an increase in physical fitness, play a role. In line with this assumption, Pathak et al [6] observed a significant dose-response relationship between improvements in physical fitness and reduction in the risk of atrial fibrillation recurrence. Other studies [26,28] have shown positive effects of comprehensive management of concomitant cardiovascular risk factors on atrial fibrillation recurrence. Although these studies [26,28,29] underline that targeting modifiable risk factors, obesity and physical fitness should be an essential pillar of atrial fibrillation care, the optimal approach to achieve sustained long-term effects in obese patients with atrial fibrillation remains to be established.

Limitations

An important limitation of this study was the small number of study participants. We, therefore, described conclusions only about feasibility and not about the outcomes. Furthermore, a control group was not included because the primary goal of this study was to evaluate feasibility and adherence; therefore, the

reported effects of the intervention on weight and atrial fibrillation symptoms should be regarded as exploratory. The results of this feasibility study will applied to an ongoing study.

Conclusions

This study showed that a nurse-coordinated multidisciplinary lifestyle program for obese patients with atrial fibrillation is feasible, with a high level of completion and adherence. Effects on atrial fibrillation symptoms and weight reduction remain to be determined in a randomized controlled trial.

Abstract

Background: Poor adherence to oral medications is common in people with type 2 diabetes and can lead to an increased chance of health complications. Text messages may provide an effective delivery method for an intervention; however, thus far, the majority of these interventions do not specify either a theoretical basis or propose specific mechanisms of action. This makes it hard to determine how and whether an intervention is having an effect. The text messages included in the current intervention have been developed to deliver specific behavior change techniques. These techniques are the “active ingredients” of the intervention and were selected to target psychological constructs identified as predictors of medication adherence.

Objective: There are 2 aims of this study: (1) to assess whether a text message intervention with specified behavior change techniques can change the constructs that predict medication adherence behaviors in people with type 2 diabetes and (2) to assess whether changes to psychological constructs are associated with changes in self-reported medication adherence.

Methods: We conducted a randomized controlled, 6-month feasibility trial. Adults prescribed oral medication for type 2 diabetes (N=209) were recruited from general practice and randomized to either receive a text message–based intervention or care as usual. Data were analyzed with repeated measures analysis of covariance and Spearman rho correlation coefficients.

Results: For 8 of the 14 constructs that were measured, a significant time-by-condition interaction was found: necessity beliefs, intention, maintenance self-efficacy, recovery self-efficacy, action control, prompts and cues, social support, and satisfaction with experienced consequences all increased in the intervention group compared to the control group. Changes in action self-efficacy, intention, automaticity, maintenance self-efficacy, and satisfaction with experienced consequences were positively associated with changes in self-reported medication adherence.

Conclusions: A relatively low-cost, scalable, text message–only intervention targeting medication adherence using behavior change techniques can influence psychological constructs that predict adherence. Not only do these constructs predict self-reported medication adherence, but changes in these constructs are correlated with changes in self-reported medication adherence. These findings support the promise of text message–based interventions for medication adherence in this population and suggest likely mechanisms of action.

Introduction

Poor adherence to oral treatments is common in people with type 2 diabetes [1,2]. When such medication is taken suboptimally, blood glucose control can be poorer, leading to greater risk of developing complications [3], which can affect the heart, eyes, blood vessels, nerves, and other organs [4]. This has implications for people with diabetes and those supporting them, and is also associated with increased costs for health services [5].

An updated Cochrane review of 182 interventions to improve medication adherence concluded that "current methods of improving medication adherence for chronic health problems are mostly complex and not very effective," [6] and therefore, new approaches are needed to address this problem. Technology-based interventions may have the potential to improve medication adherence at scale at low unit cost. Thus far, no single approach has been identified as being the most effective or ineffective [7]. However, providing brief messages such as text messages is particularly promising, as text messages have the advantage of already being widely adopted and low-cost [8]. In a recent systematic review and meta-analysis of interventions based on multiple behavior targets, such as diet, exercise, and medication adherence, text messages were found to be effective in reducing levels of blood glucose for people with type 2 diabetes [9]. However, only 1 intervention included in this review exclusively targeted medication adherence, and this consisted only of medication reminder texts. This approach is unlikely to be sufficient unless the only barrier to adherence is forgetting, which excludes intentional nonadherence and the person with diabetes taking an active role in making adjustments to their medication regimen around their daily life, both of which have been observed in this population [10]. In a review specifically looking at medication adherence, it was concluded that although brief messages show promise, more high-quality evidence is needed [11]. Specifically, very few of the included studies stated an explicit theoretical basis, and of those that did, none discussed the results in relation to this theory.

Having an explicit theoretical basis provides clarity in terms of the proposed mechanism of action of an intervention; that is, what the intervention is intended to do and how. This helps with both the development and evaluation of digital health interventions. In development, having a logic model that describes how an intervention is intended to work can help designers choose what elements to include. By defining the constructs the intervention is targeting, components such as behavior change techniques (BCTs) that are hypothesized to affect these constructs can be chosen.

BCTs have been described as the "active ingredients" of an intervention and include techniques such as problem solving. There is currently a taxonomy of 93 BCTs with descriptions that can be used by intervention designers [12]. Using standardized BCTs as intervention components allows for easier comparison across interventions, greater transparency in what the intervention consists of, and the potential to use systematic reviewing and statistical analyses to identify effective BCTs across trials. For example, a meta-regression of randomized controlled trials that used either short messages and/or interactive voice recognition software to support medication adherence for cardio-metabolic conditions identified that the BCT, information about health consequences, was positively associated with effect size [13].

In terms of evaluation, an explicit logic model helps with understanding why a change in behavior either has or has not happened [14]. As an example, intention to take medication has been identified as a psychological construct that is important in changing medication adherence behavior [15]; therefore, an intervention designer might include BCTs thought to have an effect on intention, such as information about health consequences. Once the intervention has been delivered, evaluating the mechanism of action (ie, whether intention was changed as hypothesized) would help to explain the presence or absence of change in medication adherence behavior. This in turn would affect the further development of the intervention. Different adjustments would be made to the intervention if the proposed change in intention did not occur or if intention changed but this did not result in changes to medication adherence. Although links have been proposed between BCTs and psychological constructs, they are not often tested empirically [16]. Testing each link in the chain from BCT, to construct, to change in behavior would provide the strongest explanation of how an intervention functions and add to the understanding of medication adherence behavior. Furthermore, defining and evaluating components within an intervention and how they are proposed to work is considered key to facilitating the accumulation of evidence related to digital health interventions [17].

Prior to this study, a rapid systematic review was conducted that identified psychological constructs related to medication adherence from systematic reviews and meta-analyses as well as BCTs that target these constructs [15]. Although many of these psychological constructs have been found to predict medication adherence, there is not yet evidence that changing these constructs produces change in medication adherence. This evidence of causation is urgently needed. According to the evidence in this rapid systematic review, a conceptual model of the intervention was developed based on the Health Action Process Approach [18], with additions to reflect the evidence synthesized. This model conceptualizes medication adherence as a process, from forming an intention, acting on that intention, and then monitoring and adjusting these actions until adherence becomes habitual (see Figure 1). The approach taken follows the recommendations of the updated Medical Research Council

(MRC) framework for development and evaluation of complex interventions to develop such logic models to facilitate process analyses [19,20].

A library of text messages was developed to deliver specified BCTs that target multiple constructs relevant to this model (see Table 1). The included constructs relate to both intentional and nonintentional nonadherence.

Our previous research has confirmed that the messages in the library are good examples of the BCTs they were written to represent and are acceptable to the target population [21]. We are therefore confident that the messages can deliver the intended BCTs; however, at present we do not know if these BCTs will have the proposed effects on psychological constructs or if changes to these psychological constructs will be related to changes in medication adherence. Hence, there was a need for this formative study to indicate if changes are required to the intervention before causal links are further explored in an efficacy trial powered to conduct this analysis. To thereby test the mechanism of action of the intervention, relevant psychological constructs were measured as part of a randomized controlled feasibility trial [22] in order to answer the following 2 research questions: (1) Does a BCT-based brief message intervention produce changes in psychological constructs relative to control group?; (2) Are changes in psychological constructs correlated with changes in medication adherence?

Figure 1. Proposed theoretical model based on the Health Action Process Approach [17]. Underlined constructs indicate those that were significantly increased in the intervention group vs. the control group.

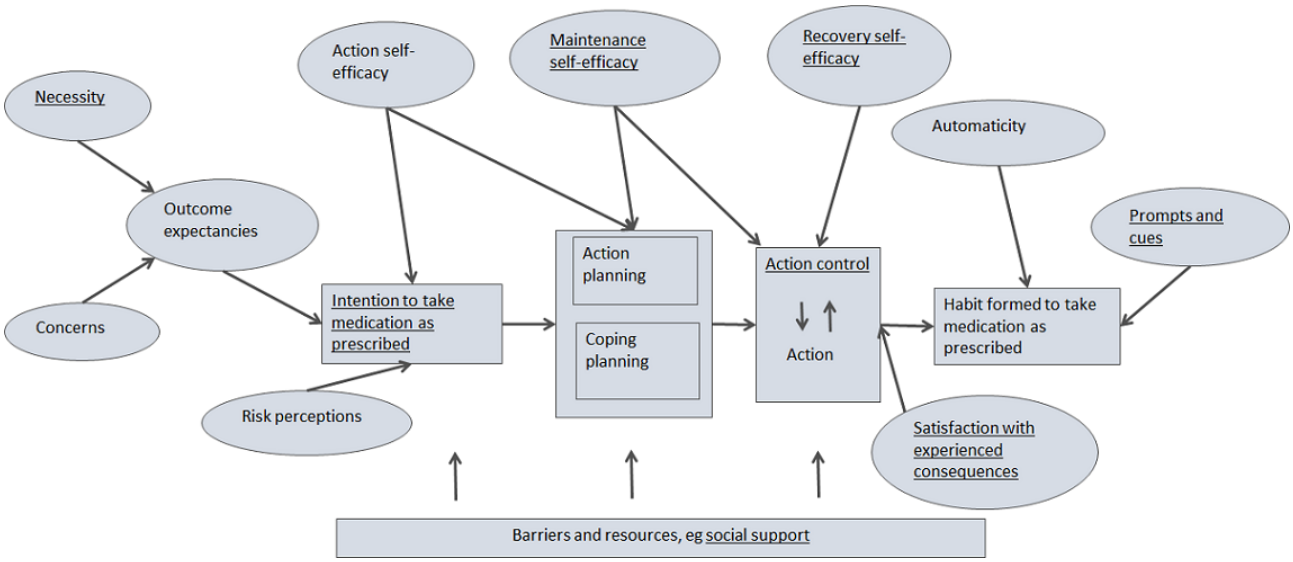

Table 1. Example messages with associated BCTs (replicated from Bartlett et al [21]).

Target and category of message	BCT[a]/belief or concern	Example messages
Medication adherence, BCT	1.4[b] Action planning	"Plan when, where and how you are going to take your medication."
Medication adherence, BCT	15.1[b] Verbal persuasion about capability	"If you are struggling with your diabetes tablets then don't worry, you will be able to master it in time. You will get on top of it."
Medication adherence, BCT	7.1[b] Prompts/cues	"It can be difficult to remember to take your tablets. Why not set an alarm to remind you to take them?"
Medication adherence, beliefs, and concerns	Health care system–related concerns	"Lots of questions? Check who the best person to see might be."

[a]BCT: behavior change technique.

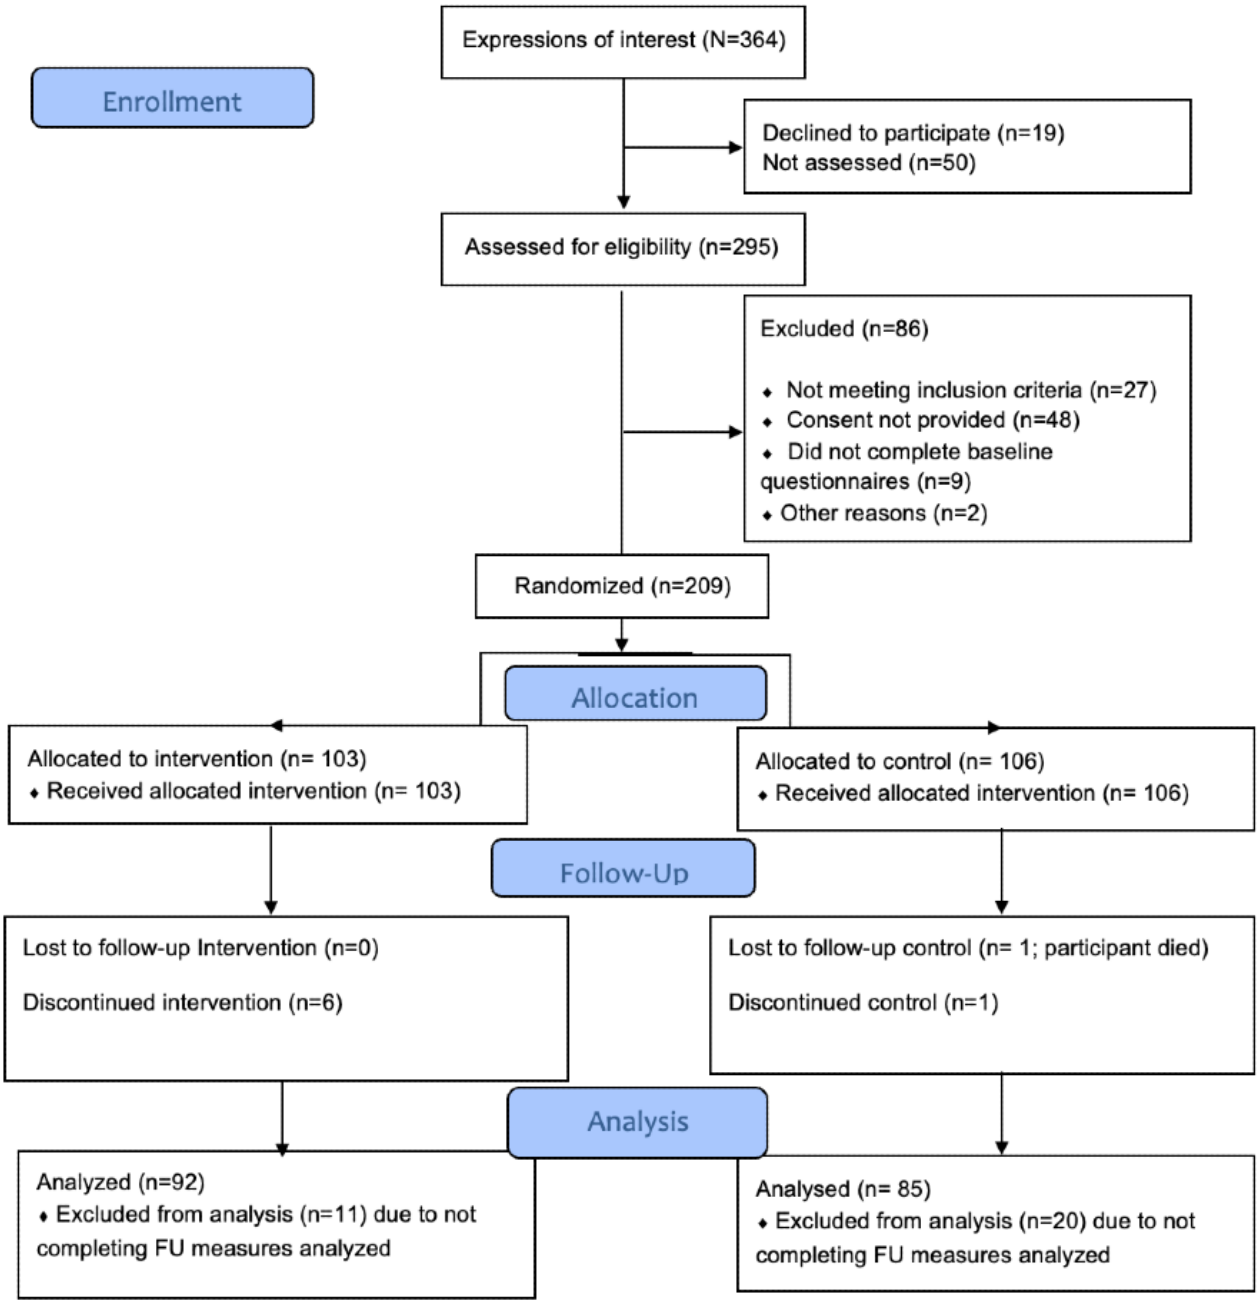
[b]Numerical identifiers from the taxonomy [12].

Methods

Recruitment

Participants were recruited from 16 general practices in England between January 2019 and June 2019. Potentially eligible patients were contacted about the study by the practice and invited to send a text message to express interest. On receipt of the text message, further information about the study was given either online or by post, and eligibility was assessed by the researchers by phone. Eligible patients were those who were ≥35 years of age, able to use a mobile phone to send and receive text messages, and taking oral medication for type 2 diabetes (including lipid and blood pressure–lowering medications for diabetes). Patients taking oral medication either with or without concomitant insulin were eligible. Patients who had been admitted to hospital in the previous 3 months with hypo- or hyperglycemia, were pregnant, were within 3 months postpartum, were planning a pregnancy within the trial, or had a serious medical condition that, in the opinion of the investigator, made them unable to take part were ineligible. Informed consent was given either online or by post. See Figure 2 for the CONSORT (Consolidated Standards of Reporting Trials) flowchart.

Figure 2. Support Through Mobile Messaging and Digital Health Technology for Diabetes (SuMMiT-D) feasibility CONSORT (Consolidated Standards of Reporting Trials) flow diagram.



Design

Data were collected for a 6-month, parallel-group, randomized controlled feasibility trial as part of the Support Through Mobile Messaging and Digital Health Technology for Diabetes (SuMMiT-D) program of work. Participants were randomized in a 1:1 ratio to the intervention or control arm. Randomization was completed through a validated secure web-based program (Sortition) using a nondeterministic minimization algorithm to ensure groups were balanced for age, study site, gender, duration of diabetes, and number of medications. The allocated intervention was then delivered directly through an online platform. Aside from those conducting qualitative interviews and the engineering team, all other research team members and health care staff were blinded. For further details of the design and development, see the protocol paper [22].

Ethical Approval

Ethical approval for the study was granted by National Health Service (NHS) West of Scotland Research Ethics Committee 05 (reference number 18/WS/0173). The trial is registered in the ISRCTN registry (ISRCTN13404264).

Intervention

Participants in the intervention group were sent up to 4 text messages per week for 6 months. There were 2 categories of messages: (1) those targeting medication adherence based on BCTs identified as relevant for this population [15] that have previously been confirmed as representing the intended BCT and being acceptable to the target population [21] and (2) those targeting diet and physical activity, introduced as a response to feedback during the development process, indicating that a broader view of diabetes self-management may benefit engagement. Messages in category 2 provided information from and links to credible sources such as the Diabetes UK or NHS Choices website. All messages were sent at a preferred time (AM or PM), and participants were able to text back “like” or “dislike” after any message received. For messages targeting medication adherence, texting “like” doubled the chance a future message would come from the same BCT as the message that had been liked, while texting “dislike” halved the chance of a future message coming from the same BCT as the disliked message. Texting “like” or “dislike” following messages targeting diet or physical activity did not result in any change.

Control

Participants in the control group received 1 message per month for 6 months thanking them for their participation in the study; this was in addition to their usual care.

Assessments

Assessments were completed online or on paper. At baseline, participants completed a demographic questionnaire and provided their postcode, and at baseline and 6 months, participants completed the 5-item Medication Adherence Report Scale (MARS) [23,24] and a health psychology questionnaire. The 5 items on the MARS are nonadherent behaviors, and thus participants respond by indicating how true each statement is for them on a 5-point scale from “always true” to “never true.” One item referred to nonintentional nonadherence, “I forget to take my diabetes medicines,” while the other 4 items measured intentional nonadherence.

The hypothesized mechanisms of action questionnaire was developed for this study and measured key constructs targeted by the messages (see Table 2). Two items were used to measure each of the following fourteen constructs: action self-efficacy, necessity, concerns, intention, automaticity, maintenance self-efficacy, recovery self-efficacy, action planning, coping planning, action control, prompts and cues, social support, satisfaction with the experienced consequences of behavior, and risk perception. The 28 items were sourced or adapted from previously developed questionnaires where possible and were phrased to specifically relate to taking diabetes tablets as prescribed (see Table 2). All questions were answered using a 5-point Likert scale with the anchors strongly disagree, disagree, neither agree nor disagree, agree, and strongly agree. For further details on additional measures taken but not reported here, see Farmer et al [22].

Table 2. Properties of the psychological construct scales.

Construct	Example item	Interitem correlation at baseline			Paper adapted from
		Correlation coefficient (R_s)	*n*	*P* value	
Action self-efficacy	"I am confident that I can take my diabetes tablets as prescribed"	0.82	203	<.001	Schwarzer et al [25]
Necessity	"My health in the future will depend on my diabetes tablets"	0.53	203	<.001	Horne et al [26]
Concerns	"I sometimes worry about the long-term effects of my diabetes tablets"	0.19	203	.007	Horne et al [26]
Intention	"I will take my diabetes tablets as prescribed every day over the next 3 months"	0.81	204	<.001	Presseau et al [27]
Automaticity	"Taking my diabetes tablets as prescribed is something I do without thinking"	0.50	199	<.001	Gardner et al [28]
Maintenance self-efficacy	"I am confident that I am able to take my diabetes tablets as prescribed even when something disrupts my routine"	0.54	200	<.001	Greer et al [29]
Recovery self-efficacy	"If I don't take my diabetes tablets for any reason, I am confident that I am able to start taking them again even if I feel no different to when I was not taking them"	0.63	201	<.001	Greer et al [29]
Action planning	"I have made a detailed plan about exactly where to take my diabetes tablets"	0.72	200	<.001	Greer et al [29]
Coping planning	"I have made a detailed plan for how to deal with unpleasant side effects of taking my diabetes tablets as prescribed"	0.46	200	<.001	Greer et al [29]
Action control	"During the last 4 weeks I consistently monitored when, where, and how I took my diabetes tablets"	0.23	201	.001	Sniehotta et al [30]
Prompts and cues	"I use things around me to help me to take my diabetes tablets as prescribed (e.g. notes, phone reminders)"	0.63	202	<.001	N/A[a]
Social support	"I have felt supported in taking my diabetes tablets as prescribed"	0.29	202	<.001	Presseau et al [27]
Satisfaction with experienced consequences	"I am content with what I have experienced as a result of taking my diabetes tablets"	0.75	203	<.001	Baldwin et al [31]
Risk perception	"I feel very at risk of developing complications, or experiencing worsening of existing complications from my diabetes if I do not take my tablets"	0.64	201	<.001	N/A

[a]N/A: not applicable.

Analysis

The index of multiple deprivation (IMD) is a measure of relative deprivation used by the English government. Areas (32,844 across England) are ranked according to a variety of domains, including income, employment, health, and crime, and then the ranked list is divided into deciles [32]. Participants' postcodes were used to identify their IMD decile (1 missing, postcode invalid). Descriptive statistics were used to describe age, gender, and IMD, while a *t* test or chi-squared test was used to assess differences in these variables between those who did and did not complete follow-up assessments. Responses were coded in the following fashion according to the MARS: never true=5, rarely true=4, sometimes true=3, often true =2, and always true=1. Thus, higher scores would be associated with better self-reported adherence. The hypothesized mechanisms of action questionnaire was scored as follows: strongly agree=5, agree=4, neither agree nor disagree=3, disagree=2, and strongly disagree=1. Thus, higher scores would be associated with higher levels of the construct (eg, greater action control, higher self-efficacy, or higher concerns). Construct scores were calculated by summing the scores for both items. Interitem correlations were calculated (see Table 2).

Research Question 1: Does a BCT-Based Brief Message Intervention Produce Changes in Psychological Constructs Relative to a Control Group?

Repeated-measures analysis of covariance (ANCOVA) was conducted for each construct, with time as a within-subject factor at 2 levels (baseline and 6-month follow-up); group (intervention or control) as a between-subject factor; and age, gender, and IMD included as covariates. As a sensitivity analysis, univariate ANCOVA for each construct were conducted, with construct at follow-up as the dependent variable; gender and experimental group as fixed factors; and construct at baseline, age, and IMD as covariates.

Research Question 2: Are Changes in Psychological Constructs Correlated With Changes in Medication Adherence?

Standardized residual change scores were calculated using linear regression for each construct (baseline to follow-up) and MARS (baseline to follow-up). Spearman rho correlation coefficients were then calculated to assess the relationship between change in standardized residuals for each construct and change in self-reported adherence.

Results

Participants

Participants (N=209) had a mean age of 63.4 years (SD 10.16), were 41.1% (86/209) female, and were recruited from all 10 of the IMD deciles with a mean of 6.38 (SD 2.73). Thirty-one participants were excluded from this analysis, as they did not complete the follow-up assessments analyzed here, and one participant died prior to follow-up. There were no significant differences between groups in age, gender, or IMD at baseline or between those who completed and did not complete the questionnaire measures at follow-up (see Table 3).

Table 3. Demographics.

Variable	Overall, mean (SD) (N=209)	Intervention, mean (SD) (N=103)	Control, mean (SD), (N=106)	Between-group differences at baseline[a]	Differences between completers (n=177) and noncompleters (n=31)—hypothesized mechanisms of action questionnaire assessing constructs[a]	Differences between completers (n=168) and noncompleters (n=40) in MARS[ab]
Age, (years)	63.44 (10.16)	63.47 (10.64)	63.42 (9.72)	.98	.96	.91
Female	86 (41.1)[c]	42 (40.8)[c]	44 (41.5)[c]	.51	.36	.22

[d]IMD: index of multiple deprivation.

[e]n=208: 1 postcode was incorrect and could not by mapped onto the IMD.

Research Question 1: Does a BCT-Based Brief Message Intervention Produce Changes in Psychological Constructs Relative to a Control Group?

A significant interaction between time and experimental group was seen in necessity (*P*=.009), intention (*P*<.001), maintenance self-efficacy (*P*=.03), recovery self-efficacy (*P*=.02), action control (*P*=.001), prompts and cues (*P*=.002), social support (*P*<.001), and satisfaction with experienced consequences (*P*=.002; see Table 4). All effects were such that the constructs increased between baseline and follow-up in the intervention group compared to the control group. Of the covariates (age, gender, IMD), only age had a significant effect on any constructs. Age had a significant effect on the model for necessity, action planning, social support, and satisfaction with experienced consequences. Sensitivity analysis treating baseline variables as covariates rather than as within-subject factors showed aligned significant or nonsignificant effects for 12 of the 14 constructs measured. Previously significant effects on recovery self-efficacy (*P*=.12) and maintenance self-efficacy (*P*=.30) were not replicated.

Table 4. Repeated-measures analysis of covariance effect of the text message intervention on psychological constructs.

Coping planning	5.88 (1.83)	6.32 (1.66)	6.05 (1.63)	6.70 (1.77)	.11	.42	N/A
Action control	7.10 (1.79)	7.05 (1.81)	6.99 (1.74)	7.88 (1.59)	.12	$F_{1,160}$=10.80, .001	N/A
Prompts and cues	5.38 (2.07)	5.59 (2.09)	4.91 (1.75)	6.26 (1.99)	.22	$F_{1,160}$=10.31, .002	N/A
Social support	4.71 (1.55)	4.74 (1.71)	4.95 (1.75)	6.11 (1.65)	.24	$F_{1, 160}$=16.40, <.001	Age: $F_{1,160}$=4.80, .03
Satisfaction with experienced consequences	7.78 (1.91)	7.60 (1.68)	7.47 (1.81)	8.16 (1.62)	.45	$F_{1, 162}$=9.77, .002	Age: $F_{1,160}$=4.73, .03
Risk perception	8.08 (1.53)	8.78 (1.76)	8.07 (1.44)	8.22 (1.61)	.70	.53	N/A

[a]Test statistic and degrees of freedom are only reported for *P* values <.05 in this column.

[b]BL: baseline.

[c]FU: follow-up.

[d]N/A: not applicable (no significant covariates were found).

[e]Potentially there is less confidence in this result as recovery self-efficacy was significantly different between groups at baseline such that intervention (mean 8.07, SD 1.54) was higher than the control (mean 7.98, SD 1.52; t_{199}=2.59; *P*=.01).

Research Question 2: Are Changes in Psychological Constructs Correlated With Changes in Medication Adherence?

Standardized residual change scores in 5 of the 14 psychological constructs were significantly positively correlated with those in self-reported medication adherence, such that increases in the construct represented improvements in medication adherence action self-efficacy (r_s=0.28; n=149; *P*=.001), intention (r_s=0.20; n=149; *P*=.02), automaticity (r_s=.33; n=143; *P*<.001), maintenance self-efficacy (r_s=0.30; n=147; *P*<.001), and satisfaction with experienced consequences (r_s=0.16; n=148; *P*=.05).

Discussion

Principal Results

In this analysis we have shown that first, provision of a text message–based intervention using behavior change techniques results in improvements to multiple psychological constructs compared to usual care. Second, we have identified that changes in psychological constructs are correlated with changes in self-reported medication adherence. These findings support the hypothesized mechanisms of action that are amenable to change through a low-cost, scalable intervention, and that when changed, may have an effect on medication adherence in people with type 2 diabetes. These findings, although tentative, provide a strong base on which to progress to a full efficacy trial.

Strengths and Weaknesses

The intervention messages use a wide variety of BCTs that are thought to target different points in the process of adherence. The incorporation of a wide variety of techniques, including some BCTs that have not been applied in this context previously, constitutes one of the strengths of this intervention, as this represents a new way to approach medication adherence. However, a corresponding weakness is that this could make looking at each individual link between BCTs and constructs more difficult, as several BCTs might have affected the same construct.

These findings have shown that this intervention can have an effect on multiple constructs that may influence people at different points in the process of improving medication adherence from forming an intention, acting on that intention, to monitoring and adjusting these actions until adherence becomes habitual (see Figure 1). In addition, the intervention targets sources of both intentional and nonintentional nonadherence. The potential to affect change in people wherever they are in the process of improving medication adherence is a definite strength, from which a wide range of people with type 2 diabetes can benefit. In this feasibility study, we were not powered to conduct a formal mediation analysis, however this is planned for the definitive trial which is now underway (ISRCTN 15952379).

Medication adherence has been self-reported here using the MARS. In the future, we plan to take additional measures of adherence (eg, from medical records) so that the relationships between these constructs, self-reported adherence, and adherence measured through more direct means can be explored. Future work could also explore the use of objective measures of medication adherence, such as urine samples [33]. Overall, this study provides a more detailed picture of the potential mechanism of action for this intervention, which can be used to support development of further interventions for this target behavior.

The eventual aim is that the brief text message intervention can be delivered at scale, through general practice. In terms of future scalability, basing the intervention solely on text messages is highly cost-effective. Recent research has indicated combining text messages with interactive voice recognition can be an effective intervention for medication adherence in this population [34]; there is further evidence that incorporating tailoring can make interventions more effective [13]. Any additional components and technology required above and beyond text messages, and any additional complexity may limit the eventual scalability of the intervention. Understanding the unique effects of nontailored text messages alone in the first instance is useful, as this is the lowest-cost approach. Additional elements could then be added to the intervention where they would provide the most benefit and when the evidence is clearer on which conditions tailoring can be optimally applied to.

The measures of psychological constructs used in this study were by necessity brief to minimize participant burden. There is increasing recognition that high questionnaire burden in trials has undesirable consequences, such as reducing recruitment, increasing dropout in low socioeconomic status or minority ethnic groups, and producing unintended reactions to this measurement [35]. It was therefore necessary to use a questionnaire developed for this study. Items from pre-existing scales were used when possible, and the correlations for the majority of items were considered moderately or strongly correlated [36]. However, there were 3 constructs with weak correlations between items (concerns, action control, and social support), and we aim to improve these items for our future research. An alternative approach could be to use this preliminary work to identify specific constructs of interest and measure a smaller number of constructs with validated scales.

Future Development

Future research could use these findings for the following purposes: to investigate those constructs that did not change in this instance, and whether there are more effective BCTs to target these constructs than those used here; to explore those constructs where changes did not correlate with changes in medication adherence; and to improve the measurement of constructs where correlations between the 2 items were weak. This work would help to gather additional information that could be used to optimize interventions for this population.

The findings reported indicate that certain constructs are both amenable to change by text message and, when changed, are associated with changes in self-reported medication adherence (eg, intention, maintenance self-efficacy, and satisfaction with experienced consequences). These constructs could indicate the importance of continued feedback and adjustment within medication adherence interventions; following initial changes to intention, it may be necessary to support people to maintain and highlight the positive effects of changes made to support satisfaction with continued adherence. BCTs that target these constructs may be useful for focusing on future research into medication adherence.

This feasibility trial was not powered to look at direct effects of the intervention on the outcome. The findings do provide a clear indication of the potential value of an intervention such as this, but in the planned trial of this intervention participant numbers will be sufficiently high to ascertain efficacy of the intervention and allow for mediation analysis to further explore the potential mechanisms of action suggested here. By identifying likely mechanisms of action of the intervention beforehand, efficacy results will be more easily interpreted. In addition, with a larger sample, it may be possible to conduct subanalysis to explore whether changes in constructs are associated with particular participant characteristics, and this could provide evidence to inform future tailoring strategies. Incorporating tailoring increases the complexity of an intervention and potentially reduces the scalability. However, if future tailored interventions were compared with this nontailored intervention, an evidence base could be built on how to tailor in the most effective way, which would only introduce additional complexity where there is likely to be maximum benefit.

Conclusions

A text message intervention based on behavior change techniques can affect psychological constructs that are correlated with medication adherence. The use of a logic model enabled clear proposed mechanisms of action to be defined and tested. Future research can explore these potential mechanisms further to improve the understanding of adherence behavior and intervention design.

Abstract

Background: With increased reliance on digital health care, including telehealth, efficient and effective ways are needed to assess patients' comfort and confidence with using these services.

Objective: The goal of this study was to develop and validate a brief scale that assesses digital health care literacy.

Methods: We first developed an item pool using existing literature and expert review. We then administered the items to participants as part of a larger study. Participants were caregivers of children receiving care at a pediatric clinic who completed a survey either on the web or over the telephone. We randomized participants into development and confirmatory samples, stratifying by language so that exploratory factor analysis and confirmatory factor analysis could be performed with separate samples of participants. We assessed the scale's validity by examining its associations with participants' demographics, digital access, and prior digital health care use.

Results: Participants (N=508) were, on average, aged 34.7 (SD 7.7) years, and 89.4% (454/508) were women. Of the 508 participants, 280 (55.1%) preferred English as their primary language, 157 (30.9%) preferred Spanish, and 71 (14%) preferred Arabic; 228 (45%) had a high school degree or less; and 230 (45.3%) had an annual household income of <US $35,000. Using exploratory factor analysis, 3 items were retained in a reduced scale with excellent reliability (Cronbach α=.90) and a high variance explained (78%). The reduced scale had excellent fit, with factor loadings between 0.82 and 0.94. All fit statistics exceeded the criteria for good fit between the proposed factor structure and the data. We refer to this scale as the Digital Health Care Literacy Scale. The scale was positively associated with education (ρ=0.139; *P*=.005) and income (ρ=0.379; *P*<.001). Arabic speakers had lower scores than English (*P*<.001) and Spanish speakers (*P*=.02), and Spanish speakers had lower scores than English speakers (*P*<.001). Participants who did not own a smartphone (*P*=.13) or laptop computer (*P*<.001) had lower scores than those who owned these devices. Finally, participants who had not used digital tools, including health apps (*P*<.001) and video telehealth (*P*<.001), had lower scores than those who had used these tools.

Conclusions: Despite the potential for digital health care to improve quality of life and clinical outcomes, many individuals may not have the skills to engage with and benefit from it. Moreover, these individuals may be those who already experience worse outcomes. A screening tool such as the Digital Health Care Literacy Scale could be a useful resource to identify patients who require additional assistance to use digital health services and help ensure health equity.

digital literacy; digital health care; telehealth; health equity; scale development; mobile phone

Introduction

Background

Digital technologies for managing health have proliferated in recent years, in large part as a response to the COVID-19 pandemic [1-3]. These technologies include telehealth, patient portals, and mobile health, such as app-based programs. Telehealth or the delivery of health care services at a distance using information and communication technology has been particularly helpful for allowing individuals to still receive treatment when in-person interaction is not possible. Given its convenience and now integration with many clinic workflows, it is likely that telehealth will continue to be offered as a delivery modality [4]. From a clinical trial standpoint, evidence supports the efficacy of telehealth to improve clinical outcomes across a variety of conditions [5]. Moreover, it may be more cost-effective than other approaches and patients who use it are generally satisfied with the experience [6,7]. However, to promote the continued utility of telehealth, consideration must be given to the types of individuals who have both access to, and confidence in using, it.

Despite increased access to technology over the past decade, disparities in access persist among those with lower income, with less education, or who are racial or ethnic minorities [8,9]. With respect to telehealth access, specifically, numerous studies have demonstrated stark racial and socioeconomic disparities during the COVID-19 pandemic [10-13]. This concept, known as the digital divide or the gap between people who do and do not have access to technology, affects health equity. Namely, there is concern that with the advancement in digital technologies, we may leave behind those individuals who tend to have worse health outcomes and need help the most, thereby widening the gap [14,15]. Recent efforts to expand broadband and telehealth access have begun at the federal and state levels and will require long-term, widespread investment [16,17]. An additional component of addressing the digital divide includes determining whether individuals who have access to the internet and digital devices also have the skills to use technology for accessing health care.

A certain level of digital literacy is necessary to effectively engage with, and benefit from, digital health tools. For example, individuals must feel somewhat confident in their skills using technology to install and engage with a health app or start up a telehealth visit with their provider. The telehealth modality of today's world requires that patients initiate the visit compared with prior telehealth approaches where clinics provided all required digital health care connection. Digital literacy is considered unique and separate from technology access. In a recent study of patients admitted to the hospital, most of the participants with low health literacy had access to digital devices and had used the internet previously but were unable to perform web-based tasks without assistance [18]. Digital literacy may in fact present as a larger barrier to using digital tools than access, which underscores the need to appropriately measure and understand it.

There have been attempts in the past to measure digital literacy, although many are based on using computers generally or using the internet to find health information [19-22]. For example, the Computer Literacy Scale focuses only on computers and recognizing computer symbols and terms [22]. Likewise, the eHealth Literacy Assessment Toolkit is a compilation of scales for assessing both health literacy and digital literacy; however, the digital literacy scales primarily focus on familiarity with computer terms and confidence using computers [21]. The eHealth Literacy Scale is a popular scale for assessing electronic health literacy, but all items are anchored on using the internet to find health information [20,23]. Another scale for assessing digital literacy, the Digital Health Literacy Instrument, assesses competencies for both gathering health information and using the internet; however, the skills it assesses are very specific (ie, protecting privacy and adding self-generated content, such as writing health-related messages to a physician) [19]. It was also developed among a highly educated sample, limiting its generalizability, and the full scale consists of 21 items, limiting its efficiency [19]. To our knowledge, there are no scales that assess one's comfort and confidence with the foundational digital skills necessary to use digital health care services such as telehealth. We refer to this as digital health care literacy. Such a scale has critical implications for clinical care and understanding the types of patients who are strong candidates for telehealth versus those who may need additional assistance.

Objectives

To address these gaps, we sought to develop a brief measure that assesses digital health care literacy called the Digital Health Care Literacy Scale (DHLS). The item pool was developed using existing literature and expert review, and the survey was then administered to participants as part of a larger study on telehealth equity. Participants in the larger study were randomly split into development and confirmatory samples to identify a reduced version of the survey. We assessed the scale's validity in a variety of ways, including examining its associations with digital access; prior digital health care use; and demographics, including education, income, language, race, and ethnicity.

Methods

Data Collection and Sample

This research was conducted as part of a larger study that sought to examine telehealth use among caregivers of young children from diverse populations. Participants were recruited from the Vanderbilt Pediatric Primary Care Clinic at Vanderbilt University Medical Center (VUMC) in Nashville, Tennessee. This clinic predominantly cares for underserved populations with higher medical and social needs. Eligible participants were aged ≥18 years; spoke a primary language of English, Spanish, or Arabic; and were a parent or guardian of a child aged <13 years who received care at the clinic between March 1, 2020,

and September 30, 2020. We used the electronic medical record to query for caregivers of children who met the inclusion criteria and received permission from their providers to recruit them through telephone calls.

Interested and eligible caregivers completed informed consent and a baseline survey. All data were collected using REDCap (Research Electronic Data Capture; Vanderbilt University), a secure web-based application designed exclusively to support data capture for research studies. Surveys were administered either on the web or over the telephone and in the participant's primary language (English, Spanish, or Arabic). Because of technical specifications in REDCap at the time of this study (ie, content was formatted to only read from left to right), all Arabic speakers (except for a single participant) completed the survey over the telephone. All key study personnel (KSP) were trained and certified before data collection and survey administration. KSP who collected survey data in a non-English language were either native speakers or fluent in the language concerned.

KSP started making telephone calls to caregivers on December 14, 2020. Rolling recruitment occurred for approximately 6 months until 500 eligible families of pediatric patients completed the survey. The final participant completed the survey on June 6, 2021. Participants were compensated with a US $15 Walmart gift card for completing the survey.

Ethics Approval

The Vanderbilt University institutional review board approved all study procedures (approval number: 201990).

Item Pool Development

Relevant literature and gaps in the literature were reviewed by 2 research team members (ECS and FP) to develop an initial potential item pool, covering a range of digital literacy domains and related digital skills and abilities. Input from experts from within and outside VUMC was then used to narrow down and finalize the set of items that was ultimately administered. Experts could also suggest modifications to existing items or propose new items to represent any aspects of digital literacy that may have been missing. Experts within VUMC included clinicians from the Vanderbilt Pediatric Primary Care Clinic and directors from Patient Care Operations, Interpreter Services, the Telemedicine Department, and the Department of Biomedical Informatics. We also elicited input from the manager of Nashville Public Library's Digital Inclusion Initiatives Program. The initial item pool consisted of 81 items; after synthesizing feedback, the refined item pool for administration consisted of 6 items that were focused on confidence in the ability to use technological programs or services and the ability to independently troubleshoot technical issues (Table 1).

Table 1. Finalized item pool for administration and factor analysis.

Item number	Refined item pool
1	I can install applications/programs (like Zoom) on my cell phone, computer, or another electronic device on my own (without asking for help from someone else).[a]
2	I can use applications/programs (like Zoom) on my cell phone, computer, or another electronic device on my own (without asking for help from someone else).[a]
3	I can set up a video chat using my cell phone, computer, or another electronic device on my own (without asking for help from someone else).[a]
4	I can solve or figure out how to solve basic technical issues on my own (without asking for help from someone else).[a]
5	If you encounter a technical issue while using your cell phone, computer, or another electronic device, what do you do first?[b]
6	How often do you need someone (like your child/children) to help you with using your digital devices?[c]

[a]Response options range from 0 (strongly disagree) to 4 (strongly agree).

[b]Response options include 0 (ask someone for help) and 1 (try and solve the technical issue on my own—without help from someone else).

[c]Response options include 0 (always), 1 (almost always), 2 (about half the time), 3 (not very often), and 4 (never).

Translation Process

The items were translated into Spanish by a native Spanish speaker from the VUMC Division of Academic General Pediatrics. The items were translated into Arabic by a formally trained medical translator and native Arabic speaker from the VUMC Interpreter Services Department. Both translators are fluent in, and understand, both English and their native language (Spanish or Arabic). Other than their role as translators, the Spanish and Arabic translators had no other involvement in the study. Both the Spanish and Arabic translations were checked by KSP from the research team to ensure that the translations were accurate. KSP who were involved in this process were either native speakers of, or fluent in, the language concerned. The original documents (in English), translated documents (in Spanish and Arabic), and translator declaration forms (for the Spanish and Arabic translators) were submitted to, and approved by, the Vanderbilt University institutional review board before participant recruitment and data collection.

Measures

The survey included (1) the 6 digital health care literacy items (Table 1), (2) demographic questions, (3) questions about digital access, and (4) questions about digital health care use.

To score the digital health care literacy items (Table 1), we used a sum score of all the items such that higher scores indicated higher digital health care literacy. For item 5, we recoded the response values—0=1 and 1=3—to better align with the

response values of the other items within the scale. The possible sum score for the 6 items ranged from 0 to 23.

Demographic data included age, gender, race, ethnicity, language, education, and income. Regarding digital access, participants were asked whether they owned a smartphone, a laptop computer, and/or a desktop computer. Participants were also asked about the stability of their network connection to use Internet at home and a cell phone data plan. Response options ranged from 1 (no internet or cell phone data plan) to 4 (very good). Finally, several questions assessed participants' prior experience using digital health care. Specifically, among participants who said that they owned a smartphone, we asked whether they had ever accessed a health app. We also asked participants whether they were currently signed up for the patient portal at VUMC. The portal is a secure, web-based tool that provides patients with 24-hour access to personal health information, visit summaries, test results, and secure messaging. Finally, we asked participants whether they had used video telehealth to get care for their child in the past year. Those who had used telehealth in the past year were asked how easy it was to schedule the visit, and those who had not used telehealth in the past year were asked how difficult they thought it would be to schedule a visit. For both these items, response options ranged from 1 (very difficult) to 5 (very easy).

Analyses

Data cleaning included evaluation of missing data, checking implausible values, and evaluating variable distributions. To evaluate the proposed scale, the participants were first divided into development and confirmatory samples so that exploratory factor analysis (EFA) and confirmatory factor analysis (CFA) could be conducted with separate samples of participants. To ensure a balanced number of surveys in each language, participants were randomized into the development and confirmatory samples stratified by language. Demographic characteristics were reported for the overall sample as well as divided by sample. Chi-square tests of independence and independent samples 2-tailed *t* tests were computed to check for balance in demographic characteristics by sample. SPSS software (version 28.0; IBM Corp) was used for data cleaning, EFA, and validation analysis. The lavaan package in R (version 3.6.2; The R Foundation for Statistical Computing) was used for CFA analysis [24], and α was set at .05 for statistical significance.

EFA of Development Sample

EFA was performed on the development sample using principal axis factoring, and varimax rotation was allowed in the case of a solution with more than one factor. EFA was used to evaluate the factor structure of the 6 items proposed for inclusion in the scale as well as to reduce the 6 items to a smaller set of items that could potentially be used to measure digital health care literacy more parsimoniously. Eigenvalues >1, factor loadings >0.4, Cronbach α>.75, and variance explained >0.40 were used as the criteria to evaluate the items retained in the full factors and to attempt to create a reduced factor [25-27]. Once the full and reduced factors were finalized, CFA was performed on the confirmatory sample using the items suggested by the EFA.

CFA of Confirmatory Sample

The CFA was conducted using robust maximum likelihood estimation to test the goodness of fit between the theorized factor structure suggested by the EFA and the confirmatory sample data set. The robust estimation was used because of the Likert-type ordinal responses of the items and does not assume multivariate normality of the items. A constraint value of 1 was placed on 1 item in the factor as is common in modeling analyses with a defined scale. Goodness of fit for the CFA was assessed evaluating the absolute fit, incremental fit, and parsimonious fit of the full and reduced factors [28]. The absolute fit criteria to conclude good fit between the proposed factor structure and the data included nonsignificant chi-square values, root mean square error of approximation, and standardized root mean square residual <0.08 [29]. Incremental fit criteria included the comparative fit index and nonnormed fit index >0.95. Parsimonious fit was indicated by adjusted chi-square (c2/*df*)<3.0 [30]. To assess the reliability of the full and reduced factors, Cronbach α was computed for the EFA and CFA. Composite reliabilities, calculated according to the weighted Ω formula from McDonald [31], were also calculated for the CFA because of concerns that Cronbach α may be inappropriate for use in structural equation modeling [32]. The variance explained was also reported for the EFA, and the average variance explained (AVE) values were calculated for the CFA with the recommended critical value >0.50 indicating that the factors explained enough of the variance in the construct [33].

Validation

We assessed the scale's validity by examining its associations with participants' demographics (ie, gender, race, ethnicity, language, education, and income), digital access, and prior digital health care use. We used the Spearman ρ for continuous variables and the Kruskal-Wallis test for categorical variables.

Results

Sample Characteristics

Participants were, on average, aged 34.7 (SD 7.7) years. Of the 508 participants, 454 (89.4%) were women; 173 (34.1%) were Hispanic, 129 (25.4%) Black, 95 (18.7%) White, and 78 (15.4%) Middle Eastern; 280 (55.1%) preferred English as their primary language, 157 (30.9%) preferred Spanish, and 71 (14%) preferred Arabic; 228 (45%) had an educational attainment of high school degree or less; 230 (45.4%) had an annual household income of <US $35,000; and 351 (69.1%) had children with Medicaid insurance (Table 2). Chi-square and independent samples 2-tailed *t* tests revealed no significant differences between the development and confirmatory samples for any demographic characteristics.

Table 2. Demographic characteristics of the sample overall and by development and confirmatory samples (N=508).

Characteristic	Overall	Development sample (n=254)	Confirmatory sample (n=254)
Participant age (years), mean (SD)	34.7 (7.7)	34.3 (7.9)	35.0 (7.6)
Gender, female,[a] n (%)	454 (89.4)	223 (87.8)	231 (90.9)
Race and ethnicity,[b] n (%)

Digital Health Care Literacy Scale reduced score, mean (SD)	8.6 (3.1)	8.7 (3.0)	8.5 (3.3)

[a]Gender was assessed with the following response options: male, female, and other. No participant identified as other.

[b]Separate databases were used for English-, Spanish-, and Arabic-speaking participants, and the data were combined for analysis. Race and ethnicity were collected with a single item; the response options included White, Black, Asian, Middle Eastern, Hispanic, Native American, Native Hawaiian, other race or ethnicity, and prefer not to answer. In the English and Arabic database, participants could select all options that applied. Participants were coded as multiple if they selected more than one race and/or ethnicity, except for Middle Eastern+White, which was coded as Middle Eastern. Because of incorrect configuration, the race and ethnicity item was not enabled as a check-all item in the Spanish-speaking database (ie, these participants could only check 1 race or ethnicity). Of the 151 participants who completed the Spanish survey, 144 (95.4%) selected Hispanic, 6 (4%) selected White, and 1 (0.6%) selected Black.

[c]GED: General Educational Development.

EFA of Development Sample

To evaluate the full digital health care literacy score, all 6 items were initially entered into the EFA, and 1 factor was extracted with an eigenvalue >1 and factor loadings between 0.45 and 0.96. Cronbach α was excellent at .89, and the variance explained was high at 62% (Table 3). Next, a reduced factor was created by eliminating items from the full factor one at a time and evaluating the resulting factor loadings and variance explained. Items were eliminated based on correlations with other items >0.90 with conceptual overlap (1 item; *I can install applications/programs...* overlapped with *I can use applications/programs...*) and the lowest factor loadings (2 items). On the basis of these criteria, 3 items were retained in the reduced scale (Table 3), with a resulting excellent reliability (Cronbach α=.90) and a high variance explained (78%).

Table 3. Summary of factor loadings and fit statistics for the full and reduced models.

	Full		Reduced	
	EFA[a]	CFA[b]	EFA	CFA
I can use applications/programs (such as Zoom) on my cell phone, computer, or another electronic device on my own (without asking for help from someone else)	0.96	0.95	0.96	0.94
I can set up a video chat using my cell phone, computer, or another electronic device on my own (without asking for help from someone else)	0.89	0.81	0.89	0.82
I can solve or figure out how to solve basic technical issues on my own (without asking for help from someone else)	0.81	0.84	0.80	0.85
I can install applications/programs (such as Zoom) on my cellphone, computer, or another electronic device on my own (without asking for help from someone else)	0.93	0.93	N/A[c]	N/A
If you encounter a technical issue while using your cell phone, computer, or another electronic device, what do you do first?	0.52	0.42	N/A	N/A
How often do you need someone (like your child/children) to help you with using your digital devices?	0.45	0.38	N/A	N/A
Absolute fit

CFI[f]	N/A	0.99	N/A	>0.99
NNFI[g]	N/A	0.98	N/A	>0.99
Parsimonious fit, adjusted chi-square	N/A	1.78	N/A	0.00
Reliability				
Cronbach α	.89	.88	.91	.90
Composite reliability (coefficient Ω)	N/A	0.88	N/A	0.90
Variance explained (EFA); average variance explained (CFA)	0.62	0.62	0.78	0.75

[a]EFA: exploratory factor analysis.

[b]CFA: confirmatory factor analysis.

[c]N/A: not applicable.

[d]RMSEA: root mean square error of approximation.

[e]SRMR: standardized root mean square residual.

[f]CFI: comparative fit index.

[g]NNFI: nonnormed fit index.

CFA of Confirmatory Sample

Both the full and reduced factors were evaluated with CFA (Table 3). The factor loadings for the full factor ranged from 0.38 to 0.95, with model statistics of χ^2_9=16.0; *P*=.07. All the fit statistics exceeded the criteria for good fit between the proposed factor structure and the data. The reliability was excellent, with coefficient Ω=0.88, and the AVE was high at 0.62. The reduced scale also had excellent CFA fit, with factor loadings between 0.82 and 0.94. The chi-square value was 0, meaning the model was saturated (equal number of parameters and df). This also means that the factor was perfectly parsimonious (adjusted chi-square value of 0). All the fit statistics well exceeded the criteria for good fit between the proposed factor structure and the data. The reliability was

excellent, with coefficient Ω=0.90, and the AVE was high at 0.75.

DHLS Validation

Overview

Because of the excellent fit of the reduced factor, we focus on this version of the scale and its validity in the following sections.

Figure 1 shows the final version of the scale with response options and scoring instructions. The associations between the DHLS and measured categorical variables are shown in box plots in Figure 2. Associations with continuous variables are described only in the text.

Figure 1. Digital Health Care Literacy Scale (DHLS).

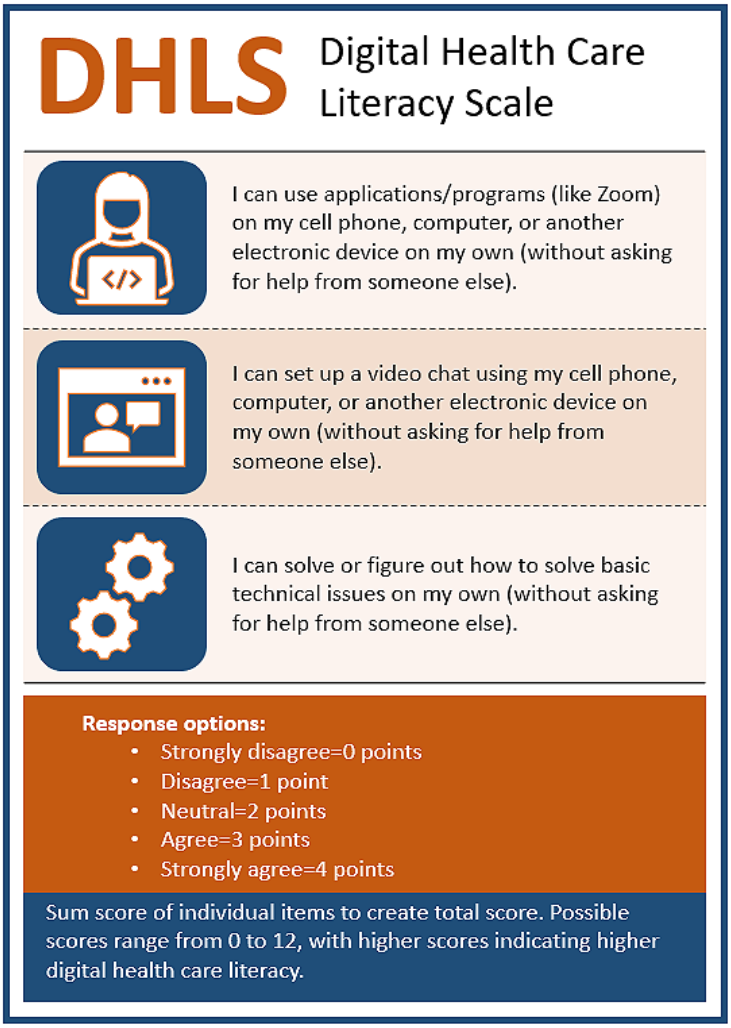

Figure 2. Associations between scores on the Digital Health Care Literacy Scale and participants' demographic variables, digital access, and digital health care use. For all variables with the same superscripted designator, the difference between the medians is not statistically different. If 2 variables have different superscripted designators, they are significantly different from each other.

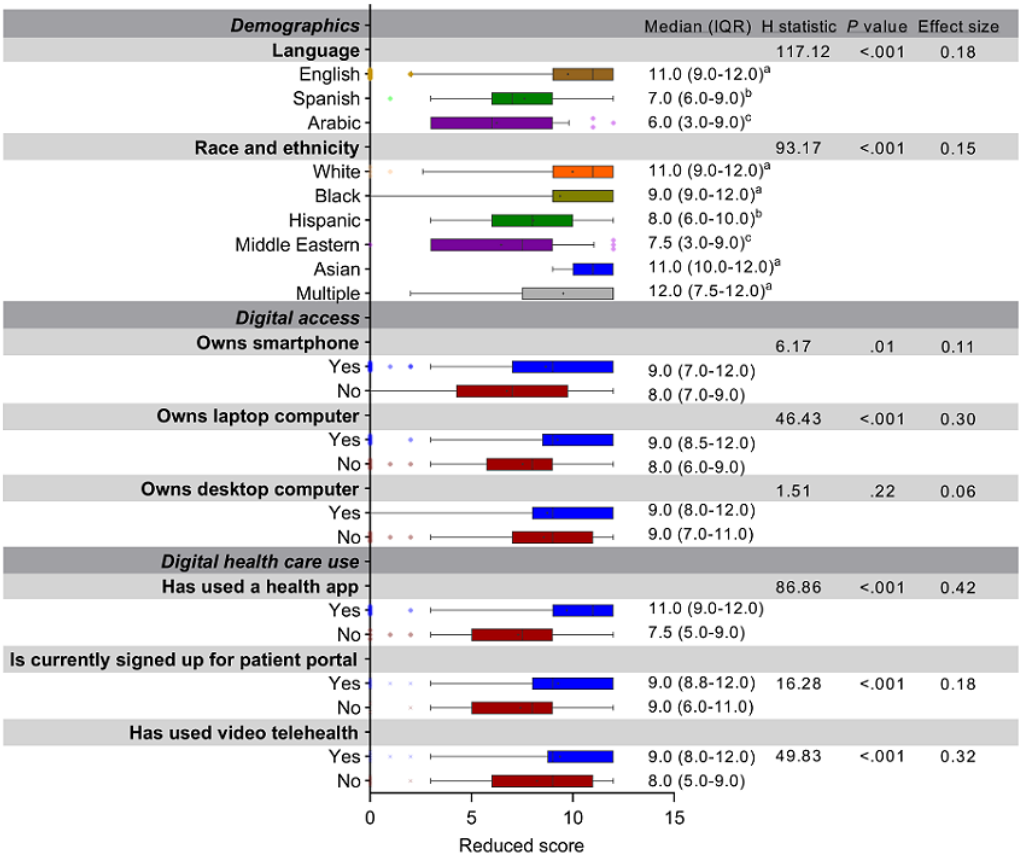

Demographics

The DHLS score was negatively associated with age (ρ=–0.164; *P*<.001), and positively associated with both education (ρ=0.139; *P*=.005) and income (ρ=0.379; *P*<.001). There was not a significant association with gender, H_1=1.267; *P*=.26. The overall model for language was significant, H_2=117.115; *P*<.001. Arabic speakers had lower scores than English and Spanish speakers, and Spanish speakers had lower scores than English speakers (Figure 2). The model for race was also significant, H_5=93.167; *P*<001. Middle Eastern participants had lower scores than all other racial groups, and Hispanic participants had lower scores than all groups, except Middle Eastern (Figure 2).

Digital Access

Among the 508 participants in the study, 25 (4.9%) did not own a smartphone, 191 (37.6%) did not own a laptop computer, and 401 (78.9%) did not own a desktop computer; in addition, 30 (5.9%) did not have internet access at home and 43 (8.5%) said that their internet connection was not good. We found significant associations between most of our digital access items and the DHLS score such that participants who did not have digital tool access had lower scores than those who did. Specifically, participants who did not own a smartphone or a laptop computer had lower digital literacy scores (Figure 2). However, there was not an association between desktop computer ownership and scores (Figure 2). Having a more stable network connection to use the internet at home (ρ=0.343; *P*<.001) and to use a cell phone data plan (ρ=0.312; *P*<.001) were both associated with higher scores.

Digital Health Care Use

Nearly half of the participants (211/508, 41.5%) had never accessed a health app, and 35.8% (182/508) were not signed up for the patient portal. Most (341/508, 67.1%) had not used video telehealth to obtain care for their children. Participants who had never used a health app had lower digital health care literacy scores than those who had (Figure 2). In addition, participants who were not signed up for the patient portal had lower scores than those who were signed up. Participants who had not used video telehealth to obtain care for their children had lower literacy scores than those who had (Figure 2). Among those who had, there was a positive association between the ease of scheduling the visit and their DHLS score (ρ=0.279; *P*=.001). Among those who had not used video telehealth, perceived difficulty of scheduling a visit was associated with lower scores (ρ=0.459; *P*<.001).

Discussion

Principal Findings

Given the increased reliance on digital technologies during the COVID-19 pandemic, it is critical that we understand which

patients are and are not equipped for this shift in health care delivery. Without gauging patients' confidence in skills for using telehealth and similar health care technologies, we risk exacerbating health disparities [14,17]. We developed the DHLS, a scale designed to measure an individual's digital health care literacy, and validated it among a diverse sample of caregivers of young children. Overall, the scale had strong psychometric properties, and the reduced version of the scale performed just as well as the full version, supporting its continued and more efficient use. Participants with lower digital health care literacy had less experience with digital health care and were less likely to own digital tools. In addition, those with less education, with lower income, and people of color had lower digital health care literacy.

To our knowledge, this is one of the first tools intended to measure confidence with the skills necessary for using digital health care services, including telehealth. The Digital Health Literacy Instrument is another scale designed to measure digital health literacy; however, the items are complex and highly specific (eg, *When typing a message [e.g., to your doctor, on a forum, or on social media such as Facebook or Twitter] how easy or difficult is it for you to clearly formulate your question or health-related worry*); furthermore, the scale is long (21 items), which could lead to attrition among users with less education or literacy. The DHLS is a brief, 3-item assessment developed among a racially and socioeconomically diverse sample, and it measures the basic skills necessary for using digital health services. Of note, we focused our application of the scale in this paper on telehealth; however, it may have application to other types of digital tools. This is supported by our study, which validated the scale against the use of similar technologies (eg, whether patients had used a health app and whether they were signed up for a patient portal). Although the reduced 3-item scale is easier to administer, we encourage other researchers to use either the reduced or full scale (the latter includes additional items about digital skills, more broadly, beyond video chat) to explore other applications.

Overall, we found similar associations between participants' characteristics and DHLS scores as other studies reporting on similar digital literacy tools. For example, having less education and lower income has previously been associated with lower eHealth Literacy Scale scores [34]. Although lower telehealth literacy was associated with older age, aligning with other studies examining digital literacy [35,36], the effect was very small. This is likely due to the limited variation in age among our sample: all participants were caregivers of children aged <13 years, with the average caregiver age being only 34.7 (SD 7.7) years. In our study, we found that Hispanic and Middle Eastern participants had lower digital health care literacy than White and Black participants, and Middle Eastern participants had significantly lower scores than Hispanic participants. A similar pattern emerged when looking at language such that Arabic speakers had the lowest digital health care literacy, followed by Spanish speakers, and then English speakers. The findings highlight the importance of examining differences in race and language by unique groups rather than collapsing groups into non-White or non-English.

Our scale could be applied as a brief assessment in clinical settings when assessing individuals' ability to use telehealth. If a participant identifies as more digitally fluent, they may be a strong candidate for telehealth and can receive subsequent instructions for setting up a visit. However, if they identify as being less digitally fluent, resources can be provided to help that individual be better equipped for a visit. Several organizations are exploring solutions to help those with lower technology literacy prepare for telehealth appointments. For example, at VUMC, a medical student–led volunteer initiative was started to help patients set up and test devices for their telehealth appointments [37]. Students used a standardized telephone script to guide patients with downloading the proper software and understanding what to expect for the visit [37]. Another approach in Harris County, Texas, included a nonphysician staff member reaching out to ensure that patients had the proper technology and had resolved issues before the appointment [38]. Primary care practices at University of California San Francisco started an outreach program to all patients aged >65 years with scheduled visits to walk them through setting up and using the video platform app [39]. Although such initiatives have had success with preparing patients for telehealth, they are extremely time and resource intensive; a screening tool such as the DHLS could help identify only those who are most in need of assistance, thereby increasing efficiency and effectiveness. Another approach could be to simply ask patients whether they need extra help setting up a telehealth visit; however, this may have the opposite effect and lead to missing patients who do require help. That is, it is possible that some individuals may not know they need the help, especially if they have never had a telehealth visit. By using items that target the basic skills necessary to use digital tools, the scale could help to accurately identify patients who are unaware that they need assistance. Moreover, some patients may feel uncomfortable communicating that they need help. We hope that this tool provides a respectful approach for identifying those patients who require assistance.

With respect to research, the DHLS could be used as a way to help describe the digital literacy of the sample and determine whether there was representation from low digital literacy communities. It could also be useful to assess whether the use rates or efficacy of a digital technology or program were related to digital literacy. In general, we hope that the scale is included in other studies, whether for descriptive purposes, as a predictor, or as a covariate, to broaden our understanding of its applications and how it functions.

This study includes several limitations. First, these data were collected cross-sectionally; therefore, we cannot draw conclusions regarding causality. It is possible that having lower digital health care literacy leads to a lower likelihood of accessing digital health care services or vice versa. Similarly, as part of a cross-sectional study, we are limited in our ability to propose a cutoff score for determining who requires additional assistance with digital health care; however, certain study designs can effectively answer this question. For example, a future study might administer the DHLS and then attempt to conduct a telehealth visit with all participants. By examining the difference in scores between those who were and were not

successful with completing the visit, we could determine a cutoff score that helps identify the likelihood of being able to successfully carry out a telehealth visit in typical circumstances. In this study, one of our goals was to explore associations between the scale and a variety of barriers to telehealth, of which scheduling a visit was one; however, scheduling a visit is likely reflecting both clinic-level and patient-level characteristics and therefore we recommend interpreting this association with some degree of caution. All participants were caregivers of children and recruited from a clinic in Middle Tennessee, which limits generalizability to other populations and other regions; however, we enrolled a racially, ethnically, and socioeconomically diverse sample of participants. We developed the items such that they can theoretically be used widely with different types of individuals, and we encourage researchers to use and validate the scale in other populations. Although the DHLS was negatively correlated with age, the sample was, on average, of younger age (mean age 34.7, SD 7.7 years), and it will be especially important to see how the scale functions with older populations who tend to experience more barriers to digital health [40-42]. In addition, although we included participants who spoke English, Spanish, and Arabic, there were likely confounding differences among the groups, and we did not use a sample-matching approach to ensure comparability of participant characteristics among languages. To consider the scale validated for all languages, a future study would need to include large numbers of individuals who spoke each language with sufficient heterogeneity and representation of participant characteristics. Relatedly, because our scale items were originally written and derived by English speakers, it is possible that the lower mean scores observed within the Spanish and Arabic groups could have been at least partially caused by intrinsic bias. Full validation within each language would help to confirm whether intrinsic bias was present. Finally, patients were not included in the development of the scale; it is possible that the inclusion of patient input could have strengthened it.

Conclusions

Widespread adoption of telehealth by clinicians and patients alike has the potential to revolutionize health care delivery, improving both quality of life and clinical outcomes. However, as part of this quest, we must consider those patients who may not have the digital access or skills to use telehealth—in many cases, these are the same patients who tend to have worse outcomes. A screening tool such as the DHLS can be a useful resource to identify patients who require additional assistance to effectively engage with telehealth. Validating the scale among other patient populations and in other settings will support the scale's ultimate utility to reduce health care inequities.

Abstract

Background: We have developed a series of knowledge translation (KT) tools that integrate parental experiences to communicate evidence-based information about acute childhood health conditions to parents and caregivers. While we created these tools with parent input, it is unclear if they are useful for diverse parent groups, including specific immigrant and refugee groups in Canada.

Objective: This study aims to explore the usefulness of our preexisting KT tools within our local Somali community, and understand what cultural and linguistic adaptations could improve their usability.

Methods: After viewing 4 KT tools (differing in design and format) about various acute child health conditions, health care providers (HCPs) and knowledge brokers (KBs) who work with Somali families were interviewed about the usability of these tools and discussed considerations for adapting KT tools for use within the Somali community.

Results: A total of 13 HCPs and KBs participated and indicated that the Somali community values accessibility, representation, and the role of trusted others in delivering effective KT products. Understanding accessibility barriers, the power of adequate representation, and engaging meaningfully with prominent community leaders were key suggestions for ensuring relevance of KT products and uptake by community members.

Conclusions: This study represents an essential piece of understanding processes for adapting or developing KT products for culturally and linguistically diverse communities.

Introduction

Knowledge translation (KT) efforts in health promotion, education, and communication are the avenues through which end users obtain and implement evidence-based information with relevance and meaning for their lives [1]. Over the past decade there have been considerable advances to involve end users in this process, spurred by the notion that collaborating with end users creates more applicable, accessible, and meaningful products [2].

Recognizing this, our research program is focused on improving health outcomes for children with acute health conditions through the application of the best available evidence. Situating our work within the Knowledge-to-Action Framework [3], we

involve end users throughout the process to identify priority topics [4], learn of their experiences and needs [5-16], develop prototypes, and evaluate final products through usability testing [17-23], to ensure they are tailored to their needs. To date, we have developed over 24 evidence-based KT tools for parents of children with acute health conditions [24].

Although integrating end user feedback is a valued component in KT product development [25], majority cultures often comprise the accessible pool of engaged end users [26,27]. Consequently, KT products to improve patient knowledge and inform health care decisions within Canada frequently entail English or French communication, and mainstream cultural images. Additionally, the majority of resources assume end users possess a certain level of health literacy, which may not represent the knowledge base of those unfamiliar with Canadian health care systems. It is currently unknown how preexisting KT tools are received by those less familiar with Canadian health care systems.

In situations where new comers or immigrants may face challenges in adjusting to new social environments and health systems, health-related KT is particularly important to address their needs [28]. Unfortunately, there are only few sources offering guidance to researchers interested in pursuing cultural and linguistic adaptation of health information resources. Ideally, researchers would create KT products through collaboration with the end users for effective and relevant health messaging [29], but this may not be feasible for those with finite resources and time.

As diversity and immigration increase in Canada, there will be a greater need for understanding the cultural and linguistic considerations for developing and adapting KT products. Acknowledging this need, we engaged with stakeholders at multicultural organizations who voiced the lack of health resources for the Somali community. In an effort to address this gap, we sought to understand if our KT tools (in their current form) could be useful for the Somali community, and what specific cultural and linguistic adaptations could improve their usability. Additionally, we explored what sociocultural contexts should be considered to increase KT tool usability in general.

Minority cultural groups in Canada, like the Somali community, are not always readily accessible to engage in research processes [30]. Often knowledge brokers (KBs) who can help bridge the gap between research processes and community partnerships support diverse community groups. Through working with researchers and community members they help build and maintain relationships, speak on behalf of community interests, and are able to prioritize community perspectives and values [31]. In the context of health care, moving evidence into action is a key role KBs play [32]. Therefore, as a means of *initially* exploring the usability of our existing KT tools and understanding cultural and linguistic considerations for adapting our products, we first approached stakeholders (health care providers [HCPs] and KBs) who work closely with the Somali community.

Methods

Overview

We conducted 1-on-1 semistructured interviews with HCPs and KBs who have previously worked, or currently work, with the local Somali community. Four different KT tools (differing in design, format, and topic) were sent to participants to review in advance. Participants were then asked to comment on the usefulness and appropriateness of each tool's content and format for use with Somali parents and families.

Recruitment

Following institutional ethics approval, HCPs and KBs serving Somali families were recruited through known multicultural community connections and snowball sampling [33]. Two research team members (MM and AF) are part of the Somali community and helped guide our recruitment efforts, and provided linkages to community associations. All participants provided informed consent prior to data collection.

Survey and Interview

Participants were asked to complete a brief online demographic survey to collect information on their age, sex, cultural identity, job title, work setting, and years of practice. Data were collected and managed using REDCap electronic data capture tools hosted at the University of Alberta [34,35].

Participants then attended a one-on-one interview over Zoom with a research team member (MM or KSW). Prior to each interview, the participants received emailed links to 4 of our existing KT tools: (1) a whiteboard animation video on croup, (2) an interactive infographic on fever, (3) an animated video on what to expect at the emergency department, and (4) an eBook on bronchiolitis, and asked to view each of the tools ahead of the meeting (Multimedia Appendix 1). Participants also had the opportunity to view the KT tools at the start of the interview and while they were providing their feedback.

Members of the research team conducted the interviews by following a semistructured interview guide (Multimedia Appendix 2). For each tool, participants were asked to comment on (1) how useful the tool would be in helping Somali parents, families, and/or caregivers make decisions when their child is sick, (2) if the tool met the needs of Somali parents and families, (3) what adaptations would be needed to make the tool more suitable for Somali parents, families, and/or caregivers. Participants were also asked about what current child health resources they use, and what general considerations were needed when developing tools for diverse community groups.

The semistructured nature of the interviews allowed for exploration of the most meaningful components of participants' testimonies. During and after each interview, the involved researcher wrote detailed field notes to capture nonverbal communication and reflect on their biases [36]. The interviews were conducted in English, recorded, and transcribed verbatim.

Data Analysis

Qualitative data management and analysis were facilitated using NVivo version 12 (QSR International PTY Ltd.). Each interview

transcript was analyzed through thematic analysis [37] where they were read multiple times, and coded with verbatim terms [38]. These codes were then grouped into preliminary categories, which were organized into themes once all transcripts were compared. The common themes were reviewed by several members of the research team to promote analytic rigor and trustworthiness [39]. Rigor was enhanced through continual communication within the research team and detailed field notes [40], where researcher bias was acknowledged and challenged [41]. Descriptive statistics were computed in a Microsoft Office Excel workbook (version 2016; Microsoft Corporation) and were used to describe the study sample.

Ethics Approval

Ethics approval was granted by the University of Alberta Health Research Ethics Board (approval number Pro00102950).

Results

Participants

A total of 13 HCPs and KBs who work with Somali parents in Alberta, Canada, participated in interviews, and 11 completed the demographic questionnaire.

Demographics

Participant demographics are shown in Table 1. Among the 11 participants, 8 (73%) identified as Somali, with 4 of these preferentially speaking Somali within the home. The most common occupation of participants was community KB (6/11, 55%), while others were nurse (1/11, 9%), social workers (2/11, 18%), and pediatricians (2/11, 18%), all serving Somali families within the community.

Table 1. Demographic characteristics of participants (n=11).

Variable	Value, n (%)

Qualitative Interview Findings

Interviews with participants revealed 3 key themes relevant for developing or adapting KT tools for Somali parents: accessibility, representation, and the role of trusted others.

Theme 1: Accessibility

Overview

The HCPs and KBs who participated in this study described several barriers that would limit the access of information for members of the Somali community. Primarily, accessibility barriers were related to language and dissemination considerations.

Language

One of the most prevalent themes across the interviews was the necessity for oral translations of health information. Participants emphasized the importance of translating health information into the Somali language when communicating evidence with the community. Beyond literal translations, participants emphasized the need for a deeper understanding of Somali language and culture to provide high-quality translations. One participant described this need in saying,

> *Many terminologies actually don't exist in Somali that exist in English. So it's not just interpreting things directly, it's actually having a solid understanding of the Somali language in order to assist someone.* [Participant_002]

Additionally, many of the interviewed HCPs mentioned that even those whose only spoken language is Somali may not have knowledge of the written language, making oral communication essential. One participant described the importance of oral communication in saying,

> *The illiteracy rate is very high. So when resources are being created for the Somali community, I think if it's a written material often likely won't reach its audience widely.* [Participant_001]

Those interviewed suggested videos would be more effective than any text-based KT tool, which could lend itself to online dissemination.

Dissemination

HCPs and KBs interviewed suggested that producing videos would be more accessible than text-based KT tools, but often community members (families) are unaware of culturally more "accessible" tools. To enhance the reach of dissemination, HCPs and KBs suggested using applications such as WhatsApp. When asked where to connect with Somali parents, one participant said,

> *A WhatsApp group. On a scale from 1 to 10, I think it has been an 11 when connecting with Somali individuals.* [Participant_003]

One participant mentioned that online dissemination should be used with caution, as some members of the Somali community may not have the technological proficiency to easily access information online. Participants described a technology divide primarily based on age:

> *Our younger generation are more tech savvy...I would like to pass it on verbally. Or to my friend or a neighbor. We are more oral people.* [Participant_004]

In-person communication, although unavailable during the current pandemic, was proposed as a future means of sharing health information. Many of the participants in this study represented organizations where parent information sessions are held. A participant involved with leading in-person parenting classes said,

> *When we did the parenting class with the Somali community in person, you wouldn't believe how much they keep discussing things around the course.* [Participant_008]

Participants believed that the parent sessions they hosted were successful in enriching members' learning experiences.

Theme 2: Representation

Overview

Participants suggested various ways through which KT tools could more accurately portray the lived experiences of Somali parents. The diverse daily lives of community members may not be fully represented in 1 version of illustrations, but the HCPs and KBs suggested that considering character depictions and home remedies would more accurately represent Somali families.

Character Depictions

Along with the importance of having Somali translations available through face-to-face parenting programs, participants suggested including representative characters, family structures, and environments in any visual KT product. Through relatable visuals, Somali community members might feel the content is relevant for their lives. For some families, having a multigeneration household or a single-parent household would increase relatability and improve information reception. One participant articulated the value of accurate character portrayal:

> *The more we showcase people that look like [Somali people] it just makes it a lot easier for them to relate.* [Participant_003]

Another consideration for culturally adapting KT tools is recognition of current health practices in communities.

Home Remedies

Rather than navigating barriers with language, culture, and tangible resources, parents may adopt home remedies suggested by friends and family. Several participants described alternative treatments Somali patients use, as "herbal remedies are very common." (Participant_009).

Understanding how Somali parents respond to their child's illness is an important consideration for KT tools. Moreover, physicians who are unfamiliar with home remedies that are common in Somali culture may not think to ask about existing treatments. One participant suggested that the key to understanding current health practices requires "just being very specific in asking what cultural practices have you done to try to help with your illness." (Participant_010). These practices of Somali parents shape the way they view acute childhood illnesses, and therefore change their information needs.

Theme 3: Trusted Others

Overview

Navigating health care in Canada may be particularly daunting for Somali parents. Numerous barriers prevent Somali families from accessing care and utilizing health care information resources. Participants explained that community leaders have an influential presence in the community, and could be helpful in bridging the gap between HCPs and community members. Understanding the role of community leaders would improve outreach and dissemination efforts. Similarly, participants suggested further exploring relationship dynamics with

physicians and the impact on help seeking and treatment adherence.

Physicians

Participants described the frustration some Somali parents feel when speaking with their physician. One participant described,

> *Many of my clients they tell me the doctor they just ask 1 minute question and they say okay take these medications sometimes they say there is no proper diagnoses.* [Participant_012]

When physicians were available for longer, participants explained that lack of cultural competency prevented meaningful care:

> *Physicians try to send the husband out and that doesn't really go well either because sometimes they don't want to leave the wife with a man physician in the room or something. There can be lots of little challenges and if the health professional have more understanding of the culture then it can be handled in a lot more positive ways.* [Participant_010]

Without appropriate levels of cultural competence, physicians may inadvertently alienate their Somali patients and reinforce distrust in Canadian health services. One participant furthered this point in saying,

> *When there is a cultural barrier there is also a power dynamic that plays. Within the Somali community HCPs are considered important people. And then they hold a sense of authority, so to challenge authority is kind of a taboo thing to do.* [Participant_004]

Somali parents hold physicians in high regard and feel as though they cannot voice concerns or speak frankly with medical professionals. One of the HCPs in this study explained that Somali people "don't want to seek assistance because they lost trust." (Participant_012). As barriers to access and negative experiences mount, Somali parents may be more reliant on community leaders for health advice.

Community Leaders

Rather than working against various barriers to seek professional medical advice, many Somali parents reach out to community leaders for support. In place of seeking medical attention, as a Somali parent, "you'd call family members to find out different cultural herbal remedies to kind of handle an illness." (Participant_010)

Community leaders were also mentioned during interviews as a viable avenue for information dissemination. One participant (Participant_005) suggested "community leaders can work with health care providers to initiate lectures and medical awareness" where Somali parents can learn from a trusted source. Navigating meaningful communication with community organizations was described as a sensitive process, as researchers and government agencies may be viewed an untrustworthy. Above all, participants emphasized recognizing Somali parent experiences:

> *Respect for that is important in gaining trust of families and really helping them benefit from the health care system.* [Participant_001]

Discussion

Principal Findings

Influence of Accessibility Barriers, Representation, and the Role of Trusted Others on KT Tool Development and Uptake

Through engaging with community HCPs and KBs, we aimed to explore the usability of 4 preexisting KT tools and understand what cultural adaptations should be considered to increase their usability with Somali parents and families. Community HCPs and KBs discussed the components of each KT tool through the perspective of using each tool with the Somali families they serve. Through this process, they described how accessibility barriers, representation, and the role of trusted others influence uptake of KT tools.

Accessibility Barriers

Participants suggested that Somali parents may have technological and language barriers that prevent them from accessing online tools in English. Although studies have found that parents often rely on the internet for health information [42], this may not hold true for Somali parents, particularly those that are new to Canada. Participants described parents and families having a spectrum of comfort with both English language and technology. The overwhelming preference voiced by HCPs and KBs was for communicating health information in Somali and in person. Participants described the strong oral culture of Somali communities where they preferentially sought information through peers rather than online or from health clinics. This finding aligns with a previously reported project with Somali refugees where they voiced a preference for 1-on-1 social support when navigating social services [43]. If oral communication and social support are the most impactful ways through which KT tools are presented to Somali parents, then the role of trusted community leaders should be further explored to help guide dissemination efforts.

Representation

It should be noted that the Somali community is diverse in and of itself. There is a great difference between the experiences of refugees and immigrants entering Canada [44]. Somali people may have gained permanent residency in Canada through family class, economic class, humanitarian relief, or through refugee status; others may have been born in Canada and have a greater understanding of the health care system [45]. Evidence suggests that immigrants from racialized groups are at risk of worsening health throughout their stay in Canada [46]. Compared with skilled workers, refugees reported a worse health status overall [47]. Additionally, length of residency in Canada may impact health resource needs (eg, established immigrants have had more exposure to harmful postmigration environments than recent immigrants [48]). Families just settling into their new life in Canada may have more needs related to how to access health care services, as many face barriers in navigating the health care system [45]. By contrast, families who are settled

may be wanting information on specific health-related topics such as nutrition and immunizations that have arisen over time. As Somali community members could represent a wide range of health literacy and have varying priorities, it is important for researchers to fully understand the information needs of the specific end user group.

Role of Trusted Others

The experiences of Somali parents relayed by HCPs and KBs in this study suggested that community leaders and family play a significant role in dissemination of health information. Similarly, participants in this study described that Somali parents who have lived in Canada for a longer period may also prefer seeking health information from friends due to negative experiences with the Canadian health care system. Home remedies and advice from friends may be more appealing and familiar than navigating barriers to health care access. As reported in this study, and by Clark and Missal [30], community leaders may be an impactful way of reaching Somali community members. Delivering this information via online media may be helpful, but only if it is accessible to the target audience. If community leaders could be involved with creating and disseminating KT products, there may be greater uptake. It should be noted that relying on community leaders also requires cultural sensitivity and reciprocity for ethical compensation of their time and effort [30].

Cultural Adaptation and KT Strategies

Bottom-up processes with participatory engagement may be the most impactful method for developing relevant and appropriate messaging [29], but these processes are often time-consuming and can be costly for researchers. Navigating appropriate and truly patient-driven health information campaigns is a nuanced process for each specific end user population [49]. Researchers who have previously developed KT tools for majority cultures may not have the time or resources to engage in this process for other cultural communities; instead, they may seek to adapt their current work for use with more diverse populations [50]. There are several processes of cultural adaptation that have been previously applied to adapt health intervention programs [51], decision aids [52], and patient-reported outcome scales [53]. When a niche community has a statistically higher prevalence of a certain disease or illness, an intervention may be designed to enact change on the behavior or environment [30]. However, little information or guidance exists on how best to adapt KT products that reach diverse end user needs. Additionally, the situational context regarding how cultural assimilation plays a role should be further explored. We recently set out to understand perspectives of French and Filipino parents in Alberta regarding our KT tools [54], who they themselves recognized that “their cultures were assimilated into a western Canadian lifestyle” and thus the needs of newcomer populations may be different.

Impactful KT goes beyond dissemination, and involves engagement, participation, and impact evaluation by knowledge users, alongside efforts focused on sustainability. Several studies emphasize the importance of consultation with specific cultural groups during KT activities and health promotion campaigns [28]. Of particular note, Telenta and colleagues [55] found that engaging directly with niche cultural communities allows stakeholders to invest in the research process, and respond more positively to KT products. Engaging with specific end users such as the Somali community to understand their unique needs and knowledge gaps can ensure that these tools are relatable, useful, and accessible by increasing cultural relevancy. In turn, utilization of these tools can potentially lead to improved health outcomes for Somali children.

A key driver of engagement with end users is the role KBs play as intermediaries within the community. Often they are flexible and responsive to both the researcher’s and community’s needs, building mutual understandings of goals and cultures to support the specific initiative [56]. Within their roles (including knowledge management and building capacity) KBs are essential to understanding how to access, adapt, and disseminate knowledge [31]. In the context of health care, this is integral to the success of moving evidence into action through the development of tailored KT products.

Limitations

This exploratory study involved HCPs and KBs, some of whom were community members, but others who were outsiders to the lived experiences of Somali parents. This insider knowledge with culturally and linguistically diverse communities has proved beneficial in KT projects [26,27]. Future research with integrated feedback from Somali parents would produce more relevant, impactful work. Additionally, only Albertan HCPs and KBs were recruited during this study, so the contextual pieces from other geographical areas may not be represented in their experiences. Undoubtedly the most effective method of producing relevant messaging would be truly participatory in nature, gaining insight from bottom-up data derivation [29]. Nonetheless, this formative study adds to the understandings of how health messaging could be conveyed more effectively to diverse communities. It also gives pause for thought to other researchers considering adapting or developing resources for linguistically and culturally diverse communities.

Innovation

Increasingly diverse populations in Canada necessitate greater effort in reaching culturally and linguistically diverse communities with KT strategies. As researchers become more interested in culturally adapting their KT tools, studies as described above will prove helpful for guidance.

These findings contribute to the evidence base regarding the need for early engagement with community members, and the need for cultural and linguistic adaptations of KT tools to improve accessibility for diverse communities. Furthermore, we advocate for an innovative approach to ensure adaptations go beyond the literal translation and encompass the fluid and dynamic phenomenon of culture.

When developing KT products there will undoubtedly be unique considerations specific to different cultural groups, but common threads for practice will help guide future efforts. This study represents an essential piece of understanding processes and resource needs for adapting KT products for culturally and linguistically diverse communities.

Conclusions

Community HCPs and KBs who serve Somali families believed that adding appropriate visuals, providing translated audio, and considering environmental contexts would improve KT tool usability. Prioritizing reciprocity and building relationships with trusted community members would also enhance the reach and trustworthiness of the tools.

Acknowledgments

This work was supported by funding from the Stollery Children's Hospital Foundation through the Stollery Science Lab. The funding body had no role in the design of the study and collection, analysis, and interpretation of data and in writing the manuscript. Abstract

Background: Accurately and unobtrusively testing the effects of snoring and sleep interventions at home has become possible with recent advances in digital measurement technologies.

Objective: The aim of this study was to examine the effectiveness of using an adjustable bed base to sleep with the upper body in an inclined position to reduce snoring and improve sleep, measured at home using commercially available trackers.

Methods: Self-reported snorers (N=25) monitored their snoring and sleep nightly and completed questionnaires daily for 8 weeks. They slept flat for the first 4 weeks, then used an adjustable bed base to sleep with the upper body at a 12-degree incline for the next 4 weeks.

Results: Over 1000 nights of data were analyzed. Objective snoring data showed a 7% relative reduction in snoring duration (*P*=.001) in the inclined position. Objective sleep data showed 4% fewer awakenings (*P*=.04) and a 5% increase in the proportion of time spent in deep sleep (*P*=.02) in the inclined position. Consistent with these objective findings, snoring and sleep measured by self-report improved.

Conclusions: New measurement technologies allow intervention studies to be conducted in the comfort of research participants' own bedrooms. This study showed that sleeping at an incline has potential as a nonobtrusive means of reducing snoring and improving sleep in a nonclinical snoring population.

Introduction

Snoring is common and has been associated with poor sleep, increased risk of coronary artery disease, depressive disorders, and other health-related problems [1]. Changing one's sleeping posture has long been known as a way to reduce snoring [2]. This can include repositioning the upper body to an inclined position to open the upper airways, which can be achieved using specialized pillows, wedges, or bed bases.

These approaches have shown some effectiveness in patients with sleep apnea and other disorders [3]. For example, Skinner et al [4] reported mixed results after testing a shoulder-head elevation pillow for the management of obstructive sleep apnea (OSA). More recently, Souza et al [5] showed that head-of-bed elevation using a laboratory bed reduced the severity of OSA without interfering with sleep architecture. Similarly, a study of a bed that automatically lifted the trunk of the user upon detection of snoring found that it was able to reduce episodes of snoring in the laboratory [6].

However, evidence is lacking in nonclinical populations and settings. The accuracy of new unobtrusive sleep and snoring measurement technologies allows intervention studies to be conducted in research participants' own bedrooms and may contribute new evidence-based knowledge to the field of applied

sleep and snoring research. This method of in-home research using innovative digital health tools has an advantage over traditional sleep laboratory studies. It provides insight into the effectiveness of the intervention under real-life conditions, yielding ecologically valid results while still capturing objective data [7].

In this study, using an adjustable bed base to sleep with the upper body at a 12-degree incline was compared to sleeping in a flat position. The 12-degree angle is sufficient to elevate the head while still being comfortable for sleep. A mild degree of head-of-bed elevation, compared to larger angles, is most likely to be well tolerated while still being effective according to laboratory studies [5,6]. The inclined position was hypothesized to reduce snoring and improve sleep. This was measured objectively over 1000 nights of data collected using commercially available trackers as well as by self-report.

Methods

Participants

The sample included 25 users of SleepScore Labs technology who self-reported nightly snoring and screened negatively for sleep apnea based on the NoSAS (Neck Circumference, Obesity, Snoring, Age, Sex) screening tool, using a cut-off score of >8 [8], and/or had a BMI <30 kg/m^2. Users who reported having a partner who snored were excluded. Users with self-reported sleep disorders or other medical conditions (eg, hyperthyroidism) or lifestyle factors (eg, shift work) affecting sleep were excluded. Of the 25 participants, 60% (n=15) were male and the average age was 38 (SD 11.38) years, ranging from 21-62 years.

Ethics Approval

All participants provided written informed consent, and all procedures were conducted in accordance with the ethical standards of the 1964 Declaration of Helsinki. Western Institutional Review Board-Copernicus Group reviewed the study under the Common Rule and applicable guidance and determined this to be exempt research.

Study Design and Procedures

A within-subjects pre-post design was used. During the baseline period, participants slept on their own mattress in a flat position for 4 weeks. During the intervention period, their bed base was replaced with the Dr Oz Good Life Adjustable Base Pro (2020 collection, Maven) to allow for sleeping in an inclined position for 4 weeks using their original mattress. Participants used the preprogrammed Anti-Snore position, resulting in an electrical motor elevating the head of the bed to a 12-degree incline prior to sleep. During the entire 8-week study, participants were instructed to record their snoring and sleep nightly and complete questionnaires daily. Data were collected during the same time period across all participants to account for weekday and weekend variation.

Measurement of Outcomes

Objective snoring was measured using the Do I Snore or Grind app (Version 1.2.4(2); SleepScore Labs) on an Apple iPod touch sixth generation (Model A1574; Apple Inc) with snoring sensitivity set to high and grinding sensitivity set to low. This consumer app captures sounds using the microphone of the mobile device and identifies snoring using artificial intelligence–based algorithms that filter out nonsnoring sounds. The app quantifies snoring duration exceeding the set level of sensitivity and transforms the percentage of the night during which the user snored into a snore score.

Objective sleep was measured with the SleepScore Max (SleepScore Labs), a noncontact monitoring device using respiratory and motion signals to detect sleep. It uses ultralow-power radiofrequency waves to monitor body movement while in bed; this measurement is unaffected by bedding or nightwear. High-resolution magnitude and duration data of gross movements, micromovements, and full breathing cycles are captured and transformed into 30-second epoch sleep stage data (Wake, Light, Deep, rapid eye movement [REM]) using proprietary algorithms. Studies have shown good agreement between this approach and polysomnography [9,10]. Using the 30-second epoch data, standard sleep metrics were calculated. In addition, the following 3 SleepScore Labs proprietary sleep measures reflecting sleep quality were calculated, all ranging from 0-100 and normalized for age and sex using reference values from the meta-analysis of quantitative sleep parameters by Ohayon et al [11]: SleepScore, which is an overall sleep quality metric that includes objectively measured total sleep time, sleep onset latency, and sleep stage durations; BodyScore, which reflects the age- and sex-normalized amount of deep (non–rapid eye movement stage 3 [NREM-3]) sleep; and MindScore, which reflects the age- and sex-normalized amount of REM sleep. The device's sensor is placed next to the bed and a companion app shows users their sleep data along with insights and advice.

Self-report items were developed for the current study. Perceived snoring (nights per week snored and frequency of waking from snoring) was measured before and after the intervention period and perceived sleep (time to fall asleep, number of awakenings during the night, amount of time spent awake after initially falling asleep, feeling well-rested in the morning, and overall sleep quality) was measured daily. These data were collected on the internet using SurveyMonkey (Momentive Inc).

Statistical Analyses

Statistical analyses were performed in R (version 3.5.2; R Foundation for Statistical Computing). Nightly objective snoring data, objective sleep data, and self-reported sleep data were analyzed using multilevel regression with a random intercept model, accounting for nights nested within participants and comparing nights during the baseline period to nights during the intervention period for each outcome. The regression model used was the following: $SleepMeasure_{ij} = Const_{0ij} + \beta \times TestPeriod_{ij}$; TestPeriod was coded as 0 for observations during the baseline and 1 for nights during the intervention period.

Self-reported snoring outcomes were analyzed with paired-samples *t* tests.

Discrepancies in sample sizes (N=1181 for snoring, N=991 for sleep, and N=1185 for self-report) occurred as the data sources were incomplete. Participants tracked their snoring and sleep

at home and at times were not fully compliant with using these measurement tools or completing daily surveys on the internet. All results reported reflect the largest sample available for each set of analyses.

Results

Snoring-Related Outcomes

Night-to-night objective measurement of snoring (1181 nights nested within 25 participants) revealed a 7% relative reduction in snoring duration (P=.001) when sleeping in the inclined position compared to the flat position (see Table 1).

Similar to the objective findings, self-report data indicated that participants felt they snored less often (decreasing on average from 6 nights per week to 5; P=.01) and were woken up by their snoring less often (decreasing on average from sometimes to rarely; P<.001) in the inclined position compared to the flat position. Participants with a bed partner (n=10) reported that their partner woke them less often to stop snoring (decreasing on average from sometimes to rarely; P<.01) when sleeping in the inclined position.

Table 1. Objective snoring and objective sleep multilevel regression results comparing the baseline to the intervention period.

Outcomes	Observed mean (SD)[a]		Estimated marginal means[b]		
	Baseline period	Intervention period	Intercept (SE)	β[c]	*P* value
Objective snoring (1181 nights)					
Snore score[d]	9.28 (4.29)	8.61 (3.64)	9.31 (0.24)	–0.756	.001
Objective sleep (991 nights)					
Time in bed in minutes	452.76 (76.35)	445.66(75.57)	450.24 (5.16)	–4.689	.18
Total sleep time in minutes	391.27 (69.05)	383.78(68.16)	388.79 (4.61)	–5.534	.12
Sleep efficiency[e]	85.43 (5.66)	84.02(5.92)	86.19 (0.41)	0.137	.37
Sleep onset latency in minutes	18.65 (14.81)	18.05(13.23)	18.54 (1.01)	0.095	.46
Number of awakenings	4.45 (1.99)	4.25(2.07)	4.43 (0.13)	–0.237	.04
Percentage of time spent awake after sleep onset	9.10 (4.87)	9.25(5.52)	9.10 (0.37)	0.032	.47
Percentage of time in light sleep	54.30 (7.07)	53.55(6.86)	54.40 (0.46)	–0.668	.07
Percentage of time in deep sleep	19.30 (6.55)	20.20(7.44)	19.30 (0.45)	0.905	.02
Percentage of time in REM[f] sleep	17.30 (5.37)	17.00(5.66)	17.20 (0.36)	–0.298	.21
SleepScore[g]	77.63 (9.73)	78.27(9.98)	77.40 (0.67)	0.633	.17
BodyScore[g]	78.93 (9.59)	81.10(10.13)	78.85 (0.63)	2.109	<.001
MindScore[g]	76.99 (12.99)	75.62(14.46)	76.61 (0.93)	–1.421	.06

[a]For the baseline and intervention periods, each mean was calculated by averaging nights across participants, then averaging those participants' averages to a single simple average.

[b]These are the outcomes of separate multilevel regression analyses. Each row shows results from a different single-predictor, single-outcome model.

[c]The beta values are unstandardized and can therefore be interpreted on the same scale as the original data.

[d]Snore score is reported as a percentage.

[e]Sleep efficiency is calculated as the ratio of time spent asleep to time spent in bed and reported as a percentage.

[f]REM: rapid eye movement.

[g]These scores range from 0 to 100.

Sleep-Related Outcomes

Night-to-night objective measurement of sleep (991 nights nested within 25 participants) revealed that when sleeping in the inclined position, participants woke up less often (4% decrease in number of awakenings; P=.04) and experienced a greater proportion of deep sleep (5% relative increase; P=.02), reflected by an improved BodyScore (3% increase; P<.001). Detailed sleep metrics are displayed in Table 1.

Multilevel analyses of the self-reported sleep data (1185 nights nested within 25 participants) showed that participants perceived that they fell asleep faster (20% decrease in sleep onset latency; P<.001), woke up less often (15% decrease in number of awakenings; P=.001), felt more rested in the morning (17% increase in the score on the 0-100 scale; P<.001), and experienced better sleep quality (14% increase in the score on the 0-100 scale; P<.001) in the inclined position compared to the flat position (see Table 2).

Table 2. Multilevel regression results for self-reported sleep (1185 nights), comparing the baseline to the intervention period.

Outcomes	Observed mean (SD)[a]		Estimated marginal means[b]		
	Baseline period	Intervention period	Intercept (SE)	β[c]	*P* value
Perceived sleep onset latency in minutes	16.38 (11.80)	13.13 (9.35)	16.23 (0.79)	–2.922	<.001
Perceived number of awakenings	2.33 (1.44)	1.97 (1.31)	2.31 (0.10)	–0.320	.001
Perceived amount of time spent awake after sleep onset in minutes	14.10 (14.43)	13.00 (13.36)	14.13 (1.38)	–0.898	.26
Feeling well-rested in morning[d]	56.29 (16.38)	66.09 (16.30)	56.60 (1.08)	9.651	<.001
Perceived sleep quality[d]	58.94 (15.52)	67.47 (16.78)	59.47 (1.06)	8.078	<.001

[a]For the baseline and intervention period, each mean was calculated by averaging nights across participants, then averaging those participants' averages to a single simple average.

[b]These are the outcomes of separate multilevel regression analyses. Each row shows results from a different single-predictor, single-outcome model.

[c]The beta values are unstandardized and can therefore be interpreted on the same scale as the original data.

[d]These outcomes are reported as a score ranging from 0-100.

Discussion

Recent technological advances enable the accurate digital measurement of sleep and snoring in the comfort and familiarity of one's habitual bedroom [12,13]. In this study, participants slept on their own mattresses in their homes for the duration of the study, recording their snoring and sleep nightly with commercially available trackers and by self-report. They slept flat for 4 weeks and then used the Anti-Snore setting (12-degree incline) of the Adjustable Base Pro for 4 weeks.

Analyses of over 1000 nights of data showed a significant improvement across all 4 areas measured: objective snoring, perceived snoring, objective sleep, and perceived sleep. When sleeping with the upper body in the inclined position, compared to when sleeping flat, objectively measured snoring duration decreased and self-reported snoring outcomes improved. Objective sleep measurements revealed fewer awakenings and more time in deep sleep when sleeping in the inclined position. Related to the increase in deep sleep, participants' average BodyScore increased. Self-reported sleep data showed fewer perceived awakenings and better sleep quality; additionally, participants felt more well-rested in the morning. Participants also felt that they fell asleep faster in the inclined position, but this finding was not confirmed by the objective sleep data. Taken together, these findings suggest that future in-home product intervention research using commercially available snoring and sleep trackers is merited.

In conclusion, sleeping with the upper body at an incline has potential as a simple nonobtrusive means of reducing snoring and improving sleep in a nonclinical snoring population. This sleeping position is thought to lead to benefits by decreasing upper airway collapsibility and increasing the upper airway area, compared to the flat position, leading to improved breathing and, in turn, better sleep [5]. Elevating the upper body at night is also frequently recommended to alleviate heartburn symptoms and improve sleep in individuals experiencing nocturnal gastroesophageal reflux [14]. This nonpharmacologic approach is preferred by many patients. Similarly, snorers might prefer this intervention because it is incorporated into their bedroom furniture, does not require extra pillows or devices, and may provide more comfort than nasal or oral appliances that can reduce snoring.

Study limitations include the need for further validation testing of the commercially available snoring app and the absence of a control group. Applied in-home product intervention studies have limitations compared to clinical trials; the key is to assess any change from no product use to product use as it would be experienced outside of a research setting. The design best reflecting this real-life experience is a baseline-controlled intervention. By using a within-subjects design with long-term use of the intervention, we have confidence that the observed changes are due to the intervention itself.

In this study, data were not collected regarding the sleeper's preferred body position (eg, supine or lateral) and therefore, possible interactions of sleeping position with the incline were not explored. These interactions have been shown to be relevant in determining optimal positional therapy for sleep apnea [15] and would be an interesting addition to future studies of snorers at home. Another useful future research direction could be measuring the sleep of snorers' bed partners because the elimination of snoring has been shown to benefit partners' sleep [16]. These types of research questions can now be studied using digital technology that is commercially available to consumers for home use.

Abstract

Background: Transition to home after hospitalization involves the potential risk of adverse patient events, such as knowledge deficits related to self-care, medication errors, and readmissions. Despite broad organizational efforts to provide better care transitions for patients, there are challenges in implementing interventions that effectively improve care transition outcomes, as evidenced by readmission rates. Collaborative efforts that require health care professionals, patients, and caregivers to work together are necessary to identify gaps associated with transitions of care and generate effective transitional care interventions.

Objective: This study aims to understand the usefulness of participatory design approaches in identifying the design implications of transition of care interventions in health care settings. Through a series of participatory design workshops, we have brought stakeholders of the health care system together. With a shared understanding of care transition and patient experience, we have provided participants with opportunities to generate possible design implications for care transitions.

Methods: We selected field observations in clinical settings and participatory design workshops to develop transitional care interventions that serve each hospital's unique situation and context. Patient journey maps were created and functioned as tools for creating a shared understanding of the discharge process across different stakeholders in the health care environment. The intervention sustainability was also assessed. By applying thematic analysis methods, we analyzed the problem statements and proposed interventions collected from participatory design workshops. The findings showed patterns of major discussion during the workshop.

Results: On the basis of the workshop results, we formalized the transition of care model—the socioeconomic, active engagement, follow-up, education, discharge readiness tool, and consistency (Integrated Michigan Patient-centered Alliance in Care Transitions transition of care model)—which other organizations can apply to improve patient experiences in care transition. This model highlights the most significant themes that should necessarily be considered to improve the transition of care.

Conclusions: Our study presents the benefits of the participatory design approach in defining the challenges associated with transitions of care related to patient discharge and generating sustainable interventions to improve care transitions.

Introduction

Improving Transitions of Care to Reduce Hospital Readmission

The US health care system has undergone a drastic shift in the past decade as payment to health systems has transitioned to rewarding value over the volume of care. Quality-based repayment programs incentivize hospitals through payment withholding or incentive-based payments based on outcomes instead of volume. Models such as the Hospital Readmission Reduction Program (HRRP), established in 2012 under the Affordable Care Act, financially penalize hospitals if they have higher than expected risk-standardized 30-day readmission rates [1,2].

Many quality reimbursement models focus on conditions that have a large morbidity and mortality burden, contribute to significant direct and indirect health care costs, and have clear and direct measures to target [3]. Many value-based purchasing programs, including HRRP, focus on improving the treatment of specific disease conditions such as acute myocardial infarction, heart failure, pneumonia, chronic obstructive pulmonary disease, coronary artery bypass graft surgery, elective primary total hip arthroplasty, and total knee arthroplasty [4].

In particular, the HRRP has forced hospitals to recognize that the transition to home after hospitalization carries a significant risk of adverse patient events, readmissions, and increased costs [5]. Transition of care interventions refer to improvements developed to reduce readmission rates among populations transitioning from one care setting to another [6]. Despite ongoing organizational efforts to improve care transitions, there continue to be challenges in implementing interventions that consistently affect key care transition quality indicators such as 30-day readmission rates [7,8].

Although transitions involve multiple stakeholders in the care continuum, including physicians, nurses, hospitals, primary care organizations, and patients, the transition of care interventions were traditionally developed from the health care provider perspective [9]. These interventions are often limited to a single phase in the care continuum, involve only a single institution, and are often limited to interventions considered important from the provider's perspective [10]. Patients often remain passive participants in the health care system when discussing care transitions. As a result of these hierarchical approaches, developing and implementing effective interventions has been a significant challenge in improving care transitions.

As hospitals and physician organizations (POs) have recognized the benefits of working together to reduce readmissions through programs such as the HRRP [11,12], health care organizations have started to highlight the increased benefits of nonhierarchical collaborative efforts that bring health care professionals, patients, and caregivers together. This collaboration is necessary to identify gaps associated with transitions of care and generate effective interventions.

Health care organizations, private payers, the Centers for Medicare and Medicaid Services, and policy makers have been charged with the task of creating unique ways of incentivizing hospitals and POs to improve patient outcomes and reduce readmissions. An example of this collaborative approach is the Integrated Michigan Patient-centered Alliance in Care (I-MPACT) Collaborative Quality Initiative (CQI) [13]. I-MPACT is a patient-centered CQI that engages hospitals, POs, and patients throughout Michigan and supports the development and implementation of innovative approaches for improving care transitions. The collaborative is composed of numerous health system groups, or clusters, in the Michigan area, which comprise a hospital, a partnering outpatient PO, and patients and caregivers from the local community. Within the CQI, clusters are asked to identify the target population and implement interventions to reduce readmissions for the target population. This initiative offers a unique opportunity for hospitals and PO groups to collaborate to improve care and aligns seamlessly with value-based programs such as the HRRP.

Although the benefits of nonhierarchical collaborative efforts are acknowledged, the lack of effective tools to engage stakeholders often discourages collaborative, multidisciplinary solutions that bring together patients, hospital systems, and outpatient systems [14,15]. As a result, patients' voices are still marginalized and devalued when identifying problems or creating effective approaches to alleviate readmission [16]. There is a call for effective tools that will help hospitals, associated outpatient organizations, patients, and community caregivers in defining gaps associated with transitions of care.

Need for a Novel Approach to Identify Gaps Associated With Transitions of Care: Value of Participatory Design

Participatory design is often defined as the involvement of end users of services or products in the early phases of the development process [17-19]. The origins of the participatory design approach are from the 1970s Scandinavian cooperative design movement. When computers were first introduced in the work environment, workers were concerned that they would no longer have the agency to control their tasks and that they would be replaced by newly implemented technologies [17]. To respond to these changes, they aimed to take an active role in managing their work environment. This workplace democracy movement influenced the origin of the participatory design approach and yielded detailed design techniques to invite users throughout the design process [19]. Activity-based methods, including collaborative workshops, brainstorming, and drawing activities, are effective in understanding end users' expertise and experiences [20,21]. As participatory design has emerged beyond the field of design and human-computer interaction, researchers in other fields, including health care, have started

to apply different participatory methods and tools during projects [18,22]. As health care interventions are often designed and implemented from providers' perspectives, participatory design approaches are considered effective cocreation methods when they include the patient's perspective.

One of the most widely used participatory design methods is the collaborative design workshop. During the workshops, participants with different perspectives often form subgroups and discuss experiences, insights, and ideas regarding health care interventions through collaborative activities [17,23]. In these collaborative workshops, participants are recognized as knowledgeable stakeholders and experts on particular health issues (eg, disease-specific experiences). Recent health care and human-computer interaction literature has highlighted the benefits of a participatory design workshop with people with special needs in health care contexts (eg, older adults [24], people with dementia [25], pediatric patients, and their caregivers) [24-28]. By participating in different activities, participants can open up conversations regarding complex and unfamiliar social issues during participatory design sessions. For example, Harrington et al [26,29] conducted 2 community-based workshops with underserved populations in the United States. They identified how participants managed their health and the function of design workshops as facilitators for health-related discussions in their communities. Different activities were considered, including mapping activities, to draw participants' insights into their health management. Similarly, Unbehaun et a [30] conducted participatory, co-design sessions with 14 people with dementia and their caregivers to understand how exergames can be integrated into their daily routines. From multiple design sessions, researchers were able to iteratively modify their design ideas toward users' motivations and interests. As these examples show, participatory design approaches helped health care researchers develop a deeper understanding of the lived experiences of technology users and engage them in the design of interventions.

To our knowledge, this study is the first to apply participatory design approaches in the context of care transition. As care transitions are a series of events throughout the care continuum rather than a single event, professionals who are engaged in a patient's care transition typically witness only a part of the whole process. As participants perceive care transitions from multiple perspectives, the authors sought to develop a shared understanding of the care transition. A participatory design workshop was proposed as an effective approach to build a consensus on the care transition processes among different stakeholders.

Building on previous studies that showed the benefits of participatory design methods in different health care settings, this study suggests expanding the application of participatory design workshops beyond a single institution and a single trial. The authors set out to examine the usefulness of inviting multiple health care institutions into the participatory design workshop and the sustainability of the interventions, including long-term follow-up with the participants.

Research Aims

The overall purpose of this study is to identify the design implications of transition of care interventions derived from the participatory design workshop series. On the basis of qualitative analyses of ideas collected during the workshop, we discuss the major themes of transitional care interventions developed by the project clusters. Our study will contribute to improving methodological innovations in developing a shared understanding of the transition of care that encompasses the patient's perspective.

Methods

Study Design

The goal of this study was to apply participatory design approaches in the context of care transition and generate emerging themes for interventions across different hospitals. We highlight the benefits of gathering stakeholders from a local hospital for collaboration, using patient-centered perspectives, and incorporating participant observation in the hospital setting. During the postworkshop period, we also captured the following: (1) the status of the intervention (active or inactive, modifications, and maintenance), (2) the status of the cluster (participated or dropped out during the study), and (3) whether the cluster conducted an observation. In the *Intervention Sustainability Follow-up* section, we summarize the data collected from 2016 to August 2020.

Ethical Considerations

I-MPACT's quality improvement efforts were reviewed by the Institutional Review Board at the University of Michigan (IRB# HUM00126940) and determined to be exempt.

Data Collection

Observation and Patient Journey Maps

Within each cluster, on the day of discharge, a charge nurse identified each patient for observation from the target population. Observations were conducted before discharge from early morning to when the patient physically left the hospital, by an I-MPACT representative not affiliated with the hospital, after obtaining consent from the patient [17]. Observations lasted between 2 and 8 hours and were primarily focused on the patient's perspective during the process. Timestamps were recorded of patient-provider interactions; patients' and caregivers' behaviors; and details surrounding any type of patient instruction or education, including medication administration, self-care activities, mobility restrictions, and wait or idle time. On the basis of the observation data, we created a journey map that shows an overview of each patient's day of hospital discharge [31]. As a result, 26 unique patient journey maps were created from these observations, with at least one or more patient journey maps from each cluster (Multimedia Appendix 1). The 26 patient journey maps were generated from each participating hospital and shared with all stakeholders at the start of participatory design workshops. These patient journey maps represented a discharge timeline from the patient's perspective and included all events associated

with the discharge process that were considered significant (Multimedia Appendix 1).

Participatory Design Workshop

When each cluster joined I-MPACT, they were required to attend a participatory design workshop. This all-day commencement event was intended to bring a cluster together to discuss the local transition of care data and share ideas and insights around the patient's perspective from various points along the care continuum. Clusters were asked to use this workshop to generate ideas about the problems that the local cluster would target during their participation in I-MPACT over the next several years to improve transitions of care and patient experiences. To create a more collaborative environment and draw rich insights from multiple stakeholders, each commencement event was organized to create a collaborative environment, draw rich insight from multiple stakeholders, and highlight the patient perspective.

A total of 5 participatory design workshops were held between 2016 and 2018 (Table 1). With each cluster attending this commencement event, the aim was to foster discussions where participants could share multiple perspectives, capture the full scope of the care transition process, and generate practical design implications for improvement in care transitions. Each workshop had approximately 40 to 65 participants. During the full-day workshops, participants, comprising patients, caregivers, physicians, nurses, administrators, and designers, worked in groups of 7 to 9 people within their cluster to generate problem statements and begin initial discussions regarding interventions. Each cluster cohort participated in 1 workshop.

Table 1. Study cohorts and their commencement dates.

Cohort	Clusters involved in the cohort	Start date
Cohort 1	1 CHF[a] and 1 SNF[b]	February 2016
Cohort 2	4 CHF	September 2016
Cohort 3	1 SNF and 5 CHF	February 2017
Cohort 4	2 COPD[c] and 1 CHF	September 2017
Cohort 5	1 CHF and 3 SNF	September 2018

[a]CHF: congestive heart failure.

[b]SNF: skilled nursing facility.

[c]COPD: chronic obstructive pulmonary disease.

At each commencement workshop, participants were provided with patient journey maps created from the observation of a patient discharged from the hospital within their cluster (Multimedia Appendix 2). The details shared from each of the 26 observed discharges focused on the transition of care discussion from the patient's perspective in an effort to enable participants to gain a better perspective on problems that may otherwise have gone unnoticed by others. Participants also shared their individual experiences regarding care transition, which contributed to a shared understanding of the entire discharge process.

After reviewing the patient journey map and initial discussions, participants were asked to collaboratively generate major problem areas that they aimed to improve through transitions of care interventions. Inspired by service blueprint mapping in service design [32], we encouraged participants to create their own hospital's discharge timeline that detailed the core activities of a typical patient's care transition. This process enabled the participants to create a broader representation of the discharge process and consider the major barriers and details that affect a patient's experience during the care transition (Multimedia Appendix 3). During this process, each group was able to identify barriers, draft problem statements, and generate potential design interventions aimed at improving patient experiences throughout the care transition. If brainstorming was not completed during the workshop, each hospital finalized their brainstormed ideas for transitional care interventions during the postworkshop phase. As a result, 47 original interventions were generated with the aim of facilitating and improving care transitions. Each cluster was required to update its progress in a biannual report called the quality initiative (QI) log, and the August 2020 report was used to assess the status of their interventions. In the *Results* section, we have provided an overview of postworkshop progress to gauge the sustainability of these interventions.

Data Analysis

We followed a constructivist grounded theory approach for data analysis [33]. Without a predetermined conceptual frame, we iteratively read the participants' problem statements and identified commonly addressed themes in a collaborative manner. This methodology enabled the team to understand participants' experiences and views on care transition rather than our views or the preconceptions of health care researchers. To identify the patterns of major discussion during the participatory design workshop, we analyzed problem statements and proposed interventions collected from 79% (19/24) of the hospitals after the workshop. A total of 5 hospitals were not included in the study as 3 (60%) hospitals did not conduct an observation to generate a patient journey map, and the other 2 (40%) hospitals opted out of I-MPACT before August 2020. The lead author (JYS) performed open coding using NVivo Pro 12. While data analysis was performed, the team discussed the general direction and primary focus to create a shared understanding. The team iteratively reviewed the data to identify the major themes for open coding. This resulted in the following topic areas: (1) emerging obstacles during the discharge processes, (2) problem statements that represent the most

significant and feasible areas for improving care transitions among identified issues, and (3) generated design opportunities that could be turned into practical interventions. With these themes, we aggregated the problem statements until they did not overlap. This open coding yielded 206 codes, including 106 (51.5%) emerging problems of care transition and 100 (48.5%) opportunities to contribute to interventions. Some examples of coded problems included *lack of patient's involvement in managing their health* and *lack of consistent scheduling of follow-up appointments*. Opportunities for interventions included the following: *ensure that patient and family caregivers understand education* and *encourage patients to take control over their care*. We used affinity clustering to identify the commonalities and hierarchies of the 206 codes. The lead author (JYS) performed the affinity clustering based on the commonalities and relationships between themes, identifying the most salient emerging themes. The results were presented to the rest of the team to resolve any lack of agreement on the themes. Affinity diagramming resulted in themes with 3 different levels, which allowed the team to capture overarching themes that encompassed the lower-level themes. Themes at the third or lowest level included *patients cannot afford prescriptions* and *differences in the role of social workers and case managers at a hospital.* Second-level themes included *lack of early communication among providers* and *documenting patients' goals.* Top-level themes included *needs for screening tools* and *the importance of consistency.* This iterative analysis allowed the team to identify themes that workshop participants deemed most critical and recognized as areas needing significant transitions of care improvement.

Results

Overview

Six major themes emerged from the 206 codes that were developed out of open coding and affinity clustering: (1) screening tools for identifying social determinants of health (SDOH) barriers after discharge, (2) active patient and caregiver engagement in the discharge process, (3) follow-up postdischarge phone calls, (4) patient comprehension of discharge education, (5) team-based readiness tools to assess patient readiness for safe discharge from the hospital, and (6) consistency across the care continuum.

On the basis of these 6 themes, we formalized the transition of care model—the socioeconomic screening, active patient engagement, follow-up, education, discharge readiness tool, and consistency (SAFEDC) model (I-MPACT transition of care model)—that future initiatives can adopt and use to improve patient experience in care transitions (see Multimedia Appendix 4).

Theme 1: SDOH Screening—Screening Tools to Identify Specific Health or Socioeconomic Barriers After Discharge

One of the critical factors identified for transitions of care improvement is the need for tools to better identify SDOH factors that affect patients after discharge. The lack of such screening tools was identified as a barrier to optimizing tailored care for patients. For example, targeted interventions for patients with specific health conditions are difficult to conduct if some of these conditions are not appropriately identified until after hospital discharge. One such intervention developed by workshop participants involves a multilevel, team-based screening system that captures feedback from multiple clinicians at different points along the care continuum. The screening system would help identify patients with lower socioeconomic status and ensure that a patient has the means to obtain medications, adhere to their prescribed treatment plan, and make it to their follow-up appointments after discharge. Another intervention highlights the importance of screening all patients who transfer to a skilled nursing facility with a standardized SDOH screening tool before discharge. Once the standardized SDOH screening is completed, the hospital-based care coordination team can determine whether patients need further assistance. If a need for assistance is identified, care coordinators will communicate with each facility independently based on the patient's needs so that they can offer aid with the necessary resources (eg, options for medications). Screened information and identified needs can be integrated into the electronic health record (eg, Epic) and transferred to respective care coordination programs or other hospitals. See Multimedia Appendix 5 for an example of the SDOH Assessment Screening Tool that was implemented by one of the hospitals participating in the workshop.

Theme 2: Active Patient Engagement—Active Patient and Caregiver Engagement in the Discharge Process

Another barrier identified in care transitions is the lack of patient and caregiver involvement in the discharge process. Participants noted that the current discharge process often does not provide enough options for patients and their caregivers to communicate their specific health care needs with providers after hospital discharge. The lack of active patient and caregiver involvement negatively affects the patient's care transition experience.

To effectively engage patients and caregivers across the care continuum, participants highlighted the necessity of creating explicit systems to better allow patients to engage in their care. The use of practical tools for providers to better understand and support patients' specific health-related goals and motivations was theorized to lead to a more effective and patient-tailored care plan. For example, providers pointed out the need for more patient-friendly communication tools that can better empower patients to improve medication adherence when medication noncompliance has been identified. In addition, a patient-tailored tool could invite and empower patients to engage in advanced care planning conversations at various stages of their illness and better equip clinicians to deliver care personalized to meet individual patients' needs. During the workshop, providers shared that when they perceive barriers to patient or caregiver engagement, the providers feel less equipped, are less motivated, and perceive that there is more bias when offering additional support to their patients at the time of discharge. A standard protocol for patient engagement may help reduce these barriers and better engage patients and caregivers in patient-centered care plans.

In addition, participants suggested technology-mediated interventions that could facilitate goal planning and tracking. One of the examples presented by the participants was to provide ways of generating personal goals and regularly document them in their heart failure symptom tracker (eg, Heart Smart Calendar and My Heart Failure Action Plan). See Multimedia Appendix 5 for an example of an intervention aimed at promoting active patient and caregiver engagement during the discharge process.

Theme 3: Follow-up—Improving Postdischarge Follow-up

A prerequisite for participation in the I-MPACT workshops was a commitment to increase rates of the 7-day posthospital follow-up for patients. In addition to improving the postdischarge follow-up, participants also identified the need for more complete postdischarge follow-up protocols. Although many hospitals noted that they often call patients after discharge, it was determined that current phone calls are often unstructured and uncoordinated between the different organizations that provide posthospital care. The lack of an integrated call process between the hospital and POs results in fragmentation of care, creating difficulties in ensuring whether patients receive appropriate follow-up assistance, as well as important information (eg, follow-up clinic appointment schedule) from their care providers.

To alleviate this problem, our participants emphasized the need to have clear goals, protocols, and improved structures for follow-up phone calls. For example, the participants suggested that there would be value in having a standard approach to close follow-up phone calls with patients in both the immediate postdischarge period (eg, within 2 days of discharge) and the early postdischarge period (eg, within a week). See Multimedia Appendix 5 for an example of a structured postdischarge phone call, which was implemented by one of the hospitals that participated in the workshop.

Theme 4: Education—Patient's Comprehension of Discharge Education

We also identified that a patient's comprehension of discharge education was a potential factor that affects the effectiveness and quality of care transition. Workshop participants raised concerns that patients often do not comprehend the educational materials and are given an extensive amount of information (eg, precautions, safety protocols, and medication instructions) in later phases of their hospital stay and at the time of discharge. Patients often receive lengthy handbooks and materials to review after they leave; however, the patients participating in the workshop stated that these materials are often unread. Participants noted that patient education materials could be ineffective as they are often generic and not tailored to each patient's individual circumstances.

It was further noted that current discharge processes do not involve effective methods to ensure that patients comprehend the information that they are given. Workshop participants pointed out the need for effective strategies to deliver core discharge information, such as medication teaching, to patients and their caregivers earlier during hospitalization. Examples of recommended interventions included applying teach-back methods with tailored tools and simplified educational materials. Re-educating nursing staff about teach-back methods and clarifying caregivers' roles and responsibilities for patient education were proposed as ways of improving the effectiveness and quality of discharge education. Multimedia Appendix 5 provides an example of an intervention to promote patient comprehension of discharge education—a simplified, patient-centered education that was implemented by one of the hospitals participating in the workshop.

Theme 5: Discharge Readiness—Team-Based Tools That Assess Readiness for Safe Discharge

The findings highlight the importance of having a standardized, multidisciplinary discharge readiness assessment, in which all team members can provide input and receive feedback regarding the patient's readiness for safe hospital discharge. The participants agreed that, currently, there is limited availability of such a tool; however, its creation and use would allow the multidisciplinary team to better understand and communicate discharge readiness.

Participants discussed the value of a team-based perspective to determine whether the patient is ready for discharge and a multidisciplinary approach for how to best minimize risk and improve safety for the patient. Participants hypothesized that using a team-based readiness tool would improve communication, optimize workflow, and allow an improved multidisciplinary approach to identifying potential barriers and the action plans needed to overcome them. By prioritizing and adjusting the workload for a multidisciplinary team, a team-based readiness assessment tool could assist in the evaluation of safe discharge. See Multimedia Appendix 5 for an example of implementing a team-based discharge readiness assessment tool that was implemented by one of the hospitals.

Theme 6: Consistency—Consistent Transition of Care Processes Across the Care Continuum

One of the most frequently mentioned themes across the clusters was that patients and caregivers experience a lack of consistency as they move from one episode of care to the next. The workshop participants noted that inconsistency could significantly affect patients' experiences. Participants shared how uncoordinated and inconsistent information received from different providers negatively affected a patient's comprehension and interfered with their ability to actively engage and participate in their own care. Examples of inconsistent care included conflicting information from the provider (eg, discrepancies in discharge instructions), uncoordinated phone calls from multiple providers after discharge, incongruent follow-up appointments, and incomplete information or misinformation from different clinics (eg, incorrect physician names). In addition, the multitude of inaccessible electronic health records across the continuum of care prevents patients from accessing important records and impedes their awareness and comprehension. These findings challenged our participants to consider the use of a standard communication process between providers and patients and the implementation of active collaboration across multidisciplinary teams to proactively plan discharge.

The proposed intervention involved a hospital notifying the PO that their patient had been admitted to the hospital and the PO then providing a longitudinal care management program for the patient to follow for 90 days after discharge. Another intervention involved a care management program for all patients transferred from the hospital to a skilled nursing facility. See Multimedia Appendix 5 for an example of an intervention aimed at improving consistency across the care continuum.

Intervention Sustainability Follow-up

In this section, we summarize the current status of intervention implementation in hospitals during the postworkshop phase. Initial interventions were conducted during or shortly after the workshop. Furthermore, each cluster updated the QI log biannually, recording how the intervention was adopted, modified, or maintained. Interventions could be adopted depending on the hospital's resources, patient needs, and what could be sustainable and widely disseminated for that cluster's target population. To receive points in the program, the cluster must meet a certain threshold for intervention dissemination. Each hospital generated the most feasible care transition intervention tailored to the needs of its health system during the postworkshop period based on the 6 themes. Examples of practical interventions included a 90-day PO care management enrollment program, advanced care planning, and follow-up phone calls after discharge (see Multimedia Appendix 4 for example interventions). Although our primary aim was to present the impact of the participatory design process on brainstorming interventions for care transition rather than longitudinally following up on the implementation process, we also captured postworkshop progress to assess the sustainability of these ideas. Each cluster updated its progress in a biannual progress report called the QI log. We used the August 2020 progress report to gauge the intervention's sustainability.

Of the 24 hospitals that joined the I-MPACT and participated in the workshop, 5 (21%) were not included in the study as 3 (60%) hospitals did not conduct an observation to generate a patient journey map, and the other 2 (40%) hospitals opted out of the I-MPACT before August 2020. As a result, 79% (19/24) of hospitals remained in the project for follow-up and were analyzed in this study. Each of the 19 hospitals generated and implemented at least two feasible transition of care interventions, resulting in a total of 47 original interventions. From the August 2020 progress report, there were 47 total interventions, of which 24 (51%) were original interventions generated during or after the workshop, 10 (21%) interventions changed but were related to the originally proposed interventions, and 13 (28%) interventions were new interventions that hospitals generated by themselves during the postworkshop period. Of the 19 clusters that participated, 13 (68%) sustained at least one of their original interventions, 2 (11%) sustained all of their original interventions, and 4 (21%) did not sustain any of their original interventions. In summary, it was found that most clusters currently implemented the same interventions or those incorporated themes similar to the original interventions.

Discussion

Principal Findings

This study aimed to explore the effectiveness of the collaborative design approach in creating transition of care interventions that can potentially improve the hospital discharge experience for patients and reduce adverse outcomes, including readmissions. Through our qualitative analysis, six primary themes that facilitate patient care transitions emerged: (1) screening tools for identifying SDOH barriers after discharge, (2) active patient and caregiver engagement in the discharge process, (3) follow-up postdischarge phone calls, (4) patient comprehension of discharge education, (5) team-based readiness tools that can assess a patient's readiness for safe hospital discharge, and (6) consistency across the care continuum. On the basis of these themes, each hospital developed tailored interventions to improve patients' care transition experiences in their hospitals. During the follow-up period, all hospitals implemented at least one intervention originating from the initial workshop.

The SAFEDC model can be applied to improve patients' experiences during care transitions. Our findings support the usefulness of gathering stakeholders from a local hospital and involving the patient perspective to help identify local gaps associated with transitions of care.

By presenting how collaborative efforts can be transformed into practical interventions, our study makes two main contributions: (1) generated insights and useful innovations for transition of care interventions by forming multidisciplinary teams involving patients, hospital systems, and outpatient systems across the care continuum and (2) established the usefulness of the participatory design approach in the context of health care quality improvement.

Implications for Transitional Care Interventions

Given the number of health care interventions developed by workshop participants to improve care transitions, our study contributes to the current literature by highlighting the types of interventions that have been developed to improve care transitions and reduce hospital readmission rates. Previous studies in the context of care transition often involved 1 to 2 institutions as the target site [9,34,35]. However, in this study, close to 300 people from 19 health systems generated major concerns that should be considered when designing transition of care interventions. This study is an example of a large-scale project addressing care transitions using a participatory design approach. On the basis of workshop participants' insights and interventions, we established 6 major themes that health systems could address when establishing transitional care interventions.

Patient-targeted approaches (eg, interventions directly involving the patient), provider-targeted approaches (eg, interventions aimed at better equipping the provider with information), and system-targeted approaches (eg, interventions aimed at improving care consistency) were generated. For example, 33% (2/6) of the important themes, including the team-based assessment of a patient's readiness for safe discharge and screening to better identify vulnerable patients with particular conditions, particularly emphasized the provider role, which is

historically less visible to patients. Alternatively, 3 themes were patient centered: active patient and caregiver engagement in the discharge process, postdischarge follow-up to ensure patients are on the right track, and patient comprehension of discharge education. The last theme highlights improving consistency across the care continuum, requires a more integrated view of the health system, and emphasizes the importance of cohesive work within hospitals and between health organizations. This study highlights the need for a multipronged approach to transition of care interventions.

These themes show that transitions of care should be regarded as an ongoing and continuous process rather than a series of intermittent events, which aligns with previous literature highlighting the importance of multidisciplinary, patient-centered approaches to care transitions that span the care continuum [36-39]. There is no one size fits all intervention that can facilitate care transitions for every individual or context. Depending on each hospital's unique situation, including the available resources, targeted population, and prioritized problems, the specific details of an intervention should be carefully considered.

Using the SAFEDC model, future studies might propose simple collaborative activities or educational materials (eg, predesigned format to fill out and view multimedia content explaining the SAFEDC model) for health care institutions seeking to determine the six salient areas needing improvement within their specific context. For example, multiple stakeholders from health care institutions can apply the SAFEDC model to their situation and exchange perspectives to generate in-depth discussion.

Sustainability of Participatory Design in the Health Care Environment

By highlighting the various roles of the stakeholders involved in transitions of care who developed sustainable interventions, this study shows the benefits of using a participatory design workshop in large-scale quality improvement efforts.

Implementing interventions within health care systems beyond the project timeline has been an important focus of recent studies on participatory design [40]. Although valuable insights and discussions were generated during the workshop, previous studies noted that many useful outcomes were minimally incorporated into the organization or community after the events because of the lack of follow-up and sustained methods of implementing outcomes [40,41]. Consequently, participatory design outcomes are often poorly diffused to the organization or community when a research project ends [40,41]. In complex social settings such as hospitals, limited use of available resources (eg, human resources and infrastructure) has become the main barrier that negatively affects the impact of participatory design recommendations. As we followed up with each hospital to understand their postworkshop practices, we shed light on the improved sustainability of participatory design outcomes.

We brought together various stakeholders of the health care environment, including patients and caregivers, and successfully generated transition of care interventions. We confirmed from our follow-up review that of 47 interventions implemented across 19 hospitals, 24 (51%) of the 47 interventions had remained the same over a period of approximately 3 years. As long-term outcomes (eg, 3 years) of participatory design efforts have been infrequently discussed in previous studies, our study demonstrates that participatory design as a sustained approach is capable of generating large-scale interventions that can be implemented in hospitals and health care systems.

Limitations

Our study has some limitations. First, the lack of measurement tools to understand sustainability across hospitals was one of our limitations. Although we did our best to provide details of the intervention evaluation process across hospitals, this study does not offer an effective tool for the in-depth understanding of the long-term effectiveness of the intervention. Second, we did not collect sufficient information on why the clusters no longer used their interventions at certain points. Despite the specific number of clusters that continued with their original interventions, we have limited information on the specific factors that did not work in certain situations or contexts. Future studies should address these issues and generate contextual implications from long-term follow-ups using practical measurement tools.

Conclusions

We conducted observations aimed at understanding patient discharge experiences and held a participatory design workshop to gather rich end user perspectives of stakeholders, including health care professionals and patients. Patient journey maps were used as useful triggers for conversations among various stakeholders during the workshop. On the basis of these findings, we proposed the use of a transition of care model, SAFEDC, in which future research and practices can be used to improve patient experiences in care transitions. As the study did not examine the direct opinions of workshop participants or intervention users, future studies may gain additional insights by following up with intervention user experiences, real use cases, and factors that may aid in understanding the facilitators and challenges for each implemented intervention. Given the increasing interest in quality improvement through patient-centered approaches to designing health care interventions, this study demonstrates ways of enhancing care transitions through user-centered interventions.

Acknowledgments

The authors wish to thank the stakeholders, particularly the patients and caregivers, who participated in the workshop.

Authors' Contributions

JYS, AP, and DB were involved in writing the original draft, data curation, and data analysis. JYS, NO, and DB were involved in visualization. NO and KH were involved in data collection, data curation, data analysis, reviewing, and editing of the paper. KH, AP, GJ, and DB were also involved in reviewing and editing the paper. AP also performed data collection. GJ was involved in data interpretation and supervision. DB was involved in investigation, methodology, data analysis, resources, and supervision.

Abstract

Background: Cardiovascular diseases remain the leading cause of morbidity and mortality worldwide. Gene therapies (GTs) may become a novel therapeutic option for cardiovascular diseases.

Objective: We aimed to characterize all trials involving human subjects utilizing GT to treat noncongenital cardiovascular diseases.

Methods: In March 2021, we searched for clinical trials on the ClinicalTrials.gov (CT), International Clinical Trials Registry Platform (ICTRP), and International Standard Randomised Controlled Trials Number (ISRCTN) databases. Two authors screened the titles and registry notes of all the searched studies. We collected details of the included studies regarding their design, location funding source, treated conditions, completion, publication statuses, and final outcomes.

Results: We generated a total of 3508 records, and 50 unique clinical trials met our eligibility criteria. Of these, 20 (40%) concerned peripheral artery disease, and 18 (36%) concerned coronary artery disease. Most studies were randomized (34/50, 68%) and were performed in multiple locations (30/50, 60%), and around half of the trials compared GT with a placebo (27/50, 54%), while one in four were single-arm (14/50, 28%), and the rest concerned dose-finding (22%). More than half of the trials (29/50, 58%) were funded by industry. Of the 50 clinical trials, 28 (56%) published their results by the data collection date (March 2021), and 22 of 31 (71%) were slated to be completed before 2021. Overall, 12 of 28 (42.9%) clinical trials showed favorable outcomes of the intervention.

Conclusions: Among noncongenital cardiovascular diseases, GTs are mostly investigated in peripheral artery disease and coronary artery disease. Many clinical trials on GT use in noncongenital cardiovascular diseases did not disclose their results. Regardless of the trial phase, less than half of published studies on GT in noncongenital cardiovascular diseases showed promising results.

Introduction

Cardiovascular diseases remain the leading cause of morbidity and mortality worldwide, despite developments in treatment and diagnostics. In 2005, they were responsible for 29.7% of global deaths and for 32.1% in 2015 [1]. Therefore, there is a need for novel strategies to prevent and treat cardiovascular diseases and mitigate their consequences. Gene therapies (GTs) are methods of gene modification or expression to achieve specific cellular effects [2]. This novel class of therapeutics may improve the prevention and treatment of many diseases, including cardiovascular diseases. One of the first approved GTs was alipogene tiparvovec (Glybera; AMT-011,

AAV1-LPLS447X), aimed at adults with familial lipoprotein lipase deficiency [3,4]. The potential of GT in noncongenital cardiovascular diseases was studied from the early 21st century, but its efficacy was limited [5,6]. In the past 15 years, several promising phase II randomized controlled trials (RCTs) of GT in heart failure (HF) [7,8] and peripheral artery disease (PAD) [9-11] were published. However, none of those GTs are currently approved (eg, NV1FGF for PAD failed to reduce major amputation or death in a phase III RCT [12]). In 2011, GT (Neovasculgen; cambiogenplasmid, PL-VEGFR165) for PAD was approved in Russia [13]. A postapproval observation of PL-VEGFR165 (Neovasculgen; cambiogenplasmid) suggested persistence of the therapeutic effect for individuals with PAD [13]. However, in the United States and Europe, there is currently no GT approved for noncongenital cardiovascular diseases. RCTs are considered the most reliable method for assessing the efficacy of therapeutics [14,15] and should also be used in gene therapy research. However, interventional trials may have many limitations in terms of design, sample selection, and end points. Moreover, it has been observed that many scientific groups do not publish the results of their clinical trials [16-20]. Nonpublication wastes scientists' funds and efforts to generate data. Clinical trials are expensive, and participants are exposed to adverse events; thus, they should be precisely designed and their results published. If the results of previous trials are unavailable, other scientists have limited opportunities to assess the benefits and risks of similar interventions. Performing a study with a similar intervention may expose participants to unnecessary risk. Taken together, the publication of clinical trial results, even if negative, is not only an important part of the scientific process but also an ethical imperative. Gupta et al [20] analyzed obstetrical and gynecological RCTs registered on ClinicalTrials.gov between 2009 and 2013 and found that less than two-thirds of the trials were completed and only one-third published. The last known review of previous and ongoing clinical trials of GT in PAD, coronary artery diseases (CAD), and HF was performed in 2017 [6]. Since then, no study has described all clinical trials using GTs among noncongenital cardiovascular diseases.

In this cross-sectional study, we aimed to characterize all trials involving human participants utilizing GT for the treatment of noncongenital cardiovascular diseases.

Methods

Ethics Approval

This is a cross-sectional analysis of clinical trial registries and processes found in publicly available data and does not involve human or animal subjects. Therefore, the project did not require Ethical Committee approval. The analysis does not violate the terms of service of the registries used.

Data Collection

We generated a list of clinical trials involving those registered at ClinicalTrials.gov (CT), the International Clinical Trials Registry Platform (ICTRP), and the International Standard Randomised Controlled Trial Number (ISRCTN) databases. We included all studies up to March 15, 2021, which was the date of the data collection. We included only trials that met the following eligibility criteria: (1) those that involved human participants, (2) where at least one of the study arms received gene therapy, and (3) where the study aimed to treat noncongenital cardiovascular disease according to the World Health Organization (WHO) definition [21].

In the CT database, we used the available filters as follows: other terms: "gene therapy," study type: "interventional (clinical trial)," and conditions by category: "heart and blood diseases." In other databases, we typed the phrase "gene therapy" into the search engine. We removed all "noninterventional" studies from .csv file generated from the ICTRP search engine. Furthermore, duplicated registered clinical trials were excluded.

Two authors (WP and ST) independently screened the titles and registry notes of all the generated studies. A third researcher (author MK) resolved any disputes or discrepancies after the initial classification. Additionally, we removed duplicated registered clinical trials.

Data Processing and Statistical Analysis

We read the clinical trial design (study record details) published on the registry and publication if available. We then extracted self-reported study characteristics (eg, study design, trial location, funding source, treated condition, intervention, comparator, age of participants, sample size, initiation date, completion date, completion status, publication status, and outcome measures). In the case of incomplete reporting in some study records, we checked publications for missing information. Trials that were not categorized as single or multicenter were assigned to appropriate groups based on location. If the study claimed to be completed but no publication was linked in the registry, we searched for the registry number, study title, or keywords in PubMed and Google Scholar. We analyzed probable matches for trial design, location, sample size, therapy name, and date of publishing results. We considered those studies with posted results in the registry record or publication in a peer-reviewed journal as published. For all papers with published results, we searched for favorable outcomes. Favorable outcomes were defined as reaching either of the following primary aims: (1) optimal dose was established in early clinical trials, (2) GT showed acceptable safety profile, or (3) GT was better than the comparator in the primary aim or reached the primary aim in single-arm studies. We did not perform a risk of bias assessment on individual studies. In addition, we performed descriptive statistics. The primary outcome was the proportion of completed studies with favorable outcomes. The secondary outcomes included descriptive statistics of the studies' analyzed features. Furthermore, we compared features of clinical trials that either published or did not publish their results. We included only trials that aimed to be completed before the day of data collection, which was March 15, 2021. We used the chi-square test for categorical variables and the Mann-Whitney U test for numerical variables.

Results

We generated a total of 3508 records through database searching: 1032 records from CT, 2279 from ICTRP, and 197 from ISRCTN (Figure 1). We screened 2711 records based on

titles and registry notes. A total of 50 trials with 4436 total participants ultimately met our eligibility criteria. In Table 1, we present the characteristics of the included studies. We distinguished four groups depending on the treated disease: (1) PAD, (2) CAD, (3) HF, and (4) Other (pulmonary hypertension, ischemic cardiomyopathy, and secondary Raynaud's phenomenon). The predominant group was PAD, represented by 20 out of 50 (40%) studies, followed by CAD, with 18 (36%) studies. Most studies (34/50, 68%) were randomized and were performed in multiple places (30/50, 60%), and around half of the trials compared GT with the placebo (27/50, 54%), while one in four were single-arm (14/50, 28%), and the rest concerned dose finding (22%). More than half of the trials (29/50, 58%) were funded by industry. To date, 28 (56%) of the 50 clinical trials published their results (NCT02016755, JPRN-jRCTs053180162, JPRN-UMIN000014918) [7-13,22-40]. Of these, 12 (42.9%) revealed a favorable outcome of the interventions.

We present the results for all analyzed trials in Multimedia Appendices 1-4. One study (NCT00438867; AWARE study; phase III) only recruited females, while the rest included both sexes. All the studies involved only adults. Most studies had wide age ranges, but 2 studies (NCT00956332, NCT00566657) included individuals at least 50 years old. Most of the studies (34/50, 68%) were initiated within the last 10 years (2012-2021). A total of 31 trials were slated to finish before the date of data collection (March 2021). Of these, 22 (71%) were published. Three publications came from ongoing trials with completion dates after 2021 and three from projects with unknown completion dates. The most prevalent vectors were plasmids (25/50, 50%) and adenoviruses (18/50, 36%). GTs were mostly delivered via intramuscular injection (19/50, 38%), intramyocardial injection (17/50, 34%), and intracoronary infusion (11/50, 22%). Eighteen of 50 (36%) GTs transferred vascular endothelial growth factor (VEGF) genes. We did not find information about deaths related to the used GT. All collected variables are presented jointly in Multimedia Appendix 5.

We performed a comparison between published and unpublished clinical trials that should be completed before March 2021 (Table 2). We identified that the published clinical trials were initiated and completed in later years than those that were unpublished. We did not detect any significant differences in the other analyzed variables.

Discussion

Principal Findings

In this paper, we characterized all clinical trials on GTs for noncongenital cardiovascular diseases. The trials concerned mostly PAD and CAD, and most had positive traits in terms of good design, including randomization, multicenter design, and placebo as the comparator. Over half of all included clinical trials disclosed their results.

We found that most trials searched for efficient GTs for the atherosclerotic cardiovascular diseases PAD and CAD. GT in PAD was used to stimulate angiogenesis to heal ulcers or increase pain-free distance [6]. The pathophysiology of PAD and CAD results from atherosclerotic cardiovascular disease. Progressive occlusion of small vessels in the heart or limbs causes a decrease of tissue perfusion and consequently cell hypoxia and necrosis. Angiogenesis stimulated by VEGFs offers a potential approach for improving ischemic tissue function by inducing blood vessel growth to restore perfusion and regeneration. Similarly, the stimulation of angiogenesis CAD can improve myocardial perfusion and tolerability of physical activity. However, GT has limited success against these diseases [6]. The most recent meta-analysis from 2013 on GT in PAD did not find clear benefits from the treatment [41]. However, the high number of clinical trials on GT atherosclerotic cardiovascular diseases provides hope that effective GTs will be developed.

The primary cause of HF is a progressive loss of contractile function, which can be caused by both ischemic and nonischemic factors. Understanding how these factors affect heart function is key to developing an effective and targeted treatment. Regardless of its etiology, there is decreased sarcoplasmic reticulum Ca2+-ATPase (SERCA2a) activity in heart failure [42]. Abnormalities in the relaxation and contraction of cardiomyocytes are associated with calcium levels and reduced SERCA2a activity, and they can be treated by

increasing the SERCA2a activity. In the database, we found six studies that used GT with adenoviral vector gene transfer to improve SERCA2a function. A leading cause in HF pathophysiology is an ischemic factor—CAD. The progression of atherosclerosis causes a decrease in the blood supply to cardiomyocytes, tissue damage, and decreased cardiac contractility. Potential treatment methods are VEGFs, which enhance angiogenesis in the ischemic heart [5]. These studies were conducted without favorable clinical outcomes. Another potential GT to treat ischemic cardiomyocytes is stem cell-derived factor 1 (SDF-1). SDF-1 recruits bone marrow-derived stem cells to the site of myocardial injury in a failing heart, where it induces tissue repair [43]. Desensitization of β-adrenergic receptors is another cause of HF, which could be targeted at the molecular level. Downregulation of receptors causes a weaker contraction response and lower levels of cAMP inside cardiomyocytes. This was treated by administering an adenoviral vector, which improved cAMP expression and activation of adenyl cyclase type 6 [44], showing promising results. GT in HF relies mostly on optimizing myocardial contraction and excitation processes and reducing myocardial wall remodeling [5,6,45]. To date, there are no registered GTs on HF, but this area of research is intensively developed, with 4 of 6 published clinical trials on GT in HF revealing favorable outcomes. Therefore, we can expect that future trials will bolster the possibilities of GT in cardiology.

Furthermore, we analyzed the publication rate of the included clinical trials. Approximately one in four completed clinical trials in urology reported results [46]. Liu et al [47] found that only 34% of oncology interventional trials registered on ClinicalTrials.gov published their results. A similar proportion of published clinical trials were noted for obstetrical and gynecological RCTs [20]. A higher publication rate was observed in orthopedic trauma trials (43.2%) [48], National Institutes of Health–funded trials (46%) [18], and RCTs involving patients with rare diseases (48.3%) [49]. However, Bourgeois et al [50] found that up to 66.3% of clinical trials conducted between 2000 and 2006 on anticholesteremics, antidepressants, antipsychotics, proton-pump inhibitors, and vasodilators were published. Moreover, the majority (71%) of large RCTs were published [16]. Considering publication rates from the aforementioned trials, 71% (22/31) of the disclosed results of clinical trials on GT in noncongenital cardiovascular diseases were very high. We speculate that this may be the result of: (1) a high priority given to trials on GT, (2) pressure from sponsors, and (3) the high citation potential of GT trials. However, ~30% of clinical trials that were planned to be completed before 2021 did not disclose their results. We found that unpublished trials were initiated and completed later than those published, which is similar to the previous observations [49]. Moreover, we found that many variables were not described in <10% of the clinical trial records.

In addition, we found that most clinical trials revealed positive traits of good design: 68% (34/50) were randomized, 60% (30/50) were multicenter studies, and 54% (27/50) used a placebo as a comparator. Interestingly, the reported outcomes were mostly negative (16/28, 57%). In the study by Bourgeois et al [50], drug trials funded by industry showed positive outcomes in 85.4% of publications, nonprofit or nonfederal organizations in 71.9%, and government-funded in 50%. However, a higher number of negative trials on GT in noncongenital cardiovascular disease may be caused by the relatively high rate of trials disclosing results.

Future Directions

Further studies may deploy contemporary technologies, including artificial intelligence (AI), to simplify medical data processing. Human-like tasks can now be performed by machines (eg, image analysis, computer-aided diagnosis, patterns, and cost of health care studies), augmenting clinicians' and researchers' work. The power of AI may discover unmeasured confounders and associations impacting publication rates. Therefore, such analyses may help reduce health care costs while improving the overall morbidity and mortality associated with noncongenital cardiovascular diseases [51]. For that to be accomplished, there is a need for a large-scale study based on a database dedicated specifically for RCTs on novel gene therapies instead of several noncompatible databases containing incomplete information about RCT characteristics [52]. It should contain complete data to enable research on factors affecting the publishing rate, outcomes of treatments, quality, and costs of RCTs.

Limitations

We acknowledge several limitations of the study. First, many of the analyzed clinical trial records had missing information. Second, the number of trials that should have been completed before the data collection date was low. For this reason, we could not perform a multivariate logistic regression analysis to indicate independent factors associated with results disclosure. Finally, we did not contact investigators of the trials to verify the status of the projects and the reason for termination or nonpublication of the trial.

Conclusions

Among noncongenital cardiovascular diseases, GTs are mostly investigated in PAD and CAD. Many clinical trials on GT use in noncongenital cardiovascular diseases did not disclose their results. Regardless of the trial phase, less than half of published studies on GT in noncongenital cardiovascular diseases showed promising results.

Data Availability

The data sets used and analyzed in this study are available from the corresponding author on reasonable request.

Authors' Contributions

WP and ST collected the data, performed the formal analysis, prepared the tables, drafted the initial manuscript, and reviewed and revised the manuscript. MK conceptualized and designed the study, collected data, performed formal analysis, performed statistical analysis, prepared tables, interpreted the data drafted the initial manuscript, and reviewed and revised the manuscript. All authors have approved the final manuscript and agree to be accountable for all aspects of the work.

Abstract

Background: There is a paucity of information in the literature on core nursing staff knowledge on the requirements of specific intravenous administration lines for medications regularly given in critical care. There is also a lack of well-researched and appropriate information in the literature for intravenous administration line selection, and the need for filtration, protection from light, and other line-material selection precautions for many critical and noncritical medications used in these settings to maintain their potency and efficacy.

Objective: We aimed to assess the knowledge gap of clinicians with respect to intravenous administration line set material requirements for critical care medications.

Methods: Data were drawn from a clinician knowledge questionnaire, a region-wide database of administered infusions, and regional data on standard and special intravenous administration line consumption for 1 year (2019-2020) from an enterprise resource planning system log. The clinician knowledge questionnaire was validated with 3 groups (n=35) and then released for a general survey of critical care nurses (n=72) by assessing response dispersal and interrater reliability (Cronbach α=.889). Correct answers were determined by referencing available literature, with consensus between the team's pharmacists. Percentage deviations from correct answers (which had multiple possible selections) were calculated for control and test groups. We reviewed all 3 sources of information to identify the gap between required usage and real usage, and the impact of knowledge deficits on this disparity.

Results: Percentage deviations from correct answers were substantial in the control groups and extensive in the test group for all medications tested (percentage deviation range –43% to 93%), with the exception of for total parenteral nutrition. Respondents scored poorly on questions about medications requiring light protection, and there was a difference of 2.75% between actual consumption of lines and expected consumption based on medication type requirement. Confusion over the requirements for low-sorbing lines, light protection of infusions, and the requirement for filtration of specific solutions was evident in all evidence sources. The consumption of low-sorbing lines (125,090/1,454,440, 8.60%) was larger than the regional data of medication usage data would suggest as being appropriate (15,063/592,392, 2.54%).

Conclusions: There is no single source of truth for clinicians on the interactions of critical care intravenous medications and administration line materials, protection from light, and filtration. Nursing staff showed limited knowledge of these requirements.

To reduce clinical variability in this area, it is desirable to have succinct easy-to-access information available for clinicians to make decisions on which administration line type to use for each medication. The study's results will be used to formulate solutions for bedside delivery of accurate information on special intravenous line requirements for critical care medications.

Introduction

Background

There is a paucity of information in the literature on core nursing staff knowledge on the requirements of specific intravenous lines for medications regularly administered in settings such as critical care, coronary care, and high-dependency units. This is matched by the lack of well-researched and appropriate information in the literature on material compatibility, the need for filtration, protection from light, and other selection precautions for many medications administered intravenously in these settings.

Within critical care, and particularly in pediatric and neonatal critical care, evidence is beginning to emerge that incompatibility between medications can cause the precipitation of medications in the venous access device [1], which may result in intravenous access failure or partial occlusion of peripheral access devices and central lines. A recent study [2] showed that venous access occlusion alarms are responsible for 55% of all intravenous infusion pump alarms in neonatal intensive care units and that noninfusion of critical short–half-life infusions (due to such occlusions) has the potential to cause severe cardiovascular instability in critical care patients receiving vasoactive medications. Maintaining line patency and ensuring noninterruption of medications such as inotropes and cardiac glycosides are very much patient safety issues [3].

The problem of limited access and multiple infusions running into a single venous access device is common in critical care, particularly in pediatric and neonatal critical care settings. Fonzo-Christe et al [1] suggested that the filtration of medications might be one method of reducing the risk of precipitation during multiple concurrent infusions; however, the questions—for which medications? and how can we ensure that nursing staff are aware of and able to comply with such requirements?—should be asked.

Critical care costs are high and increasing. Pharmaceutical costs are a sizeable component of these costs. Indeed, in all hospital areas, the price of pharmaceuticals is increasing rapidly year-on-year with a 30.1% rise in per capita spending (adjusted for purchasing power parity) between 2010 and 2018 across Organization for Economic Cooperation and Development nations, despite overall consumption only increasing by 7.1% in the same period [4,5]. Cost reduction approaches undertaken by health care systems, however, often ignore the actual use of these medications once they are purchased; storage, compounding, and administration of these medications are areas in which value and efficacy can be lost and waste can be generated through incorrect medication management.

With some medications, the manufacturer's instructions for administration are clear, but with others, the manufacturer's instructions may give information on storage only, for example, Pfizer's package insert for sodium nitroprusside has very clear statements about the requirement for light-protected administration postdilution [6]; however, the same active molecule marketed as a generic by another manufacturer does not discuss protection during administration [7].

Even if pharmaceutical manufacturers do give adequate guidance on storage and protection of base medications, there is generally much more sparse information available to the end-user postreconstitution or after compounding processes have been undertaken. Furthermore, package inserts will usually remain within the central pharmacy if compounding is undertaken in isolated intravenous clean rooms, as per many accreditation bodies and pharmaceutical safety societies' recommendations for medication compounding and reconstitution [8], and therefore, may be unavailable for consultation by the nursing staff who administer the medication.

The diluent used for intravenous medication compounding and can also change the requirements for protection from light and filtration, for example, epinephrine (adrenaline) is photostable when mixed in normal saline, but it is photolabile when mixed in dextrose solutions [9]. Even well-constructed and researched bedside intravenous administration manuals, such as those of the Royal Children's Hospital in Melbourne [10] and the British National Formulary [11], do not generally include information on material selection, guidance on protection from light, and required filtration of the compounded medication for intravenous administration lines.

Clearly, more could be done in terms of labeling medications requiring special administration lines during centralized compounding processes to give nurses better information on administration. Some intravenous smart pumps carry clinical advisories on their user interfaces, which are customizable for individual medications, and these have been successfully used in failure modes and effects analysis of intravenous medication safety strategies for reducing medication administration errors by users. The user cannot proceed with programming without confirming that they have read the advisory. In one study [12], a medication safety strategy that used centrally applied medication labels from the central compounding service to match the dose, dilution, advisories, and warnings as presented on the patient's electronic medication administration record (aligned with the medication information available on the

automated dispensing cabinet and integrated refrigeration unit and on the intravenous smart pump) was described. The drawback of this approach is that the nurse has often primed the intravenous administration line manually (either by gravity for a volume pump or by manual purge in the case of a syringe driver); therefore, the clinical advisory may be ignored in the interest of convenience, either because a considerable amount of pump programming has already taken place to get to the clinical advisory or in order to avoid wasting the medication that has already travelled through the intravenous administration set (this can be around 20 mL with most volume pump intravenous administration sets, thus, not an inconsiderable amount, particularly in the case of pediatric and neonatal patients).

A second issue is that despite the growth of central intravenous additive services in many facilities many critical care medications are still compounded by nurses at the bedside or in the medication room. Critical care prescriptions are not uncommonly urgent orders, and the consumption of medications can be so large and rapid that even a well-functioning central compounding unit may struggle to keep up with demand.

The above is also based on the assumption that connected and integrated intravenous smart pumps are available to update clinical advisories to match compounding changes. This scenario is rare. Many intravenous smart pumps are not connected to a central server, particularly when they are deployed to dispersed high-dependency beds or to infection-isolation units. Wireless connectivity can facilitate updates, but with older intravenous pumps, updates are dependent on biomedical engineers uploading new libraries manually to each intravenous smart pump [12,13].

A recent survey of sterile compounding errors indicated that 74% of survey respondents were aware of at least one pharmacy sterile compounding error in the preceding 12 months, for the purposes of the current study what was particularly pertinent in the survey was that 41% of these errors involved labelling of a compounded sterile preparation (including omission of administration guidance) and that wrong preparation techniques, including the attachment of an incorrect administration line, were found in 26% of compounding errors [14]. Approximately 30% of the degradation of clear medication solutions due to light occur in the line or tubing of the infusion set [9].

It is a common misconception that all intravenous administration lines are the same. They are not. Incorrect administration line selection by the clinician can cause deleterious changes to the active ingredients in the medication being given. Not only is this potentially harmful to the patient, as chemical change may take place in the medication upon contact and interaction with administration line material (for example, the creation of peroxides when total parental nutrition is exposed to light during administration), but there may also be a significant loss in the efficacy of the medication and degradation of its therapeutic value. Not only is this equivalent to incorrect administration of the medication, it is also potentially a waste of the full monetary value of the medication. There are a small number of papers delineating a significant financial impact to organizations from incomplete intravenous medication dosing and subsequent requirement for redosing [15,16].

Up to 80% of most facilities' infusion activities take place in critical care. This is also an area where stat-prescribing is common, where first doses of many medications are commonly not prepared in pharmacy, and where compounding by nursing staff is also common.

Objectives

The study had 4 goals. First, we wanted to create a verified, reliable, dependable, and easily replicated survey tool to assess the knowledge gap of clinicians in terms of their abilities to select the correct administration set for medications commonly encountered in their care area. Second, we wanted to investigate the gap between what clinicians should seek to apply, in terms of infusion protection through the use of special administration sets and what, in fact, takes place in terms of consumption of these lines across average uses of critical care medications with known requirements in terms of material, filters and light protection. Third, we wanted to be able to use this information to consider solutions in terms of information availability and education leading to consistent and accurate selection of special intravenous administration lines. Finally, we wanted to suggest a strategy to ensure that the medication administration line information given to end users is up-to-date, pertinent, evidence-based, and appropriate for their specific needs.

Methods

Study Design and Data

We collected data using a clinician knowledge questionnaire via web-based survey, direct email request, and in-person (at critical care conferences). To compare perceived or potential usage based on survey responses with real-world critical care usage, regional data on standard and special intravenous administration line consumables for a 1-year period (2019-2020) and the amount of critical care medications, for which special intravenous lines (light-protective, filtered, or low-sorbing) were necessary, were obtained from two sources. We used an enterprise resource planning system log for the Middle East and North Africa. This database comprises 2.2 million infusions given across Europe and the Middle East, which has been previously used in a study on infusion pump alarms [2]. In addition, we reviewed individual hospital accounts.

Clinician Knowledge Assessment Survey

Inclusion and Exclusion Criteria

Nurses working in critical care areas (adult intensive care units, pediatric intensive care units, neonatal intensive care units, high-acuity high-dependency units, and coronary care units) where parental drug administration of the medications addressed in the survey are commonly used were included.

Nursing staff working outside of critical care settings, with the exception of nurse educators and clinical leads with crossover roles within clusters of care areas (applied generally to critical care directorates), were not included.

First Pilot

We prospectively validated the clinician knowledge assessment survey. Prospective validation is widely used in such areas as the production of new and innovative practice guidelines, policies, and clinical decision-making tools to assess them for dependability [17].

The questionnaire was pretested among a convenience sample of clinicians, who were divided into 2 groups (A and B), with moderate to extensive experience with infusion therapy. Clinicians received an email invitation to take part in the survey. Reminder invitations were sent out at 3-day intervals to improve response rates. Our aim was to assess the clarity of wording and to verify the coherence of the questions. The groups were drawn from European, west Asian, and African countries where English was a second language. We evaluated answer groupings from each group and clustering or dispersal of answers. Overall, response dispersal for the survey (Cronbach α=.889) indicated interrater consistency (Cronbach α>.7 is acceptable).

Some minor changes to question language were made at this point in response to differences in answer clustering that may have been related to poor understanding of individual questions. For example, the nomenclature *epinephrine* was added to the survey tool with the original *adrenaline*. Overall, the questionnaire was deemed to be valid because the groups showed similar selection grouping and consistency in their answers. We discussed changing the phrase *light-protective* to *light-sensitive* because a lot of regional educational and guidance materials for nurses use the phrase *light-sensitive* to describe this special type administration line, but for clarity, we rejected the change—although medications may be described as *light-sensitive*, most authoritative texts use *light-protective* to describe administration lines [18]. We also discussed removing the question pertaining to the medication *epoprostenol*, because several respondents had commented that they were not familiar with this medication. We decided to retain the question based on its use in extracorporeal circuit management in many critical care units and its use in neonatal intensive care.

The response rate was 100%; we believe this was due to the succinct nature of the assessment, because respondents could complete it quickly.

Second Pilot

An introduction was added, to give respondents an impetus for completing the survey and to act as informed consent, and the questionnaire was released (Multimedia Appendix 1) in 20 countries via Google Forms, as a second-stage pilot. A total of 15 responses (Group C) were obtained. No further changes were made because good internal consistency was demonstrated and there was no evidence of spurious answers; the pattern of answers was similar to those in the initial pilot (Table 1). Though the number of respondents was small, this group was a useful adjunct because they, like the initial test groups, potentially had access to medication information from the internet. Although they were asked to complete the survey using their own knowledge, there was an opportunity for cheating. Groups A, B, and C formed the control group (n=25).

Table 1. Response dispersal during questionnaire validation.

Question	Medications assessed, n	Group A (n=10)	Group B (n=10)	Group C (n=15)
1	10	Dispersed over 5 choices	Dispersed over 6 choices	Dispersed over 5 choices
2	10	Dispersed over 5 choices	Dispersed over 5 choices	Dispersed over 5 choices
3	4	Concentrated over 2 choices	Mildly dispersed over 3 choices	Concentrated over 2 choices
4	4	Concentrated over 2 choices	Concentrated over 2 choices	Concentrated over 2 choices
5	4	Mildly dispersed over 3 choices	Dispersed over 4 choices	Dispersed over 4 choices
6	4	Mildly dispersed over 3 choices	Dispersed over 4 choices	Dispersed over 4 choices

Test

A test group of respondents (n=72) completed the survey independently. No access to internet information sources was permitted, and respondents were asked to complete the survey independently. The surveys were conducted in 2021 at the World Federation of Critical Care Nurses Congress and the Emirates Critical Care Congress, which were held in Dubai. Analysis of survey results for interrater reliability was undertaken using Minitab (version 18).

In assessing respondents' answers as either correct or incorrect, we defined standard lines as those not made with di(2-ethylhexyl) phthalate, because infusion therapy is moving toward not using the plasticizer *di(2-ethylhexyl) phthalate* due to concerns over its interaction with multiple medications and fluids in even, what may be considered to be, nonspecial infusions [18] and special lines (Table 2), in accordance with definitions used by the other data sources.

Correct answers were defined based on the findings of an extensive literature search (Multimedia Appendix 2), and consensus between the team's pharmacists (RAJ and AC) was required.

Answers from the control and test groups were calculated as percentage deviations from a fully correct selection. This approach was taken due to the nature of the questions, wherein multiple item selections could be made, leading to the chance of multiple wrong and correct selections. The selection of all medications correctly was scored as 0; an incorrect selection was scored –1, and the omission of a correct selection was scored as +1.

Table 2. Definitions and characteristics of standard and special intravenous administration lines [19-22].

Administration line type	Definition	Characteristics	Comments or usage example
Nonspecial line	Standard	• Not made with di(2-ethylhexyl) phthalate • Made with polyvinylchloride	General medication administration
Low-protein binding 0.2-micron filter	Specialty	• Not made with di(2-ethylhexyl) phthalate • Made with polyvinylchloride • Polyurethane filter	Amiodarone, total parental nutrition (lipid-free, crystalloid, vamin)
Low-protein binding 1.2-micron filter	Specialty	• Not made with di(2-ethylhexyl) phthalate • Made with polyvinylchloride • Polyurethane filter	Total parenteral nutrition containing lipid emulsion or lipid infusions
Low-sorbing line	Specialty	• Not made with di(2-ethylhexyl) phthalate • Made with polyvinylchloride • Polyethylene lined	Insulin, nitroglycerin, alemtuzumab, bleomycin, cabazitaxel, docetaxel, ifosfamide
Low-sorbing line with low-protein binding 0.2-micron filter	Specialty	• Not made with di(2-ethylhexyl) phthalate • Made with polyvinylchloride • Polyethylene lined • Polyurethane filter	Epoprostenol, alemtuzumab, thiotepa, ofatumumab, panitumumab, cetuximab, paclitaxel
Light-protective	Specialty	• Amber • Not made with di(2-ethylhexyl) phthalate • Made with polyvinylchloride	Adrenaline (epinephrine), amiodarone, labetalol, digoxin, bleomycin, doxorubicin, methotrexate, rituximab, vincristine

Analysis of Intravenous Line Usage and Medication Usage Data

Regional data on standard and special intravenous line consumable usage were grouped by specific characteristics. The amount of medication for which special intravenous administration lines would be required was assayed using a software program (Alaris CQI, version 4.3; Becton, Dickinson and Company).

Mapping between these 2 sources of information was undertaken for evidence of the degree of discrepancy between actual use of special intravenous administration lines in the region and what should have been used assuming full knowledge of the intravenous administration line requirements for the total number of medications requiring special intravenous administration lines given. We suggest that any knowledge deficit identified in the survey of nurses could be an important cause for incorrect use (under or overuse) of special intravenous administration lines identified in the database contrasting.

Results

It became evident that the test group found question 3 to be problematic, despite its interrater consistency; the interrater consistency was acceptable for all other questions (Table 3). Many respondents gave rapid feedback that the question was confusing, because they were confident that none of the medications required filtering. Respondents therefore appeared to have randomly selected 1 incorrect option. The question was, therefore, removed from final survey results.

There was a substantial discrepancy between actual usage (enterprise resource planning data on standard and special intravenous administration line consumable use) and correct usage of medication with special line requirements (Table 4).

Table 3. Interrater consistency (control and test groups).

Question	Item-adjusted total correlation	Squared multiple correlation	Cronbach α
1	0.2299	0.4336	.7923
2	0.7281	0.7493	.6978
3	0.1693	0.5101	.7966
4	0.6414	0.5419	.7117
5	0.6508	0.7266	.7045
6	0.7678	0.6426	.6636

Table 4. Enterprise resource planning and facility consumption and intravenous medication administration requiring special lines.

Specialty line type	Intravenous consumables usage (n=1,454,440), n (%)	Required usage based on medications administered (n=592,392), n (%)
Low-protein binding 0.2-micron filter	0 (0.00)	27,428 (4.63)
Low-protein binding 1.2-micron filter	6600 (0.45)	2987 (0.50)
Low-sorbing line	125,090 (8.60)	15,063 (2.54)
Low-sorbing line with low-protein binding 0.2-micron filter	6000 (0.41)	3407 (0.58)
Light-protective	109,400 (7.52)	60,812 (10.27)

Discussion

Principal Findings

A good example of the absolute need for the correct selection of administration line for a particular medication is that of epoprostenol. This medication requires light protection and 0.2-micron filtration and reacts with polyethylene (which is commonly used in low-sorbing lines). Question 6, which was related to this medication was poorly answered by respondents in the control group (percentage deviation range –19% to 41%) and answered particularly poorly in the test group (percentage deviation range –43% to 93%). Given its extremely short half-life and use of this medication for critical interventions such as extracorporeal circuit management and pulmonary hypertension treatment, degradation of the active molecule due to incorrect line selection has potentially serious effects.

Question 1, which was about medications requiring protection from light, also showed a large deviation in the test group (percentage deviation range –25% to 92%), with multiple omissions including short half-life vasopressors and cardiac medications. The control group (percentage deviation range –13% to 47%) performed far better on this question. Each group was asked to not use internet resources while answering each question, but individuals in the control group were unsupervised during the completion of the survey and may have submitted to the temptation to use medication guides on the internet.

In fact, the test group (Figure 1) consistently performed worse than the control group (Figure 2) for every question (Figure 3). There was no time limit applied to completion of the questionnaire for either group, but the opportunity to review medication guides on the internet or medication manufacturers' package inserts cannot be discounted, and in the study, demonstrates that, although access to information improves performance, there is conflicting information and a lack of hierarchy associated with information on this topic. Reducing clinical variability has been a goal in health care for a considerable amount of time. It is desirable that we verify, concentrate, and distill information for clinicians.

There was a discrepancy between the relative amount of intravenous line consumables that should be used and that being consumed. This was notably evident for consumed (109,400/1,454,440) and required (60,812/592,392) light-protective lines—a difference of 2.75%.

There was reasonable agreement between usage percentages for the low-sorbing line combined with a low-protein binding 0.2-micron filter (consumed: 6000/1,454,440, 0.41%; appropriate: 3407/592,392, 0.58%) and the standard line with a low-protein binding 1.2-micron filter (consumed: 6600/1,454,440, 0.45%; appropriate: 2987/592,392, 0.50%). This may be related to the fact that these are products commonly used for total parental nutrition, either with or without lipids, and that instructions are usually marked very clearly on these products as they are almost exclusively dispensed (and very commonly compounded) by the pharmacy department. It is notable that, in the survey, both the control group (percentage deviation range –22% to 22%) and the test group (percentage deviation range –44% to 44%) showed substantially less deviation for the question on the filtration requirements for total parental nutrition containing lipids than those for the other questions.

Consumption of low-sorbing lines was substantially larger (125,090/1,454,440, 8.60%) than that indicated to be appropriate (15,063/592,392, 2.54%), which may be related to the fact that many facilities in the region use this particular line type for vasoactive infusion administration because the line itself has no lower Y-site, which helps mitigate against inadvertent flushes or push medications being administered into a line that is delivering medications that must be given at a constant and uninterrupted rate.

Figure 1. Tornado distribution plot (percentage deviation from correct selections) for the test group.

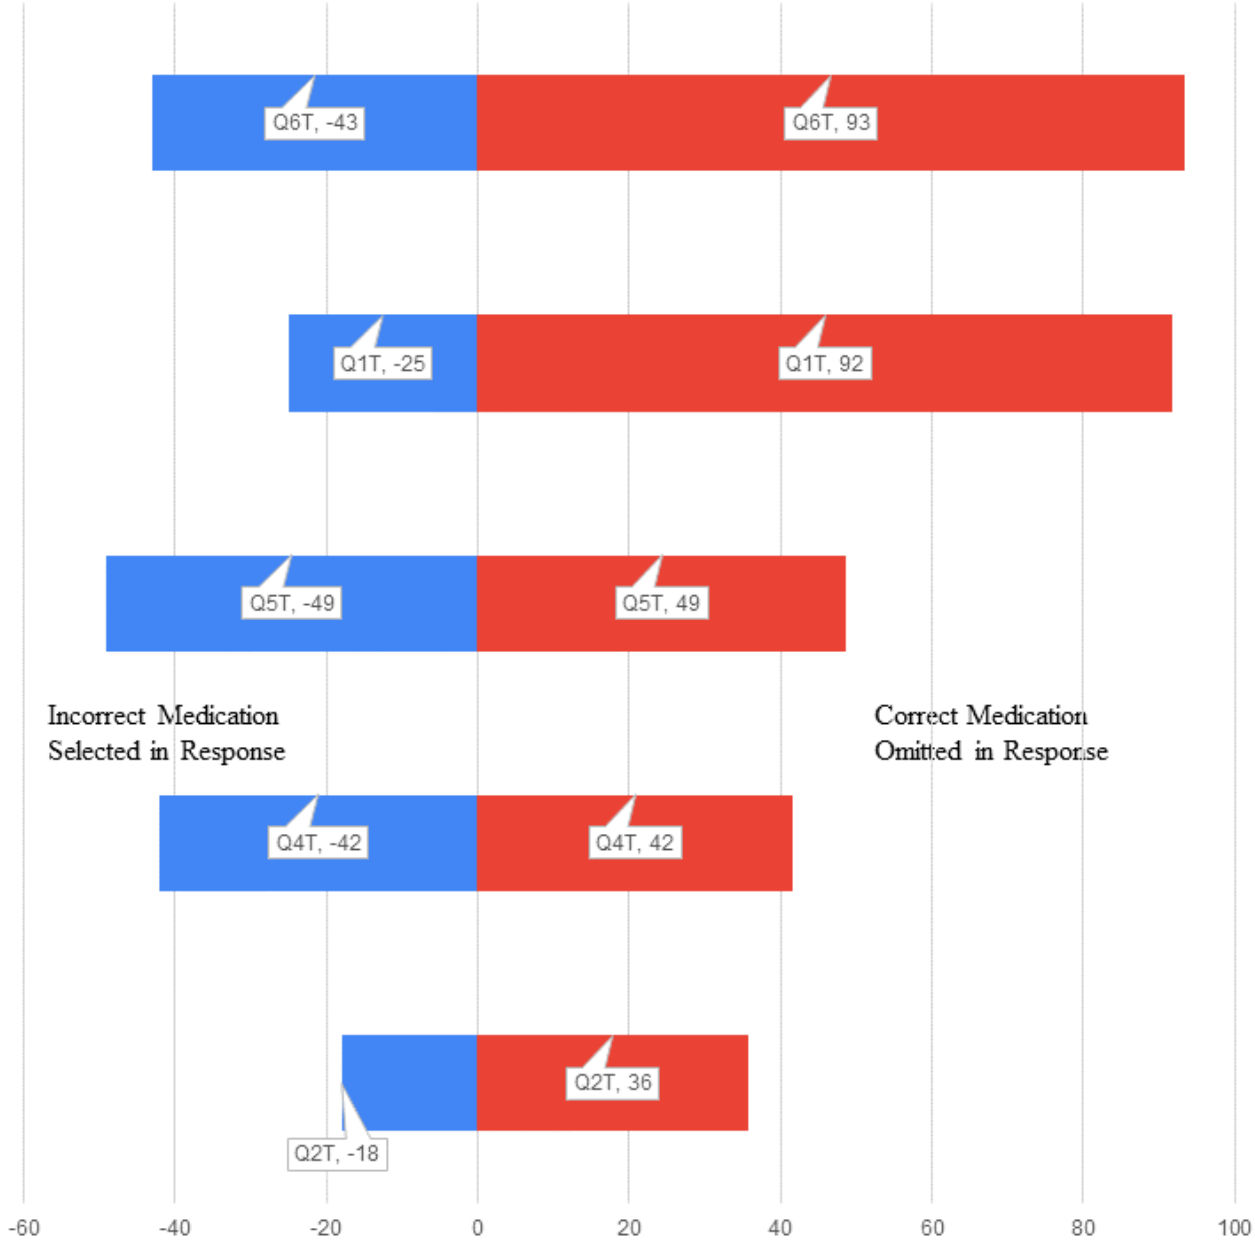

Figure 2. Tornado distribution plot (percentage deviation from correct selections) for the control group.

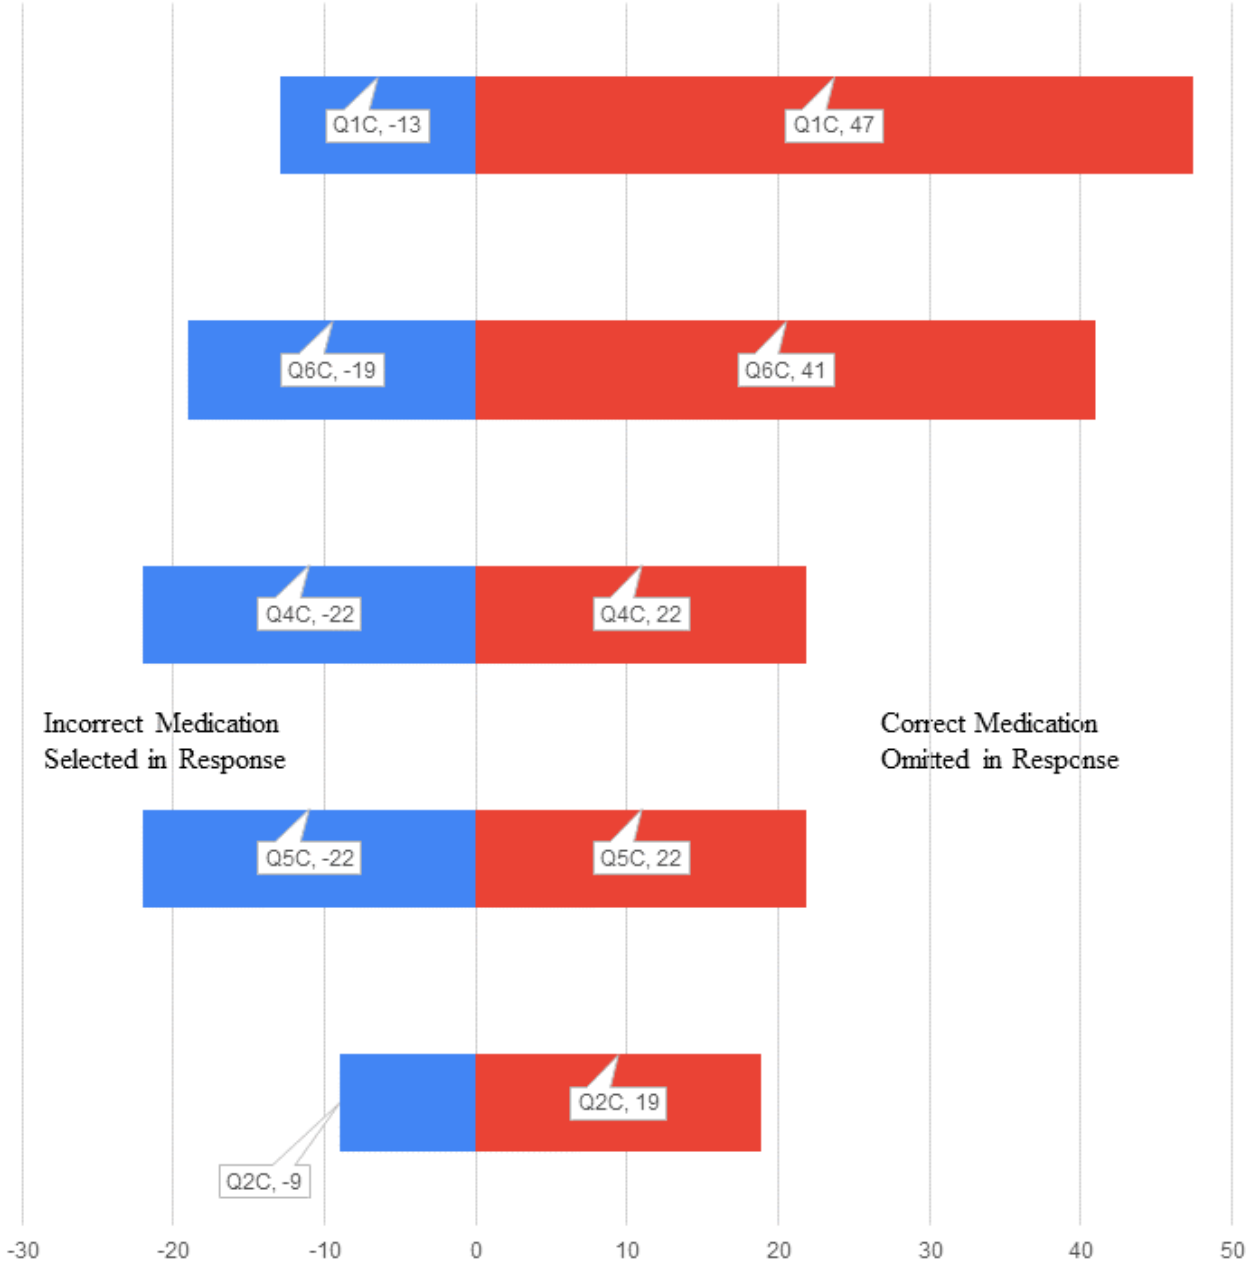

Figure 3. Distribution plots (percentage deviation from correct selections) for control and test groups.

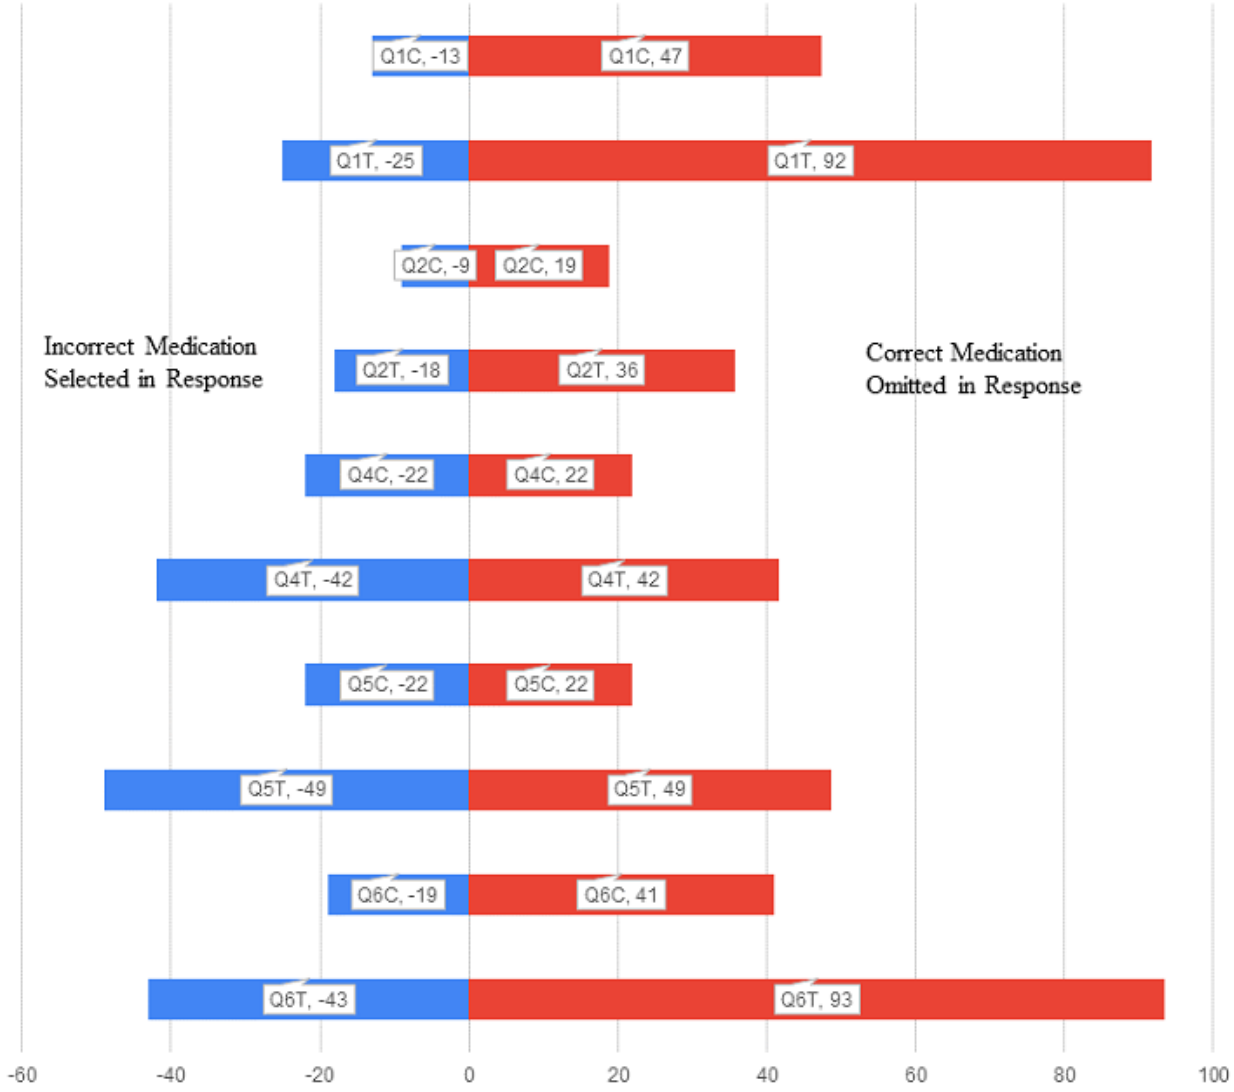

Study Limitations

The study was limited to the Middle East for the main part of the survey, but the control group was composed of clinicians from Europe, the Middle East and Africa. There was certainly a small degree of discussion between some respondents at the in-person survey despite surveyors' requests to complete the survey individually, but this behavior, in fact, imitates nurses' decision-making practices [23].

The test group was predominately composed of nurses who work in intensive care units (all: 44/72, 61.11%; pediatric 14/72, 19.42%; neonatal: 12/72, 16.66%; high-acuity high-dependency: 2/72, 2.81%).

Conclusions

The survey and the review of real-world data and enterprise resource planning data indicated a large degree of clinical variation.

The survey included medications that are in common use throughout critical care, and there was a large difference of opinion among respondents on line type and material required for their administration. This is worrisome, particularly because the medications in the survey are core intensive care unit medications—the risk of incorrect intravenous administration line selection would be expected to increase with unfamiliar medications. The competency pyramid is built on knowledge, skills, and attitude [24]. Competency is difficult to maintain with limited exposure to tasks such as reconstituting and administering uncommonly used medications, and the knowledge environment in which the clinician is operating may also be limited, with no experienced peers or easily accessible information available. In the last two years, we have observed multiple cases of staff working outside of their regular units to meet the needs of expanded critical care units, and crisis conditions that have largely precluded the full supply of central intravenous additive services medications to critical care units.

Furthermore, in critical care, the likelihood of an ideal situation for integrated compounding-administration, with products and information flowing from the central pharmacy to the bedside clinician who receives accurate information from the medication's barcode label, including patient details, drug dose

and volume, and important instructions for administration such as which intravenous administration line is required for safe, effective, and uncorrupted administration, and the product being tracked through connected inventory systems to ensure correct storage of the reconstituted product (particularly those requiring temperature control and protection from light) is unlikely [25]. The Institute for Safe Medication Practices [25] recorded that 28% of respondents to their survey in November 2020 reported "often or always admixing intravenous continuous infusions or titrations, particularly insulin, vasopressors, or lifesaving drug infusions required during emergencies." Much of this reconstitution and mixing takes place outside of the medication room and away from compounding information sources; at the bedside (37%), nursing station desks (28%), and bedside computer workstations (16%) [25].

It is of even greater concern that 53% of the respondents of that survey [25] disagreed or strongly disagreed that their organization requires practitioners who prepare sterile injectable medications and infusions to undergo formal training. Similarly, 49% of respondents disagreed or strongly disagreed that they have been formally trained for the task, and 32% reported no formal training or annual competencies for compounding and reconstitution of intravenous medications [25]. The likelihood of a knowledge gap, not just in terms of dose and dilution but also in terms of administration line requirements for medications, is evident.

The need for a trusted bedside guide for administration line usage and compatibilities is evident. We have known about the ability for handheld and bedside applications to deliver immediate information at the bedside for a considerable time [26]. We suggest that the issue of guidance for administration line selection would be best managed by a handheld device app that could be downloaded to either dedicated facility-owned handheld devices which may have other functions such as barcode reading or alarm routing, or to so-called bring-your-own-device mobile phones or tablets. Any medication and special intravenous administration line guide needs to be accurate, current, and complete. This means that it requires a valid process for both initial and ongoing review. We propose that the best way to manage such a process would be via an initial Delphi panel [27] as this technique is structured around independent work—meetings are kept to a minimum and the participants can be in distant locations and time-zones and still participate. It has also been used to address complex and difficult questions in health care where expert opinion is often the only method of obtaining a cogent outcome, for example, acceptable limits of polypharmacy and types of medication that can be safely prescribed for older adults [28,29]. This could be followed by annual review via the same method. (The initial panel should be tasked with setting this review period.) The findings of this panel could then be incorporated and presented in an easy-to-use guide.

We concentrated on critical care medications, but in the future, we would like to further extend the survey technique to a review of intravenous oncology medications, as this is an area where special administration lines are often required and where loss of efficacy or even debasing of the active molecule has serious consequences for patients and for the facility if cycles of chemotherapy require repeat administration because of incorrect administration [4].

One particular issue with all medication regimens, but one which has a particular resonance with high-value medications and for pediatric oncology, is ensuring a complete dose. Loss of efficacy is a risk, but running infusions to completely empty the intravenous tube of all medication, and thereby, give the complete dose, can also be difficult to manage in a busy ward or outpatient unit, where a single nurse is managing several patients. The choice of administration line can also have consequences here. So-called *short sets* can allow independent intravenous channel rate-control over cytotoxic infusions to run into primary infusions of maintenance or hydration fluids. Administration lines with self-sealing connections that allow the clinician to unlock from a primary bag, lock to the medication to be given, complete the infusion, and run the medication bag dry while avoiding entry of any air into the administration line before switching back to the primary line can help with total delivery, the clinician needs to be aware of them and to know when to use them. Again, a bedside guide that can be consulted prior to medication administration preparation that identifies the material, light protection and filtration requirements, and the most effective administration line would add value.

This formative study was a step toward such a tool. We assayed the extent of the issue of lack of knowledge and information available to nursing staff and compounding pharmacists at the point of care. The survey method would need further development to be able to address pre- and postintervention education, with the addition of nonparametric testing for groups exposed to bedside tools and those who use traditional methods to choosing intravenous administration lines for specific medications.

Abstract

Background: The greatest stressor for outpatients is the waiting time before an examination. If the patient is able to use their smartphone to check in with reception, the patient can wait for their examination at any location, and the burden of waiting can be reduced.

Objective: This study aimed to report the system design and postintroductory outcomes of the Tori RinRin (TR2) system that was developed to reduce outpatient burden imposed by wait times before examination.

Methods: The TR2 system was introduced at Tottori University Hospital, a large medical facility that accepts a daily average of 1500 outpatients. The system, which links the hospital's electronic medical record database with patients' mobile devices, has the following functions: (1) GPS-based examination check-in processing and (2) sending appointment notification messages via a cloud notification service. In order to evaluate the usefulness of the TR2 system, we surveyed the utilization rate of the TR2 system among outpatients, implemented a user questionnaire, and polled the average time required for patients to respond to call notifications about their turn.

Results: The 3-month average of TR2 users 9 months after the TR 2 system introduction was 17.9% (14,536/81,066). In an investigation of 363 subjects, the mean examination call message response time using the TR2 system was 31 seconds (median 14 seconds). Among 166 subjects who responded to a user survey, 86.7% (144/166) said that the system helped reduce the burden of waiting time.

Conclusions: The app allowed 17.9% of outpatients at a large medical facility to check in remotely and wait for examinations anywhere. Hence, it is effective in preventing the spread of infection, especially during pandemics such as that of coronavirus disease. The app reported in this study is beneficial for large medical facilities striving to reduce outpatient burden imposed by wait times.

Introduction

For patients undergoing outpatient examination, the wait time from check-in to the start of examination restricts their activity, contributing to mental and physical stress [1-5]. SARS-CoV-2, which causes COVID-19, was first confirmed in 2019 and is spread via droplets through close contact [6-10]. Since COVID-19 is a disease that spreads via droplets, it is important to wear a mask and keep distance among people [11-15]. In

large medical institutions, where many patients have a serious underlying respiratory illness, it is important to prevent in-hospital outbreaks in crowded examination rooms. In recent years, health care apps for smartphones have become widespread in the medical field [16-19]. If patients are able to check-in for their examinations and confirm wait times and queues from their mobile devices, they can avoid crowded spaces as they wait to be seen by a health care provider.

The EasyHos System, designed by Vorakulpipat et al [20], uses patient check-in data stored in hospital information system databases to send notifications to patients' mobile devices regarding their place in the queue for examination. The EasyHos System not only made waiting more convenient for patients but also alleviated work-related burdens on hospital staff. However, it was not introduced at large-scale medical facilities since physicians usually decide the order of examination at such facilities based on the severity of the patient's condition and the arrival of test results, precluding automated notifications of examination start times.

To address this issue, we developed the Tori RinRin (TR2) system, an examination guidance app that can be implemented at large medical facilities. In the TR2 System, a physician can send a notification to an app installed on the patient's mobile phone to call them for examination. This notification is generated while the physician operates the electronic medical record (EMR) screen and reviews information such as the patient's pre-examination test results and check-in queue. This system allows the patient to arrive outside the examination room just before their examination begins, thereby shortening the time spent in the waiting room. The TR2 System is also equipped with a GPS-based examination check-in function that allows patients to check-in for their examination from outside the hospital as long as they are within a 500-meter radius of the hospital. Notifications to patients' mobile devices are sent using a cloud messaging notification function that does not depend on the type of mobile device or operating system.

The inclusion of these features in the TR2 system has enabled its introduction at Tottori University Hospital (TUH), a large medical facility that receives over 1500 outpatients a day. In this study, we aimed to retrospectively assess system design and introduction of the TR2 system to examine the performance of the system's cloud messaging notification function and user registration during the COVID-19 pandemic in order to improve outpatient convenience.

Methods

Experimental Setting

This retrospective study was an analysis of existing, anonymized patient data and materials. According to clinical and epidemiological research guidelines concerning anonymous patient data, ethical review was not required.

TUH, where the TR2 system was developed and introduced, is a medical facility with 40 departments and 697 beds. TUH provides high-level advanced medical care. The TR2 system was developed and named by a research group, which includes the authors of this study who are affiliated with TUH. TUH did not provide a medical guidance application as a countermeasure for outpatient waiting time before the introduction of the TR2 system. The introduction of the TR2 system enabled patients to use an examination guidance app free of charge. The examination guidance app allows users to receive an advance notification message before the start of an examination on their smartphones indicating the expected start time. To promote use of the examination guidance app at TUH, 2 dedicated operators were stationed at the main entrance of the outpatient facility to assist patients in registering for and using the app. For patients who did not have a smartphone owing to financial or other reasons, we rented out an iPod touch with the examination guidance app installed, if desired. There was no change in the waiting order for medical examination regardless of whether the medical examination guide app was used; however, if the patient did not present to the medical examination room when they were notified via the app, the next patient was examined.

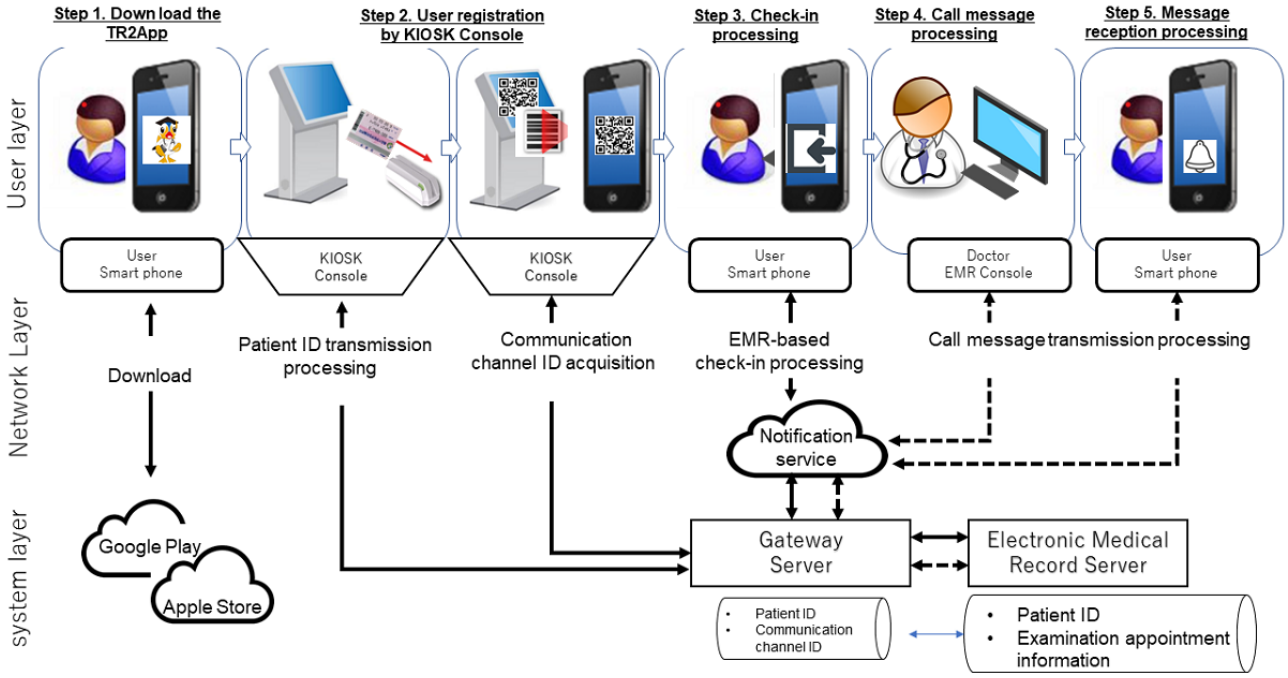
The TR2 system was introduced on a trial basis in 3 clinical departments in July 2019 and started operation in October 2019 for all 40 outpatient facilities.

From July 2020, to prevent nosocomial transmission of COVID-19, TUH has used posters and pamphlets to promote the use of its examination guidance app to help patients maintain distance from others as they wait within the hospital for their examinations.

Outline of the TR2 System

The system processing that occurs from the time of app registration to the time of receiving examination call messages is shown in Figure 1.

Figure 1. Schematic diagram of the Tori RinRin (TR2) system. EMR: electronic medical record.



Step 1: Download the TR2 App

First, outpatients downloaded and installed the examination guidance app (TR2 app) from the internet onto their mobile devices. The TR2 app can be downloaded for free from the Apple Store and Google Play.

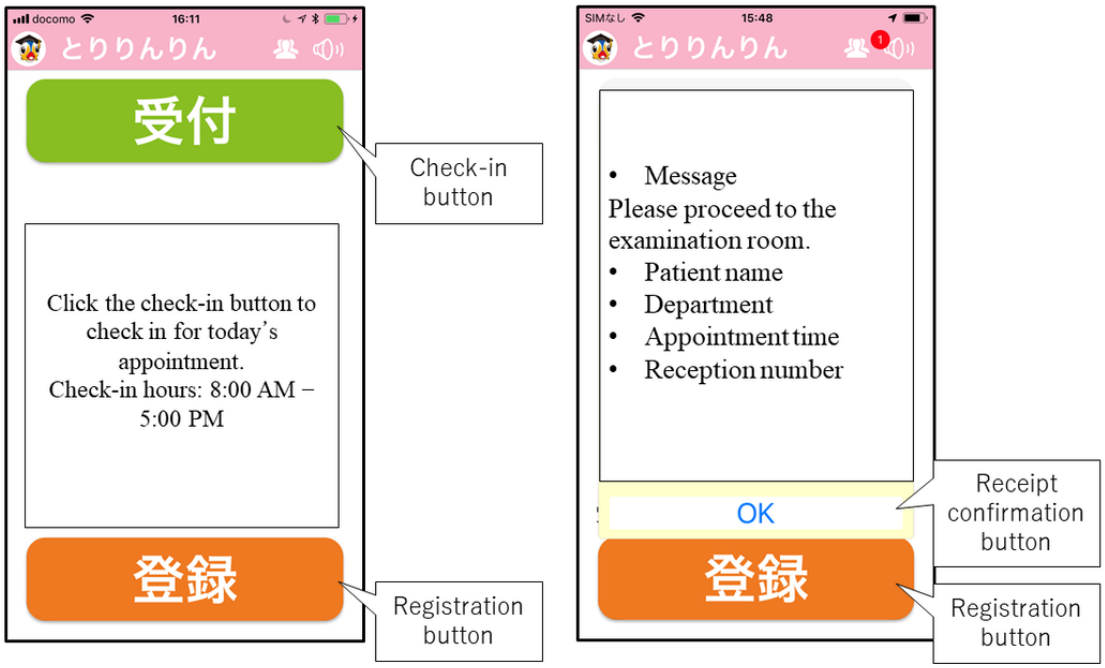
Step 2: Communication Channel ID Acquisition

Outpatients used a barcode reader on a kiosk terminal in the hospital to read the patient ID number on their examination card. kiosk terminals are installed on all floors at which examination check-in is possible. The kiosk terminal sends the patient ID to a gateway server and acquires a communication channel ID. This communication channel ID, issued by Firebase Cloud Messaging (FCM) in the case of Android and by Apple Push Notification service (APNs) in the case of iOS, was used to send a text to the patient's mobile device from their EMR via the internet [21,22]. The patient opened the examination guidance app and read the communication channel ID, which is displayed as a QR code on the kiosk terminal. This series of processes enables the linkage of data between the EMR console and the patient's mobile device.

Step 3: EMR-Based Examination Check-in Using the Examination Guidance App

When outpatients opened the examination guidance app, their location was identified by a GPS function, permitting them to check-in for their examination if they were within a 500-meter radius of TUH (Figure 2). When the outpatient tapped the check-in button on the examination guidance app, a message regarding their examination check-in was sent to their EMR via a gateway server, thereby concluding examination check-in. This operation allowed the physician to confirm that a patient scheduled for an examination that day had arrived at TUH.

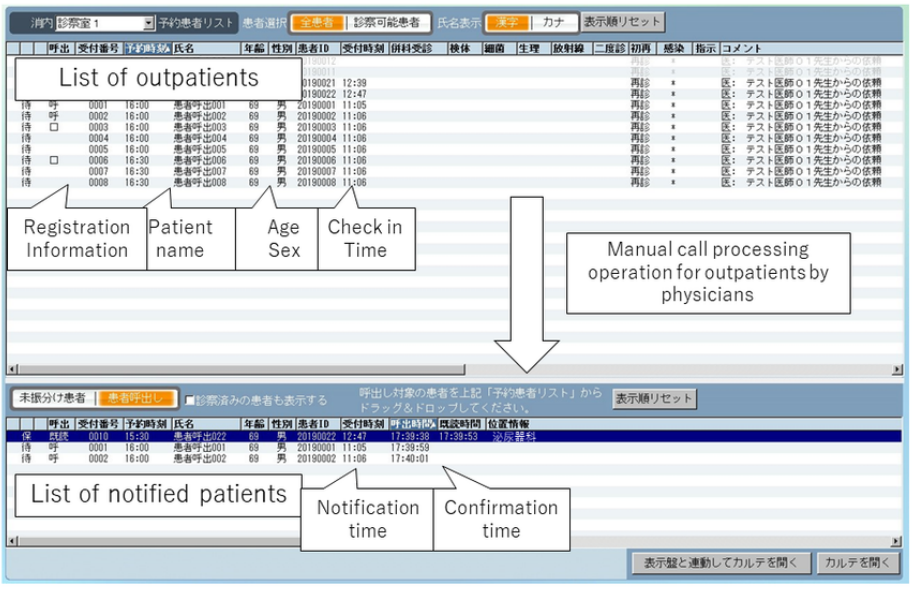
Figure 2. Example screens on the examination guidance app on the outpatient's mobile phone.



Step 4: Transmission of the Examination Call Message From the EMR Console to the Examination Guidance App

The EMR console displays a list of patients scheduled for examination that day; when the physician selected a patient to call from that list, a notification was sent to the patient's smartphone, calling the patient to the examination room (Figure 2). This notification operation is executed approximately 10 minutes before the examination begins. The message is sent via a gateway server as a push notification (Figure 3).

Figure 3. Electronic medical record (EMR)–based notification operation screen used by the physician.



Step 5: Patient Response to the Call Message

Outpatients can receive guidance notifications on their smartphones from doctors before the start of medical examinations. When the patient presses the response button on the call message displayed on their smartphone, the response time is recorded in the "Confirmation time" column of the EMR (Figure 3).

Components Comprising the TR2 System

Table 1 lists the components introduced to run the examination guidance app. The app can be used with both Android and iOS operating systems. To adapt the app to be used by a wide patient age range, the user interface was designed so that all operations can be completed simply by tapping buttons, without the need for flicking or typing. Confirmation operations from examination check-in (Step 3) to the examination call notification (Step 5) can be completed solely by tapping buttons. There were 4 kiosk terminals (1 on each floor) that were operated with a touch panel interface. As the kiosk terminal sent the patient's ID (which is stored in the patient's examination card) to the gateway server, it simultaneously acquired a communication channel ID from the gateway server. The gateway server has a mapping function to associate the patient ID used in the EMR with the communication channel ID and relays text messages to the patient's smartphone via FCM/APNs.

Table 1. Components of the TR2 system.

Name	Use	Source	Hardware: operating system
Examination guidance app	Examination check-in, notification, and guidance	eBase Solutions	Android 8.0/iOS 11 or higher
Kiosk terminal	Data linkage	eBase Solutions	HP ProDesk 400 G6 SF: Windows 10pro
Gateway server	Message transmission, ID mapping	IBM Japan	Windows server 2016 Standard
EMR[a] system	Examination records and patient notification operations	IBM Japan	IBM Power System E950, AIX

[a]EMR: electronic medical record.

Postintroductory Evaluation of the TR2 System

To evaluate the usage of the TR2 system after its introduction, the following parameters were observed: (1) patient response time to the call notification function, (2) the number of registered medical guide apps, and (3) responses to an online questionnaire survey.

Patient Response Time

To evaluate the utility of the app-based messaging service, we investigated the time between notification transmission by the physician to confirmation of the message by the patient. Response time to calls was determined from data recorded in the EMR server database. The target data were collected from 363 people who used the TR2 system for 5 days from February 2, 2020 to February 7, 2020.

Number of Registered Medical Information Apps

From October 1, 2019 to September 31, 2020, we surveyed the number of newly registered patients in the TR2 system on a monthly basis to evaluate app usage. Additionally, from June 2020, as a countermeasure against COVID-19 infection, outpatients were encouraged to use the TR2 system to maintain social distancing. This COVID-19 countermeasure campaign was posted on a poster that recommended the registration and use of the TR2 system at outpatient reception areas of all medical facilities. We compared the utilization rate of the TR2 system in outpatients for the 3 months before and the 3 months after the COVID-19 countermeasure campaign was implemented. The utilization rate was calculated as the cumulative number of outpatients using the TR2 app during the 90-day period divided by the cumulative number of outpatients at TUH during the same period.

Evaluation of Convenience

To evaluate the convenience of the TR2 system, we conducted a questionnaire survey based on a 5-point scale. The question in this survey was "Did the TR2 system help reduce the burden of waiting time?" Respondents to the questionnaire were also able to voluntarily write comments. Respondents were selected by sending an electronic copy of the questionnaire form to patients who used the TR2 system for a period of 5 days from February 2, 2020 to February 7, 2020.

Statistical Analysis

Statistical analyses were performed using R version 3.1.2. Differences in percentages between groups were compared using chi-square tests. *P* values <.05 were considered statistically significant.

Results

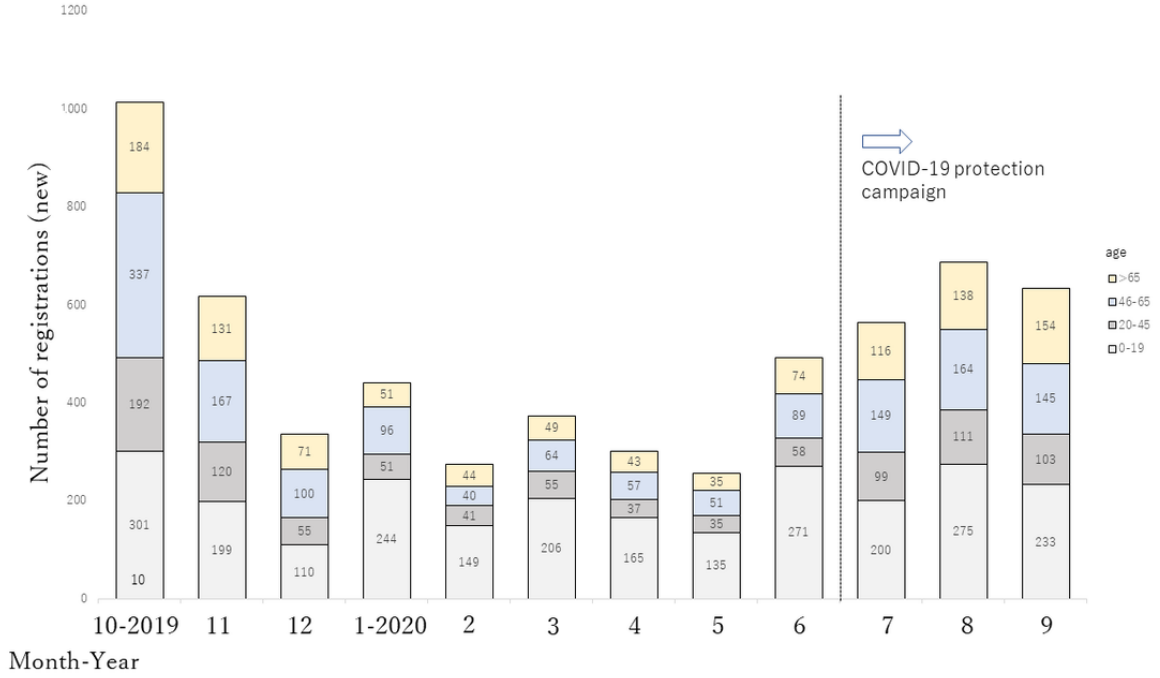
Time From Examination Call Message Transmission to Patient Response

We investigated the time from notification transmission by the physician to confirmation of the message by the patient. This investigation included 363 response times from 363 patients recorded from February 2, 2020 to February 7, 2020. The mean patient response time was 31 seconds, with a median of 14 seconds. Patients took ≥600 seconds to respond to notifications in 19 of 363 cases (5.2%). As a rule, physicians sent notifications 10 minutes before an examination was scheduled to start, and if patients failed to show up to the examination room by the start time, the physician could alter the examination queue.

Changes in the Number of Registered Examination Guidance App Users

A total of 5994 patients registered for the examination guidance app from July 1, 2019 to September 30, 2020 (Figure 4).

Figure 4. Changes in the number of registered examination guidance app users.



From December 2019 to June 2020, the monthly mean number of new registered users was 353 (SD 81). In July 2020, TUH began to promote the use of the examination guidance app to prevent the spread of COVID-19. To assess the effect of promoting the examination guidance app usage as a measure to prevent COVID-19, we compared user registration rates before and after the introduction of the TUH COVID-19 prevention campaign. A comparison of the number of newly registered users for the 3 months before and after the start of the TUH COVID-19 prevention campaign revealed that the number of users increased 1.79-fold after the start of the campaign. Consequently, we found that app usage rate increased significantly from 16.4% (12,444 new registered users of 75,791 total outpatients) prior to campaign introduction to 17.7% (14,536 new registered users of 81,066 total outpatients) after campaign introduction.

Results From the Anonymous Online Surveys of App Users

For the questionnaire survey for users, we decided to send a web-based, 5-point evaluation questionnaire to outpatients using the TR2 app. The number of respondents to the questionnaire was 166 of 363 (45.7%). The 5-point scale for assessing convenience consisted of the following responses: “Strongly agree,” “Agree,” “Neutral,” “Disagree,” and “Strongly disagree.” These responses were given by 82, 66, 15, 1, and 2 patients, respectively. From the results of the 5-point scale, we found that the TR2 system succeeded in its objective of reducing the burden imposed by wait times. Comments from the 41 patients who wrote in the free-response section of the survey were broadly divided into 3 categories (Table 2). From 41 respondents, 17 wrote favorably about the ability to wait for their examination at any location (such as in their cars or the cafeteria) and the ability to check-in for their examinations from outside the hospital. In contrast, the survey also revealed bugs such as notifications not being received by outpatients’ mobile devices.

Table 2. Classification of free-form questionnaire results about the Tori RinRin (TR2) system.

Category	Number of respondents	Responses
Reduction of stress imposed by wait times	17	Being able to wait where I wanted until my examination reduced my stress. Being able to check-in for my examination from outside the hospital was convenient. Being able to avoid crowded spaces while waiting for examinations can help to prevent COVID-19.
Opinions and requests regarding functions	16	I’d like to have an idea of how much longer I have to wait until my examination or how many people are waiting in front of me. They should let us check-in for examinations from more than 500 meters away. I want to know how many people are waiting in front of me so I can avoid COVID-19 exposure in crowded waiting rooms. They should add a page for blood tests and radiological tests. The text should be bigger, and the app should be easy to use.
Bugs in the app	8	I didn’t get an examination call message. The notification sound didn’t stop until I stopped it.

Discussion

Principal Findings

This study assessed the effectiveness of the TR2 system, which was developed to reduce the burden of outpatient waiting time, based on the system's operation and user registration. The study determined patient response time to notifications regarding examination calls, changes in the number of registered users, and users' assessments of the system, all of which revealed the advantages of introducing the system at a large medical facility as well as the associated problems in its implementation.

The examination guidance app's call notification function employs push notifications using cloud messaging services (FCM and APMs). If the patient cannot receive examination call messages via push notifications normally, the outpatient examination queue will be disrupted, resulting in major inconvenience to the physician and patients. Our investigation of patient response times to messages revealed that approximately 5.1% of patients were unable to respond in fewer than 10 minutes; 10 patients reported that their examination notification messages were delayed. Push notifications can convey more information than other forms of notification such as phone calls and can reduce communications costs, which are advantages that have led many companies to adopt push notifications; however, they are highly dependent on individual smart devices. For example, in low power mode in iOS, when the device's battery percentage falls below a certain level, push notifications are delayed [23]. We believe that the cause of 5.1% of delays in response to call messages were because of these smartphone-specific functionalities. One conceivable solution to such problems is to check for delays based on gateway server logs and switch from push notifications to phone calls or text messages when patients do not respond.

Regarding the number of registered examination guidance app users, approximately 12 months after the system was launched, about 6000 patients were registered for the TR2 system.

We learned that the change in the number of users was greatly affected by factors such as the app promotion campaign, COVID-19 pandemic, and outpatient age. Many apps developed to combat COVID-19 use iBeacon and GPS to enable determination of infected patients' contact history and tracking of their actions [14,24-29]. In contrast, while our examination guidance app was not developed with the intention to combat COVID-19, it enables outpatients to wait in the parking lot or anywhere else until their examinations, thereby allowing them to avoid crowded waiting areas, reducing contact among patients and subsequently reducing COVID-19 exposure. As indicated by the results of this study, the number of examination guidance app users increased significantly following the promotion of the app as a COVID-19 countermeasure, suggesting that outpatients had a positive attitude toward using the examination guidance app to prevent the spread of COVID-19. Japan has not yet reported sufficient studies on cases of infection among patients in waiting rooms or on the causes of such infections. We also do not know how effective our examination guidance app is in preventing COVID-19. However, when medical facilities provide examination guidance apps free of charge, patients who are wary of COVID-19 can use their own judgment to avoid crowded spaces and wait elsewhere for their examinations. As revealed in our study, this allows patients to wait where they please and helps reduce their physical and mental stress.

Comparison With Prior Work

Similar examination guidance apps, including the Outpatient Guidance System (OGS) developed by Baek et al [30] and the EasyHos System by Vorakulpipat et al [20], have been previously developed [31]. These systems also send a notification of the day's outpatient schedule (stored in the hospital information system database) to the patient's mobile device. Although the studies that introduced these systems introduced their functions and reported on user registration outcomes and improvements in hospital duties, they did not sufficiently assess how the systems notified patients. Although there are other methods of notifying patients, such as email and phone calls, the rates of patient response to these have not been examined. Therefore, push notifications, which were used in this study, are an effective form of communication for medical facilities, considering the system design and implementation of the TR2 system.

A guidance function that uses iBeacon based on an OGS can determine a patient's location within a hospital. With these functions installed, an examination guidance app can determine the crowding of patients within a hospital (which was not performed in this study) and enable assessment of the app's effects in preventing COVID-19 transmission.

Reported methods for examination guidance other than providing an app, include lending mobile devices to patients. With this method, the initial investment in hardware is extremely expensive. A single mobile device costs approximately US $400, while a management unit costs at least US $20,000. At TUH, where about 1500 outpatients are examined per day, lending out mobile devices would require approximately 1000 devices. Therefore, introducing this system at TUH was estimated to cost about US $420,000. If TUH had developed its own examination app, constructing the system (including the cost to revamp the EMR) would have cost US $120,000. As smartphones have recently exploded in popularity, many of our outpatients already own smart devices. When the initial investment and hardware management costs are also considered, providing an examination call function with an app is advantageous in terms of introduction costs. However, as stated earlier, the causes of defects in the system are difficult to investigate, and operation verification would be required whenever iOS or Android operating systems are updated. Introducing an examination guidance app requires consideration of these merits and demerits as well as consideration of the facility's budget.

Limitations

Clinical features such as sex and underlying disease of TR2 system users were not examined in this study. If the relationship between the clinical characteristics of users and the utilization rate is clarified, it will be useful information for medical institutions targeting specific diseases when considering

introduction of this medical guidance app. By using the EMR of the Gateway server that comprises the TR2 system and the mapping information of the communication channel ID, it is possible to link to the medical care database and analyze the clinical characteristics of each user. In this study, the effects and problems of system introduction on the outpatient clinic have not been completely evaluated. These evaluations will be conducted by polling doctors and outpatient staff using questionnaires.

Conclusion

In this study, we evaluated the introduction and usage record of the medical guidance application TR2 developed to reduce the burden of waiting time for outpatients in large-scale medical institutions. The utilization rate of the app by outpatients 1 year after introduction of the app was about 17.9%. According to the results of the anonymized questionnaire targeting app users, 88% of the users of this system reported a reduction in the burden of waiting time. In addition, by using the TR2 system, outpatients could wait away from crowded places until the start of their medical examinations, allowing the app to be used as an infection control measure in outpatient waiting areas. In the future, in order to prove its effectiveness as an infection control measure, it will be necessary to assess the location of the patient prior to the start of the patient's examination and the congestion of the waiting area outside of the outpatient examination rooms. The results of this study will be a useful index for medical institutions considering the introduction of medical guidance apps.

Abstract

Background: Dietary habits offer crucial information on one's health and form a considerable part of the patient-generated health data. Dietary data are collected through various channels and formats; thus, interoperability is a significant challenge to reusing this type of data. The vast scope of dietary concepts and the colloquial expression style add difficulty to standardizing the data. The interoperability issues of dietary data can be addressed through Common Data Elements with metadata annotation to some extent. However, making culture-specific dietary habits and questionnaire-based dietary assessment data interoperable still requires substantial efforts.

Objective: The main goal of this study was to address the interoperability challenge of questionnaire-based dietary data from different cultural backgrounds by combining ontological curation and metadata annotation of dietary concepts. Specifically, this study aimed to develop a Dietary Lifestyle Ontology (DILON) and demonstrate the improved interoperability of questionnaire-based dietary data by annotating its main semantics with DILON.

Methods: By analyzing 1158 dietary assessment data elements (367 in Korean and 791 in English), 515 dietary concepts were extracted and used to construct DILON. To demonstrate the utility of DILON in addressing the interoperability challenges of questionnaire-based multicultural dietary data, we developed 10 competency questions that asked to identify data elements sharing the same dietary topics and assessment properties. We instantiated 68 data elements on dietary habits selected from Korean and English questionnaires and annotated them with DILON to answer the competency questions. We translated the competency questions into Semantic Query-Enhanced Web Rule Language and reviewed the query results for accuracy.

Results: DILON was built with 262 concept classes and validated with ontology validation tools. A small overlap (72 concepts) in the concepts extracted from the questionnaires in 2 languages indicates that we need to pay closer attention to representing culture-specific dietary concepts. The Semantic Query-Enhanced Web Rule Language queries reflecting the 10 competency questions yielded correct results.

Conclusions: Ensuring the interoperability of dietary lifestyle data is a demanding task due to its vast scope and variations in expression. This study demonstrated that we could improve the interoperability of dietary data generated in different cultural contexts and expressed in various styles by annotating their core semantics with DILON.

dietary lifestyle data; person-generated health data; ontology; common data element; data interoperability; data standardization; dietary; health informatics

Introduction

Background

Health-related lifestyle data (health lifelog data) provide essential information on one's daily behaviors that directly influence health; thus, such data needs to be used for the management of one's health [1-3]. Health-related lifestyle data are usually captured outside the clinical environment by patients and form a considerable part of the patient-generated health data (PGHD) [4]. Analyzing health-related lifestyle data with clinical, biological, and environmental data may offer additional insights into one's health status [5]. Despite its ever-increasing importance, challenges in data accuracy, data interoperability, and clinical workflow integration have been hindering the utilization of PGHD [6-8].

Capturing health lifelog data in a consistent and interoperable manner is a well-known challenge [9]. Similar to other types of PGHD, data interoperability is a significant challenge to reusing dietary data due to the inconsistent format and the colloquial terms used in describing the data. In addition, dietary data are captured through multiple channels with varying resolutions. One may directly type in the names and amounts of the foods she eats into a food diary app [10,11] or let an artificial intelligence (AI) camera app automatically recognize the type, amount, and nutritional components of the food [10]. Dietary habits are also often assessed using a questionnaire in many clinical or research settings. In this case, respondents need to recall their usual dietary habits for the past week, month, or even year.

The purpose of this study was to build an ontology for dietary behavior to address the interoperability challenge of dietary lifelog data. In particular, this study aimed to construct a dietary lifestyle ontology that incorporates culture-specific dietary concepts and demonstrates its utility in recognizing the data elements designed to assess similar dietary behaviors.

Interoperability Challenges of Dietary Behavior Data

Lack of interoperability is one of the main barriers to using PGHD for patient care [12-14]. PGHD encompasses various health domains and is generated via multiple channels. For example, behavioral health history is collected using health questionnaires, while heart rate, physical activity, and sleep data are automatically captured through wearable sensor devices [15]. Dietary data are collected mainly by direct input from the users, either using a food diary app [16] or a dietary assessment questionnaire [17]. An AI camera automatically captures the type, amount, and nutritional components of the food that one eats, although users still need to confirm the accuracy of the captured information [10]. We may assess eating behavior at each moment of food intake or for a specific period as a health history. Because dietary data are presented in various forms and granularities, standardizing the data is not a trivial task.

Because diet-related lifestyle data are described mainly with nonprofessional terms and a free-text format, standardizing the data becomes more challenging. Dietary questionnaires usually adopt everyday language so that the respondents can easily understand the questions and provide accurate answers. For example, usual protein intake is assessed by asking how often people eat protein-rich food (eg, meat, milk, egg, tofu) in a given period instead of directly asking how many servings of protein they usually have. Therefore, numerous questions can be designed to obtain the same information using different food examples. This approach becomes a barrier to the interoperability of the questionnaire-based data in the nutritional domain unless the food examples are recognized as pointing to the same nutritional components.

Table 1 shows the questions designed to assess the same dietary behavior but with different food examples in different styles. English translations of the two examples from Korean dietary assessment scales are also provided in the table. Systematically identifying and recognizing these assessment items as similar or distinctive is an essential precursor to reusing these data for further analyses.

Table 1. Data elements sharing similar assessment topics.

Questions	Response options	Source	Logical Observation Identifiers Names and Codes (LOINC; version 2.72)
우유나 유제품(치즈, 요플레)을 얼마나 드십니까? [English translation: How often do you have milk or milk product (eg, yogurt, cheese)?]	거의 매일(주6-7일)^가끔(주3-5일)^거의 먹지않는다(주0-2일) [English translation: Almost every day (6-7 times per week), occasionally (3-5 times per week), or rarely (0-2 times per week)]	식습관 평가하기 (대한 영양사 협회) [English translation: Diet checklist (the Korean Dietetic Association)]	N/A[a]
우유나 유제품(요구르트, 치즈) 등을 매일 먹는다. [English translation: I have milk or milk product (eg, yogurt, cheese) every day.]	예^가끔^아니오 [English translation: yes, occasionally, or no]	나의 식생활 평가표 (국가암정보센터) [English translation: My Diet Checklist (National Cancer Information Center)]	N/A
How often do you eat cheese (including on salads or in sandwiches or subs)?	Never or less than one time per month, one time per month, 2-3 times per month, 1-2 times per week, 3-4 times per week, 5-6 times per week, or one or more times per day	Consensus measures for phenotypes and exposures	61441-2
How often do you eat yogurt?	Never or less than one time per month, one time per month, 2-3 times per month, 1-2 times per week, 3-4 times per week, 5-6 times per week, or one or more times per day	Consensus measures for phenotypes and exposures	61457-8
Each time you eat cheese, how much do you usually eat?	less than one slice, one slice, or more than one slice	Consensus measures for Phenotypes and Exposures	61442-0

[a]N/A: not applicable.

Approaches to Standardizing Dietary Behavior Data

Common Data Elements

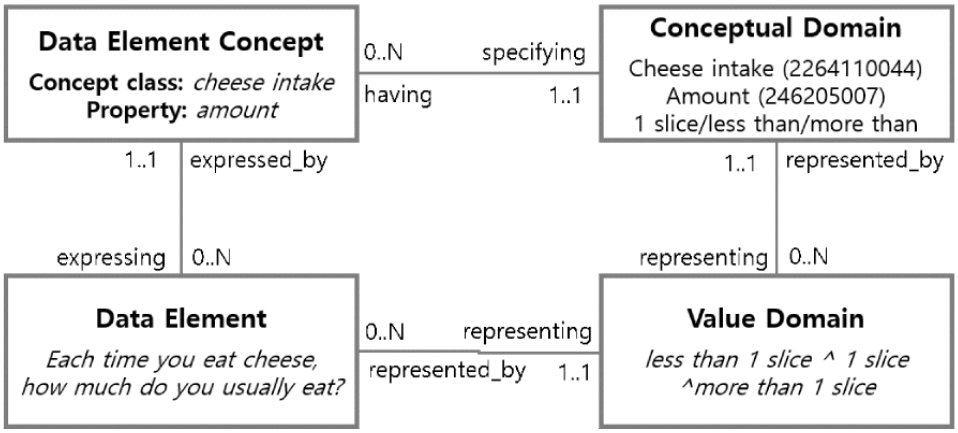
Common Data Element (CDE) is the most popular standardization approach to health-related lifestyle data, especially patient-generated health history data. The National Institutes of Health (NIH) maintains the CDE repository containing various structured data elements that health researchers should consider adopting to produce interoperable data [18]. The CDE repository provides detailed information on a data element, including definition, the development context, and standardized concept mapping with Logical Observation Identifiers Names and Codes if available [18]. The well-organized and reusable CDEs certainly help us address the interoperability challenges of questionnaire-generated data to some extent. However, treating an entire data element as a single concept makes a data element distinctive if it contains a slight variation in the wording of a question or a response option, as shown in Table 1.

Metadata Annotation

The International Organization for Standardization/International Electrotechnical Commission (ISO/IEC) 11179 metadata registry (MDR) standard offers a means of attaching more detailed semantic information to data elements [19]. MDR standard-based metadata annotation requires specifying concept layers and representation layers of a data element (Figure 1). Data element concepts are divided into object classes and properties in a concept layer. The data element concepts and the response options (ie, value domain) are coded with standardized terminologies [19]. The concept layer of a data element enables us to identify the data elements that share similar assessment topics and permissible values, which thus can be analyzed together. However, existing standardized biomedical terminology systems provide limited dietary lifestyle concepts (and other health-related lifestyle concepts); therefore, it is hard to achieve complete vocabulary encoding of the concepts identified in the conceptual domain annotation.

Systematized Nomenclature of Medicine (SNOMED) is a comprehensive health terminology containing many health-related lifestyle concepts [20]. Even if appropriate concept codes are available in SNOMED [20], identifying similar or related questions through the conceptual structure of SNOMED is cumbersome because SNOMED is a large and complex system encompassing the broad scope of a health domain. The concepts relevant to dietary lifestyle are indeed scattered across the conceptual structure of SNOMED. In this regard, metadata annotation with the MDR standard alone is still limited in achieving interoperability of dietary lifestyle data, even though it enables capturing more detailed semantic information of a data element with standardized terminology encoding.

Figure 1. The International Organization for Standardization/International Electrotechnical Commission 11179 metadata model (Systematized Nomenclature of Medicine concept ID is included in parentheses).



Ontologies for Food and Dietary Behavior

Multiple ontologies have been developed to serve various food and nutrition domains. A few examples include tracking the food production process [21], representing nutrient-related isotopic information [22], incorporating metabolomics of nutrients [23], systematically organizing culture-specific food names [24], recommending food for global travelers [25], and representing food additives for food safety [26]. Finally, FoodOn is a comprehensive food ontology that aims to be "a farm to fork ontology," encompassing the concepts from food production to the food names in a restaurant menu [27].

Several studies reported adopting a food ontology to support various health management tasks. For example, food recommendation systems that targeted patients with specific chronic medical conditions were built based on food ontologies [28,29]. Applications that monitor one's general behavioral health and provide personalized healthy lifestyle choices were developed based on an ontology covering a dietary domain [30,31]. These studies indicated that ontologies had been actively used to represent dietary concepts in health domains. However, the ontologies used in these efforts primarily focused on describing food names, nutritional components, and the food production process. The existing ontologies have not sufficiently covered the concepts of diet-related lifestyle.

Food Is a Cultural Concept

As a dietary lifestyle, we are primarily concerned about the types, amount, and time of food intake. A dietary lifestyle depends highly on one's culture. Food names, cooking methods, and food preservation methods vary across different regions and populations. Therefore, the scope and the number of concepts of dietary behavior are inherently vast, and developing a single standardized vocabulary system that encompasses all dietary concepts in the world is a daunting task.

FoodOn is a highly sophisticated and comprehensive food ontology covering food sources, categories, products, and manufacturing concepts [27,32]. However, it misses many culture-specific dietary concepts. For example, FoodOn lacks iconic food or common dietary behaviors frequently used to assess Korean people's eating habits. Typical unhealthy dietary patterns in Korea include eating convenience store food, late-night delivery food, and too much hot and spicy instant noodle soups (ramen). Examples of salty food are Jeot-gal and Jang-a-chi, crudely translated in English as salted fish and pickled vegetables. Various seasoned vegetables (namul-muchim) and kimchi are typically considered healthy food in Korean culture. These typical Korean foods and dietary patterns are not included in the food ontology developed in Western countries, including the most comprehensive one like FoodOn. A few culture-specific diet ontologies exist, but their primary developmental goals were to demonstrate modeling domain knowledge with an ontology [33] or organizing specific food names and nutritional components [24]. Therefore, they were not extensible to incorporate dietary lifestyle concepts from different cultural contexts.

Purpose

The primary purpose of this study was to develop a dietary ontology with an extensible concept structure to support the interoperability of dietary lifestyle data from different cultural contexts. This study also demonstrated the utility of this ontology by addressing the interoperability issues presented in a set of ontology competency questions prepared for this study.

Methods

Developing Competency Questions

To guide the ontology development and evaluation process, we first prepared a set of ontology competency questions. The primary purpose of developing a dietary lifestyle ontology in this study is to support the interoperability of questionnaire-generated dietary behavior data by explicitly capturing the main concepts and relationships of a data element. Therefore, we designed the competency questions reflecting the use cases of systematically identifying data elements assessing similar dietary behaviors based on assessment topics or measurement types (Textbox 1).

Textbox 1. Competency questions.

CQ1. Identify the questions by the assessment domain.

- **CQ1.1** questions on protein intakes.
- **CQ1.2** questions on carbohydrate intakes.
- **CQ1.3** questions on unhealthy eating behaviors.

CQ2. Identify the questions by assessment properties.

- **CQ2.1** assessing frequencies.
- **CQ2.2** assessing general degrees.
- **CQ2.3** assessing applicability (ie, true or false).

CQ3. Identify the questions that specify an observation period.

- **CQ3.1** assessing the behavior of the past month.
- **CQ3.2** assessing the behavior of the past 6 months.

CQ4. Identify the questions that share the same assessment domain and property.

- **CQ4.1** questions on the frequency of high-calorie food intake.
- **CQ4.2** questions on the applicability of unhealthy eating behavior.

Collecting Dietary Terms and Concepts From Existing Questionnaires

Diet-related data elements were retrieved from the NIH's CDE repository with “eating,” “diet,” and “nutrition” as search keywords. Korean dietary assessment questionnaires were retrieved from a web search using similar search keywords. These searches yielded 367 unique Korean data elements and 791 unique English ones. Note that the data elements were treated as distinctive unless expressed in precisely the same words and styles, even if they carry the same information. For example, the examples presented in Table 1 were treated as distinctive data elements.

For this study, 2 nursing students and 1 medical informatics student reviewed and curated the questions following the ISO/IEC 11179 MDR standard [19]. This metadata curation includes identifying essential concepts such as extracting data element concepts from the questions and dividing the data element concepts into an object class and properties. The object class and properties were decomposed into atomic dietary concepts when necessary. This concept extraction process yielded 515 unique dietary concepts (224 from Korean data elements, 363 from English data elements, and 72 overlapping Korean and English data elements). The concepts extracted from the questions and the permissible values were the main ingredients for building the dietary lifestyle ontology.

Reviewing Existing Food and Nutrition Ontologies

We reviewed the FoodOn [27] ontology to benchmark its high-level conceptual structure. Major concept branches (or axes), concept categorization schemes, and higher-level class labels were examined and borrowed to construct the backbone structure of the dietary lifestyle ontology. The food product and food transformation process classes of FoodOn provided valuable insights into categorizing food names and food handling methods.

Ontology Building

The authors reviewed the extracted terms and grouped them into broad categories benchmarking the existing ontologies. The broad categories were food items, food preparation or handling, eating behaviors, and descriptors. These top-level categories were further divided into subcategories representing more specific dietary concepts.

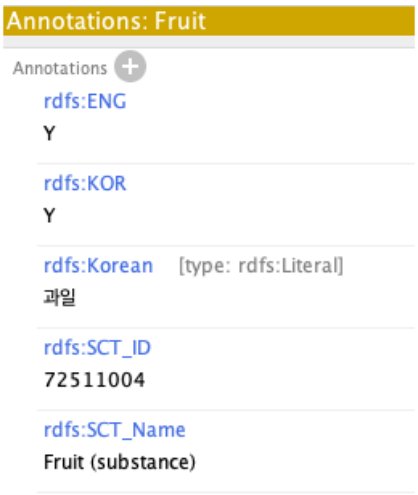
The scope of the dietary domain is vast, spanning from specific food names to physical and mental health status related to food intake. In particular, incorporating the names of all the existing food in the world in this ontology is a demanding and maybe unnecessary task. Therefore, the concept branch that includes food names is structured to facilitate the future addition of food names. The food item class focuses on representing broad types of food, and specific food names were added as instances.

We first built a draft ontology that included every concept we extracted from the text source (ie, 367 Korean data elements and 791 English data elements). We then pruned the ontology by removing the concepts that are too peculiar (eg, salty snack) or already well reflected in other related concepts. For example, we removed “eating out” and kept “restaurant food,” “delivery food,” and “convenience store food.” We also added new concepts to make the concept classes more complete. For example, “appetizer” and “chopstick” were added to the meal course and the utensil classes, respectively, although our text source did not include those concepts.

We built the dietary lifestyle ontology considering the structural component of the ontology quality evaluation and requirement (OQuaRE) [34]. A few examples of the structural elements of OQuaRE include cohesiveness, consistency, lack of redundancy, lack of cyclic structure, and good domain coverage [34]. The concept classes were labeled in English, even those extracted from a Korean questionnaire. All concepts took a singular noun form, and the first character of a concept label was capitalized.

Each concept was annotated with a Korean translation of the concept, language of the concept source (ie, Korean questionnaire or English questionnaire), and SNOMED CT (SNOMED Clinical Terms) concept codes when available. We used the September 1, 2021, version of the US edition SNOMED CT (Figure 2).

Figure 2. Annotation of a concept.



Ontology Evaluation

We evaluated the dietary lifestyle ontology built in this study for concept coverage, structural quality, and utility.

Concept Coverage

We evaluated the concept coverage of the dietary lifestyle ontology with the concepts extracted from the dietary habit questions not used for the ontology building. We pulled 374 concepts from 134 Korean data elements and 92 concepts from 50 English data elements using the same process described in the "Collecting dietary terms and concepts from existing questionnaires" of the methods section. We then examined the extent to which the dietary lifestyle ontology covered this newly prepared set of concepts.

Structural Quality

We evaluated the structural quality of the dietary lifestyle ontology using the ontology Debugger plug-in of Protégé [35] and OntOlogy Pitfall Scanner! (OOPS!) [36]. The Debugger plug-in of Protégé examines the consistency and the coherency of an ontology. If an ontology contains a class defined with two conflicting conditions (ie, unsatisfiable), the ontology is incoherent [35]. At the same time, an unsatisfiable class cannot have an instance that fits the class definition; thus, the ontology is inconsistent [35]. OOPS! is a web-based application that evaluates the quality of an ontology against common errors of ontology authoring based on state-of-the-art ontology authoring principles [37].

Utility

We evaluated the utility of the dietary lifestyle ontology by finding answers to the competency questions (CQs) presented previously. To answer the CQs, we randomly selected 68 dietary assessment data elements that we had analyzed to build this ontology and instantiated them under the data element class. The data element class has two subclasses of question and value set. We instantiated the questions under the question class and their permissible values under the value set class. The question instances took an abbreviated form for simplicity. The complete data element information, such as a full question sentence and the associated permissible value set, was captured as an annotation for better legibility. Figure 3 shows how a data element instance, "how often eat deep-fried foods away from home or take out," is annotated and defined with object properties for the utility testing.

Table 2 presents the object properties constructed to capture a data element's semantics and bind its value set to its question.

We developed query rules with the Semantic Query-Enhanced Web Rule Language (SQWRL) rules to retrieve the data element instances that satisfy the conditions of the CQs. The authors reviewed the query results for accuracy.

Figure 3. An example of the instantiated data elements.

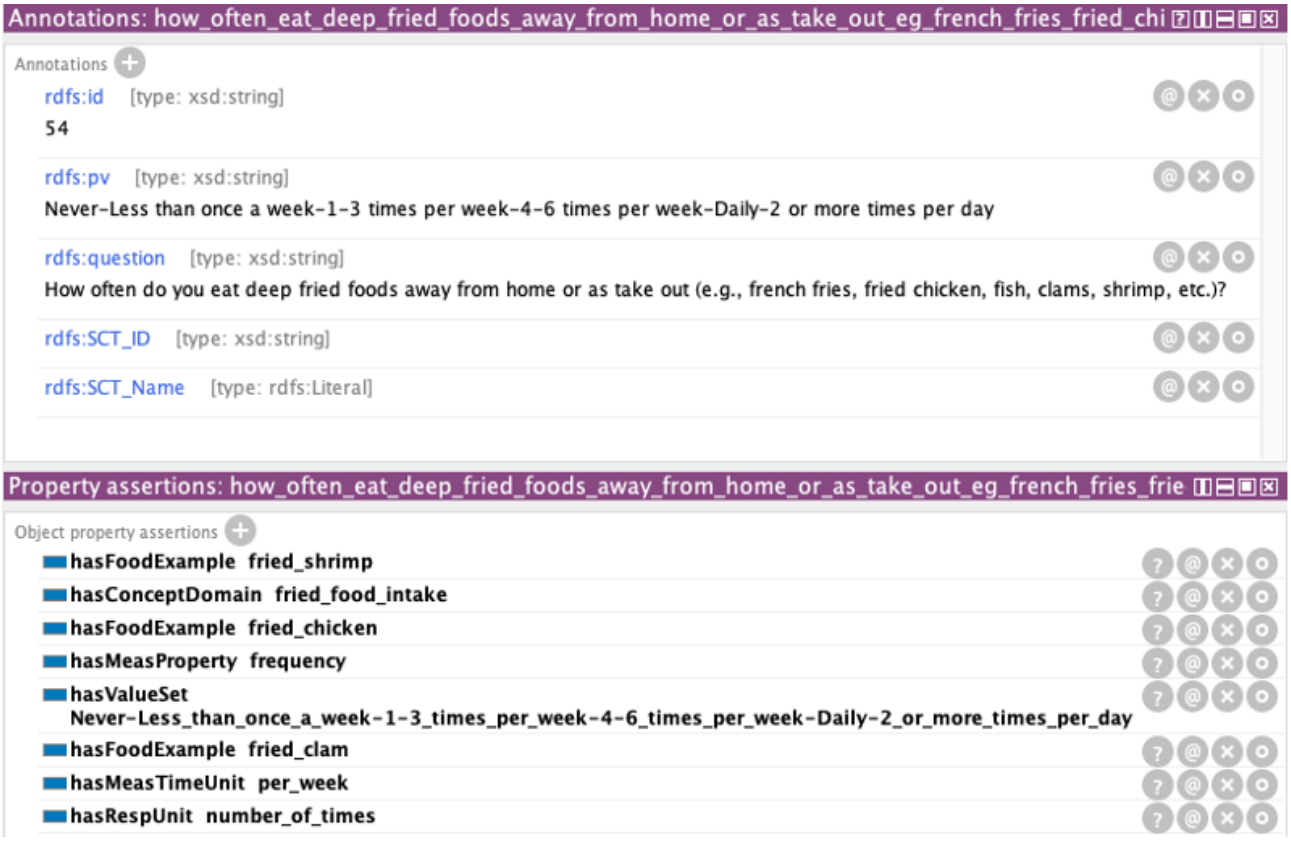


Table 2. The object properties.

Object property name	Purpose	Example
hasConceptDomain	The core topic area of a data element	Fast food intake, dairy food intake, eating speed, etc
hasMeasProperty	The property of the topic area	Frequency, amount, etc
hasFoodExample	Food examples used to explain the core topic area	Yogurt, macaroni, cheese, fruit juice, etc
hasMeasTimeUnit	Unit of assessment duration	Per day, per month, per week
hasObsPeriod	Observation period that a data element represents	Past 3 months, past week, past 6 months, etc
hasRespUnit	Response unit	Number of days, number of times, calories, etc
hasValueSet	A set of permissible values	Less than one cup, one cup (8 ounces), more than one cup

Results

The Dietary Lifestyle Ontology

The Dietary Lifestyle Ontology (DILON) was built with 262 concept classes, 513 instances, and 7 object properties. The final version of the ontology contained 224 concepts from Korean questionnaires, 363 concepts from English questionnaires, and 233 added concepts. Only 72 concepts appeared in both the Korean questionnaires and the English questionnaires. Figure 4 shows the top-level hierarchy and the key metrics of this ontology. The concept hierarchy rendered in Korean is offered with an English translation of each class label.

Figure 4. The top-level hierarchy and key metrics of the dietary lifestyle ontology.

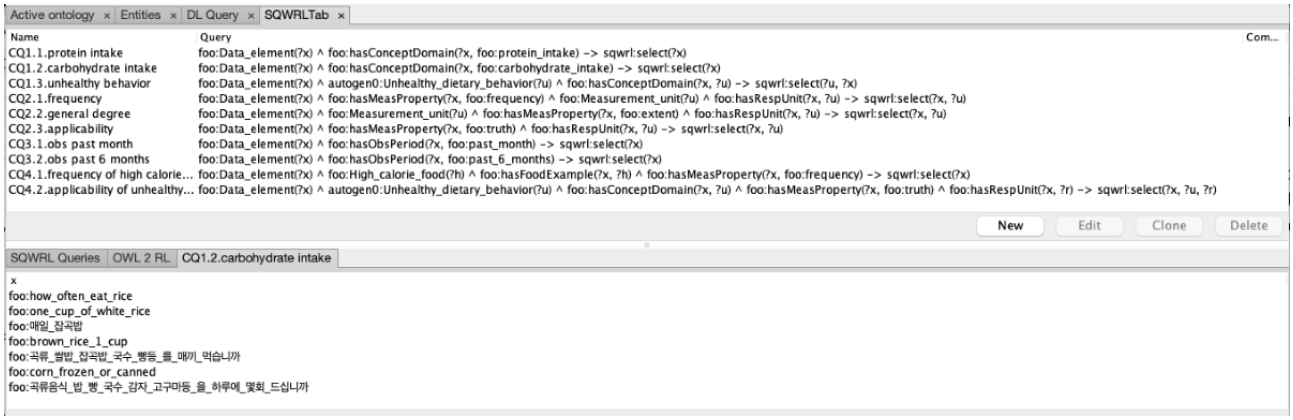
Ontology Evaluation Results

The test of concept coverage showed that DILON covered most of the dietary concepts from the text source prepared for the ontology evaluation. Only 19 concepts from Korean questions and 6 from English questions were not covered in DILON. A few examples of the concepts missing in DILON were green dietary life, food combination, retching, and teaspoon.

The Debugger plug-in for Protégé confirmed that DILON has a consistent and coherent structure. OOPS! suspected that some equivalent concepts were defined as distinctive in DILON. A few examples of the concept pairs that OOPS! suspected as equivalents were regurgitation and vomiting, frying and sauteing, grain and cereal, shellfish and mollusk, and thirst and hunger. Because these concept pairs are not equivalent, we concluded that OOPS! did not find any substantial pitfalls in DILON. DILON is available in the National Center for Biomedical Ontology BioPortal [38].

The SQWRL [39] implementation of the competency questions is presented in Figure 5. The SQWRL queries correctly identified the data elements that meet the conditions specified in the CQs. The SQWRL query results demonstrated that it is possible to systematically identify the data elements that share similar assessment topics, measurement methods, and response types when the main concepts of the data elements are annotated with DILON. The full results and SQWRL queries are presented in the supplementary file.

Figure 5. CQ evaluation using SQWRL. CQ: competency question; SQWRL: Semantic Query-Enhanced Web Rule Language.



Discussion

Principal Findings

This study demonstrated improving the interoperability of questionnaire-generated dietary lifestyle data using the proposed ontology DILON. Dietary concepts and their relationships in DILON are useful for resolving the challenges introduced when treating an entire diet-related data element as a single concept. Explicitly capturing the core semantics of a data element with the concepts and the object properties of DILON enabled us to identify the data elements that carry similar information. It is an important step toward achieving interoperability of questionnaire-generated data that can have many variations of expression for the same information.

Eating food is a cultural concept. Thus, diet-related concepts such as food names and dietary patterns vary by culture. We observed clear distinctions in food examples between Korean questionnaires and English questionnaires. FoodOn is an extensive and highly comprehensive system. Although FoodOn contains the Cultural Food Product class, this class includes only twelve food examples as subclasses. The Prepared Food Product class of FoodOn contains a long list of cooked dish names. Some of those cooked dish names are generic (eg, leafy vegetable, potato soup, sandwich), and some have a specific cultural origin (eg, brochette, chow mein, tataki). The Prepared Food Product class probably does not intend to be a complete list of culture-specific food names; thus, most typical food names from specific cultures are missing. Consistent and unambiguous representation of various food names and their nutritional information is crucial for analyzing and interpreting dietary behavior data. Of note, only 54% of the dietary concepts in DILON were mapped to SNOMED CT.

Developing a single comprehensive dietary ontology covering all food and dietary behavior concepts is a daunting task. Instead, a more feasible approach is creating a smaller yet extensible ontology representing the dietary concepts required for a specific task or a given cultural context. In addition, separating the portions common to any cultural contexts from those culture-specific would make an ontology easily extensible and later integrable with other specialized food ontologies when the need arises. For that reason, in DILON, dietary concepts common to any cultural context were created as classes with a relatively simple hierarchy, and food names were included as instances. DILON does not intend to be a comprehensive culinary taxonomy. Therefore, complex hierarchical information among food types is omitted in DILON to keep the concept structure manageable.

Many apps offer efficient ways to capture dietary intake patterns and produce additional information such as nutritional components and calorie intake. Nonetheless, questionnaire-based assessment is still helpful for capturing general patterns of dietary behavior and diet-related health history. The dietary ontology like DILON may also facilitate the integration of app-generated data and questionnaire-generated data.

Limitations

This study has several limitations. The first is using the relatively limited text sources to identify dietary lifestyle concepts. DILON was built with the terms and concepts collected from existing food ontologies and a limited number of dietary assessment questionnaires. Therefore, the current version of DILON is a small system with relatively limited content coverage, and continuous augmentation is warranted. The second is methodological scalability. DILON was developed through a manual process. Thus, the methods adopted in this study may not be scalable. We need to establish an algorithmic strategy to facilitate continuous update and augmentation of DILON. The third limitation is the scope of the utility testing. The utility testing of DILON depended on the competency questions that reflect a narrow spectrum of interoperability challenges. Therefore, the utility of DILON in addressing interoperability challenges of dietary data needs to be demonstrated through a real data integration use case in a future study.

Conclusions

Dietary lifestyle data offer crucial information on one's health, but the interoperability challenges are a significant barrier to reusing the data. The vast scope of dietary concepts, the colloquial style of expression, and the various cultural contexts reflected in dietary lifestyle data make standardizing the data a demanding task. This study showed that we could improve the interoperability of the dietary lifestyle data generated from questionnaires in different cultural contexts by annotating essential semantic information of dietary data elements with the dietary lifestyle ontology DILON.

Acknowledgments

HK designed the study, built and validated the ontology, and wrote the manuscript. JJ prepared and analyzed dietary concepts, built the ontology, and edited the manuscript. JC prepared and analyzed dietary concepts, evaluated the ontology, and edited the manuscript. We thank Yoobin Kim, Jina Lee, and Nayoung Kim for helping with corpora preparation. This study was supported by the New Faculty Startup Fund from Seoul National University.

Abstract

Background: In Denmark, approximately 150,000 people have alcohol use disorder (AUD). However, only approximately 10% seek AUD treatment, preferably outside conventional health care settings and opening hours. The AUD treatment area experiences low adherence to treatment, as well as high numbers of no-show and premature dropouts.

Objective: The purpose of the Blend-A (Blended Treatment for Alcohol Use Disorder) feasibility and pilot study was to describe the process of translating and adapting the Dutch treatment protocol into Danish and Danish culture with a high amount of user involvement and to report how patients and therapists perceived the adapted version, when trying it out.

Methods: The settings were 3 Danish public municipal outpatient alcohol clinics. Study participants were patients and therapists from the 3 settings. Data consisted of survey data from the System Usability Scale, individual patient interviews, and therapist group interviews. Statistical analyses were conducted using the Stata software and Excel. Qualitative analysis was conducted using a theoretical thematic analysis.

Results: The usability of the treatment platform was rated above average. The patients chose to use the blended treatment format because it ensured anonymity and had a flexible design. Platform use formed the basis of face-to-face sessions. The use of the self-determined platform resulted in a more thorough process. Patient involvement qualified development of a feasible system. Managerial support for time use was essential. Guidance from an experienced peer was useful.

Conclusions: This study indicates that, during the processes of translating, adapting, and implementing blended, guided, internet-based, and face-to-face AUD treatment, it is relevant to focus on patient involvement, managerial support, and guidance from experienced peers. Owing to the discrete and flexible design of the blended offer, it appears that it may reach patient groups who would not otherwise have sought treatment. Therefore, blended treatment may increase access to treatment and contribute to reaching people affected by excessive alcohol use, who would not otherwise have sought treatment. In addition, it seems that the blended offer may enhance the participants' perceived satisfaction and the effect of the treatment course. Thus, it appears that Blend-A may be able to contribute to existing treatment offers. Such findings highlight the need to determine the actual effect of the Blend-A offer; therefore, an effectiveness study with a controlled design is warranted.

alcohol use disorder; blended treatment; usability; patient perceptions; therapist perspectives; mobile phone

Introduction

Background

The long-term consequences of alcohol consumption include the risk of developing somatic diseases such as liver cirrhosis, cancer, and cardiovascular disease [1]. Furthermore, untreated alcohol use disorder (AUD) is associated with employment problems, economic burden, high rates of domestic violence, and reduced quality of life [2].

In Denmark, there is general agreement as to what constitutes high-quality treatment of AUD. National and international clinical guidelines recommend evidence-based psychological treatments such as cognitive behavioral therapy (CBT) and motivational interviewing (MI) [3]. Overall, treatment for AUD is easily accessible in Denmark and is free of cost to the patients, in addition to the possibility of patients staying anonymous during the treatment course [4].

The gap between the number of individuals with AUD and those receiving treatment is large [5,6], and those who seek treatment do so when their alcohol dependence is advanced [7]. Among people with persistent AUD, approximately one-fourth do not seek treatment even though they could benefit from it [8]. The reasons for the treatment gap and treatment delay are considered to be that treatment seeking is attached to stigma [9,10], but barriers to treatment seeking also include practical issues, lack of knowledge about treatment, and simply not wishing to stop drinking [11]. Many individuals who seek professional help to curb their alcohol problems have been reported to prefer to receive treatment outside conventional treatment settings and opening hours [12].

Internet-based treatment may be one way to minimize barriers to treatment seeking and increase access to evidence-based treatment for mental health and addictive disorders [13-15]. The potential benefits of internet-based psychological treatment modules include ease of access, cost efficiency, and ability to reach a wide range of users [16]. In particular, guided internet-based treatments have attracted interest during the last decade. Guided internet-based treatment involves a certain level of contact with a therapist, typically via asynchronous chat, text messages, or emails and may function as an important and effective treatment strategy [17,18]. Qualitative studies show that feedback and personal support are perceived positively by patients and keep them motivated [19,20]. Thus, although unguided treatment in some cases may also demonstrate good effect [21], guided internet-based treatment is overall the most promising [22].

Access to personal feedback and to a therapist are features associated with larger effects in a meta-regression of internet-based alcohol interventions [23], and a correlation has been found between personal support in internet-based interventions and positive clinical outcomes and compliance with treatment [24,25]. Departing from this observation, adding internet-based modules to face-to-face treatment [26] or combining face-to-face treatment with internet-based therapy into one integrated and blended treatment protocol has also attracted interest [27-30]. In the blended treatment approach, part of the face-to-face treatment is replaced by internet-based components, while the traditional face-to-face relationship between the therapist and patient is retained. The face-to-face element is considered to ensure that patients benefit from a supportive therapeutic relationship, which is likely to increase their motivation to complete treatment [31,32]. Internet-based elements may provide flexibility, allowing patients access to the treatment modules at the time of their choosing. The increased personal responsibility that comes with such flexibility is also reported to give patients a sense of autonomy and empowerment [33]. Furthermore, through the internet-based platform, therapists can provide feedback to patients and help them stay on track with treatment [31,34].

Pilot studies have found that offering personal support and guidance during web-based addiction treatment in a blended fashion is associated with higher completion levels, increased clinical outcomes, and cost-effectiveness [24,28,35]. Thus, blended treatment may provide a delivery format capable of reaching out to people not inclined to show up for treatment as well as keeping clients motivated during the treatment. In Denmark, however, neither therapist-guided internet-based treatment nor blended treatment for AUD is implemented in the daily clinical routine.

Blended Treatment at Jellinek

The Dutch addiction treatment clinic, Jellinek, is one of the largest treatment institutions in the Netherlands. Since 2011, Jellinek has been offering blended treatment in routine addiction treatment, and currently, 50% of the patients seek AUD treatment (N=800 per year). Jellinek developed a platform for AUD treatment together with a provider of treatment platforms for internet-based CBT. The platform treatment manual combines face-to-face and internet-based therapy into one integrated protocol [27-29]. The content of the blended protocol is similar to the face-to-face AUD treatment offer, based on evidence-based manuals for MI and CBT [3,36]; the elements are quite similar to the CBT modules in the manual used in project Combine [37]. The blended treatment consisted of a fixed set of sessions, with weekly alternating face-to-face sessions and sessions on the web (approximately 50%:50%) with web-based feedback from the therapist. Sessions on the web were delivered through a secure internet-based treatment platform.

The Jellinek blended treatment approach has not yet been investigated in effectiveness trials, but continuing quality monitoring indicates that treatment compliance is improved when combining face-to-face sessions and internet-based modules with therapist feedback. Dropout rates are lower; patient satisfaction is high; and patients are generally more actively involved in their treatment, spending more time on homework assignments compared with regular face-to-face treatment. Concerning expenditures, Jellinek saw no higher

costs per patient compared with regular face-to-face treatment. Furthermore, Jellinek clinics experience increased treatment fidelity to the treatment protocol because of the increased structure in treatment planning and integration of internet-based modules. Thus, although not properly evaluated, the Jellinek blended treatment approach seems to be meaningful, feasible, and promising.

The Blend-A Study

After a study visit to the Netherlands, we decided to implement and evaluate the treatment approach used at the Jellinek clinics because (1) our impression of the blended treatment protocol was good, (2) the content covered recommendations in Denmark, and (3) both the management and staff at the Jellinek clinics described it as possible to implement in an outpatient treatment structure that is rather similar to the Danish treatment structure. As the Dutch treatment protocol was already digitalized and implemented in the Netherlands, it seemed out of proportion to start from scratch and develop a new treatment protocol to be implemented in Denmark.

As Denmark is *naïve* in making use of internet-based tools in the treatment of AUD, Blend-A (Blended Treatment for Alcohol Use Disorder)—the Blend-A study was developed as an opportunity to evaluate the blended, guided, internet-based, and face-to-face treatment of AUD in Danish settings on a large scale. However, as a predecessor to the Blend-A study, a feasibility study was needed to minimize the need for further adjustments of the treatment platform and work schemes in a large-scale study.

The Blend-A feasibility and pilot study was therefore initiated to develop the Danish version of the Jellinek treatment platform and translate the treatment protocol from Dutch into Danish language and culture; thus, the content of the 2 programs was quite similar. Furthermore, it was initiated to carry out preliminary tests, early phase implementation, and evaluation in 3 AUD treatment clinics. As the research literature typically neither includes a description of the practical process of translating and adapting interventions nor how therapists and patients experience the use of such new internet-based tools, we also decided to collect a series of data in the process, thus making it possible to report our experiences.

Aim

The aim of this study was to describe the (1) process of developing and adapting the platform and content, (2) therapist and patient experiences of the platform and content during development, (3) implementation of the Blend-A pilot platform, and (4) pilot testing of the platform with new patients and subsequently, to examine the (1) usability of the platform, (2) patient perceptions of a blended treatment course involving the platform, and (3) therapist's perspectives on blended treatment involving the platform.

Methods

Design

The design of the Blend-A feasibility and pilot study was explorative and performed as a mixed methods study [38] based on data obtained from observations, structured questionnaires, semistructured individual patient interviews, and unstructured therapist group interviews.

Settings

The Blend-A feasibility and pilot study was conducted in collaboration with three public outpatient alcohol clinics in Southern Denmark: Haderslev, Kolding, and Svendborg municipalities. These clinics are comparable with all publicly funded clinics in Denmark. The treatment was in an outpatient setting, and the staff consisted of a multidisciplinary team of nurses, social workers, and psychiatrists. Therapists are trained in MI and CBT, receive supervision on a regular basis, and follow clinical guidelines. During a normal face-to-face treatment course, patients are initially offered detoxification, if needed. During the acute phase of treatment, they are offered MI and pharmacological treatment, if needed. When withdrawal symptoms have been treated, the patients undergo an assessment interview and are offered individual CBT. Normally, therapy sessions take place every other week and last for approximately 1 hour. The patients underwent status sessions every 3 months, and the treatment course was evaluated. A standard treatment course is planned to last for approximately 3 months but is typically prolonged, if needed [39].

Participants

From the 3 clinics, 7 therapists participated in the Blend-A feasibility and pilot study, constantly with 2 from each clinic. In the development and adaptation phase of the Blend-A pilot platform, 3 patients were invited to participate with the therapists. The 3 patients were in the midst of their treatment course, enabling them to contribute to their experiences of what to expect from a treatment protocol. When the Blend-A pilot platform was developed, a series of new, consecutive patients (a total of 20-30 patients were aimed for) from the 3 clinics were invited to participate in the Blend-A pilot study to try the platform during their individual therapy course; 22 of the invited patients agreed to help in the testing and answer the System Usability Scale (SUS) [40]. At the end of the study, 18% (4/22) of these patients were invited and agreed to participate in an individual qualitative interview about their experience of using the pilot platform. At the end of the feasibility and pilot study, the 7 therapists involved in the development, adjustment, and testing were interviewed in group settings about their experiences.

Platform Development

The development phase was inspired by participatory design [41] and was conducted in an agile process involving therapists and patients in several development and test iterations. This process lasted for 5 months.

The Blend-A Pilot Platform and Content

An overview and content description of the platform modules are provided in Table 1. The modules and submodules were organized in a fixed structure. The platform was set up to allow therapists to gradually add sessions on the web to the patient's individual platform. The sessions on the web contained text and videos with information as well as assignments. According to the treatment protocol, patients received feedback on the web

from their therapists on assignments. The platform allows the sharing of information and homework assignments with their significant others. It was estimated that future patients would use the treatment protocol for 3 months and relapse prevention for 6 months. On completion of treatment, future patients will have access to the web-based treatment platform to reread information and look up exercises.

Table 1. Blend-A (Blended Treatment for Alcohol Use Disorder) pilot platform modules.

Module number and title and submodule title	Submodule content description
1. Welcome	
Welcome to Blend-A	• Explanation of the Blend-A treatment protocol • Explanation of the Blend-A research project
Onward to a new start	• Introduction to being onward to a new start and experience cravings
Support from your social network	• Introduction to needs for support from social network • Task where it can be mapped
Test your knowledge on alcohol	• Test of knowledge on alcohol
Questions and contact	• Contact information
2. Alcohol treatment	
Preparation to change	• Explanation of disadvantages when using alcohol and advantages of change • Task with the purpose of highlighting the disadvantages of using alcohol and the advantages of quitting drinking • Explanation of alcohol registration
Goals and techniques for self-control	• Explanation of a change plan for alcohol use (goal setting) • Explanation of the SMART[a] criteria • Tips for making a change plan • Explanation of techniques for self-control concerning alcohol use • Task where techniques can be described
List of alcohol use risk situations	• Explanation of risk situations for alcohol use and instruction to questionnaire • Questionnaire where overview >80 risk situations for temptation and self-confidence can be filled out • On the basis of the questionnaire, top 5 risk situations are filled out
Function analysis and emergency plan	• Explanation of function analysis for alcohol use • Task: fill out the function analysis • Explanation of how an emergency plan can be helpful to prevent relapse or limit the harm • Task: description of emergency plans

Tackling craving	• Description of craving
	• Task: which situations trigger craving, how is craving experienced, and who can craving be explained to
	• Explanation of tasks for 4 different ways to tackle cravings:
	  • Diverting yourself by doing something else
	  • Surf with your emotions
	  • Think differently
	  • Talk to your family and friends about it

Restructuring	• Restructuring of thoughts

Turning alcohol offers down	• Explanation of how turning down alcohol offers is a skill that can be learnt through role-play
	• Task: description of 3 risk situations and examples of saying no
	• Task: description of a situation where an offer needs to be turned down
	• Task:
	  • Role-play—rehearsing turning alcohol offers down
	  • Access to diary “evaluation of turning alcohol offers down”

Evaluation	• Evaluation of turning alcohol offers down
Midterm evaluation	• Deciding optional skills

Module number and title and submodule title	Submodule content description
3. Optional skills	• Social skills—small talk • Social skills—tackling criticism • Social skills—giving criticism • Tackling feeling sad and depressed • Tackling stress • Solving problems effectively • Tackling relapse
4. Relapse prevention (maintenance)	
Month 1	• Alcohol status • Quality of life
Month 2	• Alcohol status • Quality of life—your assessment
Month 3	• Alcohol status • Quality of life—your assessment • Support
Month 4	• Alcohol status • Quality of life—your assessment • Support—your assessment
Month 5	• Alcohol status • Quality of life—your assessment • Support—your assessment • Motivation
Month 6	• Alcohol status • Quality of life—your assessment • Support—your assessment • Motivation—your assessment • Evaluation of the maintenance phase

[a]SMART: Specific, Measurable, Achievable, Realistic, and Timely.

Data and Data Collection

For patients who agreed to pilot-test the Blend-A pilot platform, data on platform use were retrieved from the platform provider. To assess how the usability developed over time during the pilot study, questionnaire data were retrieved at baseline and 5 follow-ups, with 2 weeks between each measurement. Questionnaire data were collected using a validated Danish version [42] of the questionnaire SUS [40]. The SUS questionnaire consists of 10 questions about a given system's usability, availability, and coherence. The questionnaire results are presented in Table 2. The 10 questions were answered on a Likert scale from 1 (strongly disagree) to 5 (strongly agree). These 10 responses were used to calculate an SUS score between 0 and 100. Questionnaire data were collected and managed using REDCap (Research Electronic Data Capture; Vanderbilt University) [43], hosted at the Odense Patient data Explorative Network. Questionnaire links and reminders were sent via REDCap every other week to the participants' private email addresses at baseline and 5 follow-ups, to be filled out on the web using their computer, tablet, or smartphone.

A total of 2 anthropologists and 1 sociologist observed all workshops and training sessions that were performed with patients and therapists throughout the development phase and the implementation and pilot testing of the Blend-A pilot platform and took comprehensive field notes. An anthropologist also conducted qualitative interviews with patients and therapists during the pilot phase.

Table 2. System Usability Scale (SUS; Digital Equipment Corporation, 1986).

Items	SUS scores				
	Strongly disagree				Strongly agree
1. I think that I would like to use this system frequently	1	2	3	4	5
2. I found the system unnecessarily complex	1	2	3	4	5
3. I thought the system was easy to use	1	2	3	4	5
4. I think that I would need the support of a technical person to be able to use this system	1	2	3	4	5
5. I found the various functions in this system were well integrated	1	2	3	4	5
6. I thought there was too much inconsistency in this system	1	2	3	4	5
7. I would imagine that most people would learn to use this system very quickly	1	2	3	4	5
8. I found the system very cumbersome to use	1	2	3	4	5
9. I felt very confident using the system	1	2	3	4	5
10. I needed to learn a lot of things before I could get going with this system	1	2	3	4	5

Qualitative data on patient perceptions were collected from 4 individual, semistructured interviews. When the Blend-A pilot platform was implemented in the 3 clinics for half a year and the questionnaire data were collected, patients were invited to participate in the qualitative interviews. The researchers asked the therapists at 2 clinics to invite patients who were willing to use the Blend-A pilot platform and who had answered at least some of the SUS questionnaires. The interviews consisted of open conversations about patients' experiences with the Blend-A pilot study, supported by an interview guide. Textbox 1 presents the interview guide. The 4 interviews lasted for 14, 19, 24, and 28 minutes, respectively, and were audio recorded and transcribed.

Textbox 1. Interview guide for semistructured individual patient interviews.

Interview questions

- How long have you received blended internet-based and face-to-face treatment?
- How often have you used the platform?
- Why did you use the platform as often or seldom as you did?
- How was it to use the platform?
  - to log on
  - to read the text
  - to solve the assignments
  - to receive feedback
- Would you have liked to interact with your therapist via videoconferencing?
- Why did you choose to receive internet-based treatment?
- How was it to receive internet-based treatment, compared with face-to-face treatment?
- What impact has the blended setup had for your interactions with your therapist?
- What impact had the blended setup had on your treatment course?
- Do you have any ideas for alterations?
- Do you have anything to add or ask about?

Additional qualitative data on therapist perspectives were collected from 4 unstructured group interviews conducted with the 7 therapists from the 3 clinics during the pilot study. The group interviews were conducted by an anthropologist and a sociologist. An interview guide updated before each interview inspired the interviews. Textbox 2 presents the interview guide. The group interviews were conducted as part of the implementation process and lasted for approximately 2 hours each. One group interview was audio recorded and transcribed, and field notes were taken from the 3 others.

Textbox 2. Interview guide for therapist group interviews.

Interview questions

- The Blend-A pilot platform
  - Which modules have you used?
  - Describe your experience of using the platform.
  - Describe the patients' reactions to using the platform.
  - How do you experience starting a patient up in the program?
  - Is it your impression that the patients feel well informed?
  - How is it to give feedback on the platform?
  - How do you structure your working week concerning Blend-A?
  - Are there functions in the program, which provide new insights in relation to face-to-face sessions?
  - Are there insights you do not get when using the Blend-A pilot platform for treatment?
  - Have you experienced situations where videoconferencing would have been beneficial?
- Training
  - To you who have replaced a therapist: does peer-to-peer training work?
- Workflow description
  - How often do you use it?
  - Are there workflows we have not described?
  - Are there workflows that counteract each other?
  - Have you experienced the need of actions outside the platform; for example, mails or calls?
- Supervision and clinical conference
  - In your team, how do you consult about the contact to patients using the Blend-A pilot platform?
  - Do you have the need for further sparring concerning using the Blend-A pilot platform in your workday?
- Patient recruitment
  - How many patients have you recruited?
  - How do you recruit?
  - What challenges have you found while recruiting for the Blend-A pilot?
  - Which reasons do patients provide for choosing to use the Blend-A pilot platform compared with face-to-face sessions?
  - Which reasons do patients provide for choosing not to use the Blend-A pilot platform?
- Defects
  - What defects have you experienced?
  - What defects have the patients expressed?

Analyses

Analysis of the rather little structured data from the SUS questionnaires was conducted using the Stata software and Excel.

A qualitative analysis of interviews with patients and therapists was conducted using a theoretical thematic analysis approach [44]. Thematic analysis is a widely used method for identifying and describing themes within data without being bound to any pre-existing theoretical framework. A theme was defined as a meaningful emergence relative to the research question. In the present pilot study, thematic analysis was used as an essentialist or realist method to describe participants' experiences in the development, implementation, and usability of a blended treatment course involving the Blend-A pilot platform. The analysis consisted of six phases: (1) reading and rereading studies while noting the initial ideas, (2) coding interesting features systematically in the *Results* section, (3) collating codes into potential themes, (4) checking whether the themes work in relation to the coded extracts and entire data set, (5) performing ongoing analysis to refine the specifics of each theme and to

generate names for each theme, and (6) performing final analysis of selected extracts relating the analysis to the research question.

Observational data from field notes were used to describe the development process and assess the engagement and concern expressed by both therapists and patients. Similar to the process of analyzing the qualitative interview data, the notes were read, reread, and combined into overall themes and subthemes. In the reporting of the findings from the notes, information stemming from the qualitative interviews of patients and therapists was added to the observational data when they added information about the development process and how the usability and function of the platform was experienced by the parties.

Qualitative analyses were conducted by JR and KT, originally trained as a sociologist and an anthropologist with approximately 10 years of experience each. ASN, with approximately 30 years of experience in qualitative research, supervised the analyses.

Ethics Approval

The pilot study was notified to the Danish Data Protection Agency (file number 18/1994). The study was conducted in accordance with ethical standards; however, as it is based on questionnaires and interviews, it is not notifiable to the Regional Committees on Health Research Ethics for Southern Denmark. After receiving oral and written information about the project, participants signed consent forms for participation.

Results

The Process of Developing and Adjusting Platform and Content

The Blend-A pilot platform is accessible on the web via any given web browser. As mentioned earlier, the platform consisted of 4 modules with submodules, which started with therapy information, followed by multiple exercises and homework assignments, training in optional skills after patients' individual needs, and relapse prevention.

The Dutch content was maintained overall, as it described MI and CBT-based modules, consistent with standard face-to-face treatment in Danish alcohol treatment clinics. The translation process in which the Dutch platform content was translated into Danish went through five phases: (1) translation of overall concepts and treatment flow was conducted in a full-day workshop together with the platform provider, 3 patients, 6 therapists, 2 consultants, and 2 researchers, of which 1 was a sociologist and 2 were anthropologists; (2) the platform provider made the first rough translation from Dutch to Danish, translating all text, text on buttons, and image texts and providing Danish subtitles on Dutch videos; (3) therapists, researchers, and consultants revised and edited the translation draft, focusing on linguistic, cultural, and therapy-related translations; therapy-related translation was the least time-consuming part, as the included AUD clinics already offered CBT, whereas the linguistic and cultural translation was more time consuming and involved patients, therapists, consultants, and researchers; (4) the content was implemented in a test version of the platform and tested by 6 therapists and 3 patients during a half-day workshop, in particular, during the workshop, the text fields were thoroughly considered and made easy to understand, and in this process, participating patients' feedback was of particular importance; at the workshop, both therapists and patients went through all elements and discussed the feasibility and acceptability of both the content and layout, and based on this feedback, the content and platform were revised; and (5) the content was then implemented in the production-ready platform, which was named the Blend-A pilot platform.

Therapist and Patient Experiences of Platform and Content During Development

Patients and therapists who participated in the development and adjustment phases quickly grasped the platform. Both groups provided useful information on the usability of the platform, particularly in spotting passages or larger text blocks, which might be a barrier for future use. The possibilities for flexibilities on how to combine modules were stressed. Both patients and therapists found that videos and graphics were often preferred to text to reduce cognitive load. The videos in the pilot version of Blend-A were Dutch, with the Dutch material subtitled in Danish, and both therapists and patients found that although it might work in a pilot version, it was not optimal. The participating patients became so engaged that in the development process, they kept trying the platform outside the workshop and returned to their therapist with additional information on what they found useful. The therapists found it helpful for future use that they had had the opportunity to work through the content and platform together with patients during the development and adjustment phases, as it allowed them to grasp what engaged the patients the most.

Implementation of the Blend-A Pilot Platform

During the process of implementing the pilot version, the therapists were trained on how to provide written feedback, patients were recruited, and the Blend-A platform came into operation. The Blend-A pilot platform came into operation in February 2018, and the pilot test was run for 6 months. The therapists involved in the development and translation process described earlier were also the main therapists offering treatment to the new patients via the Blend-A pilot platform. Therapist training before the pilot test consisted of 2 sessions, with 2 hours of training each in the use of the platform and a fortnight of practice in between. A Dutch psychologist experienced in blended treatment participated in preparing the training and offered support to therapists. The therapists were encouraged to offer a blend of face-to-face sessions and internet-based modules that they, together with the patients, found the most helpful and attractive. Thus, no firm structure describing a fixed number of face-to-face sessions before offering the patients the opportunity to continue the treatment course by means of internet-based modules was prescribed. Rather, therapists were encouraged to discuss this with their patients and decide on the optimal blend.

Pilot Testing of the Platform With New Patients

We planned to pilot test the Blend-A pilot platform with 20-30 new patients. Patients were recruited by means of regular

advertisements in local newspapers, Facebook posts, and face-to-face approaches among eligible patients receiving treatment at the 3 clinics. A total of 41 patients completed the Blend-A pilot platform. There was a difference between how far during the treatment program the patients came in the 3 pilot municipalities. In 1 municipality, approximately half of the patients finished the program, and the rest stopped during module 2. In the 2 other municipalities, only one-tenth finished the program, and the rest stopped during and after module 2, respectively. All 41 patients were invited to participate in the evaluation, and 22 agreed to fill out the questionnaires. During the pilot phase and upon request from the therapists, a workflow description for the blended treatment course was developed and regularly updated to provide therapists with details on how to involve a patient in the blended treatment offer. An example workflow is presented in Table 3.

The quantitative and, in particular, qualitative data analyses led to the following findings regarding usability, patient perceptions, and therapist perspectives on the Blend-A pilot platform.

Table 3. Example of workflow description.

Patient	Therapist
Contacts the clinic for treatment of AUD[a].	Offers the patient detoxification, MI[b], and assessment.
Decides to change habits and work focused.	Offers the patient a treatment course; informs the patient orally about Blend-A and that it is optional to participate, but it requires that the patient has a computer or a tablet; and hands out written information on Blend-A to the patient.
Reads the information sheet at home and decides on participation in Blend-A.	At the first treatment session (flexibility according to resources): asks the patient about participation in Blend-A.
Declines to participate in Blend-A.	Offers patient regular treatment course.
Agrees to participate in Blend-A and signs consent form.	Photocopies the signed consent form and gives the copy to the patient and scans the original form and uploads it to the secure Blend-A Sharepoint.
Receives from and agrees with therapist	Introduces the patient to Blend-A, adds the patient on the platform (administration module can be used by therapists and administrative workers), sends an invitation to the platform to the patient, informs the patient that emails from the platform provider may end up in spam filter, urges patient to store password in a safe place that the patient can remember, agrees with patient on number of sessions internet-based and face-to-face, and informs the patient that it is a possibility to bring a PC to the face-to-face sessions to be introduced to the platform.
Accepts invitation to the platform.	Assigns patient to therapist, assigns treatment modules to the patient, offers to solve some of the first assignments together with the patient, and decides on homework assignments together with the patient.
Uses the platform.	For the rest of the treatment course: receives an email when the patient has solved an assignment, reserves a time slot every week for written feedback on solved assignments (more time consuming in the beginning), and sends reminders to the patient if the assignments are not solved (brief, motivating approach).
Attends treatment session face-to-face.	Completes treatment session with the patient entailing content from the platform.
—[c]	Besides direct patient-therapist interaction: compiles mutual guideline for written feedback, undergoes professional sparring, and participates in treatment conferences.

[a]AUD: alcohol use disorder.

[b]MI: motivational interviewing.

[c]Patient has no task during this step.

Usability of the Blend-A Pilot Platform

The 22 patients who agreed to participate in the evaluation consisted of 15 (68%) men and 7 (32%) women. Of the 22 patients, 16 (73%) answered one or more SUS questionnaires. A patient was excluded because of a large amount of missing information in the questionnaire. Of the 22 patients, the remaining 15 patients (94%) consisted of 9 (60%) men and 6 (40%) women. Their mean age of the participants was 47 (SD 12) years; the youngest aged 28 years and the oldest aged 73 years.

At baseline, the mean SUS score for the patients (15/22, 68%) was 71 (range 43-85). At the first follow-up, 2 weeks after initiating treatment on the Blend-A pilot platform, the mean SUS score for the patients (10/22, 45%) was 74 (range 53-93). At the second follow-up, the mean SUS score for the patients (3/22, 14%) was 67 (range 58-73). At the third follow-up, the mean SUS score for the patients (3/22, 14%) was 69 (range 63-75). At the fourth follow-up, the mean SUS score for the patients (3/22, 14%) was 78 (range 73-80). At the fifth follow-up, the mean SUS score for the patients (3/22, 14%) was 78 (range 75-85).

Patient Perceptions of a Blended Treatment Course Involving the Blend-A Pilot Platform

A total of 4 patients who were still enrolled in the treatment agreed to participate in a qualitative interview concerning their experiences with the Blend-A pilot platform. At the time of the conclusion of the pilot study and for the final qualitative interviews, the interviewed patients had been using the Blend-A

pilot platform between 3 and 5 months. The interviewed patients used the platform to varying degrees from daily to weekly, typically more frequently at the beginning of the treatment course.

Interaction Between Internet-Based and Face-to-Face Treatment

The patients had learned about the possibility of participating in the blended treatment through newspaper advertisements and chose to use Blend-A, particularly because of the blended setup of the treatment course. The platform functioned as a basis for face-to-face sessions with the therapist. Here, a participant explained as follows:

> *It has been such a good departure point for a talk [...] where she then interprets some things, probably based on my answers [...] so that is kind of like the foundation of it, I think [...] it has worked on me [...] now we have had something to depart from [...] something concrete.* [Participant 3, female]

It was important for the patients that they could stay at home, read the texts calmly, and solve assignments on the platform. They found that reading the texts started a cognitive process and that performing the assignments touched them emotionally. Being able to use the platform when they had the time to do so had given them breaks, enabling them to think about their answers. Being able to use the platform when they felt motivated had given them the experience of a higher gain from the treatment course, enabling them to apply the therapy to their rehabilitation process, in addition to feeling in control. A participant explained as follows:

> *I think it is good, this interaction [...] it is very good, and then it is, eh, then I can work with it alone in my head at home in peace and quiet, and then I can come up here [at the clinic] and get a briefing or get a, well what is it called, a pat on the back, that may be able to support me a little to work through some of the stuff again.* [Participant 2, female]

As such, patients felt that the interaction between the use of the platform and face-to-face sessions had a positive impact on their treatment course.

Flexibility

The patients felt that an optimal blend for them was using the platform twice or more per week, together with face-to-face consultations once or twice a month. A patient stated that this cadence was adequate to secure enough substance during the treatment course.

A patient explained that the flexibility in the blended solution was the main reason they enrolled in the treatment. They elaborated on the difference between going to treatment sessions more often and receiving a blended treatment offer with the internet-based platform and fewer face-to-face sessions:

> *Here, you can do some things at home so you don't have to spend time on it, there is also a job that needs to be done [...] there are multiple work schedules that, like, has to fit into each other too [...] it is nicest that you can go to and from it and do it when you have the time, or, and when the desire is there [...] it is not something that you have hanging over your head.* [Participant 1, male]

Because of their work situation, this patient would not have been able to participate in regular treatment with more frequent face-to-face sessions.

Anonymity

In addition, the patients liked the possibility of a more anonymous treatment course. A patient explained that it was transgressive to sit in the waiting room, that they felt so wrong, and that it was unpleasant.

Another participant gave anonymity as one of the reasons for choosing the blended treatment course:

> *It is probably also because it is something that I can sit at home and do, it is a little bit more anonymous, eh, so that was probably why.* [Participant 1, male]

Another participant preferred the discretion of not attending the clinic more than necessary, as they had the wish not to be recognized as one attending treatment, which could cause feelings of not being able to manage on their own:

> *I thought that I was drinking too much, and I couldn't, I couldn't really succeed in minimizing it and, eh, then, then I saw this offer and an anonymous offer even, and I don't have to tell anyone so, eh, and I feel...So I thought this is it, now you have to get started with this [...] I could have enrolled treatment in a group with others, and I didn't feel much like that [...] I liked the anonymous [...] I want to hide myself a little bit and, eh, I don't want to be seen around by people.* [Participant 2, female]

However, 2 of them had experienced a shift toward not having the need to remain anonymous.

Usability

The patients also emphasized the importance of presenting treatment material on the platform relevant to the patient groups most likely to use Blend-A. It mattered to them that the material was in their native language and targeted to their particular patient group. The patients found it helpful that blended care involved homework assignments, including reading and specific tasks, and that it was possible to go back and repeat the reading and tasks if they felt that they needed a brush up. None of the patients described having shared the content of the platform with their significant others.

For the patients, the platform was simple with regard to the text, examples, assignments, and feedback from therapists. They were satisfied with the platform setup and the reading friendliness of the texts. They found that the platform was easily accessible to use, for example, during the log-on and submission of solved assignments.

However, they emphasized the importance of a range of factors that (1) the platform is technically stable, so it can be used when the needs and wishes are there; (2) it can be seen at first glance that assignments have already been performed; (3) it is easy to return to the assignments and revise; (4) the content is

numerically indexed so that feedback can be tracked on the assignments performed; (5) the structure was set up logically; (6) too many questionnaires should be avoided in the modules; and (7) it should be fast to monitor alcohol use, because it is frequently performed. Ideally, the frequency of monitoring should automatically be based on individual needs.

Therapist Perspectives on Blended Treatment Involving the Blend-A Pilot Platform

The 7 therapists participated in 4 group interviews conducted during the implementation of the Blend-A pilot platform and at the conclusion of the pilot study.

Implementation

The therapists emphasized the following factors to be important for training and for future use of the platform: (1) sufficient time for training, that is, reserving one whole day for a training workshop emphasizing case-based training; (2) availability of the therapeutic material in a printed version beforehand, allowing focus on the technical part of the workshop; (3) getting to know the platform properly; that is, working through the platform, pretending to be patients, to understand the program thoroughly from the patients' views; and (4) in particular, the therapists liked having an experienced peer from the Netherlands describing their experiences with using the platform and giving advice; for example, on how to give written feedback to patients via the platform as this was new to the Danish therapists.

Particularly in the early phase of the implementation of the platform, therapists emphasized the importance of having a workflow description easily available. It was important for them that the document entailed pictures describing various workflows. Moreover, they found it important to have manageable guidelines for maintaining records of the blended treatment courses.

Therapists found that the blended-care approach could easily be integrated into community-based treatment offers for AUD. Providing feedback on patients' internet-based homework was not considered a problem. On the contrary, the therapists felt that they had more time to reflect and focus compared with giving feedback in a direct face-to-face conversation. In the early days of the pilot phase, therapists allocated 40 minutes a week per patient for written feedback. Later, when they had gotten used to giving feedback in writing, approximately 20 minutes per patient every week was found to be sufficient. In the beginning, the therapists found themselves ever so often logging on to the platform, looking at the assignments handed in, and providing feedback. However, it was their experience that when they gathered it in a dedicated time slot, they gave the patients time to reflect before the new homework was assigned. One of the therapists elaborated as follows:

> *I am treating a woman over the platform, she's like 80 years old or something, and she is very industrious and reflective and not one of those who replies in short, but writes a lot, eh, and she stays at home so she has the time to do the assignments, but she, even though she is thorough, she does it quickly, so it is actually me who deliberately has chosen to stall it regarding giving the feedback and say now I will give feedback for three assignments today, and then she can look at that for a few days and then I wait for another couple of days before I give more feedback and then I stall it regarding uploading more so it is me who [...] delays it [...] I think she should have time to reflect in the meantime and not only when she is in front of the screen.* [Therapist 1, female]

The therapists emphasized managerial support for time use as essential. In addition, they felt that it was important to spend time on (1) educating a dedicated superuser who can allocate time to be the focal point of sparring and information about the use of the platform for treatment, particularly with technical aspects; (2) sparring with colleagues, for example, on how to conduct good blended AUD treatment and provide good feedback; (3) mutual sparring of technical issues when using the platform; and (4) clinical conferences with supervision of blended treatment courses.

Usability

The therapists also made several comments on the practicality of the platform. In particular, they suggested not to assign a series of assignments and submodules to the patient simultaneously, but rather to assign them one at a time. They found that the reward for completing a module was important to the patients, and if completing the modules was too time consuming, some patients lost enthusiasm. For those who had not answered the given assignments, therapists sent brief motivating reminders. One of the therapists explained as follows:

> *We try on Mondays, I give feedback on Wednesdays, so I try to send out like a reminder, and you call it a little shove, I call it something else for them, also to just say that like, you can right there orientate and say, hey where are you, are you a place where you think you need to be discharged.* [Therapist 2, female]

Thus, the therapists also recommended dividing modules into smaller versions with fewer assignments, which may potentially induce a feeling of more assignment completions and progress for the patients.

Furthermore, the possibility of flexibly combining modules was important. Thus, the therapists recommended allowing assignments to be skipped or new assignments to be released quickly, thereby avoiding waiting times between relevant assignments. They also found that it was important to provide feedback quickly after each module was completed.

Patient Recruitment

Concerning the procedure of recruiting patients and motivating them to enroll in a blended treatment course, the therapists emphasized the importance of giving interested patients an opportunity to contact the clinic via email, and not just by telephone or in person, as was the case in the pilot phase. One of the therapists elaborated on their experience of what the patients used the platform for:

> *Well, it is to stop their alcohol use or at least decrease it [and if this solution had not been a possibility] then they wouldn't have had any where to turn to, and this is what they say, it is a good way to do it, it is to be*

> *able to be totally anonymous if you are, say, a known person in town.* [Therapist 5, female]

It was their experience that this might make recruitment easier because the contact might feel more anonymous for the patients.

The therapists also experienced how the assignments on the platform were used for extended reflection and served as a foundation for the treatment sessions at the clinic. Here, one of the therapists explained how this may especially be the case for those who feel challenged by sharing in speech:

> *When he works, it is very clear that things emerge from his assignment-solving that I could not have guessed from our conversations of something, there are some areas for him that he needs to maybe talk about and work more with, and it became very clear, and then I could bring it into our conversations, which made sense for him, so for him it was actually a big help to have something elaborated that he just, which just is but he couldn't get out into the open on his own, so it is just such a good experience actually, eh, so I think that those patients who don't say much in the sessions and who think that it might be interesting to solve assignments, it might be an extra bonus in some way.* [Therapist 4, female]

As different target groups have different needs and wishes for their treatment courses, the therapists suggested offering patients different blends in the future:

1. Anonymous treatment: all initial contacts were handled by email or telephone, and the therapist could only contact the patient by email or by the feedback and message options in the platform. Information about the patient was registered anonymously, and the only information the therapist had about the patient was the patient's information in the email or in the program.
2. Platform use combined with face-to-face treatment: the patient was treated via telephone or email and was invited to a face-to-face interview. The patient was registered with personal information; that is, their social security number, in the electronic patient record before using the platform. After a month of using the program, there was a follow-up either by telephone or face-to-face conversation.
3. Platform use combined with face-to-face and pharmacological treatment: this blend is similar to face-to-face treatment combined with platform use but with the addition of a clinical treatment consisting of supportive medication. During this treatment form, the patient is followed up more closely every second or third week.

In addition, they emphasized the importance of having a pamphlet to hand out to the patients, describing the blended offer.

Discussion

Principal Findings

The purpose of this pilot study was to describe the process of translating and adapting a Dutch treatment protocol on treatment, consisting of blended face-to-face treatment sessions and internet-based modules, into the Danish language and culture. In addition, we report how patients and therapists perceived the adapted version when trying it out. In particular, we focused on experiences from the process of adaptation and pilot testing, which could inform future projects.

Even though the Netherlands and Denmark are much alike, we do have different languages and cultures, as well as slightly differently organized treatment systems. Thus, translating, culturally adjusting, and implementing effective and necessary treatment offers across borders is not straightforward. In this process, it is important to include both therapists and patients to facilitate the development of a treatment program in which they can identify themselves; thus, they choose to complete the program [45,46].

In this study, the development and translation process was inspired by participatory design [41] and was conducted in an agile process involving therapists and patients in several development and test iterations. Such collaboration with end users may more likely result in adaptations considering stakeholder views [41], ensuring the use of the platform and treatment content. Further involvement of patients in the early development phase as well as the later test phases might have helped us to better qualify assessments, videos, and length of the modules, thereby mitigating the need for further refinement of the platform. This is in line with recent qualitative studies concerning web-based alcohol treatment, which emphasized that incorporating patient feedback into the delivery may enable improvement of a treatment offer [45], and that stakeholder feedback can be used to bolster acceptability, appropriateness, and adoption of alcohol internet-based CBT, thus contributing to implementation success [47]. In this study, both patients and therapists were highly engaged in the process and added valuable, in particular pragmatic, information that led to adjustments of both the content and layout of the platform.

We found managerial endorsement and support crucial for the therapists' dedication of time to the pilot phase, enabling them to recruit patients and provide feedback to the process. Throughout the development process, the 7 therapists each spent 2 hours per week on an average for the project. During the pilot phase, the number of therapists per site (constantly 2 from each clinic) was sufficient to secure a high level of co-ownership in the development of the Blend-A pilot platform. Overall, the therapists participating in this study were very positive toward and engaged in the development and testing of the Blend-A platform. They found that giving feedback to patients in writing, in contrast to the immediate feedback that they were used to giving in face-to-face sessions, led to time to reflect and consider the feedback better. Our findings thus support previous findings on therapists' experience in delivering guidance via the internet [48]. Previous studies of therapists' experiences with internet-based CBT have, however, found that therapists may also find it more difficult to *read* patients over the internet [48-50]. Such considerations give support to the praxis of blended therapy, where the patients and therapists have a number of initial face-to-face sessions and then continue working internet-based if it suits the patients' needs. This study adds to this suggestion.

Reasons for Seeking Blended Treatment

The pilot study revealed 2 prominent reasons why patients chose to participate in the blended treatment.

The first reason was that the patients were attracted to the blended treatment setup, as it meant that they had to attend the clinic physically less often and at the same time took responsibility for their own treatment. This is in line with findings from other studies on web-based treatments [20,31,51]. In studies on barriers to treatment seeking, factors such as lack of transport and time to attend a treatment course have been found to be structural obstacles to seeking treatment [11,51].

The second reason for seeking a partly internet-based treatment offer was that the patients were attracted to the more anonymous option in the treatment offer owing to the imbedded discretion. We also found that therapists had experienced that allowing for contacting the clinic anonymously by email made patient recruitment easier. During the study, an additional number of patients who did not participate in the Blend-A pilot study were chosen to receive completely anonymous treatment via the Blend-A pilot platform, without face-to-face sessions, to ensure complete anonymity. One of the leading obstacles to seeking treatment is reported to be stigma; for example, because patients feel ashamed to be associated with the clinic and worry about what others might think [9,11,51,52]. This points to the relevance of offering an anonymous version of internet-based alcohol treatment as it might reach a group of non–treatment seekers not otherwise reached, for example, owing to stigma, as also suggested elsewhere [53].

Platform Use

We found a difference between how far during the treatment program the patients came in the 3 pilot municipalities. In one municipality, approximately half of the patients finished the program, and the rest stopped during module 2. In the 2 other municipalities, only one-tenth finished the program, and the rest stopped during and after module 2, respectively. According to a study on attrition in internet-based treatment of problem drinkers, the challenge of internet-based alcohol treatment programs is no longer their effectiveness but keeping participants involved until the end of the treatment program. In comparison, they found attrition rates of 55% and 65% [54], which seems to be the norm within internet-based alcohol intervention studies [55-57]. It is important to use a significant amount of graphics and videos in the native tongue to reduce the cognitive load. In addition to having an individualized and flexible platform with small modules, it can potentially induce feelings of more assignment completions and progress.

Among the patients, we found a baseline mean SUS score of 71. According to previous research, a system's usability can be assumed to be above average if the SUS score is ≥68 or higher [58]. We also found a patient-perceived positive impact of the blended treatment course owing to the interaction between platform use and face-to-face sessions, as the former could serve as a basis for the latter. This is in line with findings from other studies on web-based treatments, where it was found that blended therapy might be able to improve treatment usefulness, as it was possible to use input from the platform to prepare for face-to-face sessions [31,34]. However, in the study on blended depression treatment, it was emphasized that face-to-face sessions are crucial to motivate patients and facilitate the guidance of the web-based content [31]. Furthermore, we found a patient-experienced higher gain in the blended treatment, probably stemming from the ability to match treatment needs and the available time to platform use. This finding is concurrent with studies on web-based treatments, where the convenience of always having access to the platform was seen as an enhancer of self-management by enabling the patients to perform the assignments at their own pace [31,51]. In addition, we found rewarding elements in the possibilities of thinking assignments through and revisiting materials on the platform. This finding adds to the findings from previous studies on web-based treatments, where patients have found it easier to express themselves in writing, compared with face-to-face [48,59] or valued being able to download the material to use it after the treatment [45].

We found therapist-experienced importance of reserving a time slot for providing feedback, ensuring both therapist and patient time to work on assignments and feedback. This finding is in agreement with another study [60], which found that therapist feedback expressed a desire to tailor the nature and amount of support to patients. Finally, we found that it was important for the therapists to draw upon the experience of peers during training. Therefore, experiences from the pilot study will be used to inform and train new therapists in the future Danish national rollout of Blend-A.

Optimal Blend

Patients and therapists participating in the pilot study chose to use the Blend-A pilot platform to varying degrees. Other studies have discussed what might be an optimal blend [27,31]; for example, a study on blended depression treatment [31] found that patients preferred 50% to 60% of the sessions on the web, whereas therapists preferred 75% of the sessions to be face-to-face. The same study also emphasized tailoring treatment to individual patient needs by adjusting the amount and ratio of the web-based modules to patients' problems, skills, and characteristics. Supporting this, several studies on patient feedback suggest that it may be beneficial to tailor therapist support according to patient needs [32,48,49,61,62]. This might point to the importance of offering different blends targeting the needs of different patient groups, as this might make treatment accessible to an increased number of patients. Hence, the therapists in the present pilot study suggested offering 3-different blends: anonymous treatment, blended treatment, and blended treatment combined with pharmacology.

Strengths and Limitations

This study is a small feasibility and pilot study and therefore has a series of limitations. First, it was based on a few therapist and patient reports. Although it may be considered a strength that we used a validated questionnaire to assess usability, it is a severe limitation that only 3 patients answered the questionnaire at follow-ups 2 to 5. Therefore, whether the patients' assessment of the usability of the platform develops over time should be interpreted with caution. In future upscaling, we will rely as much as possible on register data and on more

routes for collecting patient data, that is telephone calls and the use of e-Boks (the Danish system for digital communication with the authorities) [63]. Moreover, some usability models are considered problematic, as theory to speculate about the relationship between measures may be lacking [64]. Instead, Drew et al [65] suggested using SUS scores for comparison between, for example, iterations or conjunction with formative usability testing methods to provide a holistic view of real and perceived user experience.

Second, the researchers and consultants who were responsible for the development, adjustment, and implementation of the Blend-A platform worked together and may have been interpreted as being a team by the therapists and patients. Thus, although we do not believe this to be the case, we cannot rule out that this may have led the therapists to be less critical toward the process of development and implementation. It is, however, a strength that 4 group interviews were conducted with therapists, refining their perspectives during the pilot study.

Third, only 4 patients participated in qualitative interviews regarding their experiences with the translated and adapted versions of the platform. We cannot rule out the possibility that those who participated in the qualitative interviews were more positive toward the use of internet-based modules in a treatment course.

Finally, it may be considered a limitation that transcripts and codes of the qualitative interviews were not stakeholder-checked [66] by letting participants provide feedback [67]. However, it is a strength that 3 independent raters were involved in the coding process, as this may enhance the credibility of the analysis [68,69] and increase reliability and internal validity [70].

Conclusions

Our study indicates that during the processes of translating, developing, and implementing blended, guided, internet-based, and face-to-face AUD treatment, it is relevant to focus on patient involvement, managerial support, and guidance from experienced peers. Owing to the discrete and flexible design of the blended treatment offer, it appears that patient groups who would not otherwise have sought treatment can be reached. Blended treatment may thus increase access to treatment and contribute to reaching people affected by excessive alcohol use, who would not otherwise have sought treatment. Our initial findings indicate that the blended treatment may enhance participants' perceived satisfaction and the effect of the treatment course. However, we still need to determine the actual effect of Blend-A; therefore, an effectiveness study is currently being performed to evaluate the effect, compliance, and cost-effectiveness of implementing the blended treatment program [63].

Acknowledgments

The Blend-A feasibility and pilot study was cofunded by the Unit of Clinical Alcohol Research, University of Southern Denmark; Centre for Telepsychiatry in the Region of Southern Denmark; Centre for Innovative Medical Technology at Odense University Hospital; Sundhed.dk; and public alcohol treatment clinics in the municipalities Haderslev, Kolding, and Svendborg.

The authors wish to thank the patients and staff from the municipal alcohol treatment clinics in Haderslev, Kolding, and Svendborg for their contributions to the Blend-A pilot study.

Abstract

Background: Although hyperactivity is a core symptom of attention-deficit/hyperactivity disorder (ADHD), there are no objective measures that are widely used in clinical settings.

Objective: We describe the development of a smartwatch app to measure hyperactivity in school-age children. The LemurDx prototype is a software system for smartwatches that uses wearable sensor technology and machine learning to measure hyperactivity. The goal is to differentiate children with ADHD combined presentation (a combination of inattentive and hyperactive/impulsive presentations) or predominantly hyperactive/impulsive presentation from children with typical levels of activity.

Methods: In this pilot study, we recruited 30 children, aged 6 to 11 years, to wear a smartwatch with the LemurDx app for 2 days. Parents also provided activity labels for 30-minute intervals to help train the algorithm. Half of the participants had ADHD combined presentation or predominantly hyperactive/impulsive presentation (n=15), and half were in the healthy control group (n=15).

Results: The results indicated high usability scores and an overall diagnostic accuracy of 0.89 (sensitivity=0.93; specificity=0.86) when the motion sensor output was paired with the activity labels.

Conclusions: State-of-the-art sensors and machine learning may provide a promising avenue for the objective measurement of hyperactivity.

Introduction

Attention-Deficit/Hyperactivity Disorder and the Need for Objective Measurement of Hyperactivity

ADHD is the most common neurodevelopmental disorder of early childhood, affecting over 5% of American children [1]. There are 3 presentations of ADHD: (1) predominantly inattentive presentation, (2) predominantly hyperactive/impulsive presentation, and (3) combined presentation. In school-age children, ADHD predominantly hyperactive/impulsive presentation and combined presentation make up 55% of all ADHD cases [2]. Although there are objective assessment tools such as the Conners Continuous

Performance Test 3rd Edition (Conners CPT 3) to measure inattention (the core symptom of the predominantly inattentive presentation of ADHD), there are no comparable objective assessment tools to measure hyperactivity (the core symptom of ADHD predominantly hyperactive/impulsive presentation). Instead, the current standard measurement for hyperactivity consists of subjective reports via questionnaires from parents and teachers, such as the Vanderbilt Assessment Scales. Reliance on subjective questionnaires to measure hyperactivity is a significant public health concern as it causes misdiagnosis including overdiagnosis and underdiagnosis [3-5]. Overdiagnosis can lead to unnecessary treatment, while underdiagnosis can lead to delayed treatment [6,7].

Sensor Technology and Machine Learning

Advances in sensor technology and machine learning provide opportunities to develop new methods of diagnoses with enhanced objectivity and precision. Wearable technologies (eg, smartwatches) with state-of-the-art sensors are practical, cost-effective solutions for providing objective measures of hyperactivity in children. The wide array of sensors (eg, accelerometer) embedded in wearable technology offer new opportunities to develop objective and accurate measures of hyperactivity. Although actigraphy has been around for decades and extensively used in research settings, its use has largely been confined to sleep studies [8]. Actigraphy has been used in a limited number of studies on children with ADHD, typically to measure sleep duration [9-11], rather than quantify daytime levels of hyperactivity to aid in diagnosis.

Multilevel Classification to Determine the Context of Symptoms

Context is critical in correctly diagnosing hyperactivity. For example, symptoms of ADHD include “often leaves seat in classroom or in other situations in which remaining seated is expected” and “often runs about or climbs excessively in situations in which it is inappropriate” [1]. While running and climbing in the playground do not contribute to a diagnosis of ADHD, running and climbing in a classroom does. Machine learning can be applied to sensor data to establish the context in which hyperactivity is present. Context is a combination of activity and situation. To assess context, we have developed a multilevel classification approach that first classifies the wearer’s activity, then contextualizes the level of motion, and finally evaluates activity level based on that context. The method analyzes hand motion to detect various activities; it collects the relationship between the wearer’s condition, activity, and magnitude of motion through accelerometer, time, and location data. Although it is not possible to have a class for every activity a user might perform (eg, fidgeting or other nonpurposeful motion), LemurDx classifies activities into common categories as a first layer of classification that is sufficient to condition algorithm parameters.

This Study

We describe the development of a smartwatch app to measure hyperactivity in school-age children. The LemurDx prototype is a software system for smartwatches that uses built-in sensors and machine learning to measure hyperactivity, with the goal of differentiating children with ADHD combined presentation or predominantly hyperactive/impulsive presentation from children with typical levels of activity. In this pilot study, we used LemurDx and supervised machine learning models paired with activity data from 30 children to develop initial classification algorithms. We report on usability scores from the LemurDx prototype and accuracy results from the initial algorithms.

Methods

Overview

This pilot study tested the feasibility of collecting, storing, and analyzing motion, as well as contextual (ie, GPS, heart rate, Bluetooth) data, from children aged 6 to 11 years who wore an Apple smartwatch with the LemurDx app for 2 days. The data from the days when the participants with ADHD were unmedicated combined with contextual data extracted from the smartwatch sensors, as well as activity labels were included in the final analyses.

Ethics Approval

The project was approved by the Institutional Review Board (19040006) at the University of Pittsburgh.

Participants

Participants were recruited via a web-based research registry called Pitt + Me, through the University of Pittsburgh’s Clinical and Translational Science Institute program. The research staff subsequently contacted interested participants via phone to complete the eligibility screening. The sample consisted of 30 children aged 6 to 11 years (ADHD combined presentation or hyperactive presentation=15; non-ADHD=15) and their families. Inclusion criteria for the ADHD sample included a formal diagnosis of ADHD combined presentation or hyperactive presentation, which was confirmed using the ADHD module of the Kiddie Schedule for Affective Disorders and Schizophrenia Present and Lifetime Version (K-SADS-PL) diagnostic interview and a score of ≥10 on the hyperactivity items of the Vanderbilt Assessment Scale–Parent report (VAS-P). Exclusion criteria included serious child psychopathology requiring alternative treatment (eg, bipolar disorder, major depressive disorder, psychosis, autism spectrum disorder).

Measures

VAS-P Report

VAS-P [12] is a 47-item survey that scores instances of behavior based on frequency of occurrence. Scoring is broken down into the following subtypes: inattentive, hyperactive/impulsive, or combined types. For the purposes of the study, only the 5 hyperactive subtype questions were asked in order to determine the level of the child’s hyperactive behavior. Symptoms are rated on a Likert scale from 0 to 3.

K-SADS-PL Diagnostic Interview

The K-SADS-PL [13] is a semistructured diagnostic interview designed to assess current and past episodes of psychopathology in children and adolescents according to Diagnostic and

Statistical Manual criteria. Probes and objective criteria are provided to rate individual symptoms. For the purposes of the study, the research staff only asked about the items related to the ADHD diagnostic criteria located in the ADHD supplement.

Post-Study System Usability Questionnaire

The Post-Study System Usability Questionnaire (PSSUQ) [14] is a 19-item survey that assesses 3 factors: system usefulness, information quality, and interface quality. The survey uses a 7-point Likert scale in which participants indicate the degree to which they agree or disagree with each item. Lower scores indicate higher levels of agreement, while higher scores indicate lower levels of agreement.

Activity Labels

Parents also provided activity labels to help train the algorithm. The activities were logged at a 30-minute resolution. For each 30-minute increment of time, from 6 Am to midnight, the parent had a drop-down menu of 5 activity classifications that best summarized the child's activities over the course of the 30-minute block. The activity categories were as follows: sleeping (eg, napping, sleeping); sitting/quiet activity (eg, watching TV, reading a book, using the internet, etc); everyday/household activity (eg, taking a walk, cleaning room, going shopping, playing an instrument, etc); exercise (eg, playing a sport, running, playing in the playground); and not wearing the watch. The activity labels created an additional level of qualification to the motion data collected. The purpose was to be able to later use the deidentified activity labels data to parallel the sensor data, to check the fidelity of the sensor data, and qualify outliers found in the sensor data.

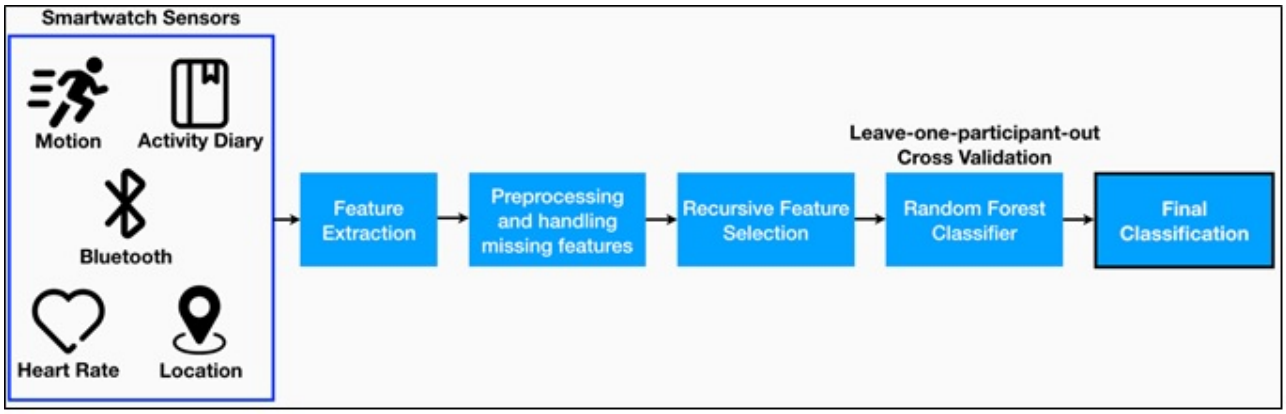
Procedure

After obtaining informed consent from the parent and assent from the child, the participants wore an Apple smartwatch with the LemurDx app running on it for 2 days. One arm of the study (n=15) consisted of children diagnosed with ADHD predominantly hyperactive/impulsive presentation or combined presentation, confirmed using the K-SADS-PL. The children wore the smartwatch for at least 1 day when they did not take their medication (eg, Saturday, Sunday, medication holidays), given that properly titrated stimulant medication reduces hyperactivity. The control arm (n=15) included children without an ADHD diagnosis, confirmed using the K-SADS-PL. The parents also provided activity labels via an automated remote assessment.

Data Processing and Analyses

The data processing and analysis pipeline consisted of three main steps: (1) feature extraction to calculate a set of motion and behavioral features over different time periods, (2) feature selection to identify a set of useful features and reduce the dimensionality, and (3) modeling the final set of features (Figure 1) to identify children with ADHD using a supervised machine learning approach.

Figure 1. LemurDx classification pipeline.



Feature Extraction

We computed 3 sets of features from the motion data collected on the watch. The first set included information about the shape of the motion curves over time and included features such as skewness and kurtosis. These features allowed us to identify the *type* of motion the children were making. The second set of features included statistical summaries of the motion data and included features such as mean, variance, median, magnitude, and hour quantiles of the observed motion. These features tend to capture both the *amount* of and the *changes* in motion. The third set of features included the cumulative motion recorded by the watch. This feature captured the total amount of motion exhibited over a time window. We calculated all 3 sets of features for 3 axes of the acceleration data and over 3 time windows, that is 1, 5, and 10 minutes. Apart from calculating these features over the course of the whole day, we also divided the features into times of the day when the children were performing specific activities as recorded in the activity labels. We used features from 3 activity classes: sitting/quiet, exercise, and everyday/household activity. Next, we handled the missing features due to missing sensor data. We occasionally missed sensor data due to technical issues with the app or watch, or compliance and human factors issues (eg, the family forgot to charge the watch). We imputed all the missing features with a value of –1.

Feature Selection

We used the randomized logistic regression (RLR) method to select an optimal set of features before classifying the data. RLR randomly subsamples the data and calculates feature importance based on their performance in a classification task, using logistic

regression [15]. This approach usually leads to a stable and reproducible set of selected features. We selected the top 20 features outputted from RLR implementation of scikit-learn.

Modeling

We used Python's scikit-learn library (Python Software Foundation) for the model building and for all analyses. We tried 3 types of learning algorithms: random forests, support vector machines (SVMs), and logistic regression. We chose these algorithms for their ability to generalize, capture inherent nonlinearity in the data (using specific kernels in case of SVMs), and their ability to model noisy data. Our analyses showed that random forests (with 2000 decision stumps or estimators) gave the best performance. Analyses were performed with leave-one-participant-out cross-validation to ensure that the models did not overfit. This approach builds a separate model for each participant in the validation phase and ensures that no participant's data are shared between training and testing.

Results

Participant Demographics

Key demographic variables and hyperactivity scores are summarized in Table 1.

Table 1. Participant demographics.

Characteristics	All participants (N=30)	
	ADHD[a] (n=15), n (%)	Non-ADHD (n=15), n (%)
Age (year), mean (SD)	9.6 (1.6)	10.1 (1.8)
Gender, n (%)		
Female	6 (40)	9 (60)
Male	8 (53)	6 (40)
Other	1 (6.7)	0 (0)
Race, n (%)		
White	11 (73.3)	14 (93.3)
Black or African American	1 (6.7)	1 (6.7)
More than one race	1 (6.7)	0 (0)
Chose not to answer	2 (13.3)	0 (0)
VAS-P[b] hyperactivity scores, mean (SD)	11.5 (2.2)	1.9 (1.7)

[a]ADHD: attention-deficit/hyperactivity disorder.

[b]VAS-P: Vanderbilt Assessment Scale-Parent report.

Usability

Sensor data from the LemurDx app were successfully collected for 28 of the 30 child participants. A total of 2 participants accidentally turned off location recording in the settings of the watch. For 3 other participants, the watch failed to record heart rate. Also, 5 participants (3 in the ADHD group and 2 in the control group) had trouble recording additional sensor data. We theorized that this failure was due to a loose fit of the watch on the children's small wrists. The overall PSSUQ usability scores were high (mean 1.81, SD 0.93) as were all the other subscale scores including usefulness (mean 1.81, SD 1.13), information quality (mean 1.75, SD 0.89), and interface quality (mean 1.92, SD 1.16). There were 3 common themes among the qualitative survey results: challenges with the app's interface, low battery life, and participants who enjoyed using the app. Fewer than 20% of the participants had some trouble with the watch's interface. Qualitative feedback is summarized in Table 2.

Table 2. Smartwatch app usability survey qualitative feedback.

Theme	Example quotes	Frequency, n (%)
Challenges with the interface	• "It would be helpful if it showed something on the face of the watch to let you know that the app was running in the background." • "There was really very little we saw of the study app. Just that we turned it on, saw how long it was running for and turned it off. It's hard to say how satisfied we were with its functions."	5 (17)
Low battery life	• "We struggled with the battery running out before we were finished recording a full day's data, despite the battery being at 100% at 7.30 AM." • "Phone ran out of battery on first day- hope that did not affect things- we can redo it if needed."	4 (13)
Enjoyed the app	• "It was fun to participate." • "Study is well organized and was easy to follow instructions."	3 (10)

Accuracy

The top 20 motion features extracted from motion sensor data are summarized in Table 3.

Alone, the model was no better than chance at differentiating between ADHD and non-ADHD children (accuracy=0.46; X^2_1=0.14, P=.70). When the motion sensor data was paired with the contextual sensors (ie, GPS, heart rate, Bluetooth), the model performance improved significantly (accuracy=0.71) and could differentiate between ADHD and non-ADHD children at better than chance level (X^2_1=5.25, P=.02). Model performance was best when the sensor data was paired with the activity labels (accuracy=0.89) and could reliably differentiate between ADHD and non-ADHD children (X^2_1=17.37, P<.001). Sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) for each model are summarized in Table 4. Finally, our analyses showed (Figure 2) that the magnitude of motion when the child was expected to "sit quietly" was the biggest differentiator between ADHD and non-ADHD children, consistent with a clinical profile of hyperactivity.

Table 3. Top 20 features extracted from motion sensors.

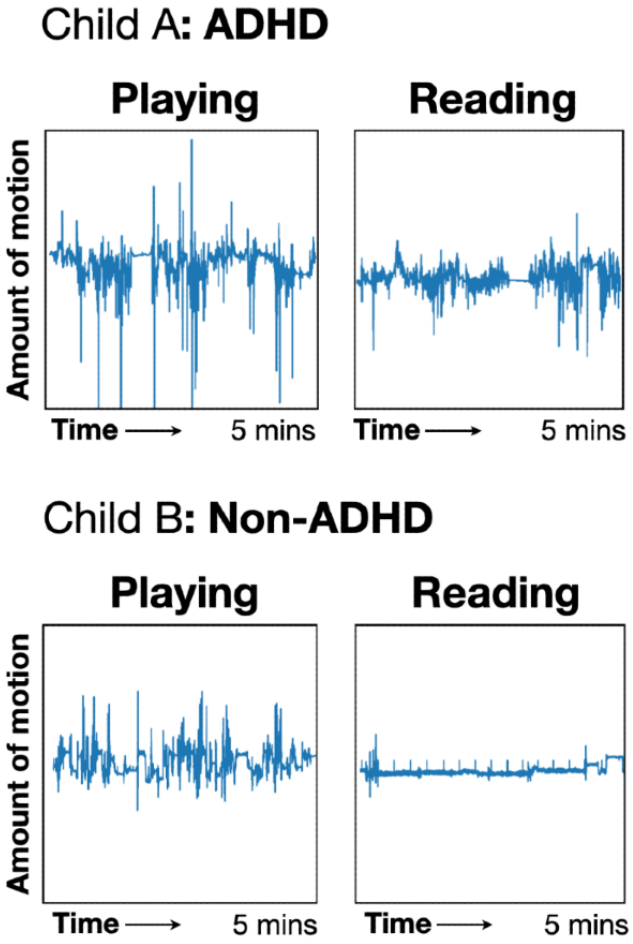
Number	Motion feature	Axis	Time interval
1	Cumulative variance	X-axis	10 minutes
2	Cumulative mean	X-axis	1 minute
3	Cumulative mean	X-axis	5 minutes
4	Cumulative mean	Y-axis	10 minutes
5	Cumulative variance	Z-axis	1 minute
6	Cumulative mean	All 3 axes	10 minutes
7	Cumulative variance	All 3 axes	5 minutes
8	Mean motion	X-axis	10 minutes
9	Variance	X-axis	10 minutes
10	Variance	X-axis	1 minute
11	Mean	Y-axis	10 minutes
12	Variance	Y-axis	10 minutes
13	Mean	Y-axis	1 minute
14	Variance	Y-axis	1 minute
15	Mean	Y-axis	5 minutes
16	Variance	Y-axis	5 minutes
17	Variance	Z-axis	10 minutes
18	Mean	Z-axis	1 minute
19	Variance	Z-axis	1 minute
20	Mean	Z-axis	5 minutes

Table 4. LemurDx accuracy, sensitivity, specificity, positive productive value (PPV), and negative productive value (NPV).

Model	Accuracy	Sensitivity	Specificity	PPV	NPV
Motion sensors plus activity labels	0.89	0.93	0.86	0.87	0.92
Motion sensors plus contextual sensors[a]	0.71	0.79	0.64	0.69	0.75
Motion sensors alone	0.46	0.50	0.43	0.47	0.46

[a]Contextual sensors included GPS, heart rate, and Bluetooth.

Figure 2. Motion spectrograms (x-axis: time; y-axis: motion) for 5-minute periods. A: The top panels are for a child with attention-deficit/hyperactivity disorder (ADHD). B: The bottom panels are for a child from the control group. In the first panel (playing), the child with ADHD moved 24.7 % more than the child in the control group. In the second panel (reading), the child with ADHD moved 41.2 % more than the child in the control group. ADHD: attention-deficit/hyperactivity disorder.



Discussion

Principal Findings

This study examined the LemurDx smartwatch app prototype among a sample of 30 children. Usability scores were high, pointing to the potential clinical utility of this approach to provide an objective measure of hyperactivity. However, qualitative feedback pointed to some issues with the interface and battery life, indicating that further development is needed in these areas. Despite these limitations, the app performed well enough to collect usable sensor data from 93% of the sample and successfully classify children with high accuracy.

As expected based on past actigraphy studies, motion data alone were a poor classifier of hyperactivity. Using motion sensors alone, model performance was no better than chance level at differentiating children with ADHD (hyperactive or combined presentations) from the ones in the healthy control group. Accuracy improved significantly when contextual information and activity labels were added to the models. These results suggest that contextual information is important when using sensor motion data to make inferences about the presence of hyperactivity.

These promising results point to the value of further research on contextualizing motion data for clinical purposes. Using the range of sensors provided in modern smartwatches could allow us to further refine the machine learning algorithms. These results would likely yield increases in accuracy based on variables specific to each child. The LemurDx app also has the potential to provide an objective measure of response to stimulant medication, thereby providing clinicians with objective

data based on which medication titration decisions could be made. Overall, the data from this study support the further refinement of the LemurDx app and algorithms in order to provide an objective measure of hyperactivity to supplement the subjective parent and teacher questionnaires.

Limitations

A limitation of this study was the absence of children with borderline levels of hyperactivity. Only children who met the specific cutoff numbers on the Vanderbilt's hyperactivity screen were recruited. Children had to score an 8 or above to meet the ADHD condition, while a score of 5 or below was needed for the control condition. Recruiting children who scored an 8 or higher but still met the control condition would help with diversifying the data. Another limitation of this pilot study was the small sample size, as only 30 families were included in the study sample, with usable motion data from 28 children. The sample size, however, was sufficient for this preliminary pilot work. A larger sample in the future will allow for stronger indicators of context, better visualization tools for clinicians, and more precise machine learning models.

Abstract

Background: Public safety personnel (PSP) impacted by operational stress injuries can find themselves needing both time off work and support reintegrating back into the workforce. Work reintegration programs have been introduced in PSP organizations to support those who aim to return to work. One such peer-led workplace reintegration program (RP) was created in 2009 by members of the Edmonton Police Service (EPS). The primary goal of the EPSRP is to assist PSP in returning to work as soon as possible following a critical incident, illness, or injury while diminishing the potential for long-term psychological injury. The EPSRP is delivered by peers through 3 interrelated components: (1) the Reintegration Program Facilitator Training (RPFT) Program; (2) a short-term Critical Incident RP; and (3) a long-term RP. There is a dire need for research that incorporates strong study designs to the determine long-term effectiveness of the program on increasing workplace reintegration, improving mental health knowledge, and creating culture change within PSP organizations. Simultaneously, the efficacy, effectiveness, and fidelity of the RPFT in providing the tools, mental health knowledge, and skills the RP peer facilitators will need for the RP must be evaluated.

Objective: The purpose of this quasi-experimental pre-post pilot cohort study is to evaluate the effectiveness of the EPSRPFT course on influencing mental health knowledge and attitudes of RPFT attendees who will be future RP peer facilitators.

Methods: This pre-post cohort study collected data via 2 questionnaires from RPFT participants (N=60) which included the Mental Health Knowledge Survey (MAKS) and the Open Minds Survey of Workplace Attitudes (OMSWA). Descriptive, parametric (sample *t* tests), and nonparametric (Wilcoxon signed rank tests) statistics were used to compare the pre- and post-RPFT results and to analyze results by gender and profession.

Results: Statistically significant changes were observed in pre-post questionnaire scores in the domains of mental health attitudes and knowledge.

Conclusions: Although results are explorative, the RPFT may facilitate positive changes in workplace mental health attitudes and knowledge among PSP. It is hoped these findings will contribute to a broader evidence base that can inform changes to the program, practices, and policies, and inform decision-making regarding the EPSRP.

public safety personnel; mental health; return to work; reintegration; first responders

Introduction

Background

Public safety personnel (PSP; eg, correctional workers, dispatchers, firefighters, paramedics, police officers) are at an elevated risk of experiencing occupational stress injuries (OSIs) [1]. OSIs which are more common among PSP are work-related psychological distress, mental illness, and work place injuries that result from exposure to events and tasks that can be unpredictable, traumatic, and high risk [2]. A recent study surveying 5813 PSP in Canada found that 36.7% of municipal police, 34.1% of firefighters, 50.2% of Royal Canadian Mounted Police (RCMP), and 49.1% of paramedical staff screened positive for a mental health condition, such as posttraumatic stress disorder (PTSD), depression, anxiety, or substance abuse [3]. These prevalence rates are similar to those in other nations where there are elevated rates of mental health conditions and suicidality among their PSP when compared to the civilian public [4-8]. In an Australian study, 1 in 3 emergency services personnel were reported to experience high or very high psychological distress [7]. In the United States, it is estimated that 30% of first responders develop mental health conditions compared with 20% in the general population [8].

High rates of OSIs can lead to elevated levels of work absenteeism, which risks compromising the level of service that PSP organizations can provide in their communities and increasing the burden on health care and workers' compensation. OSIs interfere with daily functioning in social, work, or family activities and can leave PSP in need of time off work or unable to return to work in the short- or long-term [9]. These conditions have the potential to impact an individual's quality of life and can result in decreased community integration, increased social isolation, and greater difficulty forming and maintaining meaningful relationships [10,11]. OSIs such as PTSD can lead to issues with self-care, health, and sleep, all of which can negatively affect success in productive roles such as employment [12]. Productivity-related occupational performance issues attributed to OSIs can cause difficulty with returning to and maintaining work [12].

Facilitating return to work among PSP who have experienced posttraumatic stress injuries and OSIs is a primary concern for PSP, their families, and their organizations. Workplace reintegration interventions offered in clinical health or workers' compensation settings to address posttraumatic stress injuries and OSIs can be effective in reducing psychological distress and improving daily function. They may have a limited ability, however, to help PSP constructively engage with real-world occupational stressors given that they are offered outside of the PSP service environment [13]. As a result, peer-support interventions and programs offered as an adjunct to clinical evidence-based interventions have become more common within military and PSP organizations.

Peer-support relationships—supportive relationships between people who have a common lived experience—may both enable PSP to take a first step toward recovery and assist individuals throughout the rehabilitation process [14]. Research has illustrated that many PSP feel more comfortable and are more likely to share psychological health challenges with their peers than with a health care professional [15,16]. Commonly shared PSP peer experiences may relate to their career paths and roles as well as mental health challenges or illnesses [14].

Peer-support programs can differ in their area of focus, delivery format and context, and aims. Some programs are associated with critical-incident stress debriefing, critical-incident stress management, peer support, psychological first aid, and trauma risk management [17]. Such programs are delivered in community, clinical, and workplace contexts in both group and one-to-one formats which can contribute to increased accessibility for PSP [14]. Peer-support programs may also be introduced prior to, during, or upon conclusion of clinical interventions and a person's return to work, and may be the first step a person takes toward recovery. They may also bridge care gaps when geography or organizational security requirements are barriers to care (eg, while clinicians are unable to access PSP environments that require specialized training, certification, and security clearance). In these circumstances, peers can support the therapeutic process within PSP-specific environments, provide a more nuanced understanding of specific occupational stressors and triggers, and help to support or develop creative occupational-specific coping strategies.

Evidence-based literature to support peer-support initiatives among PSP is scarce but emerging. A small body of literature demonstrates promise for peer-support programs in effectively reducing symptoms of psychological distress and increasing self-efficacy and empowerment in civilian and veteran populations with various mental health diagnoses [18,19]. A recent scoping review focused on collating evidence on the use of early interventions for trauma in workers in organizations such as police, fire and rescue, ambulance, and health professionals where traumatic events are routinely experienced due to the nature of the work. With respect to peer-based or peer-led interventions, the reviewers noted that interventions inclusive of peer-group debriefings led to significant reductions in trauma-related absenteeism, and 25 out of 34 studies that delivered an early intervention in a group format found that peer support had facilitated recovery or made for a better experience [20]. A 2015 Finnish survey found that a majority of police officers endorse peer support as a preferred method of learning about stress, health, and posttraumatic treatment [16]. The current literature does not provide information on the functional implications and workplace reintegration outcomes of peer-support programs, which may include workplace presenteeism, work satisfaction, postinjury job demands, perceived organizational justice, perceived work-life balance, and interpersonal workplace relationships as well as the type, intensity, and frequency of the postinjury work (eg, full or part time, modified duties, change in role). Moreover, while some research exists regarding peer-support programs, there is little research evaluating the efficacy and effectiveness of the training

that PSP peer-support facilitators receive prior to engaging as leaders in peer-led initiatives.

In 2009, the Edmonton Police Service (EPS) developed a peer-led work reintegration program (RP) that engages police officers in a step-by-step occupation-specific process in actual policing contexts. The primary goal of the EPSRP is to enable officers to return to work as soon as possible, while diminishing the potential for long-term psychological injury [13]. It accomplishes this by engaging the officer in a step-by-step process that addresses the unique stressors that an officer may experience. The pace, scope, depth, and goals of the program are guided by the individual officer with support from the officer's clinical team. The EPSRP, which includes relationship building, reintroduction to equipment, skill building, exposure therapy, and street exposures [13], is delivered by peers through 3 interrelated components: (1) a RP Facilitator Training Program (RPFT), (2) a short-term Critical Incident RP, and (3) a long-term RP [13]. The short-term Critical Incident RP is offered to support PSP following critical incidents, such as officer-involved shootings. Goals of the long-term RP are to assist officers who have been off work for an extended period of time to return to the normalcy of work settings by providing support and training that are outside the scope of what they have received from their health care provider (ie, psychologist, clinician, or occupational therapist). This study focuses on the first component, the RPFT, and will be outlined in depth in the Methods section.

Since the RP's inception, 185 EPS officers and 200 plus Alberta Health Services (AHS) emergency services and RCMP K Division staff in Alberta, Canada, have participated in the RP. In the province of Ontario, the Ottawa Police Service and RCMP O Division are actively using the RP with participants while the London Police Service, Ontario Provincial Police, and the Niagara Police Service are in the process of implementing the RP [21]. Evidence regarding the effectiveness of the EPSRP is evolving. Findings from a 2018 internal study by the EPS indicated a 70% reduction in days lost following introduction of the program [13]. A further analysis conducted by the AHS comparing 2 cohorts of emergency services employees demonstrated promising numbers, with 50% more work-days lost in the cohort without the RP compared to the cohort with access to it [21]. Interest in the EPSRP has been stimulated among various PSP groups as a result of positive anecdotal reports. A qualitative analysis of the RPFT was published in 2021, concluding that while the EPSRP holds promise, it is essential that evidence-based research be used to guide RPFT and RP spread and sustainability [22]. PSP organizations in other Canadian provinces, New Zealand, and the United Kingdom are also at various stages of exploring or implementing the EPSRP.

Although PSP organizations are beginning to integrate peer-supported workplace reintegration programs into their mental health strategies, caution must be used. Despite emerging research, a body of scientific literature supporting the efficacy, safety, and effectiveness of peer-lead workplace RPs is lacking, making conclusive decisions about their implementation and use difficult [23]. High-quality RP effectiveness studies that incorporate stronger study designs, rigor, validity, and reliability are needed. Determination of their long-term effects are also required, together with an assessment of potential risk of harm to the participants and facilitators [23]. Research of peer-supported RPs, as well as the facilitator training programs within the Canadian, provincial, and municipal contexts, are needed to ensure that this approach is safe and beneficial for PSP [23,24].

Objective

The purpose of this quasi-experimental, pre-post, pilot cohort study is to measure changes in the mental health knowledge and attitudes of PSP attendees of the RPFT based on self-reported outcome measures. This study is unique in that it aims to be the first externally peer-reviewed quantitative research regarding this RP that incorporates an a priori study design and includes considerations of rigor, validity, and reliability. The results of this study may assist with the further development, fidelity, and implementation of the RPFT, with the goal of strengthening the RP and initiating further research to meet the aforementioned need for addressing questions regarding efficacy, effectiveness, and safety.

Methods

Study Design

This pre-post, quantitative, quasi-experimental, pilot cohort study was part of a larger mixed methods pilot project which employed a convergent parallel design [25,26]. Concurrent collection of quantitative and qualitative data and triangulation occurred once all data were collected.

Ethical Approval

This study received ethical approval from the University of Alberta Research Ethics Board (study approval #Pro00089517) and was supported by the EPS.

Reintegration Program Facilitator Training

The 5-day RPFT course was developed and implemented to prepare PSP peers to deliver the EPSRP to colleagues who sought to reintegrate back into work following an OSI and to increase the spread of the RP across PSP organizations. EPS offers the RPFT program multiple times per year for PSP who are interested in becoming RP facilitators or who are implementing an RP within their organizations. The training includes both psychoeducational and experiential components. Examples of psychoeducational topics include the physiological effects of trauma, basic neuroanatomy and physiology, mental health disorders, specific counseling exercises, and interpersonal skills, such as active listening. Experiential components include hands-on graded activities, such as firearms exposures on the firing range for police, mock interrogations for border patrol personnel, donning of equipment for firefighters, and specific scenarios in an ambulance for paramedics. Participants were required to attend and engage in the 40-hour training prior to being designated a RP peer facilitator within their respective PSP organizations.

Recruitment and Sampling

Participants (N=60) included Alberta-based PSP (eg, RCMP, police, emergency medical services, fire, sheriffs) and clinicians (psychologists and occupational therapists) working with PSPs who attended the RPFT. The participants voluntarily signed up to attend the 5-day RPFT course and had attained approval to participate from their employer. All RPFT attendees were invited to participate in this research study. Upon registering in the RPFT, attendees were asked by the reintegration coordinator if they were interested in participating in the study. Those interested were enrolled and, prior to commencing the RPFT, provided written and verbal consent.

Outcome Measures

Questionnaires that were administered pre- and posttraining captured descriptive data (eg, age, gender, role), along with information about participant knowledge, skills and attitudes, mental health literacy (Mental Health Knowledge Survey [MAKS]) [27], work reintegration, mental health stigma, and workplace attitude (Open Minds Survey of Workplace Attitudes [OMSWA]) [28].

The MAKS was developed from the theoretical underpinning that stigma comprises 3 constructs: knowledge (ignorance), attitudes (prejudice), and behavior (discrimination) [27]. The MAKS is a 12-item self-report questionnaire designed to measure mental health literacy and stigma [27]. Items are rated on a 5-point Likert scale measuring level of agreement ranging from 1 (strongly disagree) to 5 (strongly agree). Psychometric data support the internal consistency and test-retest reliability of the measure, and the measure appears sensitive to changes in participant responses based on interventions [27,29]. The OMSWA is a 23-item self-report questionnaire designed to measure mental health stigma and workplace attitudes. Items such as “I would be upset if a coworker with a mental illness always sat next to me at work” are rated on a 5-point Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree) [28]. There does exist psychometric data to support the internal consistency of this outcome measure, and it is commonly used by the Mental Health Commission of Canada [29].

A pre-post mental health knowledge questionnaire developed specifically for the EPSRPFT was also trialed based on the RPFT curriculum goals and objectives (Multimedia Appendix 1). This questionnaire employed a 5-point Likert scale ranging from 1 (not at all true) to 5 (very true) for 2 sections: (1) Understanding of Concepts, “I have an excellent understanding of ….” and (2) Skills, “I have excellent skills to ….” A third section required the respondent to rate their level of agreement from 1 (strongly disagree) to 5 (strongly agree) regarding statements related to workplace mental health knowledge, stigma, and attitudes.

Data Collection

After providing written and verbal consent, and prior to commencing the RPFT, participants were provided a participant number by the lead researcher (CJ) along with a blank envelope containing the precourse surveys. This allowed for participants to be reassured both that their employers were unaware of who participated in the study and their responses and that the study was being conducted externally by independent researchers. Participants were asked to complete the outcome measures and immediately return the envelope to the research team. This process was also completed at the conclusion of the RPFT. Data were then manually entered into SPSS software (IBM Corp) by the research team for analysis.

Data Analysis

Demographics of the sample were calculated for each of the measures as were total scores for each dependent variable pre- and post-RPFT. Quantitative data were analyzed using SPSS software with sample *t* tests and Wilcoxon signed rank tests. Two-level multilevel modeling analyses were conducted for each repeated measure analysis in the study. Time, as a fixed variable, was coded into 2 time points: (1) baseline and (2) postintervention. Each model included 1 of the dependent variables (ie, MAKS and OMSWA) at each time point (level 1) nested within participants (level 2). Baseline differences in scores among individuals were accounted for by including both a fixed and random intercept in the model. Each final model included the fixed effect of time as the primary predictor variable. All models were computed using the maximum likelihood estimation. All hypothesis testing was conducted using 1-tailed tests at an α level of .05. Cohen *d* effect sizes were computed for all models by standardizing each outcome measure and rerunning the resulting *z* scores in each model. All models were bootstrapped to generate robust probability values and corresponding CIs. A sample of n=30 or higher was required for a power of 0.8, and an attrition rate of 20% was predicted.

Results

The demographics of the PSP sample are displayed in Table 1. The sample was largely composed of men (n=44), which is common in PSP professions. PSP in policing professions, including municipal policing (n=14) and RCMP (n=12), were the most common among the sample. Of the participants, 32 reported already having an established RP within their home organization.

Statistically significant changes in preintervention to postintervention scores were noted for the overall sample with the MAKS (preintervention: mean 48.70, SD 3.688; postintervention: mean 50.70, SD 3.452; t_{50}= –3.373; *P*=.001) and are displayed in Table 2. The OMSWA also showed statistically significant preintervention (mean 38.01, SD 9.830) and postintervention (mean 33.18, SD 7.362; t_{49}=3.692; *P*=.001) changes. This would indicate that among the entire PSP sample, mental health knowledge, literacy, and workplace attitudes toward mental health increased while mental health stigma decreased. The sample was further broken down to analyze the significance of changes on the MAKS and OMSWA by gender and profession (Tables 3 to 6).

The scores of participants who identified as women and completed both pre- and postoutcome measures (n=15) were compared on the pre- and post-MAKS using the Wilcoxon signed rank test (Table 3). Women’s participant scores for posttraining (meaning 20.07, SD 1.32) were lower than those for pretraining (mean 20.93, SD 1.02). The Wilcoxon signed

ranks test indicated that the median posttraining ranks on the MAKS were not statistically significantly lower than the pretraining ranks on the MAKS (z= –1.67; P=.95).

The women's scores were compared on the OMSWA pre– and post–work reintegration training. The women's scores posttraining (mean 31.3, SD 1.75) were lower than those pretraining (mean 36.4, SD 2.68). However, the Wilcoxon signed rank test indicated that the median posttraining ranks on the OMSWA were not statistically significantly lower than the pretraining ranks on the OMSWA (z= –1.50; P=.13).

The scores of those participants who identified as men and completed both pre- and postoutcome measures (n=35) were compared on the MAKS before and after use of the paired sample t test (Table 4). The men's scores posttraining (mean 21.17, SD 0.82) were lower than those pretraining (mean 23.57, SD 0.82). This improvement was statistically significant (t_{34}= 4.09; P<.001). The men's scores were compared on the OMSWA pre– and post–work reintegration training. Men's participant scores posttraining (mean 34.37, SD 1.24) were lower than those pretraining (mean 41.06, SD 1.69). This improvement was statistically significant (t_{35}=3.11; P=.004).

Municipal police (n=14) were the most likely to demonstrate a change in the pre-post OMSWA (z=–1.97; P=.049), demonstrating improvements in workplace attitudes after the RPFT (Table 5). The RCMP (n=12) showed the most statistically significant changes on the MAKS (z=–2.37; P=.02; median score pretraining 28; median score post training 17.5), which demonstrated an increase in mental health knowledge (Table 6). All other pre-post comparisons of the MAKS and OMSWA for specific PSP professions were nonsignificant.

[a]OMSWA: Open Minds Survey of Workplace Attitudes.

[b]N/A: not applicable.

[c]MAKS: Mental Health Knowledge Survey.

Discussion

The purpose of this quasi-experimental, pre-post, pilot cohort study was to evaluate the effectiveness of the EPSRPFT course on influencing mental health knowledge and attitudes of RPFT attendees. The statistical results of the outcome measures, notably the MAKS, OMSWA, and EPSRPFT-specific questionnaire, indicated that the 5-day, 40-hour course likely facilitated increased knowledge of mental health and improved workplace attitudes amongst the participants. The amount of change of the overall scores was statistically significant. Improving mental health knowledge may facilitate a positive impact on stigma, facilitate help seeking, and contribute to a greater proportion of PSP with mental illness engaging in medical treatment [27-30]. It should be noted, however, that knowledge alone is not enough for behavioral change and that additional intrinsic and extrinsic factors, such as cultural awareness, life experiences, the environment, and the responses of others, will also affect whether this knowledge and awareness may influence behavioral change [31,32]. If the EPSRPFT was successful at influencing and facilitating positive change in the level of mental health knowledge, awareness, and skills while improving workplace attitudes in 5 days, this may carry over into the PSP workplace culture and organizations.

Change in scores pre-post training suggests potential gender, profession, organization, and individual differences. Data analysis found that men were more likely to see a larger pre-post change in scores as were municipal police and RCMP. It is hypothesized that the smaller number of women and the smaller subsamples being analyzed for differences between professions might have reduced the sensitivity of the statistical analysis within this study. Gender differences, however, may be important; despite being speculative, the current literature demonstrates that in general, women have greater mental health knowledge or comfort expressing that knowledge to others than do men [33,34]. The lack of change in scores, therefore, does not necessarily indicate that the RPFT program is not meeting its objectives. Rather, it may be indicative that some PSP professions, organizations, and individual PSP had more baseline mental health knowledge upon entering the RPFT and, therefore, did not have as much threshold for change.

Participants appeared to be enrolled in the RPFT for differing reasons. Notably, 53% (32/60) of the sample were from PSP organizations that had already established RPs. It is possible that some of the other participants were enrolled in the RPFT for their own personal growth and learning and did not intend to participate as RP facilitators posttraining. As previously stated, improving mental health knowledge and attitudes can

positively influence workplace culture. That being said, it may also be beneficial to reserve the RPFT for those intending to become RP facilitators, with separate learning opportunities available for those participating in the RPFT for other reasons. It is also possible that some of these participants had plans to return to their respective organizations to initiate an RP where one did not previously exist. It may be advantageous to provide information and guidance to this group on how to take steps to implement such a program.

The results of this study should be interpreted with caution, as there were a number of limitations. The data collected in this study were from a single RPFT course specific to a workplace RP without a control group. The specificity of the program and sample limits the generalizability and comparison of the findings. It should also be noted that, although unlikely within the short time period of 5 days, it is possible the observed changes in the PSP attendees mental health knowledge and attitudes could be attributed to other unknown confounding variables aside from the RPFT. A further limitation relates to barriers to open discussion among participants that may arise due to ranks and roles associated with the hierarchical nature of PSP organizations. Stigma surrounding issues regarding mental health, reintegration, PSP culture (norms of hegemonic masculinity, authoritarianism, and emotional control), and organizational culture and policies may also hinder PSP's confidence in verbally sharing ideas and answering questions. Regarding the sample size, the subsamples had a low number of participants, which might have reduced the sensitivity of the statistical analysis for a given PSP and gender. This is a constant challenge within PSP organizations that can and has been mitigated but is unlikely to be eliminated within the research of this population. As with any study with self-report measures, there are a myriad of issues with self-reporting regarding memory and social desirability biases in reporting. Furthermore, the RPFT-specific questionnaire has yet to be validated. Validation of the questionnaire, which will require more studies with additional participants, may be an asset to the RP in its evaluation as a measure of its effectiveness. Finally, although this study would have benefited from a follow-up 3 and 6 months post-RPFT, the COVID-19 pandemic prevented this from being possible. Despite these limitations and barriers, the overall RP program is experiencing international spread without peer-reviewed research supporting it. It is important to have a pragmatic approach in capturing the RP, as it is currently being deployed in real time to generate preliminary research that uses an evidence-based approach that can be applied within the given context.

More research is needed to evaluate the effectiveness, efficacy, and safety of peer-led workplace RPs and their associated facilitator training programs. As emphasized in the Blue Paper and other research on PSP peer-support initiatives, research conducted by external stakeholders could lead to the evidence-based validation of programs such as the peer-led EPSRP and RPFT program for PSP [23,24,35]. Study of organizational and cultural impact, cost-benefit, implementation drivers and processes, and knowledge mobilization strategies is also warranted. Specifically, studies which employ larger samples would allow for more sensitivity to detecting change in pre-post scores. It is critical that future studies look at the long-term impact of the RPFT and whether mental health competencies, knowledge, and attitudes are maintained over time. As this research expands, other populations at elevated risk of OSIs, such as military, veteran, and health care professionals, could also be included to examine the overall impact of peer-supported workplace reintegration initiatives. Favorable research findings would potentially pave the way for more widespread program adoption and integration that ensures risk management strategies and the maintenance of program fidelity [24]. Use of effective implementation science approaches would best facilitate sustainable spread and scale, enabling more PSP with OSIs to be supported in targeting recovery and return to work. Additionally, the pre-post EPSRPFT questionnaire would benefit from further validation studies to establish parametric data. It may be appropriate to use in future evaluations of other courses related to mental health knowledge and training.

The EPSRP is designed to assist PSP in workplace reintegration after a critical incident or long-term absence from the workplace due to mental or physical health conditions. Evidence-based, curriculum-driven training within programs such as EPSRP may increase return-to-work success among PSP. This pilot study demonstrated preliminary evidence that a 5-day RPFT may contribute to improved mental health knowledge and workplace mental health attitudes among PSP. These newly minted RP facilitators will take this information, perspective, and knowledge from the RPFT into their workplace where they will aim to assist their peers with reintegrating back into the PSP work environment. As a foundational objective evaluation of the RPFT conducted by arms-length researchers, the study responds to the imperative detailed both in the Blue Paper [23] and other publications regarding PSP peer-support programs. It is hoped these findings will contribute to a broader evidence base that can inform changes to the program, practices, and policies, and inform decision-making regarding the EPSRP.

Acknowledgments

We would like to thank the Edmonton Police Service for their support as well as those public safety personnel who participated in this study.

Abstract

Background: Clinicians need to be able to assess the quality of the available information to aid clinical decision-making. The internet has become an important source of health information for consumers and their families.

Objective: This study aimed to rate the quality of websites with psychosis-related information (to provide clinicians with a basis for recommending material to guide clinical decision-making with consumers and their families), using a validated instrument as well as a purpose-developed checklist, and consider improvement in quality over a 4-year period.

Methods: Two measures of website quality were used: the DISCERN scale and the Psychosis Website Quality Checklist (PWQC). Terms related to psychosis, including “psychotic,” “psychosis,” “schizophrenia,” “delusion,” and “hallucination,” were entered into Google, and the first 25 results were analyzed. In total, 6 raters with varying health professional backgrounds were used to evaluate the websites across two time points: January-March 2014 and January-March 2018.

Results: Of the 25 websites rated, only the 6 highest ranked websites achieved a DISCERN score, indicating that they were of “good” quality (51-62 out of a possible 75), while the mean score of the websites (mean 43.96, SD 12.08) indicated an overall “fair” quality. The PWQC revealed that websites scored highly on “availability and usability” (mean 16.82, SD 3.96) but poorly on “credibility” (mean 20.99, SD 6.68), “currency” (mean 5.16, SD 2.62), and “breadth and accuracy” (mean 77.87, SD 23.20). Most sites lacked information about early intervention, recreational drug use and suicide risk, with little change in content over time. Stating an editorial or review process on the website (found in 56% of websites) was significantly associated with a higher quality score on both scales (the DISCERN scale, P=.002; the PWQC, P=.006).

Conclusions: The information on the internet available for clinicians to recommend to people affected by psychosis tended to be of “fair” quality. While higher-quality websites exist, it is generally not easy way to assess this on face value. Evidence of an editorial or review process was one indicator of website quality. While sites generally provided basic clinical information, most lacked material addressing weighing up risks and benefits of medication and alternatives, the role of coercive treatment and other more contentious issues. Insufficient emphasis is placed on detailed information on early intervention and importance of lifestyle modifications or how families and friends can contribute. These are likely to be the very answers that consumers and carers are seeking and this gap contributes to unmet needs among this group. We suggest that clinicians should be aware of what is available and where there are gaps.

Introduction

Accessing information related to one's illness and treatment enables consumers to discuss their health and treatments more confidently with their doctors [1], is central to the patient-centered health care delivery [2] and improves clinical outcomes [3]. It also offers an opportunity to seek information privately and at one's own pace. This is particularly important in relation to psychotic disorders given the bewildering and anxiety-provoking nature of the symptoms themselves for the consumer, and their families or carers. Additionally, the impact of stigma, misinformation, and low levels of mental health literacy can impact have on outcomes of care [4,5].

Several mental illnesses, including schizophrenia, schizoaffective disorder, bipolar disorder, and some physical illnesses, can present with psychosis [6]. This is characterized by disrupted cognitive processes, delusions, hallucinations, and changes to speech and behavior patterns, which are bewildering for those who experience psychosis and their families. People experiencing psychosis, especially those with schizophrenia, often have pronounced fear and anxiety related to social engagement, and the internet offers a safe space to obtain mental health information without having to interact with others [7] and averts any possibility of feeling devalued.

The last decade has seen the internet become increasingly central to the dissemination of health care information. This technological transition has accelerated with the COVID-19 pandemic [8], where "accessing basic requirements like health and education" is increasingly achieved through web-based portals. While there is no conclusive evidence that the COVID-19 pandemic has increased the prevalence of severe psychiatric disorders such as psychosis, the associated distress, enforced social isolation, and related uncertainties may exacerbate symptoms [9]. Additionally, the pandemic has led to a decrease in face-to-face appointments with mental health professionals for those experiencing mental illness, leading to increased reliance on technology; for example, using the internet for both therapy sessions and informal information and support [9]. In one study, approximately 30% of patients with a psychotic disorder reported using the internet "a lot" during the pandemic; this rate was comparable to that of internet use by individuals with other severe mental illnesses [10].

The increasing reliance on the internet as a source of mental health information highlights the importance of clinicians being aware of what information is available on the internet. Even prior to the pandemic, approximately half of Australia's 15 million internet users reported using internet to search for health-related information [11-13]. In mental health services, over 50% of people with a previous diagnosis of mental illness and access to the internet have used the internet to find diagnosis-related information [14,15]. Research has also shown that patients with schizophrenia differ from those with other mental illnesses in their internet search behavior, including the times of the day they use the internet and the search terms used [16]. In a recent study of people hospitalized for schizophrenia [17], over 75% of them had used the internet to search mental health–related content in the previous 6 months and individuals "appear to be using the Internet for obtaining information about their early symptoms and experiences prior to their first contact with psychiatric care."

The apparent frequency and wide-ranging use of the internet by people with psychosis has associated drawbacks, primarily related to the lack of regulation of web-based content. Multiple studies of web-based mental health search behavior among people with psychosis have found that patients express a desire for their mental health clinician to provide a recommended list of reputable websites rather than needing to navigate the plethora of available information unguided [18,19]. Kirschenbaum et al [17] called for more understanding by clinicians of what consumers are looking for when conducting internet searches, and that this increased understanding should help clinicians tailor web-based resources to improve care pathways and reduce the duration of untreated psychosis. Further research has highlighted a need for clear guidance for clinicians aid them in recommending reputable web-based resources to those with severe mental illnesses [20]. As it has been noted that the development of web-based mental health resources and treatments is far outpacing their evaluation [21], mental health professionals would benefit from guidance on what resources to recommend. Hence, it is important that clinicians have some confidence in the quality of information being accessed, and whether it is targeted to the consumers' needs [22].

Despite the central role that the internet now plays in the delivery of health information and services, clinical services generally do not have formal approaches for using the internet for health information in collaboration with consumers and their support network. Clinicians have limited guidance and time to evaluate the plethora of websites available but are aware that poor-quality information can produce unnecessary worry, increase inappropriate consultations, or lead to use of ineffective treatments [13]. Inconsistencies in the quality and clarity of information on the internet make it difficult for clinicians to help guide patients to the best information available. For example, a meta-analysis [23] revealed that 42% of mental health websites are either owned by, or receive funding from, pharmaceutical companies, and that these websites are significantly more likely to be biased toward recommending medication, and not all websites disclose such funding. It has been noted that aiding clinicians to identify reputable websites has been suggested as an important enhancement to patient care [20]. The challenge for health care professionals is to know how to appraise the trustworthiness of psychosis-related website services to enable them to adequately inform consumers, their families, carers, and the general community [24].

This paper focuses on the clinician's perspective, with the aim of providing clinicians with a process to aid them in identifying

appropriate and reputable websites that may be recommended to people experiencing psychosis and their network with information. This study aimed to (1) identify which websites with psychosis-related content surfaced when common diagnostic terms for psychosis are entered into a popular search engine and (2) rate the quality of these websites using a validated instrument (the DISCERN scale) and a purpose-developed checklist of content defined specifically for psychosis. It is anticipated that these results may be useful for clinicians to guide them in recommending high-quality websites to consumers and families experiencing psychotic disorders.

Methods

Measures of Website Quality

This paper uses an operational definition of website "quality" in accordance with the criteria employed by two website quality rating scales: the DISCERN scale [25] and the Psychosis Website Quality Checklist (PWQC) as described below. While the DISCERN scale is the most widely used instrument for evaluating health information websites for any health problem, it does not evaluate specific disorders. The PWQC was used to account for this.

The DISCERN Scale

The DISCERN tool [25] was developed to "enable patients and information providers to judge the quality of written information about treatment choices." The tool is freely available in conjunction with a web-based handbook [26] to evaluate internet-based health information. It rates website reliability, treatment options, and the quality of information with 16 items using a 5-point Likert scale across two subscales: Reliability (Is the publication reliable?) and Quality (How good is the quality of information on treatment choices?). The overall DISCERN scale is obtained by summing the first 15 items of the scale (range 15-75). While the DISCERN tool is useful for rendering the results of this study comparable to that of other studies evaluating web-based health information, it is not designed for evaluating the quality of specific disorders or treatment content.

The PWQC

A disorder-specific website quality checklist was based on the Bipolar Website Quality Checklist (BWQC) devised by Barnes et al [27]. The BWQC has high interrater reliability and a strong correlation with the DISCERN instrument. Five general BWQC subscales were replicated verbatim for the PWQC (see Multimedia Appendix 1):

- Credibility (7 items): is the website reputable, does it have clear quality markers?
- Currency (2 items): is the currency of the website clear?
- Objectivity (6 items): is the website clear about its aims, sponsorship, etc?
- Availability and Usability (4 items): is the website easy to navigate?
- Design and Aesthetics (2 items): are text and images presented in a clear way?

The sixth subscale was adapted from bipolar disorder–specific to schizophrenia-specific content. The Brief Psychiatric Rating Scale [28] and information derived from the Royal Australian and New Zealand College of Psychiatrists Clinical Practice Guidelines for Treatment of Schizophrenia and Related Disorders [29] were used as the basis for developing the 29-item disorder-specific subscale measuring Breadth and Accuracy of the diagnostic and treatment-related information on psychosis.

The individual PWQC items were on a 5-point Likert scale with defined anchor points (1=no, 3=partially, and 5=yes) with a total score ranging 50-250. A PWQC User Guide detailed descriptors of each item and was provided to all raters to enhance interrater reliability (see Multimedia Appendix 1).

General Website Characteristics

The general website characteristics assessed included reporting the presence of an editorial board, ownership type, and scope of information provided [27,30]. Websites were allocated by 2 authors (KW, CMH) to an organizational type: professional (not-for-profit sites associated with a government or professional body with demonstrated health professional involvement [31]), commercial (associated with a privately owned company, professional individual, or drug company for profit), or consumer (referred to as peer-to-peer online support group, forum, virtual community, social network, bulletin board, web-based discussion forum, or live chat room). Consumer organization websites have been evidenced in previous research to support consumers to feel more active as participants in their health care decisions, improve empowerment, and reduce societal loneliness [32].

Website Selection

The search terms "psychotic," "psychosis," "schizophrenia," "delusion," and "hallucination" were entered as a string into the search box for search engine Google. These were selected based on diagnostic terms used by psychiatrists in accordance with the Diagnostic and Statistical Manual of Mental Disorders, fifth edition [33]. Google was selected as the most highly used search engine, with over between 87%-89% of the search market share in the study period. The searches were carried out on a browser where cache, cookies, and browser history were cleared. In line with previous research, the inclusion criterion was that the website fell within the first 25 sites listed by the search engine [34]. Websites were excluded if they were either of the following: a personal blog, news or a media article, not in English, or a paid listing or advertisement. The websites were assessed at 2 time points (January-March 2014 and January-March 2018) by three raters. All identified websites were evaluated using both DISCERN and PWQC instruments. When sites were checked before the second set of assessors in 2018, only one (consumer) site no longer existed and was excluded (see Multimedia Appendix 2 for flowchart and Multimedia Appendix 3 for Results of the Google search of psychosis-related terms).

Raters

In total, 5 raters evaluated the websites. There were initially 3 raters, but owing to interest expressed by further raters, we repeated the exercise 4 years later. One author (KW) rated at

both time points to provide some evaluation of whether the websites returned by the search engine were similar at each time point. However, the second rating was carried out without reference to the previous rating. Raters at each time point included individuals with specialist mental health knowledge and general medical knowledge to ensure that a range of experience and expertise was captured. Thus, raters included a consultant psychiatrist (both time points), and either a clinical nurse consultant or psychiatry registrar and a final year medical student. The aim was to have raters with a capacity to appraise accuracy and quality of the clinical information but with different levels of expertise. All raters read the PWQC manual (see Multimedia Appendix 1) and the DISCERN handbook and evaluated the websites independently of each other. Consumers were not included as the evaluations of content required an ability to critically appraise the clinical information.

Statistical Analyses

Statistical analysis was conducted using SPSS (version 24; IBM Corp). Each rater's DISCERN and PWQC scores for each website were calculated as a mean score. For the primary analysis, the Pearson product-moment correlation coefficient was calculated to examine associations between DISCERN and PWQC total scores, and the interrater reliability for each scale was examined using intraclass correlation coefficients and calculated using the 2-way mixed model with consistency type. Two-tailed paired *t* tests were used to determine changes in mean scores on the DISCERN and PWQC instrument between time 1 (2014) and time 2 (2018). One-way analyses of variance were used to compare scores on the DISCERN and PWQC instruments by website ownership type (professional, commercial, or consumer organization).

Results

Websites Retrieved

Of the 25 websites described in Multimedia Appendix 3, a total of 9 were rated as commercial organizations (links to pharmaceutical companies or seeking referrals to private services or facilities), 11 as professional organizations (mainly aimed to provide information, often backed by a university or health service rather than relying on advertising or charitable grants), and 5 as consumer organizations. Consumer blogs by people who had lost a close family member or friend to mental illness were not included as they were not intended to provide information about the disorders.

A quality marker was associated with 10 of 25 (40%) websites and membership to a code of conduct with 12 (48%) websites, while 14 (56%) websites had an editorial or review process in place and 21 (84%) websites noted sources of information provided or gave references. There were no significant changes in DISCERN or PWQC scores between the 2 data collection time points. Therefore, data were combined for the remainder of the analyses.

Overview of the DISCERN Ratings

The mean DISCERN score was 43.96 (SD 12.08) (in Multimedia Appendix 4), which DISCERN scoring criteria categorize as being of "fair" quality (total score 39-50). The range of scores was 32-57, with the 8 lowest-ranking websites being of "poor" quality (total score 27-38) and 6 highest-ranking websites meeting the criteria for "good" quality (total score 51-62). No websites were rated as "excellent." The mean overall rating (DISCERN item 16) was 2.91 (SD 1.11) of a possible total of 5: the two highest websites received a mean rating of 4.

The intraclass correlation coefficients indicate moderate interrater reliability for Reliability subscale and Overall rating, and good interrater reliability for the Quality subscale and the Total DISCERN score. For each scale, the CIs were wide, suggesting that the true interrater reliability for the Reliability subscale and overall rating was "poor" to "good," and that of the Quality subscale was "moderate" to "excellent," and the DISCERN total score was "moderate" to "good." This reflects variability in the different raters' appraisal of each website, suggesting that while there were differences in the perception of each website's reliability, clarity, and sources of information, there was greater rater agreement on the quality of information provided.

Overview of the PWQC Ratings

The overall mean score on the PWQC was 147 of a possible 250 points (Multimedia Appendix 5). Websites were rated most highly on the "Availability and Usability" subscale, where on average, websites achieved 84% of highest possible score (16.82 of possible 20), followed by "Design and Aesthetics" and "Objectivity" subscales, achieving 70% and 64% (7/10 and 19/30) of total possible scores, respectively. Websites performed poorly on remaining subscales, achieving 51%-59% of the total possible score for "Credibility," "Currency," and "Breadth and Accuracy" (21/35, 5/10, and 78/145, respectively).

The intraclass correlation coefficients indicate that the interrater reliability for most subscales was "moderate" (0.50-0.75). The "Breadth and Accuracy" subscale achieved "good" interrater reliability, while the interrater reliability for "Availability and Usability" was "poor." However, considering the wide confidence intervals, the true interrater reliability for most subscales is likely to be in the range of "poor" to "good."

The mean scores for each PWQC subscale and the total DISCERN score were grouped in accordance with organization type of the site, as proposed by Griffiths and Christensen [30]. There was no difference in website quality by organization category, except for the "Design and Aesthetics" subscale, which revealed a significantly poorer rating for commercial sites than for professional or consumer sites (Multimedia Appendix 6). Websites with an editorial board or review process were rated significantly more highly on overall PWQC and DISCERN scales, and on Credibility and Currency subscales.

There was room for comments on the rating sheet and these included notes on the lack of mention of suicide, other risks, and lack of information about the importance of early intervention, particularly for first episodes.

Correlations Between the DISCERN and PWQC Instruments

The relationship between the mean total DISCERN and PWQC scores was investigated using the Pearson product-moment

correlation coefficient. Preliminary analyses were performed to ensure that no violation of assumptions of normality, linearity, and homoscedasticity was observed in the 2 scores. There was a strong positive correlation between the DISCERN and PWQC variables (r=0.85, P<.001). Indeed, although the top-ranking website on each scale was different, 9 of the top 10 websites on each scale were the same.

Discussion

Principal Findings

This paper aimed to identify and explore the quality of websites with psychosis-related content found through a common search engine. While psychosis-related websites were generally easy to identify using common search terms, the quality of websites was overall poor to moderate, with little evidence of change in quality over a 4-year period.

Quality of Websites

Relevant websites were easy to identify with a common search engine using general search terms related to psychosis, and the search results were consistent over time. The "fair" performance of websites in this study is largely consistent with that reported in previous research examining website quality related to other mental disorders. When developing the BWQC, Barnes et al [27] reported that the 15 websites they evaluated were "disappointing" in their performance on both the BWQC and DISCERN scales. Similarly, Nemoto et al [35] evaluated 37 websites with the DISCERN scale, mostly focusing on mood disorders, panic disorder, and schizophrenia, and concluded that the information provided was generally inadequate, with an overall mean score of 46 of 75. More recently, Rathod, et al [36] reported that only 8 of 27 depression websites focusing on depression scored well on the DISCERN scale, while an evaluation of 20 websites on perinatal anxiety Kirby et al [37] reported that all websites were ranked low to moderate on the DISCERN scale. The Health of Nations Code provides an ethical code for websites and is based on eight principles, which are included in the DISCERN scale categories [38]: authority, complementarity, privacy policy, attribution and date, justifiability, transparency, financial disclosure, and advertising policy.

Findings Related to Specific Psychosis-Related Topics

Another finding was the generic nature of the information available on the websites and the lack of information on areas associated with controversy, such as recreational drug use or coercive treatment. The risks and benefits of medication were not detailed, nor were the importance of physical health aspects of treatment.

The assessors had different levels of experience (by design), and the greater agreement over quality of the website than the actual content is consistent with this observation. While some websites mentioned families and carers, most websites did not provide families with much information that would be potentially helpful in their interactions with the family member experiencing psychosis or treating clinicians. Although avoiding contentious areas may be understandable, these areas may be precisely the topics that consumers and carers want to learn more about for themselves, and we suggest that websites could at least provide a series of questions for consumers and carers to ask the treating clinicians. More recently, some US clinical groups have produced lists of question prompt lists for consumers and their families in relevant areas (and are available through Google), which seems to be a productive initiative [39].

While people with psychosis are seeking web-based information, which can be helpful as supplementary information in collaborative planning with clinicians [18], few websites mentioned the importance of early intervention or approaches to maximize recovery and long-term outcomes. These approaches are now established practice in the treatment of psychosis by mental health services in Australia [3]. We found that the same websites tended to perform relatively well on both the DISCERN and PWQC scales, although the DISCERN scale is a general measure of health information websites, and the PWQC was more psychosis specific. This enabled us to produce a relatively consistent "top 10" websites that clinicians may recommend to consumers and families with a psychosis-related condition. This is consistent with the findings of Barnes et al [27] when evaluating depression-related websites. The better-performing websites tended to display an editorial board or review process, regardless of website ownership type, suggesting that these content control measures are better indicators of website quality than organization ownership. These sites tended to belong to professional organizations associated with a government or professional body, and professional websites have previously been found to contain better-quality information on other conditions such as depression in previous research [31]. There have been mixed findings regarding the importance of website ownership type, with some studies finding that websites owned by professional or charitable organizations were of higher quality [40] and others revealed no effect [41]. It is important to note that categorizing websites was not a straightforward process when allocating to just one category. For example, many nonprofit websites still contained paid advertising and links to commercial products. As web-based advertising increases and the internet continues to evolve, these categories of ownership type may be less meaningful than that when originally conceived.

Of particular concern were our findings that website quality did not improve much over time. Although there were some nonsignificant improvements in the presentation of information on the sites, there was little change in the quality of the content of psychosis-related websites over the 4-year period of the study. This is consistent with the findings of Walsh et al [42], who reported that almost half of depression websites did not update their content over a period of 7 years, prompting them to conclude that "the internet is used more than it is trusted." Considering the importance of the internet as a source of information for people with a mental illness, as well as for their friends and family, it is concerning that many websites do not appear to provide current or comprehensive information and tend not to address issues such as early symptoms of psychosis and suicide risk, which are topics that consumers may be seeking, particularly early in their condition [17], but we have sought to identify the "best available" websites for clinicians to recommend in clinical conversation about psychotic disorders.

Limitations

Although most Australians speak English, the researchers recognize the ever-increasing diversity within the Australian population and worldwide. The inclusion of only English-language psychosis websites within this paper is a limitation, with research of websites in other languages an area of future need. Secondly, the selection of raters from a health professional background was intentional but meant that there was no consumer involvement. We intend to further investigate the process by which consumers and carers assess and judge the quality of health-related internet-based information. Finally, the interrater reliability on some subscales of the DISCERN and PWQC instruments was low, which may have influenced the accuracy of the results. Anecdotally, a lot of the variability between raters came from the ease of navigating the site, with some raters reporting that some websites required a high number of "clicks" through various tabs or pages to find the desired content.

Conclusions

The internet can provide clinicians with information that can improve decision-making with consumers and their families, but accessing helpful information can be overwhelming. However, most sites generally avoid contentious areas related to addressing illicit drug use, weighing up risks and benefits of medication or the role of coercive treatment. Insufficient emphasis is placed on providing detailed information on early intervention and the importance of lifestyle modifications, such as exercise programs or how families and friends can contribute. This is likely to be the very information that consumers and carers are seeking and thus contributes to the unmet needs of this group.

While higher-quality websites exist, there is generally no easy way to assess this on face value, as common markers such as website ownership type are not always associated with the breadth or reliability of information available. Generally, sites providing evidence of their editorial process were the most helpful. There remains significant room for improvement in website quality; however, through our review process, we were able to rank websites consistently on 2 quality scales, thereby producing a resource that may guide professionals when recommending web-based resources to consumers and carers. Our findings indicate a need for health care providers and government agencies to address the issues of poor quality, keeping information current and providing prompts about how to address more controversial areas to be available to consumers and carers.

Acknowledgments

We acknowledge Philippa Lennox (medical student at the University of New South Wales) for carrying out website appraisal in the 2014 round, Larissa Collins for data management and the initial literature review, and Andrea Millar for general administration. We would like to thank Lisa Robins, Joanna Crawford, Therese Fletcher, and Victoria Malone for work on guidelines for website ratings.

Abstract

Digital health–enabled community-centered care (D-CCC) represents a pioneering vision for the future of community-centered care. D-CCC aims to support and amplify the digital footprint of community health workers through a novel artificial intelligence–enabled closed-loop digital health platform designed for, and with, community health workers. By focusing digitalization at the level of the community health worker, D-CCC enables more timely, supported, and individualized community health worker–delivered interventions. D-CCC has the potential to move community-centered care into an expanded, digitally interconnected, and collaborative community-centered health and social care ecosystem of the future, grounded within a robust and digitally empowered community health workforce.

KEYWORDS

digital health; community-centered care; community health worker; artificial intelligence; AI; AI-enabled health delivery; eHealth; individualized delivery; interventions; collaborative health; community health; social care; digital empowerment; mobile phone

Introduction

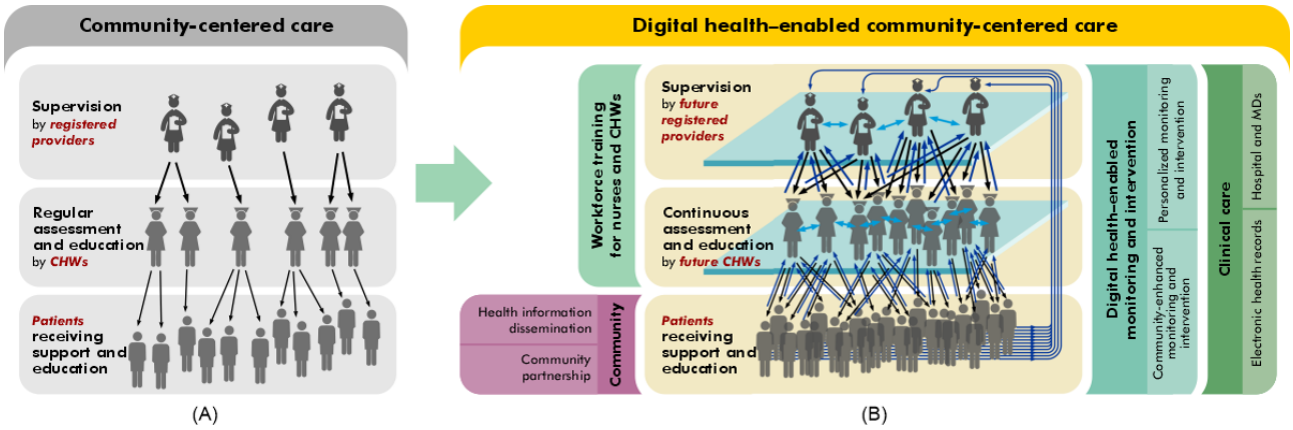
Background

Recent global health trends are necessitating a shift away from a patient-centered medical care system to an upstream health promotion approach that meets the health and social needs of individuals in the communities where they live [1]. A community-centered health and social care ecosystem, supported by a robust community health worker (CHW) workforce, aligns with this needed paradigm shift [1]. Throughout the United States, states are looking to build their CHW workforces and launch CHW initiatives as an alternative assistance to registered health care professionals to extend the reach of home-delivered services [2,3]. Recent data from the California Employment Development Department, for example, project that an additional 200,000 CHWs will be needed by 2024 to maintain current levels of coverage for home care services [4]. As the COVID-19 pandemic continues to amplify health and social support needs globally, a *rapid expansion of the* CHW *footprint is critically needed* to prevent unmet needs from escalating into expensive medical crises, particularly in vulnerable communities [5].

However, scaling the current community-centered care (CCC) model (Figure 1A) in a cost-effective manner while preserving the highly contextual and individualized care delivered by CHWs remains challenging. Increasing use of digital technologies within the CCC model demonstrate potential to expand the CHW footprint; however, existing digital technologies lack integration. In this paper, we present digital

health–enabled CCC (D-CCC) as an improved model to move CCC into the future. Through integrating future digital health technologies, the future CHW workforce, and the future health and social care needs of communities, D-CCC aims to connect the most vulnerable individuals within communities to needed health and social services.

Figure 1. (A) The current community-centered care model. (B) The proposed digital health–enabled community-centered care model. CHW: community health worker; MD: medical doctor.



CHWs as Vital Bridges

CHWs are lay members of the community whose in-depth understanding of community culture and language uniquely positions them to provide culturally appropriate health-related services and support to the community [6]. Through shared lived experience and deep familiarity with social networks and community resources, CHWs serve as vital bridges between vulnerable communities and health systems, connecting community members to critical information, resources, and services [6,7].

CHWs work in a variety of settings—from nonprofit community-based organizations to government agencies and health care systems [7,8]—and range from formal, salaried employees to informal, volunteer-based community educators [9,10]. Just as the activities and roles of CHWs are tailored to the unique health needs of the communities they serve [11], CHWs operate under a diverse set of titles, including but not limited to *promotoras*, community lay workers, outreach educators, peer support workers, home visitors, and community health volunteers [12]. In this paper we use *CHW* as an umbrella term intended to broadly capture the rich diversity of roles and titles held by this vital frontline workforce [6].

As trusted members of the community, CHWs are critically positioned to support vulnerable patient populations [13] and serve as agents of change by helping to reduce health disparities in underserved communities [14]. Documented positive impacts of CHWs include health promotion, improved patient engagement, support with adherence to treatment, improved referrals and access to care, financial return on investment, and improved quality of care and health outcomes [7]. CHW-delivered sociobehavioral interventions have demonstrated efficacy in improving health outcomes in chronic disease and noncommunicable disease (NCD) care and management [15], including cancer [16], diabetes [17-23], asthma [24,25], cardiovascular disease [26], multiple medical comorbidities [27], and mental health [28,29]. CHW-delivered interventions have demonstrated efficacy in reducing hospitalization and rehospitalization rates [27,30-32], and CHWs have proven to be powerful drivers of decreased health care costs, particularly among patients with high starting health care costs and underserved and minority populations [15,17,33,34]. The efficacy of CHWs lies in their close connection to the community, ability to influence client behaviors, and effective interaction with the larger health care team [34-36].

Recent global health trends (including the growing burden of chronic diseases and NCDs), a focus on social determinants of health and health equity, and lessons learned from the COVID-19 pandemic are necessitating a shift away from a patient-centered medical care system toward an upstream health promotion approach that meets the health and social needs of individuals in the communities where they live [1]. In place of the traditionally siloed existence of medicine, public health, and mental health [37], a community-centered health and social care ecosystem, *supported by a robust* CHW *workforce*, will be critical to realizing this shift [1] and preventing unmet needs from escalating into expensive medical crises [5].

The Current Use of Digital Technologies in CCC

Overview

Most CHWs operate within a facility-based CCC model (Figure 1A) [38]. Under the CCC model, a relatively smaller number of facility-based supervisors (most often registered health care professionals such as public health nurses, midwives, and community health officers) [38] supervise a relatively larger number of CHWs who, in turn, provide culturally tailored, language-appropriate, and individualized care to a yet larger number of clients. Although this *pyramidal* care model has demonstrated improved health outcomes and cost savings [27,32], scaling this model in a cost-effective manner while preserving the highly contextual and individually tailored care provided by CHWs remains challenging. Facility-based supervisors who themselves typically shoulder a heavy workload may additionally lack the time needed to provide supportive supervision to CHWs [38], resulting in lower quality of supervision [39] and strained CHW-supervisor relationships

[40]. However, the recent incorporation of digital health technologies into the existing CCC model is demonstrating potential for expanding the CHW footprint and improving CHW support and supervision. Existing digital technologies are discussed in the following section.

Current Digital Technologies Used in CCC

The use of digital technologies has recently been increasing among CCC organizations and is demonstrating potential to enhance CHWs' reach and diffusion of health information within communities [6,41,42]. In their scoping review of the use of mobile health (mHealth) technologies and interventions among CHWs globally, Early et al [6] highlighted some key benefits and challenges. Benefits included promotion of health equity; reduced time to diagnosis; extension of health information and services to diverse areas; improved adherence to treatment plans; increased self-efficacy of patients and CHWs; and improved attitudes of, and toward, CHWs and their role [6]. Challenges included a lack of evaluation of mHealth outcomes; development of mHealth tools and apps without cultural relevance; lack of access to, and knowledge of, mobile technologies within communities; need for effective training for CHWs to adopt mHealth tools; and need for improved communication among health care teams working with CHWs [6]. Similarly, in their narrative review of the literature, Mishra et al [11] identified key benefits and challenges to incorporating digitalization into CHW practice. Benefits included improved access and quality of services, increased efficiency in training and personnel management, and leveraging of data generated across grassroots platforms to further research and evaluation [11]. Challenges included funding for CHW programs; digital health literacy of CHWs; and systemic challenges related to motivating CHWs, including adequate CHW supervision [11].

Digital platforms currently used by CHWs within CCC-based organizations include mobile-based networking devices, web applications, videoconference, and mobile apps [11]. CHWs may use mobile phones, tablets, and other digital devices [43] in a task-specific manner (eg, digital blood pressure [BP] monitoring devices, glucometers, and spirometers) [11,44]. Digital alerts, reminders, notifications, checklists, and decision support tools may be used to facilitate compliance with protocols and improve the quality of CHW-delivered care [11,45]. In addition, although continuous monitoring of physiological parameters (eg, heart rate) has typically been available only in clinical settings because of the need for special equipment and medical expertise, the development of relatively low-cost, nonintrusive sensors present increased opportunities to enable ubiquitous home monitoring of clients' health and well-being. Current remote sensors distributed and managed by CHWs enable remote monitoring of electrocardiogram (ECG; eg, KardiaMobile [AliveCor]), BP (eg, Evolv [Omron]), blood glucose level, and physical activity [11]. Digital platforms are also being used to facilitate and augment CHW training and supervision [11,46,47] and to provide electronic decision support [11]. Digital platforms that support CHW-CHW communication and collaboration (eg, informal groups and learning networks [48-52]) may provide positive psychological benefits to care workers [50] as well as enable CHWs to exchange information and pose questions to peers [11,53]. Digitalization also presents increasing opportunities for data collection and analysis [11], allowing for critically needed outcome evaluation of CHW-delivered interventions and increasing opportunities for key CHW-focused policy advocacy. However, large-scale data acquisition, preprocessing, and validation for intelligent decision-making remain key challenges with existing methods. Limitations with current approaches are discussed in the following section.

Limitations of the Current Approaches

Although current digital technologies are demonstrating the potential to strengthen CHW capacity and quality of care [54-56], existing digital technologies targeted for use by CHWs lack integration. The current lack of ubiquitous, closed-loop monitoring and intervention within the CCC model restricts technologies used by CHWs to a passive, episodic, and reactive approach to client monitoring, education, and supportive care. CHWs engaged in NCD management and monitoring, for example, may typically provide infrequent (eg, monthly) home visits and rely on their own episodic observations and client-reported symptoms to inform care, direct education, or make referral decisions. However, direct CHW observation and client reporting of symptoms reveal only episodic snapshots of overall client physical and mental health and lifestyle. Under the CCC model, CHWs rely upon accurate reporting of health symptoms by the client or client caregivers (typically family members) [57] and must also rapidly synthesize their own observations with this information to decide an appropriate course of action (eg, educate, refer, recheck, or call for immediate medical assistance). This places a large burden of responsibility on the CHW, who must synthesize a large amount of information in a short span of time, as well as on the client or caregiver, who must accurately and honestly appraise and report their experiences to the CHW [57]. An integrated, intelligent, and automated closed-loop platform may improve upon this current model of care while maximally amplifying and expanding the CHW footprint within communities.

A New Model: D-CCC

Overview

We propose D-CCC as an improved model to move CCC into the future. Design conceptualization for the D-CCC model reflects a multidisciplinary collaboration among nursing, computer science, engineering, and human-computer interaction experts composing the D-CCC team. D-CCC constitutes a novel integrated, intelligent, and automated closed-loop technology platform designed for, and with, CHWs. By targeting the human-technology partnership at the level of the CHW, D-CCC aims to amplify human connection and collaboration while maximally expanding the CHW footprint within communities. By including development of personal models unique to each client, holistically represented within a high-dimensional cover of multiple knowledge layers, D-CCC additionally allows for an increased level of contextual and individualized care delivered by CHWs.

The D-CCC Model

The D-CCC model transforms manual and restricted aspects of CHW work into a scalable, digital, and intelligently automated space. By expanding CHW-client communication and CHW collaboration, supervision, and support, D-CCC aims to increase the quality of services delivered, in terms of personalization, cultural appropriateness, and timeliness. Through smart supervision, D-CCC may enable CCC organizations to employ and supervise a larger group of CHWs with the same number of CHW supervisors. A central aim of the D-CCC model is to expand the CHW footprint by enabling CHWs to serve a larger volume of clients or to provide more services to each client while critically striving to avoid increasing undue burden on this vital frontline workforce. Through automation of manual tasks; improved communication and connections between CHWs and clients, among CHWs, and between CHWs and supervisors; and increased modalities for ongoing education and training, D-CCC also aims to empower CHWs and improve worker experience.

Figure 1A illustrates the current CCC model. This model lacks integrated digitalization among *tiers* of care delivery and is additionally limited by unilateral communication and poor scalability. In comparison, Figure 1B illustrates the D-CCC model, which addresses these limitations and amplifies the CHW footprint by increasing CHW-client, CHW-CHW, and CHW-supervisor communication and collaboration. D-CCC constitutes a human-technology partnership integrating CHWs, supervisors, and clients through a scalable digital medium and aims to improve the efficiency and quality of care delivery. Through an intelligent and scalable artificial intelligence (AI) loop, D-CCC brings critical stakeholders under a unified communication, collaboration, education and training, and care delivery model.

D-CCC's AI-Enabled Closed-loop Health Platform

As CHWs occupy a variety of roles within communities and as CHW-delivered interventions and target outcomes vary according to the client populations served, a *one-size-fits-all* platform design will not be successful in empowering this diverse frontline workforce. D-CCC design must therefore be modular and allow for ongoing adaptability and flexibility. As cultural and contextual needs will vary according to the populations served, D-CCC design must also allow for portability across diverse communities, including translation and transferability to different languages spoken in local communities.

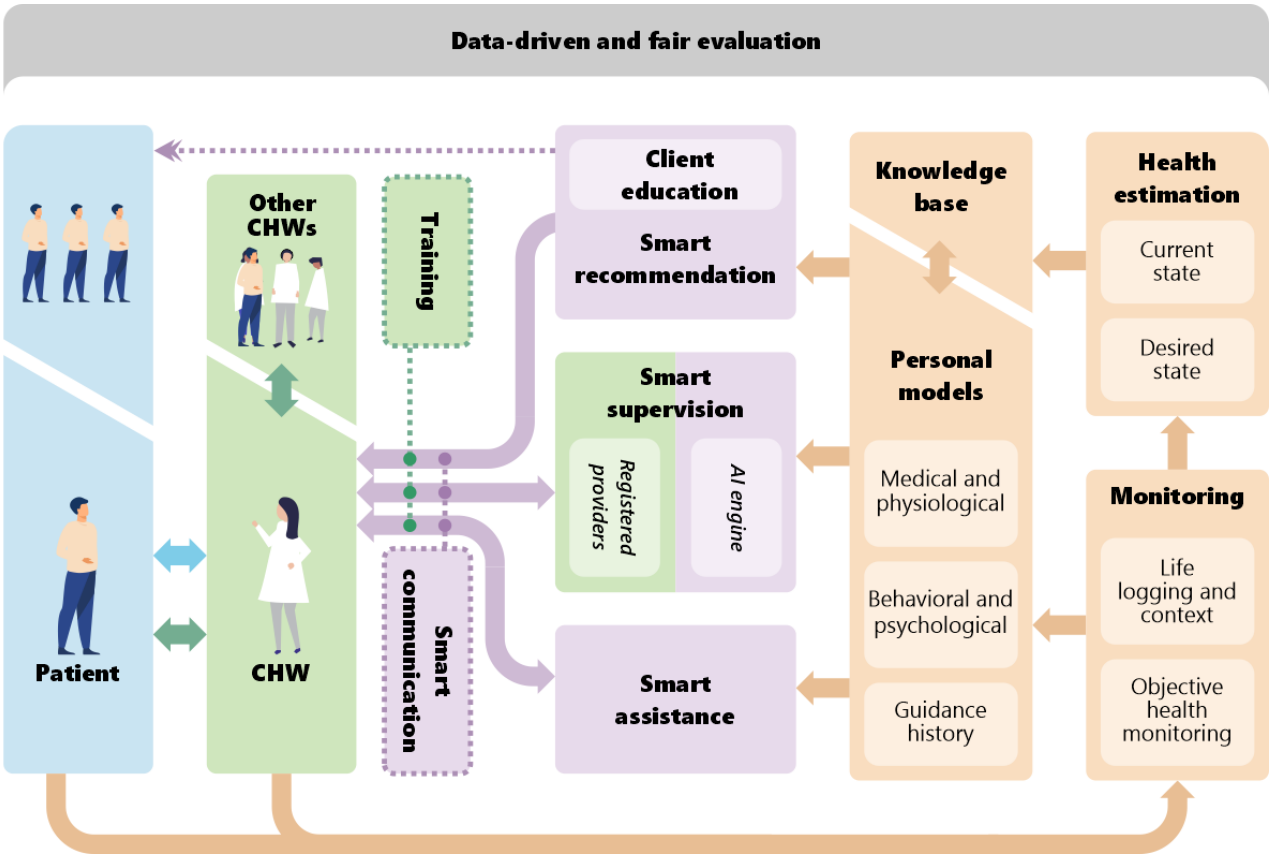
The D-CCC platform is designed to meet the diverse needs of different stakeholders, including clients, CHWs, and registered providers (RPs), and to handle diverse aspects such as communication among stakeholders, data collection and analysis, training and education, and autonomous and intelligent decision-making.

The D-CCC platform design is built on the following modules:

1. Multichannel stakeholders module: This module comprises the stakeholders who are interacting through different communication channels (including client-CHW, CHW-CHW, and CHW-supervisor) and enables the smart communication aspects of D-CCC.
2. Monitoring module: This module enables continuous monitoring and updating of physiological and contextual information collected both subjectively and objectively.
3. Health estimation module: This module enables ongoing analysis of the data collected from clients (through the monitor module, CHWs, and medical history) to determine client health status in real time.
4. Knowledge base module: This module manages the storage, access, and retrieval of built knowledge based upon data collected from clients, CHWs, and supervisors to enable personalized model building.
5. Personal models module: This module builds cognitive learning models from client physiological and contextual data to provide autonomous intelligent decisions for intervention recommendations individually tailored for each client.
6. Smart recommendation module: This module autonomously predicts appropriate health care and lifestyle recommendations for clients leveraging their personalized models. Recommendations may be delivered to CHWs or directly to clients, according to context and risk level.
7. Smart supervision module: This module supports RPs in supervising CHWs in specific areas determined through automating repetitive tasks and reflecting on personal models and the knowledge base.
8. Smart assistance module: This module improves quality of health care services by supporting CHWs making interventional, educational, or procedural decisions in the field.
9. Smart training module: This module provides training for CHWs to learn new digital technologies and enables web-based training modules to augment traditional, in-person methods of CHW training and education.

As shown in Figure 2, D-CCC's AI-enabled platform critically integrates these modules to create a holistic and data-driven approach to connect clients, CHWs, and supervisors in a continuous loop of measurement, estimation, guidance, and influence. Each module is further described in the following sections.

Figure 2. The digital health–enabled community-centered care model's artificial intelligence (AI)-enabled cybernetic platform. CHW: community health worker.



Multichannel Stakeholders Module

The D-CCC model critically enables multi-way communication among key stakeholders involved in CCC delivery networks through digital communication channels. Figure 2 shows the different combinations of multi-way communication channels among clients, CHWs, and supervisors, which can be further classified into the following communication channels:

1. Client-CHW channel: This is the point of communication between clients and CHWs. As a baseline, each client is assigned a CHW who is responsible for providing community health-related services. Traditionally, the client-CHW interaction is scheduled over fixed time windows or on demand, subject to the client's needs. D-CCC transforms this into a continuous interaction, and the digital communication medium may be made available to all clients served.
2. CHW-supervisor channel: This is the point of communication between CHWs and supervisors. As a baseline, each CHW has a supervisor assigned for supervision and feedback. As service delivery demands change, CHW supervision can be extended to include additional supervisors (eg, RPs) with expertise in different areas of care. D-CCC transforms CHW supervision to an on-demand, real-time interaction through the digital medium.
3. CHW-CHW channel: This is the point of communication among CHWs. Communication and collaboration among CHWs promote knowledge transfer and exchange of information, which may be adapted to different community-specific challenges as needed. D-CCC transforms CHW-CHW communication into an on-demand, real-time interaction through the digital medium.

Monitoring Module

This module is responsible for continuous monitoring of client physiological signs, contextual information, lifelogs, surveys, and ecological momentary assessments. State-of-the-art wearable (eg, smart rings, watches, and patches), portable (eg, smart ECG sensors, stethoscopes, and BP monitors) and stationary sensors (eg, smart beds and fall detection cameras) as well as mHealth (smartphone-based) solutions enable ubiquitous monitoring. D-CCC transforms the current landscape of disparately monitored parameters by providing a central collection point from which subsequent data integration and synthesis enable provision of smart recommendations and assistance to key stakeholders.

Health Estimation Module

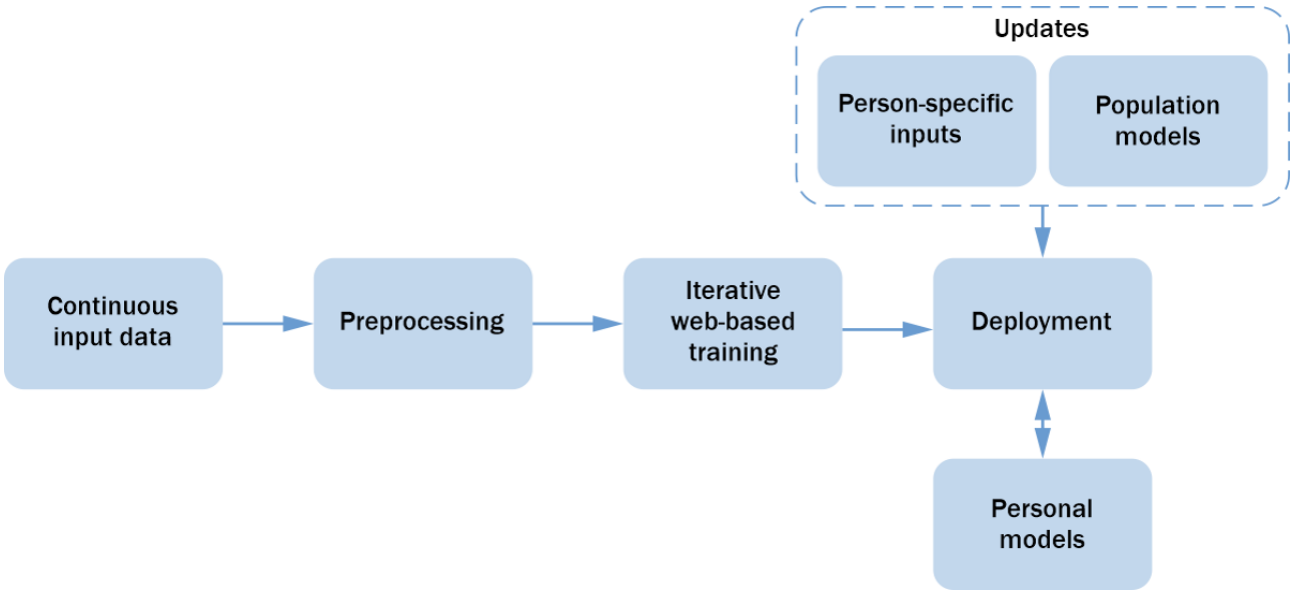
This module is responsible for determining the health status of the client. High-dimensional and holistic information collected and processed by this module identifies the client health state in real time. Each client is unique and presents multiple possibilities of health states. A key functionality of this module is to process different modalities to properly estimate health variables in different dimensions. For each client, this module holds a health status that is deemed to be safe, termed the client's *desired state*. This module continuously estimates the current state (ie, client's current health status) and compares the current state with the desired state to estimate the overall health safety

of the client. Client health status as determined by this module assists in building personal models and guides decision-making by recommendation engines.

Knowledge Base Module

This module consists of CCC-related facts, information, and skills acquired through past experience of different stakeholders (CHWs, supervisors, and clients), as well as theoretical or practical knowledge available in the CCC field. This module continuously learns and updates its knowledge based on new inputs extracted from the data generated by the entire pool of clients, CHWs, and supervisors. The knowledge base formulates knowledge graphs that represent different meaningful connections between cause-action pairs to develop a general consensus. For example, specific readings in physiological data can be connected to specific health criticality. The knowledge graphs will form the basis for developing population models that guide personal model development. Thus, the knowledge base implicitly enables reuse of key insights from a specific individual to develop comprehensive personal models for other individuals. Figure 3 illustrates the pipeline of deploying a generic learning analytics model, which can be updated with person-specific information to generate personalized models. Each client's data include physiological parameters monitored continuously and contextual information associated with each instance of lifelogging, as well as intervention procedures performed in the past and health estimation logs. Each CHW's data include the list of assigned clients, log of interventions performed per client, and effectiveness of these interventions, as well as supervision and training provided by supervisors. This module guides the building of learning analytics and cognitive models in the subsequent modules.

Figure 3. Deployment pipeline for personalized models.



Personal Models Module

This module builds analytical models for intelligent decision-making tailored to a specific individual based on a *predictive, preventive, personalized, and participatory* (P4) [58] approach to health care. The P4 approach holds that each individual constitutes a biological system that responds differently to different inputs [58]. To build an approach that makes P4 a persistent action to guide CHWs and clients, it is important to estimate and build a personal model of each client. In many areas relevant to personalization, a model is built by collecting data in the context of the application. Examples of this approach include Google, Facebook, Amazon, and Netflix, which generate personalized recommendations using models built for each individual when they interact with different applications on the platforms. The D-CCC personal models module relies on the physiological parameters, context, and health status data of each client collected by the monitoring module and the health estimation module. A variety of methods, such as machine learning, can be used for data analysis and cognitive modeling for autonomous decision-making. Figure 3 shows the deployment pipeline of individual learning models and person-specific input data to generate personal models. In the preprocessing phase, input data from different modalities are filtered to remove noisy components and motion artifacts. We use collaborative filtering to handle missing values from the data set of a specific modality by complementing the missing data with insightful information from other modalities. In the iterative web-based training phase, each modality of input data sets is used to train a suitable learning model that fits the corresponding modality. The trained models that are deployed in the initial phase are continuously updated with the iterative web-based training. From the knowledge base, we also create population models that contain heuristics to formulate rules for updating trained models with generalized person-specific inputs. As we collect person-specific data, the trained models are updated with these person-specific inputs to generate the personal models. The personal models are updated with new person-specific inputs every 6 months. As shown in Figure 2, we divide personalized modeling into three submodules, as described in the following paragraphs:

1. Medical and physiological profile: This submodule builds a personalized medical and physiological model for each client from the physiological data and health status estimate. This creates a baseline for each client's health status and

provides an intuition on determining the relative health safety under the current conditions. For example, although two clients, A and B, may have a history of the same condition, the specific health status of client A can be perceived as more alarming than that of client B based upon their personalized medical and physiological profiles.

2. Behavioral and psychological profile: This submodule builds a personalized behavioral and psychological model for each client from contextual data. This creates an insightful perspective on each client's health status and their response to interventions under specific circumstances. For example, a situation where two clients, A and B, have the same health status but different contexts would call for different intervention responses (eg, education or referral procedures). This allows CHWs to choose among actions that are customized to both the client's physiological status and their context.
3. Guidance history: This submodule logs the past health conditions of a client along with their contexts, the responsive intervention procedures imposed under each context, and the response of the client to each intervention use case. This allows for development of a baseline understanding for CHWs to decide on appropriate action in the current scenario. Given the history of interaction and guidance provided by CHWs in the past under similar situations, decisions on an improvised intervention or on reusing a previously successful intervention can be made.

We use multimodal data fusion strategy to combine the results from each of the aforementioned modalities of personal models. Data fusion improves the prediction accuracy of the personal models, particularly in instances where input data are missing from specific modalities.

Smart Recommendation Module

This module delivers autonomous health recommendations to clients and/or CHWs based on risk level and recommendation type. D-CCC combines each client's physiological and contextual data from the knowledge base module and personal models module to build smart recommendation systems. Smart recommendation is a proactive strategy to promote client self-management and improve quality of life, particularly in less-acute scenarios (eg, recommendations related to diet, physical activity, sleep, stress, and medication reminders). Smart recommendations sent to clients target everyday health maintenance and education regarding healthy life choices. This module infers to the cognitive and analytical models from the personal models module to make autonomous recommendations. The autonomous recommender primarily aims to bridge the gap between the increasing number of clients in need and the relatively lower number of CHWs and RPs and is based upon the acuity of client condition. Recommendations are also sent out to the responsible CHW to synchronize the information flow. The decision regarding whether a recommendation is delivered directly to the CHW, directly to the client, or delivered through the CHW to the client depends on the settings and recommendation type. For instance, some client populations (eg, older adults) with less access to, or comfort using, smartphones may prefer to receive recommendations through their CHWs, whereas other client populations (eg, pregnant women) with greater access to, or comfort using, smartphones may prefer to receive health promotion recommendations directly. This module adds a layer of cyber health care service delivery to D-CCC, enabling safe and timely interventions for different clients with varied needs.

Smart Supervision Module

This module automates workflow between supervisors (eg, RPs) and CHWs to improve supervision efficiency both qualitatively and quantitatively. There is a need for ongoing CHW-supervisor interaction for evaluation, feedback, and support. Under the current CCC model, supervisors manually organize supervisory tasks with different CHWs. D-CCC enables automated supervision support using AI models. Each CHW handling multiple clients in different contexts presents each RP with different supervisory challenges. The personal models module and knowledge base module contain cognitive analytical models about different clients. The smart supervision module integrates these personalized models into an AI engine that serves as the oracle to supervisors. This allows supervisors to hone their attention to specific issues that each individual CHW may have while accessing the collective record of clients specific to that CHW. In addition, enabling a common and more complete understanding of the clients' contexts may enable interactions between RPs and CHWs to become more qualitative while reducing overhead time. Supervisors may additionally choose to automate trivial repetitive tasks, allowing them to supervise a larger number of CHWs or provide more personal support and mentorship to an existing cadre of CHWs. Multi-way communication among CHWs and supervisors additionally allows for a range of choices to match supervision requirements of CHWs to expertise of the RPs. Effective supervision is an essential element of CHW programs [38]. Through improving CHW support and enabling more holistic CHW-supervisor interaction, D-CCC may enable scalability of CHW supervision strategies, leading to improved productivity, care delivery, and worker satisfaction.

Smart Assistance Module

This module supports CHWs to deliver continuous high-quality care services in the field, particularly in scenarios where CHWs may have limited access to resources. Applying intervention procedural knowledge for clients with diverse contexts can be challenging for CHWs in the field, and D-CCC supports CHWs to make client-specific decisions using personalized models. Smart assistance is a reactive and on-demand service intended to handle acute scenarios that may enhance decision-making of CHWs in the field when they do not have immediate access to supervisors; one approach includes implementing customized chatbots used by CHWs in real time to provide appropriate decisions regarding client care (eg, education, CHW-delivered intervention, and referral). This may be particularly useful when supervisors are not accessible or when CHWs encounter a situation with which they have limited expertise. Chatbots use natural language processing to parse textual information provided by CHWs to make sense of the client care situation. This module accesses the client's medical and physiological profile, behavioral and psychological profile, and previous history of CHW assistance provided from the knowledge base.

This module identifies the specific client and infers the client's personalized model to make autonomous decisions regarding CHW-delivered care.

Smart Training Module

This module enables ongoing training for CHWs to learn new digital technologies and augments traditional methods of CHW training and education for connected web-based and blended learning methods. Key challenges identified in the literature regarding current use of digital technologies include CHW digital health literacy [11] and the need for effective training for CHWs to adopt digital tools [6]. This module integrates ongoing CHW digital health training and provides CHWs with an automated technology *help desk* for ongoing additional assistance as needed. This module additionally augments traditional, in-person CHW training by providing ongoing case-based digital learning modules, which may be assigned by CHW supervisors and completed by CHWs in an independent and self-paced manner.

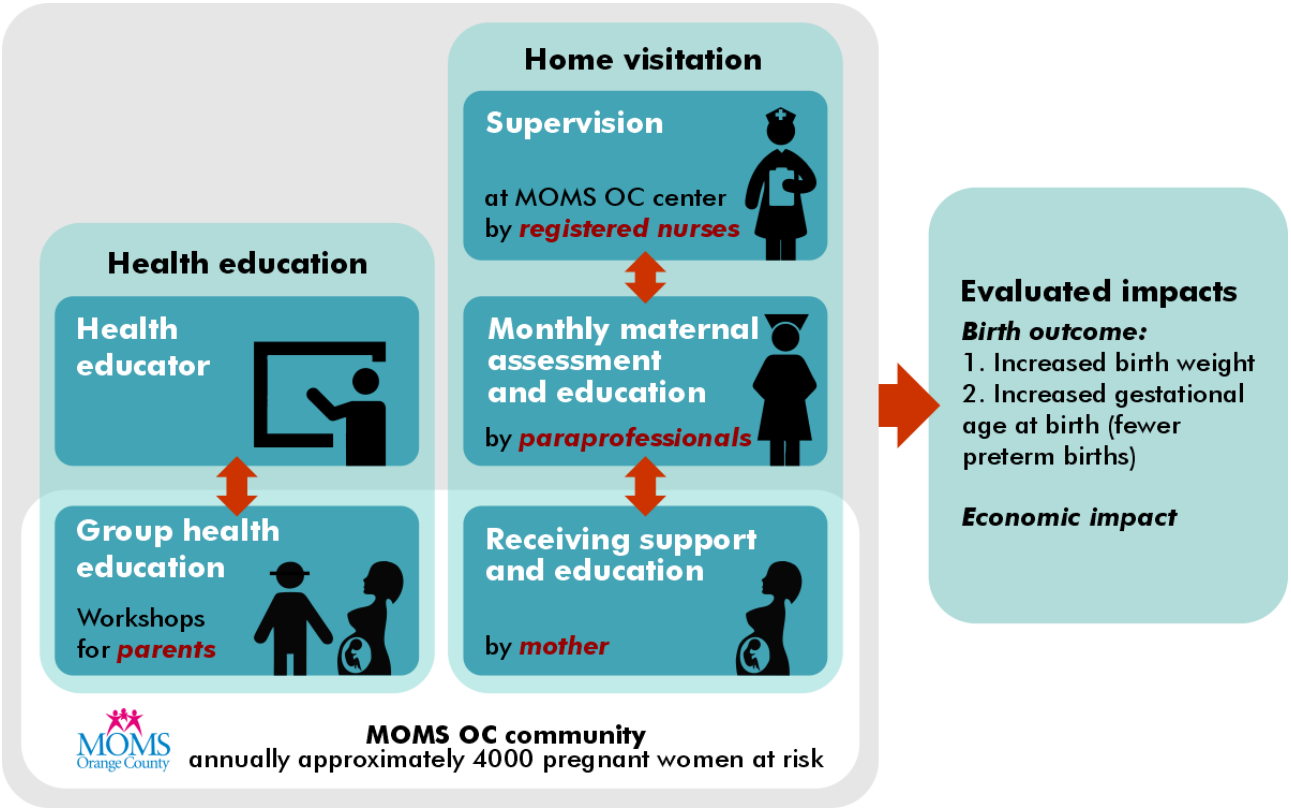
Case Study: Smart, Connected, and Coordinated Maternal Care for Underserved Communities

The D-CCC model is currently being piloted with community partner site MOMS Orange County (MOMS OC) [59]. We outline this proof-of-concept case study in the following sections.

MOMS Orange County

Registered nurse (RN)-delivered home visits for at-risk pregnant women became infeasible in the early 1990s in Orange County, California, because of the county's financial constraints. In response to the county's maternity care crisis, MOMS OC [59] was founded. MOMS OC is a nonprofit organization implementing a CCC model (Figure 4) for maternal care (MC) delivery. MOMS OC's CCC model is a CHW-delivered care coordination and home visitation program wherein RNs supervise and train CHWs, who in turn provide culturally and linguistically appropriate services, conduct home visits, and deliver group education to pregnant women considered to be at low to moderate risk and served by MOMS OC.

Figure 4. MOMS OC (Orange County) community-centered care model.



The MOMS OC CCC model has demonstrated cost efficiency [60] and improved birth outcomes [61]. However, it remains limited by barriers and gaps common to CCC models, which presents opportunities for the incorporation of technology. Barriers and gaps applicable to MOMS OC include the following:

1. *Limitations regarding outreach* using traditional mechanisms (eg, word of mouth, telephone calls, and advertisements), particularly among disadvantaged communities. This presents opportunities for technology-enabled community outreach.
2. *Limitations regarding timely intervention*, including early MC and education. This presents opportunities for new community-driven intervention enablement assisted by digital and social media.
3. *Limitations regarding monitoring* because infrequent CHW home visits (typically conducted monthly) and clients'

self-reported screenings both reveal only a snapshot of each woman's physical and mental health and lifestyle. This presents opportunities for incorporation of low-cost, nonintrusive wearable devices to enable ubiquitous monitoring.

4. *Limitations regarding communication among MC providers*, with CHWs typically unable to access health data stored as electronic health records and MC providers typically unable to easily access information collected by CHWs. This presents opportunities for networking, smart data mining, and community-enhanced recommendation systems.

A D-CCC Pilot Community Engagement Model for MC

Identifying opportunities for D-CCC to overcome these gaps and improve the quality of care delivered, we partnered with MOMS OC to launch Smart, Connected, and Coordinated Maternal Care for Underserved Communities (UNITE) [62], a D-CCC pilot community engagement model for MC that is smart (deploying ubiquitous monitoring and lifelogging), connected (bringing together a diverse cast of community members, including clients, families, RPs, and community resources), and coordinated (using technology to proactively reach out to the community and deliver personalized interventions and education for each client).

UNITE deploys technology-enhanced community care coordination and education coupled with a human-in-the-loop monitoring and intervention system to (1) proactively reach out to the community (pregnant women, families, and friends); (2) provide valuable personalized and community-enhanced information for CHWs and RNs to provide tailored support according to individual needs; and (3) combine fine-grained and personalized information together with monitoring and intervention and community outreach and education to promote healthier lifestyles for pregnant women through self-management.

UNITE leverages emerging technologies such as Wearable Internet of Things, community-enhanced learning and recommendation, big data analytics, context recognition, lifelogging, and social media, as well as a multidisciplinary partnership to bring connectivity, integration, and smartness to MOMS OC's existing CCC model. UNITE also brings ubiquitous monitoring, open information sharing, and community-enhanced personalized intervention and education to MOMS OC's CCC model. UNITE aims to strengthen connectivity among stakeholders and to improve connection and coordination across providers and agencies focused on pre- and postnatal health.

Through lifelogging, context recognition, and health monitoring, UNITE builds a holistic digital phenotype of participants using multimodal data capture. Smart mining algorithms are designed for cause assessment through personalized models. Maternal self-management is improved and incentivized through personalized community-enhanced recommendation systems and technology-enhanced community care coordination and education. The core components of the UNITE model are ubiquitous monitoring and a recommendation system capable of dynamically supporting a healthy lifestyle of enrolled women during and after pregnancy. UNITE recognizes how community-specific factors pertaining to each client enhance individual monitoring and interventions and enable more personalized recommendations to motivate better self-management. UNITE thus integrates culture- and context-sensitive mechanisms to enhance technology acceptance for improved maternal self-management and enhances connection and coordination with CHWs and other care providers and agencies focused on improving pre- and postnatal maternal health.

As part of the UNITE project, a proof-of-concept version of the AI-enabled closed-loop D-CCC platform has been implemented whereby a Wearable Internet of Things–based health-monitoring flexible and adaptable platform enables seamless capture of sensory data streams (using wearables and smartphones) and self-reported data from participants (using questionnaires and ecological momentary assessments). UNITE's dashboard allows for interaction between CHWs and the enrolled women, provides visualization and interaction with the backend system, and performs sophisticated analytics and data mining to build a holistic personal model of each participant. Each personal model combines physical and psychosocial data capture to generate feedback and recommendations to the enrolled women, their CHWs, and the CHW supervisors, as well as to other health providers with the goal of promoting healthy pregnancy outcomes.

An exemplar intervention delivered through the UNITE platform's closed-loop system is a home-based safe exercise program overseen remotely by CHWs [63]. This evidence-based exercise program, designed using the pregnancy and postpartum exercise guidelines provided by the American College of Obstetricians and Gynecologists, includes strength movement, aerobic movement, and mindful breathing. UNITE's real-time monitoring of intensity and duration of exercise using wearables (eg, by measuring heart rate elevation, maximum oxygen uptake [VO_{2max}], respiratory rate, and ratings of perceived exertion) critically enables individualization of the intervention as well as safety monitoring throughout the exercise program.

Completion of the UNITE pilot study will yield critical information regarding feasibility and user (client, CHW, supervisor, and RP) experience as well as effects on health outcomes, including cardiovascular response, sleep, physical activity, self-reported stress, depression, and anxiety.

Discussion

D-CCC as an Improved Model to Move CCC Into the Future

As current global health trends necessitate a shift away from a patient-centered medical care system to an upstream health promotion approach that meets the health and social needs of individuals in their communities, a community-centered health and social care ecosystem, supported by a robust and digitally connected CHW workforce [1], is needed to launch CCC into the future. A rapid expansion of the CHW footprint is critically needed to prevent unmet needs from escalating into expensive medical crises, particularly in vulnerable communities [5].

However, scaling the current CCC model in a cost-effective manner while preserving the highly contextual and individually tailored care provided by CHWs remains challenging. Although the recent incorporation of digital technologies into the CCC model demonstrates potential for expanding the CHW footprint, current technologies lack integration. Large-scale data acquisition, preprocessing, and validation for intelligent decision-making remain key challenges.

We propose D-CCC as an improved model to move CCC into the future and present our UNITE pilot study as an initial proof of concept in D-CCC implementation. Of note, UNITE represents *one iteration* of the D-CCC platform, designed to support the specific needs of a community partner organization providing CHW-delivered interventions to pregnant women considered to be at low to moderate risk within Orange County, California. UNITE was designed to leverage technology to facilitate client self-management as well as CHW-delivered support. However, D-CCC may also support CHW-delivered health-related interventions among client populations less able to engage in self-management or with less access to, or comfort with, technology (eg, older adults with dementia). Critically, because CHWs occupy a variety of roles within communities and because CHW-delivered interventions and target outcomes vary widely according to the client populations served, a *one-size-fits-all* platform design will not be successful in empowering the CHW workforce of the future. D-CCC is designed to be scalable and portable across diverse communities, and its modular design purposively allows for flexibility to meet the needs of different CCC organizations, populations served, and care delivery focus.

D-CCC's design addresses key challenges identified in the literature regarding current use of digital technologies by CHWs, including a lack of evaluation of outcomes; development of digital tools and apps without cultural relevance; lack of access to, or knowledge of, mobile technologies within communities; need for effective training for CHWs to adopt digital tools; inadequate CHW supervision; and the need for improved communication among health care teams working with CHWs [6,11]. Furthermore, D-CCC allows for fair and data-driven evaluation of CHW-delivered interventions, thereby increasing opportunities for key CHW-focused policy advocacy. Data-driven evaluation of CHW-delivered interventions is key to moving community organizations away from fee-for-service or grant-based governmental support models and toward value-driven models for CHW reimbursement.

However, there remain key challenges and limitations to consider. D-CCC design focuses on supporting CHWs operating within a facility-based CCC model of care delivery. Although most CHWs operate under this model [38], exploring how D-CCC might apply to other models of CHW-delivered community care remains a future endeavor. Certain aspects of digitalization (eg, BP monitors, ECG sensors, and blood glucose monitoring) may be more useful for CHWs focused on single or multi-disease management, and ubiquitous monitoring may require clients to use a smartphone and have home internet access. However, D-CCC is designed to be used by CHWs engaged in various community care roles, including use in client populations without access to smartphones or home internet. Through facilitating CHW communication (with clients, supervisors, and other CHWs), collaboration, and knowledge sharing, as well as CHW supervision, training, and decision support, D-CCC is designed to support CHWs engaged in myriad care roles. CHWs working on upstream health determinants such as job loss may also benefit from the D-CCC intelligent and integrated closed-loop digital platform designed to support communication, collaboration, and knowledge sharing of community-based resources.

In addition, the UNITE pilot is presented as a proof-of-concept case study to illustrate D-CCC deployment. However, this pilot is ongoing and limited by a lack of outcome data to present here (eg, regarding feasibility, user experience, or health outcomes). We highlight the larger need for studies conducting cost analyses of CHWs, digital technologies, and the combination of CHWs *and* digital technologies. Without these data, assertions regarding cost savings through incorporation of technologies targeted for use by CHWs remain speculative.

AI design must carefully consider the impact of digitalization on CHW relationships, workload, and workflow [64]. Deployment of AI systems will result in some additional work, most notably upon rollout and initial deployment. Some of this work may be readily apparent (eg, CHWs actually using the AI platform), but less-apparent aspects must also be considered (eg, CHWs introducing, explaining, and justifying the use of new technologies to their communities) [64]. As Okolo et al [64] highlight, AI developers must account for such added visible and invisible work shouldered by CHWs when assessing the benefits and limitations of incorporating AI systems into established CCC workflows. To this end, CHW collaboration and iterative feedback drive D-CCC design to maximize utility and acceptability while minimizing additional worker burden. Our multidisciplinary team also includes human-computer interaction experts to conduct ongoing assessments of CHW relationships and workflows during D-CCC design and implementation.

Finally, D-CCC's data-driven algorithms, key to building personalized models, also mean an unprecedented scope with regard to sensitive data collection, and the digital health ecosystem presents new ethical challenges and considerations, particularly in vulnerable populations. The D-CCC platform must critically protect data privacy and security through methods such as end-to-end encryption and distributed security schemes (eg, blockchain technology) and proper data governance policies and tools. Any commercial cloud infrastructure services used to store and manage data resources must provide Health Insurance Portability and Accountability Act–compliant services for storage and transmission of protected health information. Data privacy and shared responsibility clauses must additionally guarantee secure data management in compliance with the user and application deployer.

Although new human-technology partnerships have incredible potential to empower future workers and to promote health equity, the impacts of AI on future workers and communities must be considered, including identifying potential for inadvertent creation or exacerbation of health inequities, particularly among vulnerable populations. Consideration of

sociocultural aspects throughout D-CCC platform design and iteratively examining how these affect platform acceptability, feasibility, and reliability will be critical to avoid further propagating health inequities [65]. To this end, D-CCC design and implementation must occur iteratively and in close collaboration with all stakeholders, including CHWs, CHW supervisors, and clients.

Conclusions

The increasing use of digital technologies among CCC organizations is demonstrating the potential to expand the CHW footprint by enhancing CHWs' reach and diffusion of health information within communities [6,41,42]. However, existing digital technologies incorporated into CHW practice lack integration. We propose D-CCC as an improved model to move CCC into the future. D-CCC constitutes a human-technology partnership integrating CHWs, CHW supervisors, and communities through a scalable digital medium to improve the efficiency and quality of care delivery. By targeting a human-technology partnership at the level of the CHW, D-CCC aims to amplify human connection and collaboration while maximally expanding the CHW footprint within communities. Through integrating future digital health technologies, the future CHW workforce, and the future health and social care needs of communities, D-CCC aims to connect the most vulnerable individuals within communities to needed resources and health and social services.

Acknowledgments

This research was supported by the US National Science Foundation under the grants FW-HTF 2026614 (D-CCC: Digital Health for Future of Community-Centered Care) and SCC 1831918 (UNITE: Smart, Connected, and Coordinated Maternal Care for Underserved Communities). The authors would like to acknowledge their collaborators in the UNITE: Smart, Connected, and Coordinated Maternal Care for Underserved Communities project, in particular the co–principal investigators Dr Yuqing Guo and Dr Marco Levorato. The authors would also like to thank Arman Anzanpour for his assistance with the conceptualization and visualization of the figures.

Abstract

The COVID-19 pandemic has necessitated a rapid shift to web-based or blended design models for both ongoing and future clinical research activities. Research conducted virtually not only has the potential to increase the patient-centeredness of clinical research but may also further widen existing disparities in research participation among underrepresented individuals. In this viewpoint, we discuss practical strategies for quantitative and qualitative remote research data collection based on previous literature and our own ongoing clinical research to overcome challenges presented by the shift to remote data collection. We aim to contribute to and catalyze the dissemination of best practices related to remote data collection methodologies to address the opportunities presented by this shift and develop strategies for inclusive research.

Introduction

Background

The COVID-19 pandemic is transforming the landscape of clinical research. The pandemic has necessitated the unexpected adaptation of ongoing clinical research activities to web-based or blended design (ie, part web-based, part in-person) models [1] and has rapidly accelerated a shift within clinical research toward web-based study designs. Despite the high levels of patient and health care provider satisfaction with telemedicine and virtually conducted clinical research [2,3], many challenges exist to the web-based conduct of rigorous, efficient, and patient-centered clinical research, particularly related to the engagement of diverse and marginalized populations [4]. The aim of this paper is to discuss practical strategies to guide researchers in the remote collection of quantitative and qualitative data, derived from both previous literature and our own ongoing clinical research.

Many health care providers and clinical researchers have marveled at the way the COVID-19 pandemic catalyzed the widespread adoption and expansion of telemedicine, seemingly overnight [5,6]. Despite the sluggish adoption of telemedicine observed in academic medical centers over the past several decades [7,8], the pandemic has spurred rapid changes in public and organizational policy regulating telemedicine in the United States, facilitating a tipping point toward the web-based provision of both health care and conduct of clinical research

[1,2,5,6]. Enabled by fast-tracked institutional review board policies and amendments [1], researchers have adapted clinical research study procedures in innovative ways: engaging in web-based outreach for study recruitment, collecting electronic informed consent, conducting study visits, delivering interventions over the phone or live video, and using remote methods to collect data [1]. Several studies have reported high satisfaction of both providers and patients with the use of telemedicine during COVID-19 and a willingness to continue using telemedicine after the pandemic, including for clinical research [2,3].

This shift toward virtually conducted clinical research creates many *opportunities* to increase the accessibility of clinical research. Virtually conducted research reduces many burdens on patients associated with research participation, including time and monetary costs involved in travel to research facilities. This enables researchers to include patients who lack access to transportation or the ability to travel independently. Furthermore, web-based patient outreach allows researchers to recruit geographically diverse participants, enabling researchers to target populations through disease-specific registries, internet-based patient communities, and advocacy groups without geographical constraints [9]. By centering patients rather than investigative sites in the study design and operation, virtually conducted research has the potential to increase the patient-centeredness of clinical research [9].

At the same time, the transition to virtually conducted clinical research also presents many *challenges* to patient engagement and data collection. Losing supervision of the physical setting of research activities challenges researchers' ability to ensure patients' adherence to study protocols, engagement and interest in research activities, and privacy protections. Researchers are faced with complex decisions regarding the appropriateness of data collection methodologies or specific measures and assessments for web-based delivery [10]. Furthermore, there are barriers associated with the technology used for remote data collection (eg, telephones, electronic databases, live videoconferencing software, and ecological momentary assessment), including a lack of technology literacy and challenges using technology among both patients and research staff [1,4,8,11]. Finally, some patients lack access to smartphones, the internet, or secure and stable housing, which may preclude their participation in web-based clinical research unless researchers can allocate funding to provide these devices. Consequently, the transition to virtually conducted clinical research may further marginalize people in low-income and rural settings [4].

Objective

To thoughtfully respond to the challenges associated with remote data collection and ensure that disparities in access to clinical research do not widen, there is a critical need for practical strategies for researchers. By integrating recommendations from previous literature with examples from the ongoing clinical research projects of this authorship team with extensive patient and provider populations (ie, adults and adolescents with neurofibromatosis, older adults with chronic pain and cognitive decline, adults with cancer and serious mental illness, adults with young-onset dementia, and orthopedic medical providers), we present a discussion of practical strategies for researchers to support the rigorous, efficient, and patient-centered collection of quantitative and qualitative data remotely. Summary tables present a list of strategies related to the remote collection of quantitative (Table 1) and qualitative (Table 2) data.

Table 1. Challenges in remote quantitative data collection and associated strategies.

Challenges	Strategy	Example approach
Study staff do not have sufficient technological experience or access to technology.	Equip study staff with technology as necessary and instruct them on foundational technological skills.	Ensure that all study staff have access to necessary technology to carry out study responsibilities (eg, laptops with webcams, phones, and software programs) and have been thoroughly trained in their use.
Validating participant credentials and ensuring data quality.	Incorporate eligibility, attention, and manipulation checks throughout surveys.	Attention check: for quality assurance, please select *strongly disagree* for this line. Manipulation check: who was in the video you just watched?
Study staff lack experience remotely communicating with study participants.	Train study staff on good clinical practices and foundations of verbal and nonverbal communication that are appropriate for web-based setting.	Study staff collecting measures should be educated on best practices for protecting participant privacy and confidentiality through remote methods (ie, use of secure software and calling from private locations). Study staff should be trained on verbal and nonverbal communication appropriate for web-based settings (eg, eye contact through webcams and body language from shoulders up) and be mentored with peer or hierarchical supervision.
Managing the secure electronic distribution of measures to study participants.	Use a secure web platform to distribute measures.	Study staff can use secure electronic platforms (eg, REDCap[a] and Qualtrics[b]) to distribute measures and use functionalities (eg, scheduling surveys and automatic reminders) to maximize efficiency and organization for study team.
Assisting study participants in using technology to complete remote study measures.	Proactively identify participants' comfort with technology and then tailor individualized supportive approaches.	Study staff should first engage in *meeting participants where they are* by determining participants' technology comfortability and then supply participants with training accordingly (eg, written instructions, prerecorded videos, and live assistance). Study staff may also coordinate with members of the participants' household to collaboratively support them with technology as needed.
Engaging participants who lack access to technology or lack technological literacy to independently complete remote study measures.	Allow flexible and multimodal alternatives for measurement completion, along with offering relevant instructions on using these modalities.	Study participants can be mailed letter copies of the self-report measures or give their answer to survey questions via phone calls with study staff. Study staff should communicate with study participants about their preferred modality and support with associated burden.
Adapting study protocol to determine new ways to gather non–self-report data that previously required in-person assessment.	Conduct a literature search to identify and implement innovative, creative, and flexible alternatives.	Study teams can use previously adapted and validated measures for remote delivery, such as a mobile app to measure distance walked in 6 minutes (ie, 6-minute walk test).
Burden on participants of completing remote electronic study measures.	Asynchronous distribution of study measures.	Study staff can send participants a link from a secure web platform so that participants can complete the measurement independently at a time and place most convenient for them.
Participants who require or prefer assistance in measure completion.	Provide live assistance to participants during measure completion (ie, synchronous completion) via phone or live video.	Pay attention to participants' focus, engagement, and comprehension during synchronous measure completion (eg, ask participants if they have any questions about the phrasing of measures and offer participants the option to take pauses during the assessment).
Participants who require or prefer visual aid during synchronous measure completion.	Use *screen share* functions of HIPAA[c]-compliant videoconferencing technologies.	Using secure and institutionally approved videoconferencing technology (eg, Zoom and WebEx), study staff can *screen share* the survey so that patients can see, read, and potentially better comprehend questions.
Protecting participant privacy and confidentiality during remote calls.	Proactively promote actions in coordination with the study participant to uphold good clinical practice and protect privacy and confidentiality.	Confirm with study participants if they are in a safe space to openly answer questions, advising them of the sensitive nature of questions before administering measures, and assisting participants with strategies to maximize their privacy (eg, scheduling calls at a participant's preferred time and wearing headphones).

Challenges	Strategy	Example approach
Building rapport with study participants while communicating virtually.	Focus on body language, tone of voice, and language appropriate for web-based settings.	Use verbal strategies appropriate for web-based settings (eg, establish a conversational tone, use participants' names, speak clearly and directly into microphone, and provide technological support so that participants feel comfortable) and nonverbal strategies appropriate for web-based settings (eg, smile at participants, make direct eye contact with webcam, and sit upright).
Promoting completion of unfinished surveys.	Schedule reminders at predetermined intervals for participants who have not completed measures.	Participants who do not complete the survey in a scheduled time can be prompted to do so via automated electronic reminders within the distribution platform or individual outreach (eg, calling, texting, reminding in person). Study staff should flexibly use different outreach methods and communicate in advance to the participant how often they will send reminders through each method.
Reaching participants who are difficult to reach via technological means or who are no longer responding to outreach.	Determine standardized study procedures about who will contact the participant, how many times, and through what method.	Decide on a number of times to call a participant before transferring the matter via an established chain of command. Use creative approaches such as considering the individual's circumstances and best ways and times to reach them, involving family members, and involving incentives as appropriate.

[b]Qualtrics Survey Distribution (Qualtrics XM Platform).

[c]HIPAA: Health Insurance Portability and Accountability Act.

Table 2. Challenges in remote qualitative data collection and associated strategies.

Challenges	Strategies	Example approach
Inclusive outreach to participants.	Multimodal outreach strategies.	Send physical letters with focus group information and offer both telephone only and videoconferencing modalities.
Coordinating a meeting time for web-based interviews or focus groups.	Provide flexible hours and focus on participants' schedule preferences.	Study staff can offer multiple times for web-based focus groups to assess times that would maximize attendance.
Securely conducting web-based interviews or focus groups.	Select HIPAA[a]-compliant videoconferencing platforms.	Platforms that are HIPAA-compliant have security features such as password-protected meetings and waiting rooms that study staff can use to protect participants' privacy and confidentiality.
Encouraging active participation in web-based interviews or focus groups.	Proactively plan the focus group structure to optimize participation.	Consider the target size of the focus group to promote participation. Study staff can also give an introduction at the start of focus sessions to set a tone of welcome and inclusivity (eg, build rapport and give overview of study topics) and be intentional about the use of verbal and nonverbal communication throughout the focus group to encourage participation.
Solving technological issues with participants.	Review technological features and any problems at the start of the session and then address emerging issues as needed.	Expend a portion of the focus group, ensuring that all technological components are functioning (eg, microphones and videos turned on as appropriate) and review features of the platform. Have a study staff member on call to assist with technological problems as needed.
Conducting interviews or focus groups in a timely fashion.	Coordinate the team approach to adhering to a predetermined schedule.	Determine allotted time for aspects of the focus group's discussion in advance and divide labor among the study staff during focus groups to maximize efficiency.

[a]HIPAA: Health Insurance Portability and Accountability Act.

Strategies for Remote Data Collection

Optimizing Quantitative Measures for Effective Remote Distribution and Delivery

Asynchronous distribution and measure completion (eg, electronic distribution of surveys) maximize efficiency for the study team and flexibility for study participants but necessitates additional consideration for participants with varying levels of familiarity with and access to technology. Secure web platforms (eg, REDCap [Research Electronic Data Capture], Vanderbilt University and Qualtrics, Qualtrics XM Platform) are ideal for asynchronous distribution because they have functionalities that promote study team efficiency and organization (eg, scheduling survey distribution in advance and automatic reminders to participants to complete surveys) while enabling participants to complete measures independently and at a time most convenient for them [9]. Although these platforms are widely compliant with Health Insurance Portability and Accountability Act (HIPAA) and regulatory requirements, study teams should

ensure that platforms are compliant with institution-specific clinical research regulatory requirements before use (and consider potential differences between clinical research and clinical care requirements).

Many of these platforms also offer participant screening, consenting functionality, and mobile device compatibility, which maximize the utility for study teams [9]. Study teams relying on web-based platforms and asynchronous measure completion should also consider the adoption of flexible alternative options for measure completion to maximize completion rates and the engagement of participants. For example, study teams might offer participants the option to complete measures on paper through physically mailed surveys or over the phone with a member of the study staff, depending on participant technology access and preference. Similarly, in addition to electronic reminders integrated within the distribution platform, study teams will likely need to use other methods to contact participants and remind them to complete measures (eg, calling, texting, and reminding in person). To decrease the burden on participants and increase adherence to study procedures, participants should be informed of how many of these reminders to expect.

Validating participant credentials in studies where research staff have no personal interaction with participants (ie, web-based survey studies) is another challenge with web-based research. Data quality checks, such as eligibility, attention, and manipulation checks (see Table 1 for examples) can be introduced to protect from duplicate responses or participants falsifying information. Enabling IP address tracking is another feature of some survey platforms (eg, Qualtrics). As with all data collection, it is imperative that participants are aware of how their information is being collected and researchers have been granted previous institutional review board approval.

We use REDCap and rely on predominantly asynchronous measure completion to collect quantitative data in an ongoing randomized controlled trial of a mind-body intervention to promote quality of life in adults with a genetic condition called neurofibromatosis [12]. Participants receive links via email to complete surveys at all time points (ie, baseline, posttest, and 6- and 12-month follow-ups), and we set automatic email reminders to go out at defined intervals every 3 days until participants complete surveys. The frequency of reminders should be determined by the study team to balance the burden on study staff and participants with the desire to have high survey completion rates. We find that participants enjoy the flexibility of completing measures at their convenience from the comfort of their homes and using personal devices.

For quantitative measures other than self-report surveys, study teams may need to use innovative methods to adapt data collection methods for remote delivery. Although not all measures can be adapted for remote delivery (eg, imaging data collection), many can through a combination of creative and flexible strategies, including using mobile device data collection, mailing materials and devices to participants, and conducting assessments over live videoconferencing. Even the collection of biomarker data, common in quantitative research clinical trials, can sometimes be adapted for remote conduct through mailing of devices and use of smartphone technology, such as mailing saliva or nicotine strips for the verification of tobacco abstinence or the provision of personal devices to measure expired carbon monoxide that are compatible with smartphones [1]. In adapting measures for remote delivery, it is essential to examine previous literature to assess the availability of remote alternatives and evidence to support the validity of remote alternatives or adaptations [10]. Study teams' attention to usability and patient burden is essential [10]. It may also be important to account for the modality of data collection during data analysis (eg, evaluating whether the mode of data collection is a confounder in multimodal studies).

In our randomized controlled trial with patients with chronic pain and cognitive decline, we conducted a literature search to identify remote methods for assessing cognitive functioning as well as performance-based physical function. The Montreal Cognitive Assessment [13], a measure we previously used in our in-person study [14], has been adapted and validated for remote administration over live videoconferencing [15,16]. Accordingly, we developed a standardized protocol for applying the Montreal Cognitive Assessment audiovisual procedures, including mailing participants a paper with items that required drawing and instructing them to display the paper to the camera for us to screenshot over videoconferencing [17]. Our literature review also identified a validated, free-of-charge mobile app that uses GPS coordinates to measure the distance walked in 6 minutes to replace the 6-minute walk test (6MWT) [18] that we had previously conducted in our in-person study [14]. Before using the app with participants, we piloted the app and developed a standardized protocol to assist participants in downloading the app, using the app, and reporting the results [17].

In the process of adapting quantitative measures for remote completion, the safety of the participants must be considered. For example, in our randomized controlled trial with adults with neurofibromatosis, we used the Patient Health Questionnaire-9, which contains an item assessing suicidal ideation, to measure depression. We developed a standardized protocol to respond to cases in which participants endorse suicidality, including collecting the name and number of an emergency contact for each study participant during enrollment, having the study clinician and principal investigator receive immediate notification from REDCap, and having the study clinician or principal investigator follow up over phone with the participant within 24 hours to complete a safety assessment [12]. Similarly, in our randomized controlled trial with older adults with chronic pain and cognitive decline, we considered the safety risks associated with asking participants to complete the 6MWT independently (eg, falls). Participants were asked to create a plan to complete the 6MWT on a familiar route at a designated date and time, with support from a friend or family member when possible [17].

Synchronously Assisting Participants in Remote Completion of Quantitative Measures

Depending on the study protocol and population, the best practice may be the synchronous completion of measures (ie, in which a study team member administers the assessment to

the participant in real time). The synchronous completion of self-report measures enables study staff to directly support participants in completing measures, including ensuring participants' best effort, attention, focus, and comprehension during measure completion. Assisting participants synchronously in completing self-report measures also allows study staff to ensure that data are supplied directly from intended participants and eliminate the possibility that participants are being influenced by others such as spouses or parents. The factors to consider when making this decision include participants' age, cognitive ability, previous experience with technology, and preference. When assisting participants with assessment completion remotely, multiple modalities that can be used. First, calling participants by phone requires minimal technology access and familiarity for participants and enables study staff to *catch* participants at an opportune moment and ensure prompt survey completion with minimal effort on the part of the participant. Over the phone, study staff can ensure comprehension of every item (important for data validity); however, reading aloud every question-and-answer option can also be tedious for both study staff and participants. Strategies to address comprehension and focus include pausing to ask if clarification is needed, breaking up longer questions, and asking participants if they wish to take a break throughout the conversation.

For some participants, the visual component was beneficial for enhancing their comprehension of measure items. Video calling a participant with HIPAA-compliant, secure platforms [1] (eg, with Zoom and WebEx) and *screen sharing* the measure is a novel strategy to support participants in completing measures remotely. This *screen share* method provides the opportunity for the participant to see the questions in addition to hearing them and can enable better comprehension as well as more efficient measure completion (eg, study staff may not need to read every answer choice for items when participants can read them on-screen). Mailing participants paper copies of surveys in advance of phone calls is another method for allowing participants to have questions in front of them while also receiving live assistance in responding.

We use this novel *screen share* strategy in an ongoing randomized controlled trial of a mind-body intervention to promote quality of life in geographically diverse adolescents aged 12 to 17 years with neurofibromatosis [19]. We decided to rely on synchronous measure completion for this population, given the age of participants and high rates of learning disabilities, leading to anticipated challenges with thoughtful independent measure completion, as well as anticipated challenges with comprehension of items. The method has been effective in engaging participants during data collection to ensure participant comprehension of items and thoughtfulness when selecting answer choices. This method has also allowed us to identify and eliminate situations in which participants' parents are inappropriately coaching participants during data collection. Notably, videoconferencing does require a higher level of access and familiarity with technology; therefore, creative problem-solving abilities with participants are essential. As with all forms of technology used in data collection, study teams should consider ease of use for participants and be prepared to provide both emotional and technical support [11].

For group-based interventional studies and situations in which study staff want to be available to answer potential questions related to measure completion (about either technology use or specific items) but do not want to walk participants through every item, a group support procedure could be used using videoconferencing. In this strategy, a member of study staff can email participants the links to complete surveys on their own devices and schedule a time in which the group of participants joins a videoconferencing call to complete the measures at the same time. We use this strategy in our randomized controlled trial for older adults with chronic pain and cognitive decline [17]. Participants in a group video call are supported in navigating to their email to open the secure link to complete the questionnaires. Although completing their questionnaires independently, participants turn their video on or off, and we mute all participants and the study staff host to enhance focus and privacy and to replicate an in-person visit [14,17]. This method allows us to assist as needed when a participant takes themselves off mute to ask a question, physically raises their hand, or privately chats us. In addition, we periodically ask if anyone needs assistance, particularly after noticing that participants are not progressing as expected because REDCap allows the ability to monitor progress in real time.

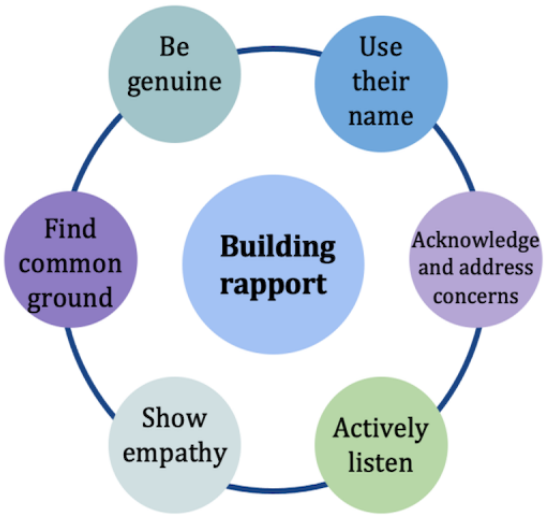
As with the shift to remote clinical care, the privacy and confidentiality of patients is not as easy to ensure as it is in person. Research staff have an obligation to ensure participant privacy and confidentiality to adhere to the principles of good clinical practice [20] and to ensure the acceptability of study procedures to participants for whom concerns of being overheard are common [11]. Informing (or reminding) participants of the sensitive nature of the questions (eg, pertaining to physical health, mental health, and intimate relationships) and ensuring that they are in a space where they feel comfortable to answer is the best practice. Working with participants to ensure the highest level of privacy may be necessary. Suggestions include using headphones (both participants and research staff), inquiring about participants' location and privacy, and allowing participants to determine the best time for the call [5,11]. Additional safety protocols are necessary when providing devices to participants, as they could be exposed to data theft or lose track of the device. We suggest enabling password protection on devices and limiting the data stored on the actual device to protect patient safety. Ultimately, although providing devices introduces the risk of needing to potentially replace the hardware, it is a readily integrable strategy to address the digital divide and increase access to research [21]. Participants should be reminded of the privacy risks associated with remote study participation (eg, possible breaches to the security of data collected remotely) and informed of the measures study staff are taking to safeguard against these risks (eg, encryption of devices and deidentification of data).

Motivating Participants to Complete Quantitative Measures Remotely

Building relationships with study participants is central to engaging participants in study procedures and ensuring thorough

and thoughtful data collection. Survey fatigue and general fatigue related to research participation pose real challenges to data collection as well as study retention [9]. Interactions with participants vary in length and frequency depending on study protocols; however, each interaction should be viewed as an opportunity to build rapport with participants. Strategies to build rapport include smiling (if on a video call), communicating clearly and confidently, and providing adequate emotional and technical support [5,11] (Figure 1). Researchers, clinicians, and patients alike cite increased mental health symptoms, stress, and added duties owing to the pandemic [22]. It is important to keep these additional burdens in mind when communicating with participants. Adjusting calls about study measures to be more conversational (eg, making time to ask participants about their day and how they are doing) can aid in establishing and maintaining rapport in the study team–participant relationship. The shared experience of COVID-19 is unifying and can be a source of common ground to relate to participants. Engaging in this way and expressing gratitude for participants' time can help build participant investment in the study.

Figure 1. Building rapport.



Study teams face additional challenges in prompting participants to complete measures when participants are difficult to reach or are unresponsive. Persisting in using creative outreach methods for calling and texting participants using HIPAA-compliant technologies (eg, Cisco Jabber and Twilio) [1] is essential. Study teams should consider adopting standardized procedures for attempted contact with participants to limit the burden on both participants and the study team. Often, research coordinators or research assistants are the first line of communication with participants and will attempt to call participants a certain number of times. It is helpful to consider when participants are usually home (ie, what time of the day is best to call) and to try different times throughout the day to achieve higher response rates. Study teams should standardize the maximum number of outreach attempts by research coordinators. Once that number is reached, it has proven useful in our experience to pass the communication up the chain to a study clinician or principal investigator. Study teams can also use this approach to allow a clinician to assess whether disengagement may be related to any concerns regarding the participant's well-being. Other strategies to bolster participant motivation include involving family members in study procedures, accommodating participants' preferred methods of communication (eg, texting, email, and phone call), and providing monetary or other forms of incentives [9,11].

Promoting Health Equity and Overcoming Barriers to Web-Based Engagement Among Participants With Varying Levels of Technology Access and Familiarity

As the COVID-19 pandemic continues to lay bare the existing health disparities in racially, ethnically, and socioeconomically minoritized groups, concerns that the increased reliance on digital technologies for clinical care and research will exacerbate the digital divide rather than mitigate systemic health inequities are prevalent [23]. Indeed, digital access is considered a social determinant of health, with 21 million adults in the United States lacking access to broadband internet [24]. With the transition to web-based research, we risk compounding this structural disadvantage and not realizing the potential to expand research access to increasingly diverse and underrepresented populations [1] without targeted measures to address digital access and literacy [21,25,26].

Building capacity for person-centered, equitable research can be facilitated by providing smartphones or internet plans to participants if access to these technologies is an inclusion requirement [1,11] as well as using multiple outreach modalities. Enabling outreach through multiple modalities has led to successful data collection during the pandemic in our ongoing randomized controlled trial for patients with serious mental illness and a new cancer diagnosis [27]. In this trial, we use multiple traditional outreach methods for data collection (ie, phone, email, and letter mail) in addition to nontraditional methods such as partnering with family caregivers and staff in congregate living settings. Despite a slower study accrual because of fewer new oncology consultations during the

pandemic, we maintained consent and survey completion rates for a marginalized population with flexible, multimodal, patient-centered outreach [28].

Providing adequate technology support is also of utmost importance. Study teams must provide training to participants for all forms of technology used, through manual documentation, prerecorded videos, or live assistance (eg, over the phone) [11]. Proactive outreach to individuals for technology coaching can promote efficiency and decrease participant frustration. Test-driving technologies and creating a short list of common technology challenges encountered by participants can help study teams troubleshoot and identify unnecessarily confusing aspects of instructions or procedures that can be changed. Study teams can also consider engaging family members in study procedures, which has been shown to aid in the adoption of technology for older populations with cognitive impairment [11]. We commonly use the approach of *meeting participants where they are* by first assessing participants' comfort with technology during a study enrollment phone call. This allows us to provide extra support where necessary, such as detailed instructions on software installation, test calls with study staff, and encouragement. We also prioritize conducting qualitative exit interviews to obtain feedback on study procedures to refine study protocols and participant instruction materials [14]. Technical support activities may increase the total time spent both preparing for and conducting a session with a participant. However, the time invested in participants proactively will contribute to improved data quality by ensuring patient understanding of the technology and study measures. Furthermore, digital solutions tailored for specific populations can aid in realizing the potential for web-based research to increase accessibility to underrepresented individuals.

Practical and Logistical Considerations to Conducting Qualitative Interviews and Focus Groups Remotely

Focus groups, or interviews, are conducted synchronously; therefore, time (and time zone) coordination is required. For individual interviews, offering flexible hours that prioritize participants' preferences may assist in study enrollment because participants will be able to schedule and mark their calendars for a *study visit* in real time. To coordinate a focus group, study staff can ask participants about their availability within multiple potential time blocks to choose a time to maximize attendance. Once a specified time frame has the minimum target focus group size, study staff may call unavailable *participants* to assess whether there has been a change in schedule or continue recruiting to reach the maximum focus group limit, ranging anywhere from 4 to 12 participants [29], with smaller groups often preferred for web-based conduct. In general, participants should be made aware before the interview or group what the policies will be (ie, how long the group will run, expectations for video on or off, and audio-recording plan).

HIPAA-compliant videoconferencing software (eg, Zoom and WebEx) is necessary for the conduct of remote qualitative interviews or focus groups (as opposed to phone calls) to facilitate rapport building between study staff and participants to ensure that participants feel at ease. Many types of videoconferencing software contain features, such as waiting rooms and passcodes, that maximize participants' security and confidentiality. Still, participants should be informed of the privacy risks associated with participation in remote focus groups (eg, the unsanctioned audiotaping or videotaping of groups) and the rules for participation (eg, use of headphones and being against recording of groups) should be clearly articulated at the start of every group. Features such as *breakout rooms* can also be innovatively used to conduct multiple interviews at one time, such as in the case of exit interviews after focus groups. Microphone and video camera positioning should be considered for both the interviewer and the interviewee, and 5 to 10 minutes should be allotted to ensure the proper placement and functioning of microphones and video cameras to enhance the quality of data. Automated live captioning of the interview conversation (closed captions) may also benefit participants who have difficulty hearing.

Having study staff on call during interviews and focus groups is essential to provide technological support to participants in case of issues. Study staff can provide individual support to participants and troubleshoot issues related to remote participation, including poor connectivity with the internet, audio or camera issues, the use of videoconferencing software, and environmental disruptions [11]. In the case of challenges that cannot be solved within a reasonable amount of time, study staff should have backup strategies in place to conduct interviews over the phone, allow participants to join focus groups by phone, or reschedule meetings flexibly. These procedures were used in qualitative interviews with patients with young-onset dementia and their caregivers [30], as well as in focus groups with orthopedic medical providers to enable the recruitment of geographically diverse participants.

We used these strategies at the beginning of the pandemic to transition from an in-person focus group study investigating barriers to smoking cessation clinical trials for Hispanic, Latino, or Latina individuals to remote procedures. Before the pandemic, we recruited Hispanic, Latino, or Latina individuals for focus groups conducted in both English and Spanish. After transitioning to remote research, we ran the web-based focus groups with smaller numbers than intended in person (3-4 people) to ease the burden on the study team while we navigated the new technology and ensured that each participant was able to receive one-on-one assistance. We faced challenges with technology, including finding solutions for individuals who did not have email or webcam access, a noted disparity among older Hispanic individuals [31]. To increase access, we mailed information to all participants (eg, study information sheet and materials to be discussed during the group) 1 week before the group and expanded our protocol to include both telephone conference calls and videoconferencing calls to accommodate participants' varying levels of technology access. Despite technological challenges, we found that offering web-based focus groups was helpful for both participants and study staff because we could more flexibly schedule groups with the bilingual study staff member who facilitated the groups. We also offered participants the option to have a *test call* with a member of the study staff to ensure adequate internet connection, microphone or camera functioning, and confidence navigating the video software. An alternative method would be

to include a brief introduction to the video software at the beginning of a qualitative interview or focus group and encourage participants to test different functions (eg, toggling audio and video on and off).

Adapting Facilitation Strategies for Remote Qualitative Data Collection

Although remotely conducted interviews and focus groups may pose some challenges to interviewers in engaging participants, connecting with participants, and encouraging open and active dialogue among participants, there are many verbal and nonverbal strategies that interviewers can adopt. Before the interview, study staff should begin building rapport with participants (Figure 1), explain who will be conducting the interview with their credentials, and provide information on what topics the interview will cover (particularly important for sensitive topics). At the start of the interview or focus group, interviewers should warmly introduce themselves and provide additional reminders to set the appropriate tone. For example, interviewers should encourage participants to be in a quiet and private space (or use headphones) with efforts to minimize environmental distractions (eg, participants should not be driving, doing chores, or eating) [11]. Interviewers may want to encourage participants to keep their camera on if they are able to facilitate engagement and rapport building but to mute themselves when they are not talking to reduce background noise. If participants are muted, interviewers should be prepared to probe them more enthusiastically than usual to motivate active dialogue and participation. It may be helpful for interviewers to continually encourage participants to share, particularly those who have been quiet. Encouraging diversity of opinion among groups can also help participants feel comfortable expressing their personal experiences and differing perspectives.

Assuming that they are visible to participants, interviewers should also pay attention to their nonverbal communication. If interviewers must take notes during qualitative data collection and are therefore unable to maintain eye contact throughout the interview or focus group, participants should be informed to avoid potential nonverbal miscommunication. Reactive facial expressions are critical in remote qualitative data collection, as body language cannot be observed as it typically would be in person, although some aspects such as posture may be observed. Nonverbally reacting appropriately to what participants share is vital to encourage participants to be open and honest during an interview. The key aspects of nonverbal communication include eye contact (toward the participant or the camera), using facial expressions to demonstrate understanding and listening, and body language, including nodding [11].

For structured and semistructured interviews and focus groups, keeping track of the timing during the interview is also necessary to ensure that all questions are answered, with appropriate time allocated to each section or question. This is particularly important for remotely conducted interviews, in which participants may only reserve the exact expected amount of time for the call (eg, 60 minutes) and when adequate attention and focus might be more difficult to maintain than in person. To support interviewers in managing time, we commonly include time stamps in interview guides and denote the questions to be prioritized. In focus groups, it is recommended to have 2 interviewers on the call if possible. That way, at least one interviewer can be primarily concerned with active listening and engagement with the participants, whereas another interviewer can focus on note-taking and timekeeping.

In our recent qualitative study with patients with young-onset dementia and their caregivers (dyadic interviews), we found it critical to consider the specific cognitive challenges of persons with dementia in facilitation as well as the sensitive nature of dyadic interviews. All questions were piloted with experts in young-onset dementia before the interviews to ensure clarity. Interviewers were prepared to repeat questions several times as well as define or explain keywords as needed. Because couples were asked to share their perspectives regarding the person with dementia's symptoms and illness progression as well as relationship satisfaction in front of each other, we prefaced the interview by validating the difficulty of openly sharing and encouraging participants to be as open as possible. When participants were hesitant in sharing, we found that *sitting with the silence* before moving on to a new question encouraged participants to reflect and add to the conversation. Before asking about relationship challenges, the interviewer acknowledged that this might be the first time couples are discussing certain questions and assured couples that we would be available to provide support to the couple together or individually after the interview as well. It is particularly important to consider participant emotional safety and sense of support in the case of remote interviews.

Essential Training Competencies for Study Staff

At the forefront of training competencies to conduct remote data collection is ensuring study staff have familiarity with practices to promote participant privacy and security, including encrypting computer devices; using secure, encrypted video and audio software; and conducting qualitative data collection in private, quiet locations. Equipping the study team with institutionally encrypted equipment (laptops with webcams and phones) and software programs facilitates standardized and HIPAA-protected data collection [1]. It is essential that study staff have sufficient familiarity with all technologies used so that they can troubleshoot any problems that may arise for either themselves or the participants and provide technical support as needed [11]. Therefore, study staff must be thoroughly trained in the use of any relevant technology as well as provided with resources to contact in the case of questions or issues.

Given the unique challenges to rapport building and participant engagement through remote encounters, it is also important to provide study staff with adequate training in verbal and nonverbal communication. For study staff with less experience with participant interaction and without clinical training, providing some level of peer or hierarchical supervision may be helpful in supporting them in developing effective communication skills.

Discussion

Summary

In this paper, we integrated recommendations from previous literature with examples from our ongoing clinical research to identify and respond to specific challenges to remote data collection (Tables 1 and 2). We hope to catalyze other research teams to think critically about the strategies they use in remote data collection and contribute to the collective body of knowledge on best practices through the publication of protocol papers and other methodologically oriented works. It is imperative that research teams thoughtfully and creatively solve problems in response to the challenges they face in remote data collection to ensure the validity and quality of data as well as the patient-centeredness of study procedures.

Future Directions

Future research is needed to evaluate whether data collected through web-based study designs are of the same nature and quality as data collected through traditional in-person approaches and to continue to identify strategies to maximize the validity of data collected remotely. The shift toward more web-based designs prompted by the COVID-19 pandemic brings with it the opportunity to remove many barriers of access to clinical research and engage more diverse participant populations while minimizing the burden on participants. However, without proper capacity building for web-based research, we risk widening the digital divide perpetuating existing disparities. We discussed our experiences with conducting web-based research with different populations, including individuals underrepresented in research such as Hispanic, Latino, or Latina individuals, those with serious mental illness, and those who face increased barriers to research participation, such as older adults with dementia and adolescents with learning disabilities. The strategies presented (eg, device provision, increasing technological support, and using multiple modalities to conduct research) are examples of mechanisms to promote equity in research participation. We acknowledge the significant participant burden in using technology for research and that the same digital health solutions do not work for all individuals. Therefore, it is imperative that researchers assess barriers specific to their study designs and populations of interest to mitigate the threat of increasing existing disparities. Additional research is needed to further characterize strategies that can be used to ensure accessibility of virtually conducted research to marginalized and underrepresented populations.

Abstract

Machine learning applications promise to augment clinical capabilities and at least 64 models have already been approved by the US Food and Drug Administration. These tools are developed, shared, and used in an environment in which regulations and market forces remain immature. An important consideration when evaluating this environment is the introduction of open-source solutions in which innovations are freely shared; such solutions have long been a facet of digital culture. We discuss the feasibility and implications of open-source machine learning in a health care infrastructure built upon proprietary information. The decreased cost of development as compared to drugs and devices, a longstanding culture of open-source products in other industries, and the beginnings of machine learning–friendly regulatory pathways together allow for the development and deployment of open-source machine learning models. Such tools have distinct advantages including enhanced product integrity, customizability, and lower cost, leading to increased access. However, significant questions regarding engineering concerns about implementation infrastructure and model safety, a lack of incentives from intellectual property protection, and nebulous liability rules significantly complicate the ability to develop such open-source models. Ultimately, the reconciliation of open-source machine learning and the proprietary information–driven health care environment requires that policymakers, regulators, and health care organizations actively craft a conducive market in which innovative developers will continue to both work and collaborate.

KEYWORDS

machine learning; artificial intelligence; medical economics; health policy; healthcare innovation

Introduction

Background

Machine learning (ML) is a subset of artificial intelligence (AI) that uses training on existing data to generate insights on novel data. ML applications can augment physicians' ability to make evidence-based decisions by synthesizing and applying more data points into practice than can any one individual. Currently, at least 343 AI-enabled tools have been cleared or authorized by the US Food and Drug Administration (FDA) to assist with functions including reading radiographs, classifying ophthalmic imaging, and interpreting electrocardiograms [1]. However, these technologies are still relatively novel, with the potential for widespread use in the near future.

Commercial innovations in modern medicine have largely taken advantage of proprietary information. However, software has had a longstanding paradigm bifurcation into proprietary and open-source software. Open-source software differs from proprietary software in the accessibility of its underlying code. Unlike proprietary software, open-source tools make their underlying code accessible to users. The use of proprietary software in American health care systems generally exceeds the use of open-source software [2]. However, select examples, such as the United States Veterans Affairs' open-source VistA system, have found success in clinics and facilities [3].

Open-source software solutions have also been successfully implemented in developing nations' health care systems [3].

Open source looks to be an important part of the health care ML landscape. This entry has already begun; for instance, developers building clinically oriented models often share source code as part of distribution. Examples of such models include those indicated for patient risk stratification [4], cancer therapeutic selection [5], pneumothorax detection [6], and pneumonia classification [7]. Activity in this space currently exists outside of structured market, regulatory, or implementation frameworks. In this paper, we evaluate the consequences of and raise considerations for the development and distribution of open-source ML models in health care settings. We consider factors contributing to the feasibility of deployment, the advantages of open source, and challenges faced by those seeking to develop and distribute open-source models.

Feasibility

A total of 3 factors contribute to the feasibility of deploying open-source deep learning models. First, developing deep learning models, as compared to other health care solutions, requires relatively little capital on the part of developers. The collection of data is often passive, taking place routinely during encounters and hospitalizations. Although the curation of data may take effort, resources expended in collecting information for deep learning models are far less than those required while collecting information for drug development. Likewise, proving efficacy through retrospective and prospective validation can occur in a randomized fashion in the background of standard clinical operations. Performance standards can be assessed without changing the course of care. ML models also do not require the design and execution of randomized controlled clinical trials, which cost on average US $20 million per trial for stage III drug candidates [8]. Thus, open-source models require fewer incentives to recoup development costs. Given the favorable risk profile of constructing and deploying deep learning tools, developers have less incentive to keep their algorithms secret.

Second, the concept of open-source products is already familiar to the technology and information technology (IT) industries. Commonly recognized examples include Linux, the Apache HTTP Server, and Mozilla Firefox [9]. The global market for open-source projects across sectors was almost US $9 billion in 2016 and is expected to rise, with North America having the largest share [10]. Even in health care, the development of open-source models is nothing new. Scoring systems such as the PORT (Patient Outcomes Research Team), APACHE II (Acute Physiology and Chronic Health Evaluation II), and the Charlson Comorbidity Index are all open source and freely available [11]. These are all relatively simple models that apply logistic regression or points-based systems. The advent of deep learning and other sophisticated models may be considered in the context of these simpler models. Cultural, organizational, and policy factors have contributed to the notoriously slow adoption of technology in clinical settings [12]. Having strong precedents for the widespread utilization of open-source tools may decrease the magnitude of this barrier.

The third and most uncertain factor is the regulatory landscape for the entry of tools into the market. Regulation of ML in health care involves its own complex set of issues [13,14]. Many models developed and deployed in-house are unlikely to face much regulatory oversight, for various reasons that are still developing. Models developed in-house and shared noncommercially for in situ modification and deployment may still receive relatively little scrutiny. However, even at the most intense end of the scale of regulatory scrutiny, ML models under the FDA's jurisdiction are typically eligible for the 510(k) approval process, allowing for the approval of a device via proof of equivalency to another device [15]. Thus, a deep learning model that is equally performant to an existing product can gain expedited approval. As of January 2022, at least 90% of AI-enabled models gained approval via the 510(k) pathway [1]. Open-source developers can utilize this same process to release models into the market.

Advantages

There are 4 primary advantages to the development and integration of open-source ML models. First, the transparent nature of open-source software can potentiate enhanced integrity and performance. Unlike proprietary software, for which only purchasers can run models, anybody who has access to available open-source code can assess the model's performance [16]. These circumstances thus allow for validation by greater numbers of people and on greater numbers of data sets. For tools requiring FDA approval, open-source models must either undergo a process demonstrating safety and efficacy or, more feasibly, undergo a process establishing performance equivalency to a model already in existence [13]. However, these validation processes are dependent on the data used to test the models at the time of appraisal. The FDA does not yet have a neutral third-party data set to validate individual developers' models. Given these regulatory shortcomings, models require rigorous postmarketing surveillance [17]. Current efforts to interrogate proprietary software often reveal performance issues well after the commercial software has been widely distributed and implemented [18,19]. As compared to proprietary software, open-source tools would enable greater ability to detect deficits such as poor generalizability, previously unaccounted biases, and model drift.

Second, open source allows for the customization of models for a hospital's specific population. ML tools, like therapeutics, are developed on data sets of large cohorts but ultimately applied to individuals. Thus, safety and efficacy vary among individuals and between specific populations [20]. When applied to medical informatics, this phenomenon is known as the "curly braces problem": implementing models in new settings degrades their performance [21]. Facilities and departments using open-source models can somewhat mitigate this problem by calibrating the model weighting to achieve optimal performance on their unique patient populations. A cancer center, for instance, may want image reading models calibrated slightly differently from an emergency department. The capability to adjust source code to deliver increasingly personalized care may increase safety and efficacy.

Third, low-cost open-source options may speed up the adoption of ML technology in clinical settings. Inherent to the notion of open-source models is the availability of their code. Due to the nature of their transparency, open-source tools have historically been lower in price compared to their proprietary counterparts [22]. Despite a projected US $6.6 billion investment by developers and investors [23], health care facilities have proven slow to adopt ML technologies [24]. Among other reasons, hesitancy by clinicians and administrators due to potential financial or value-based consequences of using such technology hold back its implementation [24,25]. Decreasing the financial risks of adoption may encourage operational experimentation, particularly for hospitals that are naïve to ML tools.

Fourth, low-cost open-source options may increase competition, influencing price and functionality. The emergence of open-source models is not likely to end the development of proprietary technology. From word processors to COVID-19 decision support algorithms, the uptake of open-source tools has occurred alongside proprietary tools [9,26]. However, proprietary models, often priced higher than open-source models, will have to compete with effective "generic" models. Facilities looking to use deep learning for any given use case may confront a combination of proprietary and open-source options. The very existence of comparable open-source models forces proprietary developers to increase functionality in return for the higher cost [21]. Results may include a smoother user interface, enhanced integration with existing health care IT systems, or augmented implementation guidance or maintenance.

Challenges

The implementation of open-source deep learning models also faces 4 primary challenges. First, engineering issues impact the feasibility of development and maintenance. A model is one piece of a multicomponent production pipeline. The code and infrastructure around the model, known as ML operations (MLOps), are necessary to make the model production ready. For the most part, commercial services include MLOps services with the purchase of proprietary models. These services would not be included with the implementation of isolated open-source model code.

The monitoring of inputs, an important component of MLOps, ensures that the model works as intended. Changes in inputs can cause a model to produce unexpected outputs. For example, a recent electronic health record upgrade at New York University (NYU) Langone Health caused a monitoring system to flag changes in model inputs, and we were immediately able to flag the change and fix the input mappings. Alternatively, the underlying population or treatments may change. For example, NYU Langone Health researchers trained a model to predict 2-month mortality [27]. In prospective validation, the team identified a subgroup of patients with lung cancer who were unexpectedly surviving beyond 2 months. In the intervening time between model training and prospective validation, the FDA approved pembrolizumab (Keytruda) for clinical use. Patients treated with Keytruda were no longer at high risk of short-term death.

Second, increased accessibility to source code exposes models to manipulation, especially by adversarial machine learning. Adversarial machine learning techniques involve feeding models misleading data to produce faulty outputs. Researchers have used such techniques to deceive models processing multiple forms of media, including images and text [28]. Reports have described engineered attacks in which experts have been unable to distinguish between data from patients and manipulated data [29,30]. Adversarial attackers with access to model source code could release models deliberately designed to negatively impact patient care. Alternatively, because these models are open source, the attacks are transparent and thus mitigatable. Additionally, the monitoring infrastructure still exists and if done correctly, should immediately flag these attacks.

Third, the intellectual property and incentive landscape for open-source medical ML models is complex. Attempting to maintain exclusivity for models is contrary to the spirit of open-source sharing. Even if developers were to attempt to seek some intellectual property protection, patents provide relatively weak protection for models (and no protection at all for the data on which models are based), based in part on US Supreme Court decisions that expansively defined the set of abstract ideas and natural laws that cannot be patented [31]. Secrecy, the principal alternative to patents, is similarly incompatible with an open-source model, though a combination of secrecy and licensing does enable variants such as open-source products solely for noncommercial uses.

The lack of exclusivity-based supracompetitive pricing limits the incentives available for the development and validation of open-source models. This especially constrains the activities model developers would be willing to undertake; cheaper work, such as model development based on existing in-house data sets or in silico validation, is substantially easier to justify and support than more expansive and expensive work, such as prospective clinical trials to validate model performance or generalizability across contexts, that is necessary for the evidence-based adoption of an AI model [32].

Fourth and finally, developers of open-source medical ML models face complex possibilities around the question of liability, namely, whether a model developer can face liability when patients are harmed based on the use of an arguably faulty model. Fully expanding upon the possibilities of liability is outside the scope of this work, not least because courts have yet to clarify the doctrine. The frequent finding of liability for upstream open-source model developers seems relatively unlikely [33]. Among other things, courts have been reluctant to impose product liability on software developers because software is only disputably a product. Intervening actors, such as the health system implementing (and perhaps modifying) an open-source model and the health care provider caring for the patient, further complicate the causal chain and the assignment of liability. Finally, licensing terms that include indemnification for liability and the reassignment of liability by insurers both add complexity to the liability landscape. Suffice it to say that liability remains an area of uncertain concern but seems unlikely to deter a substantial amount of open-source model development and collaboration, as evidenced in part by the sharing already

occurring. Still, the area is one that developers should likely continue to monitor.

Conclusions

In this viewpoint, we have evaluated factors involved in the development and deployment of open-source ML models for use in clinical settings, considering feasibility, advantages, and challenges inherent to such a framework. The benefits of open-source technology are largely known and accepted within the technology community. The forces holding back the adoption of the proposed technology, however, lie in the lesser-known aspects of the intersection between the data sciences, clinical sciences, and health care policy. Questions surrounding regulation, liability, and market forces predominate concerns about furthering the development of tools in a manner that potentially limits the extent of profit margins.

Given these outstanding questions, we believe that policymaker interventions have a fundamental role in enabling developers. A pragmatic start would be to ensure model generalizability. An overarching concern in the applicability of open-source models is the ability to use models in different settings while trusting that performance will remain strong, especially given the MLOps factors noted above and the possibility of patient injury (and potential liability) that might result from improper translation. Demonstrating generalizability, however, is expensive and as noted, patents, since they are not available, do not create incentives for incurring that expense. Policymakers could both encourage generalizability testing and reduce attendant expenses by helping to develop a unified infrastructure to enable such testing before sharing. Such an infrastructure could involve routinely updated test data sets, mock settings, and challenge queries. Generalizability infrastructure would make it easier to develop responsible open-source models and could also reduce redundant infrastructure effort by those whose resources could be better spent developing and improving models. Although we do not take a strong view as to who could best design such an infrastructure, the FDA seems a logical contender.

More generally, the role of forward-thinking governance remains critical to the development and deployment of open-source models. The FDA has recently announced that it was considering changes to its standard approval process directed at establishing more appropriate regulation regarding ML programs [13]. Changes include a precertification pilot program where companies are approved before they develop and release models. This allows for the release of new versions without subsequent safety and efficacy trials. Similar innovations may be required in regulatory bodies, clinical facilities, and the law to provide guidance that supports a sector that intertwines proprietary and open-source models. In the meantime, developers may need to shoulder some of the risk of promoting innovations to improve patient care, including through the sharing of open-source models.

Abstract

Background: COVID-19 restrictions may make it difficult for people to engage in the recommended amounts of physical activity (PA).

Objective: The influence of the COVID-19 pandemic on PA, as well as the links between PA and mental health, was investigated in this study.

Methods: Participants were recruited using convenience sampling and responded to an online survey between April 15 and July 1, 2021, with ages ranging from 18 to 24 years (n=156, 40.9% of the sample) to ≥55 years (n=28, 7.4% of the sample). To assess general psychological distress, depression, anxiety, and pandemic anxiety, a battery of mental health assessments was used. The International Physical Activity Questionnaire - Short Form was used to collect PA data from participants, who were then classified as inactive, minimally active, or highly active. Participants also indicated the locations where they performed PA before and during COVID-19.

Results: A sample of 381 individuals was included in this research. The logistic regression analysis results were interpreted as odds ratios (ORs), where an OR higher than 1 indicated a greater chance of an event occurring and an OR less than 1 implied a lower likelihood of an event occurring. Logistic regression results revealed that inactive individuals were more likely to develop psychological distress (OR 2.17, 95% CI 1.27-3.69, *P*=.004), depression (OR 3.81, 95% CI 1.92-7.57, *P*<.001), and anxiety (OR 1.86, 95% CI 0.99-3.47, *P*=.05) as compared to highly active individuals. Furthermore, when compared to highly active people, those who were only minimally active had a higher risk of depression (OR 2.14, 95% CI 1.05-4.33, *P*=.04). Wilcoxon signed-rank tests revealed that COVID-19 has a greater impact on reducing the chances of less active individuals engaging in PA outside and in public spaces. Highly active people's physical exercise locations had changed less, and their exercise frequency at home increased.

Conclusions: Programmatic and policy interventions geared particularly toward enhancing PA among those less active may be a helpful strategy for addressing the worldwide pandemic's mental health crisis.

Introduction

Background

The current COVID-19 pandemic has swept the world since the first confirmed case in Wuhan, China. COVID-19 is characterized by rapid transmission via droplets or close contact between humans. In the United States, over 33 million COVID-19 cases were reported as of July 1, 2021. Due to a lack of suitable treatments and vaccinations during the early stages of the pandemic, most countries adopted World Health Organization (WHO)-recommended protocols. Individuals worldwide were advised to stay at home and avoid contact with anyone who was not a close family member. Several studies have been published in recent months on the effects of COVID-19-related restrictions on psychological well-being, physical activity (PA), and general life satisfaction [1-9]. Although these self-quarantine methods were critical in reducing the spread of COVID-19, they may have limited people's capacity to engage in sufficient amounts of PA to preserve health and avoid illness.

During the pandemic, people worldwide were urged to stay at home and avoid contact with others. Businesses, organizations, and institutions, for example, encouraged their workers to work from home to ensure their own safety. People who worked from home had fewer opportunities to interact with coworkers and participate in fewer PAs, such as walking between meeting locations [10]. Students were no longer allowed to participate in school-based PA, such as physical education classes or walking to and from transportation, as they moved to online learning. The majority of team sports, league training, and games were canceled. Due to lockdowns and other restrictions, people found it impossible to access gyms, parks, and other places where they might exercise. Although prepandemic PA levels were already insufficient for many, pandemic management efforts are likely to have had the unintended consequence of further lowering PA. Early investigations did, in fact, show a substantial decrease in PA levels since the pandemic began [11].

The relationship between the COVID-19 restrictions and PA may be particularly significant, given that frequent and considerable physical exercise is essential for health and well-being in general [12]. Exercise has a main effect in treating depression [13,14]. Physical inactivity, in contrast, has both acute and long-term negative psychological consequences, as well as negative effects on people's metabolic, vascular, and immune systems across a wide range of age groups, races, genders, health conditions, and body shapes [15]. To maintain psychological and physical well-being during the pandemic, WHO recommended that people engage in physical exercise, particularly while in self-quarantine.

According to a study performed in the United States during the early stages of the COVID-19 pandemic in April 2020, participants reporting decreased PA experienced higher depression, loneliness, and stress [16]. Similarly, research conducted in April 2020 on adults in Italy and Australia revealed that participants reporting decreased PA following the pandemic were more likely to have negative psychological health and well-being [6,17]. Research conducted on Canadian participants from April to May 2020 revealed that those who were more physically active had better mental health and those who became more active or who had more PAs in the outdoors had less anxiety [18]. A survey study conducted between 2015 and 2020 discovered that during the pandemic in 2020, there was a significant decline in PA and mental health among college students, while PA did not appear to protect against deterioration in mental health, with participants drawn from a large northeastern US university and predominately females and non-Hispanic Whites [1]. In a rapid systematic review of COVID-19 research on physical exercise and depression and anxiety, the authors indicated there were methodological weaknesses in some of the studies, such as the use of unvalidated instruments and failure to provide standardized statistics [5]. Furthermore, since most of previous research was performed shortly after the pandemic outbreak [3], a new study of PA and its relationship with psychological health may be needed to generate further findings after the effect of a year-long pandemic restriction.

Aims of This Study

In sum, there have been few up-to-date studies on the impact of pandemic restrictions on physical exercise and their connections to mental health. This research investigated whether physical exercise is linked to a decrease in anxiety and depression. In addition, we investigated whether there were any changes in the locations of participants' PA before the COVID-19 outbreak and during the pandemic.

Methods

Participants and Procedure

Data were collected via an online, anonymous survey via Qualtrics from April 15 to July 1, 2021. The study used convenience sampling to recruit individuals aged 18 years and above from a public university campus community located in the metropolitan region of New Jersey, United States. The research was publicized to the university community, including students, faculty, and staff, through email, flyers, and campus announcements. The completed questionnaire was submitted by 381 respondents. The questionnaire included questions about demographics, lifestyle, and socioeconomic position, as well as key variables examined, such as mental health and PAs. The data provided here were centered on factors associated with changes in physical and mental well-being. Participants would enter the draw for a $50 gift card by providing their email addresses. As an added precaution, a range of security mechanisms in Qualtrics and a human check were implemented in the survey for removing potential bots and preventing multiple submissions.

Ethics Approval

Before taking the survey, participants provided their electronic informed consent. Participants had the right to agree or refuse to participate in the research and withdraw at any time. The research was approved by the university's institutional review board (IRB).

Measurements

Mental Health Problems (Psychological Distress, Depression, and Anxiety)

A broad and well-validated 4-item Patient Health Questionnaire (PHQ-4) was used to measure psychological distress [19,20]. The PHQ-4 includes 2 items that assess depressive symptoms ("feeling down, depressed or hopeless," "little interest or pleasure in doing things") and 2 items that assess anxiety ("feeling nervous, anxious, or on edge," "not being able to stop or control worrying"). The questionnaire begins with the broad question, "Over the last 2 weeks, how often have you been bothered by the following problems?" Participants rate the number of times these problems have bothered them on a 4-point scale of 0 (*not at all*), 1 (*several days*), 2 (*more than half the days*), or 3 (*nearly every day*). The total score for the PHQ-4 ranges from 0 to 12, with higher scores indicating more symptoms of psychological distress. Following established protocols, the total score was transformed into 4 categories, which indicated various psychological distress levels: *none-to-minimal* (≤2), *mild* (3-5), *moderate* (6-8), and *severe* (9-12).

The PHQ-4 can be divided into 2 ultrabrief screening scales [21,22]: the 2-item Generalized Anxiety Disorder (GAD-2) scale for screening anxiety disorders and the PHQ-2 for screening depression disorders [23,24]. PHQ-2 and GAD-2 subscales have values ranging from 0 to 6, with higher scores suggesting more symptoms of depression and anxiety. A subscale score of 3 suggests a cut-off point between the normal range and probable clinical depression or anxiety disorder [20]. Using a cut-off value of 3, the PHQ-2 and GAD-2 scales were converted into binary variables, indicating a greater risk of depression and anxiety.

The PHQ-4 has been evaluated for construct validity in general [20,21,25], and it has been shown to correspond with suitable self-report measures and known demographic risk factors for depression and anxiety. In this research, the PHQ-4 had a Cronbach α of .88, while the GAD-2 and PHQ-2 subscales had a Cronbach α of .88 and .83, respectively. The reliabilities were comparable to those of other research that used the same scale in a similar context.

Pandemic Anxiety

A survey item assessing the prevalence of symptoms of physical anxiety linked to the COVID-19 outbreak was used to assess pandemic anxiety [26,27]. The survey question asked participants how often they had physical anxiety symptoms over a certain week, reflecting their COVID-19 experience: "In the past 7 days, have you had physical reactions, such as sweating, trouble breathing, nausea, or a pounding heart, when thinking about your experience with the COVID-19 pandemic?" Participants chose from the following list of options: *rarely or none of the time* (less than 1 day), *some or a little of the time* (1-2 days), *occasionally or a moderate amount of time* (3-4 days), or *most or all of the time* (5-7 days). This question has been modified from the Impact of Event Scale used by the American Psychiatric Association to capture reported physical discomfort following traumatic events. The criteria used are defined in the *Diagnostic and Statistical Manual of Mental Disorders* as symptoms of posttraumatic stress disorder [28]. Based on previous research, a binary measure was created by keeping the lowest variable level, *rarely or none of the time* (less than 1 day), as 0 and the 3 highest variable levels as 1 [27].

Physical Activity

The International Physical Activity Questionnaire - Short Form (IPAQ-SF) was used in the assessment of the levels of individuals' PA and had good reliability, as measured [29,30]. This questionnaire asks about PA done in the previous 7 days and details on the frequency and duration spent on 3 distinct levels of PA: vigorous-intensity activity (eg, aerobics), moderate-intensity activity (eg, carrying light load, bicycling at a regular pace), and walking activities. According to the official IPAQ scoring procedure, the participants of the study were classified into 3 different categories of PA (*highly active*, *minimally active*, and *inactive*), with the IPAQ analytic algorithms considering both the total PA volume and the number of days/sessions. Individuals who were highly active surpassed the minimal public health PA guidelines and accumulated enough exercise to maintain a healthy lifestyle. Individuals who were minimally active got the minimum amount of exercise recommended for adults in current public health guidelines but not enough to be highly active. Individuals that were inactive were engaged at the lowest level of PA, meaning they did not fulfil the minimal active requirements.

Physical Activity Locations

Participants were asked to report the frequency of the types of locations they used for PAs before the pandemic and during the COVID-19 outbreak to determine whether the pandemic impacted how individuals engaged in physical exercise. The following options were provided: parks/trails, botanical gardens, recreational sports/intramural facilities, neighborhoods, home-based activities (eg, workouts, housekeeping, fitness video games), fitness facilities (eg, gyms), time outdoors with animals, transportation to the workplace, and the workplace. Participants of the study indicated how often they used each of these locations for PA purposes over a 1-month period, on a scale of 0 (*never*), 1 (*rarely*), 2 (*sometimes*), and 3 (*frequently*), before and during the pandemic. This tool was developed by Michigan State University as part of the PhenxTookit for COVID-19 [31].

Data Analyses

First, descriptive statistics on the main variables analyzed were reported, and gender differences (female vs male) were examined using chi-square and *t* tests for categorical data and continuous data, respectively. Differences between PA groups were investigated and are reported in Multimedia Appendix 1. Second, a series of ordinal and binary logistic regression analyses were conducted to examine the effects of PA (independent variable) on the probability of experiencing mental health issues (dependent variables), considering potential confounders (age, gender, education, marital status, smoking, and ethnicity) [32-35]. Dependent variables included psychological distress (categorical data), depression (binary data), anxiety (binary data), and pandemic anxiety (binary data).

The results of the logistic regression analyses were presented as odds ratios (ORs) and their 95% CIs [36]. Third, we used Wilcoxon signed-rank tests to explore changes in the locations of participants' PA between the pre-COVID-19 period and the COVID-19 period by different PA groups. Effect sizes were reported for the relevant statistics.

Participants were given the option of stopping the survey at any time or skipping a question if they did not feel comfortable answering it. Following the cleanup of missing and irregular data, there were a small number of participants lacking PA data (n=51, 13.4%) due to unanswered questions on the scale. For PA location data, missing data varied from 0.3% to 3.9%. The percentage of missing data for questions related to pandemic anxiety was 0.3%. Many sociodemographic variables (eg, gender, education, ethnicity, marital status) had missing data ranging from 0.3% to 1.6%. There was no difference in demographic distribution between individuals with missing data and those with full data. Missing data were preserved in the analysis sample and deleted pairwise. All analyses were accomplished with SPSS Statistics version 27.

Results

Sample Characteristics

Table 1 presents the sociodemographic and health characteristics of the sample. There were 287 (75.9%) females, 88 (23.3%) males, and 3 (0.8%) others. In addition, there were 156 (40.9%) participants in the 18-24-year age range, 164 (43.0%) in the 25-44-year age range, and 61 (16.0%) in the ≥45-year age range. Over half (n=249, 66.4%) of the participants were single or never married, and 207 (54.5%) of the individuals had a bachelor's degree or above. About half of the participants (n=213, 56.3%) resided either in big cities or small cities. Almost three-quarters (n=278, 73.0%) of the sample reported being employed before COVID-19, while 67 (17.6%) reported having lost their job since the pandemic. The sample was racially diverse, with 41 (10.9%) Asians, 55 (14.6%) Black/Africans, 112 (29.7%) Caucasians, 124 (32.9%) Hispanic/Latino, and 35 (9.3%) others. Most of the participants did not smoke (n=338, 88.9%).

As assessed by the PHQ-4 (mean 4.4, SD 3.6), 134 (35.2%) of the individuals had none-to-mild, 123 (32.3%) had mild, 64 (16.8%) had moderate, and 60 (15.7%) had severe symptoms of psychological distress. In addition, 133 (34.9%) of the participants were likely to suffer from depression, whereas 145 (38.1%) of the individuals had probable anxiety. Nearly a quarter of the sample stated that they were concerned about a pandemic (n=89, 23.4%). Finally, according to the IPAQ-SF, 122 (37.0%) of 330 participants were categorized as inactive, 96 (29.1%) as minimally active, and 112 (33.9%) as highly active.

Table 2 depicts that no gender differences were observed for the majority of the variables examined, although females reported greater psychological distress and anxiety and were also less likely to be physically active (all $P<.05$).

[a]The *P* values represent chi-square/*t* tests of independence, indicating associations between sex and categorical variables. Categories were created for age (18-24, 25-44, and ≥45 years).

[b]N/A: not applicable.

[c]PA: physical activity.

Logistic Regression Analyses

We used ordinal and binary logistic regressions to estimate the ORs (and 95% CIs) for the association of PA (independent variable; categorical) with various mental health outcomes, with the confounding factors of gender, age, race, educational level, marital status, and smoking considered (Tables 3-6). Psychological distress (categorical), depression (binary), anxiety (binary), and pandemic anxiety (binary) were dependent variables.

Table 3. ORs[a] for logistic regression analyses for physical levels and mental health outcome (psychological distress).

Characteristics	OR (95% CI)	*P* value
Gender (reference "male," n=74)	1.75 (1.01-3.02)	.05
Age (years; reference≥45, n=46)

Psychological Distress

According to ordinal logistic regression, inactive people were 2.17 times more likely than highly active people to have higher levels of psychological distress (OR 2.17, 95% CI 1.27-3.69, *P*=.004).

Regarding confounding factors, individuals aged 18-24 years (OR 3.60, 95% CI 1.39-9.32, *P*=.008) and 25-44 years (OR 2.98, 95% CI 1.37-6.49, *P*=.006) were more likely to experience psychological distress than those aged ≥45 years. Females were 1.75 times more likely to experience greater psychological distress than males (OR 1.75, 95% CI 1.01-3.02, *P*=.05). Those who had just finished high school or some high school (OR 4.37, 95% CI 1.71-11.19, *P*=.002) and some college or associate degree (OR 2.56, 95% CI 1.28-5.14, *P*=.008) were more likely to experience psychological distress than those who had completed a graduate or professional school program. Single individuals had a higher risk of distress (OR 2.49, 95% CI 1.35-4.59, *P*=.003) than married people or those in a domestic partnership. Participants who smoked had increased odds of psychological distress (OR 4.35, 95% CI 2.257-8.381, *P*<.001).

Depression

Logistic regression results revealed a significant relationship between PA levels and depression (*P*<.001). Minimally active individuals were 2.14 times more likely to suffer from depression than highly active people (OR 2.14, 95% CI 1.05-4.33, *P*=.04). The odds of having depression were 3.81 times greater among inactive individuals than among highly active individuals (OR 3.81, 95% CI 1.92-7.57, *P*<.001).

Furthermore, individuals aged 18-24 years (OR 5.23, 95% CI 1.32-20.76, *P*=.02) and 25-44 years (OR 4.5, 95% CI 1.36-14.92, *P*=.01) had higher odds of depression than those aged ≥45 years. Completing just high school or some high school (OR 7.14, 95% CI 2.19-23.25, *P*=.001) and some college/associate degree (OR 2.88, 95% CI 1.19-6.99, *P*=.02) was connected to greater odds of having depression. Individuals who smoked were 3.422 times more likely to suffer from depression than those who did not (OR 3.422, 95% CI 1.56-7.51, *P*=.002).

Anxiety

We found no significant relationship between PA levels and anxiety disorder in binary logistic regression, though the odds of anxiety were marginally higher among inactive participants than among highly active participants (OR 1.86, 95% CI 0.99-3.47, *P*=.05).

Gender marginally predicted the odds of anxiety (*P*=.06), where females had 1.91 more chances of having anxiety than males (OR 1.91. 95% CI 0.984-3.702). Single individuals had greater odds of having anxiety than married people or those in a domestic partnership (OR 3.08, 95% CI 1.45-6.55, *P*=.003). Smoking increased the odds of anxiety 2.16-fold (OR 2.16, 95% CI 1.023-4.555, *P*=.04).

Pandemic Anxiety

We found no significant connection between PA levels and pandemic anxiety in logistic regression analysis or between major demographic factors and pandemic anxiety; however, those aged 25-44 years (OR 4.23, 95% CI 1.10-16.22, *P*=.04) were more likely to suffer from pandemic anxiety than those aged ≥45 years.

Changes in Locations of PA Following COVID-19

Wilcoxon signed-rank tests were conducted to examine the changes in the frequency of usage of various PA-performing locations before and during the COVID-19 outbreak and how they might vary for inactive, minimally active, and highly active people (Table 7). Inactive individuals during COVID-19 were less likely to engage in physical exercise at parks/trails (Z=–4.01, *P*<.001), botanical gardens (Z=–2.02, *P*=.04), recreational sports or intramural facilities (Z=–3.04, *P*=.002), neighborhood sidewalks and parks (Z=–3.78, *P*<.001), and fitness facilities (Z=–4.35, *P*<.001); during commuting to work (Z=–4.696, *P*<.001); and at their workplace (Z=–3.19, *P.*<001). The results for the minimally active individuals were largely the same as those for the inactive individuals such that the probability of performing PA at parks/trails (Z=–1.90, *P*=.06), botanical gardens (Z=–2.52, *P*=.01), recreational sports and intramural facilities (Z=–2.52, *P*=.01), and fitness facilities (Z=–4.29, *P*<.001) and during transport to the workplace (Z=–3.53, *P*<.001) were ranked less frequently during COVID-19. However, minimally active individuals spent a comparable amount of time performing PA in their neighborhood (*P*=.91) and at work (*P*=.52). For highly active people, although the frequency of performing PA in botanical gardens (Z=–2.545, *P*=.01) and fitness centers (Z=–4.71, *P*<.001), during transit to work (Z=–3.82, *P*<.001), and at the workplace (Z=–2.33, *P*=.02) decreased, the frequency of performing PA in parks/trails (*P*=.17), recreational sports/intramural facilities (*P*=.16), and neighborhoods (*P*=.45) did not change significantly. Furthermore, only highly active individuals increased their PA at home (eg, workouts, housekeeping, yard work, gardening, exercise, video games) during the pandemic (Z=2.93, *P*=.003). Finally, the likelihood of engaging in PA outdoors with animals did not change, and this was the same for all 3 PA groups (all *P*>.30).

Table 7. Wilcoxon signed-rank tests: comparing locations[a] of PA[b] before and during COVID-19 (split by 3 PA groups).

Discussion

Principal Findings

In this study, we examined the impact of pandemic restrictions on physical exercise and its connections to mental health in a community sample of adults. Our results showed that those who engaged in greater PA during the COVID-19 pandemic had less psychological distress, depression, and anxiety than those who engaged in less PA. Furthermore, COVID-19 was found to make it hard for people to keep up with their PA habits, especially for people who were less active in using outdoor and public PA facilities.

According to the data, approximately 133 (34.9%) and 145 (38.1%) of the sample scored above the cut-offs for depression and anxiety, respectively; about two-thirds of individuals reported mild-to-severe psychological distress. The logistic regression illustrated that not engaging in PA during COVID-19 was related to about 1.86-3.81 times' higher risks of psychological discomfort, depression, and anxiety disorders. The highest degree of PA (exceeding the minimum public health PA recommendations and accumulating enough activity for a healthy lifestyle) but not moderate PA (fulfilling minimal PA recommendation) appeared to be associated with lower psychological risk during a pandemic [9]. These results were essentially consistent with the majority of prior studies on the relationship between PA and COVID-19, showing that PA would protect people's mental health in general and lessen their risk of depression and anxiety [5,6,9,17,18,37]. The outcomes of this study might help people live healthy, resilient lives both during and after the worldwide pandemic.

When examining the different types of mental health problems, there was some evidence from logic regression analyses that PA might affect depression more than anxiety. Participants who were inactive had marginally higher odds of anxiety than those who were highly active, while those who were inactive or minimally active had higher odds of depression than those who were highly active. One explanation might be a stark temporal differentiation between the natures of depression and anxiety. For example, participants reported depression-triggering events taking place in their past, relating to loss and failures in

achieving goals, whereas anxiety-triggering events were related to fears about the future [38]. In the unique case of the COVID-19 pandemic, 1 of the most salient factors individuals were challenged with was the inherent inability to predict how long restrictions and legitimate health risks would prevail, putting enormous doubt on life in the future. Although an inability to control current circumstances might be combatted by decreasing cortisol levels and achieving personal fitness goals through PA, positively affecting depression levels, remedies for anxiety about the prevalence of the pandemic and an inability to project what is to come cannot be manufactured. Our findings were consistent with a recent study performed during COVID-19 on a Chinese sample between February and March 2020, which found that the link between PA and depression was more robust than the association between PA and anxiety [39]. Research conducted in a sample of older adults over the age of 50 years who lived in North America in April 2020 found that PA was not a significant predictor of anxiety symptoms after controlling for age, sex, and education, while PA was a significant predictor for depressive symptoms [7]. A meta-analysis of the relationship between PA and depression and anxiety in nonclinical adult populations found that PA decreased depression with a medium effect size and anxiety with a small effect size [40], independent of the pandemic. A quick systematic review conducted during the pandemic found a similar result: the relationship between PA and depression was more consistent than the relationship between PA and anxiety [5]. Further analysis is needed to find the other additional factors that are linked to anxiety in the global pandemic.

Our results revealed that the amount of time people spent on PA at various locations varied before and after the start of COVID-19. In general, reduced PA seemed to be linked to a lack of sporting opportunities. COVID-19 had a greater impact on reducing the use of PA resources (such as parks/trails, recreational sports, neighborhoods) by people who were classified as less active or minimally active. Highly active individuals might have been affected less and have adapted to doing their PA in the comfort of their homes. Individuals who participated vigorously in regular physical exercise might have acquired PA-related health literacy, which enabled them to use it as a typical coping technique for negative emotions, resulting in the fast adoption of new sports routines. Health care providers and the government may urge inactive individuals to include PAs in their everyday lives to reduce the rise in mental health issues during the current pandemic. Given the uncertainties surrounding the return to normalcy, encouraging at-home activities seems to be a viable solution. Virtual reality (VR) technologies (eg, Oculus Quest) and other home-based commercial video games (eg, Nintendo Switch) have been shown to improve PA in settings that are more pleasant and entertaining, which is especially appropriate when movement in the outdoor world is restricted [41-43].

Demographic factors associated with mental health risks included age, gender, smoking, education, and marital status, although their effects might vary depending on the kind of mental health problems studied. Females were more prone to stress, anxiety, and depression than males according to previous research [44,45]. We found that females had higher psychological distress and anxiety odds than males during the pandemic. Previous research revealed that younger people were more likely to have worse mental health than older people, and risk factors, such as loneliness and financial hardship, were more likely to impact younger people than others during the COVID-19 pandemic [45-47]. Our study found that those over 45 years had the lowest psychological distress and depression ratings. Smoking is frequently associated with poor mental health, regardless of the pandemic [48]. According to our results, individuals who smoked had higher levels of psychological distress and higher levels of depression and anxiety. In contrast to marriage, being single or divorced has been associated with poorer mental health [49]. Our study reported that those in marriage or domestic relationships experienced lower stress and anxiety during the pandemic. Our findings also revealed that higher levels of education were critical determinants related to greater positive well-being [50]. Furthermore, our supplementary analysis results indicated gender, racial, and age differences in PA, consistent with previous research [51]. To sum up, many of these health-related demographic variables had been identified in previous research prior to the pandemic. These findings suggest that sociodemographic risk factors would be linked to the risk of physical and mental health during the pandemic.

We have achieved considerable progress in studying the effects of physical exercise on psychological health during the pandemic. Wolf et al [5] noted methodological issues, such as using unvalidated measures and the inability to offer standardized coefficients, in their most recent review paper published in 2021 evaluating publications on associations between PA and depression and anxiety during COVID-19. Wolf et al [5] also stated that studies included in their review used heterogeneous statistical approaches (eg, multiple linear regression, logistic regression) and study designs (eg, cross-sectional, longitudinal design), which would have yielded a more sophisticated overall effect estimate of the relationships between PA and depression and anxiety. Based on our effect size measures, our study found similar effects of physical exercises on reducing mental health problems as prior studies conducted in a comparable context [9,52]. Furthermore, our study included data from later in the pandemic, enabling future researchers to get a more complete picture of the effect of PA on pandemic mental health.

Limitations

The study's limitations included the use of a cross-sectional research methodology. As a result, the causal nature of these relationships was unknown. PA was not linked to the pandemic anxiety and could have been attributed to lower COVID-19-related physical anxiety symptoms in individuals. Of 380 participants, 291 (76.6%) reported that they had few or non-pandemic-related concerns. Participants might have been expected to be increasingly adapted and prepared as the pandemic progresses. Furthermore, although we followed the previous study of measuring pandemic-related anxiety [27], a single question measuring anxiety related to the pandemic in the past week may not possibly sum up all the characteristics of pandemic-related stress, and additional research is necessary. Another limitation worth mentioning was the sampling method

[53]. The study used a convenience sample approach by recruiting university community members. Such samples could attract volunteers who were already engaged and interested in the issue and had internet access. Previous research suggested that people who were currently suffering from or had a serious mental illness might be less likely to participate online than those who were not [53-55]. The study also included a larger female sample, although a more balanced sample was anticipated. As we have seen, the sampling method is an important issue in research, and we will continue with caution when extrapolating our findings to a different population setting.

Because of the COVID-19-related restrictions on human subject research during the pandemic, we were unable to examine the mechanisms through which physical exercise could help people's mental health via collecting neurobiological data in the study. This warrants further investigation by other researchers. The biological pathway through which PA affects mental health is likely via the hypothalamic-pituitary-adrenal (HPA) axis regulation [56,57]. Physical fitness and physical exercise, for example, were shown to be associated with reduced cortisol release when subjects were subjected to psychosocial stressors [58]. Additionally, recent research indicated that exercise's positive benefits on the brain were associated with possible underlying biological processes, including the gut-brain, muscle-brain, and liver-brain axes [59]. Future studies may also explore the effect of COVID-19 on PA in countries with more substantial or fewer restrictions to see whether there are differences. Research in the future may focus on establishing and evaluating interventions that help people maintain regular exercise as part of their daily lives throughout and after the pandemic.

Conclusion

In summary, the results from this study showed that people who did more PA during the COVID-19 pandemic had less psychological distress, depression, and anxiety than people who engaged in less PA. Additionally, it was found that COVID-19 interrupted people's opportunities, particularly those less active in using outdoor and public PA facilities to keep PA habits. Without a doubt, the pandemic's influence, particularly the long-term effects, cannot be predicted at the moment. Promoting and encouraging PA behavior is a cost-effective way of creating a necessary distinction between those who have a basic mental health need and those who are mentally well. This strategy is particularly beneficial in communities with inadequate health resources [60].

Acknowledgments

We would like to express our gratitude to everyone who took the time to participate in the survey. The research presented in this publication was supported by the Separately Budgeted Research Projects Award from New Jersey City University to WZ.

Abstract

Background: Despite the availability of culturally responsive sexual health educational programs for American Indian and Alaska Native (AI/AN) youth, barriers to their uptake and utilization persist in tribal communities. These challenges were exacerbated by the COVID-19 pandemic, which required flexible program delivery using both in-person and virtual classrooms.

Objective: This exploratory study provides a preliminary understanding of the extent to which pre-existing challenges impact the delivery of culturally responsive sexual health education programs in Native communities and to what extent they were exacerbated by the COVID-19 pandemic. It also highlights the challenges faced by adolescent health advocates when adapting culturally responsive health curricula to online platforms. Finally, this study discloses major socioeconomic, health, and mental challenges experienced by AI/AN youth during the pandemic.

Methods: An exploratory, descriptive, qualitative design approach was adopted to carry out 5 individual and 1 collective in-depth key informant interviews. A total of 8 Native and non-Native sexual health educators served as key informants and shared their personal experiences with the delivery of sexual health education programs for youth during the COVID-19 pandemic. The interviews were conducted virtually from October to November 2020 using Zoom to reach participants dispersed across different regions of the United States. We followed the consolidated criteria for reporting qualitative research (COREQ) as a reference for the study methodology. We also used the Braun and Clarke framework (2006) to conduct a thematic analysis.

Results: Experts' opinions were structured according to 5 main themes: (1) competing community priorities during COVID-19; (2) moving to web-based programming: skills, training, support; (3) recruiting youth; and (4) challenges for implementation in a household environment; and (5) recommendations to overcome implementation challenges. These themes are complementary, connected, and should be considered holistically for the development, dissemination, and implementation of online sexual health programs for AI/AN youth, specifically during the COVID-19 pandemic. The results raised the following points for discussion: (1) Building partnerships with schools and community organizations facilitates program adaptation and implementation, (2) there is a need to adopt a holistic approach when addressing youth sexual health in AI/AN communities, (3) a systematic and culturally responsive adaptation approach ensures effective virtual program delivery, and (4) community and youth engagement is essential for the success of virtual sexual health programs.

Conclusions: Findings can provide recommendations on actions to be taken by sexual health educators and guidelines to follow to ensure cultural sensitivity, effective adaptation, and successful implementation when setting out to advocate for online sexual health programs for AI/AN youth.

(JMIR Form Res 2022;6(4):e32325) doi:10.2196/32325

Introduction

In the United States, racial and ethnic disparities in teen births and sexually transmitted infections (STIs) persist [1]. American Indian and Alaska Native (AI/AN) females aged 15-19 years have the highest teen birth rate [1,2] and the highest prevalence of repeat teen births [3,4] compared to other racial/ethnic groups. AI/AN youth are also disproportionately affected by STIs, including HIV, gonorrhea, and chlamydia [5-7].

To address these disparities, culturally responsive programs have been receiving significant attention as a means to help public health specialists deliver culturally sensitive, evidence-based preventive practices to diverse racial/ethnic populations [8-10]. Culturally responsive programs are defined as the degree to which the cultural values, norms, beliefs, and practices of the target population are integrated into the design, delivery, and evaluation of an intervention [11]. This principle is supported, in part, by research assessing the impact of certain cultural values on several psychosocial outcomes [12]. For instance, researchers have highlighted that parental involvement in a culturally responsive, technology-based intervention to improve parent-child communication on sexual health can moderate and protect AI/AN youth from engaging in early sexual debut [13-17]. The familial system in Native culture has been consistently reported to be a protective factor for major risky behaviors among AI/AN youth [18]. Hence, efforts to address sexual health disparities among AI/AN youth through evidence-informed and culturally responsive programs are essential to improve the overall health outcomes of this underrepresented population [19,20].

Despite the availability of culturally responsive sexual health educational programs on websites, such as that of Healthy Native Youth [19], barriers remain to their uptake and utilization in tribal communities [13,21-30]. Many of these challenges were exacerbated by the COVID-19 pandemic, which required flexible delivery using both in-person and virtual classrooms [31]. Since the start of the pandemic, access to sexual and reproductive health care services for AI/AN youth has become limited in scope [22]. Native youth have also experienced challenges trying to access confidential and private sexual health information when switching to the telehealth platform, along with their inability to participate in in-person school-based sexual health education programs or attend in-person appointments in health clinics [32-36]. Maintaining youth's access to appropriate and culturally tailored sexual health education programs to increase awareness of sexual health promotion and contraceptive use is essential to prevent a peak in unintended pregnancies and STIs among this vulnerable population group [37,38].

Across the United States, many health educators relied on schools as the primary channel to deliver sexual health education to youth prior to the pandemic [39-41]. Others relied on technology-based platforms as feasible mechanisms to disseminate culturally adapted sexual health content for AI/AN youth [13,20]; enhance community expertise and resources to adopt, implement, and maintain evidence-based programs; and improve the likelihood of attaining positive sexual and reproductive health outcomes [15,21,22,24-27]. However, COVID-19 restrictions significantly affected the continuity of school-based in-person programs, since health educators were faced with the challenge of tailoring health lessons to the online platform in a short period, while ensuring the cultural sensitivity of the shared material [31]. Participation in ongoing in-person programs and recruitment for new virtual programs both were impacted by school shutdowns, particularly when trying to reach youth with limited internet connectivity or unsupportive parents in conservative areas [42].

Additionally, barriers to disseminating virtual programs in tribal communities, similar to those identified for in-person programs, continue to exist for several reasons. First, the lack of community readiness and the limited availability of resources to address sensitive topics, such as adolescent sexual health, hinders the delivery of sexual health education programs in AI/AN communities [20]. Second, inconsistencies in tribal policies, protocols, and schoolboard approval processes may generate delays in program adoption and implementation [28]. Third, poverty may result in high personnel turnover or temporary closures for AI/AN youth–serving agencies, which might negatively influence implementation fidelity and program maintenance [15]. Fourth, limited access to remote villages and rural AI/AN reservations creates a recruitment challenge for adequate program implementation [15]. Finally, competing priorities in AI/AN communities, such as food insecurity and the need to focus on other academic skills (ie, math, reading, writing) for limited virtual teaching time, might lead to a lack of support from key stakeholders. This in turn results in limited knowledge of evidence-based sexual health programs and low self-efficacy to adapt and implement them [29,30].

This exploratory study shares lessons learned by educators involved in the implementation of online sexual health programs for AI/AN youth during the pandemic. It also provides an understanding of the extent to which pre-existing challenges in the delivery of culturally responsive sexual health education programs in Native communities were exacerbated by the COVID-19 pandemic. Challenges faced by tribal health experts while adapting culturally responsive health programs to the online delivery platform are also highlighted. Finally, this study describes major socioeconomic, health, and mental challenges experienced by AI/AN youth during the pandemic. Emerging themes may assist sexual health educators in the development

of key strategies for effective dissemination and implementation of virtual sexual health education programs to mitigate the impact of the COVID-19 barriers and the effects of existing underlying challenges throughout program delivery. Such guidance is of utter importance to tribal health experts who are struggling to manage new and pre-existing COVID-19 challenges influencing the successful delivery of culturally sensitive sexual health programs.

Methods

Study Design and Setting

An exploratory, descriptive, qualitative design approach was adopted to carry out 5 individual and 1 collective in-depth key informant interviews. A total of 8 Native and non-Native health educators served as key informants and shared their personal experiences with the delivery of sexual health education programs for youth during the COVID-19 pandemic. They also shared their diverse perspectives on the utility of using online sexual health education platforms and programs to increase reach and accessibility to youth during uncertain times. Some of the key informants were newly adapting their sexual health program to an online platform, while others were already acquainted with online delivery and had been implementing such programs for an extensive period. The interviews were conducted virtually from October to November 2020 using Zoom (Health Insurance Portability and Accountability Act of 1996 [HIPAA]-compliant Zoom session) to reach participants dispersed across different regions of the United States (Northwest, Southwest, and mid-Atlantic Pacific). We followed the consolidated criteria for reporting qualitative research (COREQ) as a reference for the study methodology (Multimedia Appendix 1).

Ethical Considerations

The study was approved by the Committee for the Protection of Human Subjects at the University of Texas Health Science Center Houston (HSC-SPH-11-0577). The lead author obtained oral recorded informed consent from the participants prior to the start of the interview. Since the interview covered topics solely related to their professional experience, a waiver of written consent was granted, and each participant was provided, instead, with a letter of information (Multimedia Appendix 2), which described the goals and topics of the study, along with an emphasis on the voluntary nature of participation.

Research Team

The research team comprised experts in the design and implementation of sexual health education programs for Native youth (authors CM, BH, RS, and MP) and a doctoral public health student (author LS), who served as the principal investigator of the study. LS was well trained on how to conduct qualitative research and how to effectively moderate the key informant interviews in an ethical manner.

Participant Recruitment

In total, 15 health experts working with AI/AN youth in the United States were identified from existing publications in which they were named as authors, as well as evidence-based sexual health programs in which they were credited as principal investigators or significant collaborators. These experts had different functions in diverse fields of expertise, including adolescent sexual health, mental health, and suicide prevention. Experts were eligible to participate in the study if they (1) had experience in the adoption, implementation, and maintenance of sexual health education programs (at least 1) for AI/AN youth; (2) served tribal regions within the United States; (3) had personally experienced the impact of COVID-19 on the accessibility of sexual and reproductive health services by AI/AN youth and on the delivery of adolescent sexual health education programs; and (4) identified as Native or non-Native. Experts were invited to participate in the study by email. An attached letter of information was included in the invitation to provide additional insight into the goals and objectives of the study. Of the 15 identified experts, 8 (53%) agreed to participate. The characteristics of the participant experts are presented in Table 1. No monetary incentives were provided for participation.

Table 1. Expert characteristics (N=8).

Mid-Atlantic	2 (25.0)

[a]Some experts work in different organizations and have multiple specializations, in addition to adolescent sexual health.

Data Collection and Data Management

The lead author (LS) conducted the semistructured interviews via Zoom at a day/time based on the interviewees' preferences [43]. Each interview ranged from 35 to 65 minutes. Interviews were audio-recorded and transcribed verbatim using Otter.ai software [44] after receiving the interviewees' permission. The interview guide included open-ended questions based on 3 constructs (adoption/adaptation, implementation, and maintenance) within the broader dissemination and implementation field [43,45]. Questions prompted the interviewees on sharing challenges faced in the adoption, implementation, and maintenance of sexual health education programs for Native youth during the COVID-19 pandemic, as well as actions taken to address these challenges to implement sexual health education programs (Multimedia Appendix 2) more effectively.

The interview guide was divided into 3 main sections (Introduction, Impact of COVID-19 on the Delivery of Sexual Health Education Programs, and Use of Online Sexual Health Platforms in Response to COVID-19), with open-ended questions regarding their experience addressing COVID-19-related challenges and adapting to online delivery and recommendations for developing and implementing online sexual health programs for AI/AN youth. Most of the interviews were with individuals; however, 1 small group interview was held with 3 experts who worked together.

To protect participant confidentiality, all records were stored in locked cabinets and password-protected computer systems for use by the research team only. All (n=8, 100%) participants' records were given a unique study ID number for data management purposes. No names were included in the data analysis files or in reports.

Data Analysis

We used the Braun and Clarke framework [46] to conduct a thematic analysis. This framework comprises 6 phases: (1) familiarizing yourself with your data, (2) generating initial codes, (3) searching for themes, (4) reviewing themes, (5) defining and naming themes, and (6) producing the report. In the first phase, the lead author (LS) thoroughly read each transcript to get acquainted with the collected information. In

the second phase, detailed descriptive coding was conducted using the comments section in Microsoft Word. In the third phase, an initial list of all codes and subthemes was generated by the lead author. In phase 4, a codebook of all potential themes and subthemes was created, including a list of definitions and quotes to support identified themes and subthemes (Multimedia Appendix 3). In phase 5, a list of candidate themes and subthemes was refined and condensed to highlight important recognizable issues and relationships between themes. In phase 6, the findings were presented in narrative form with quotes from key informants to support the identified themes and subthemes. A synthesis of the results was prepared to guide sexual health experts in the development of online sexual health programs for Native communities, while considering unprecedented challenges that might be encountered in the process.

Data analysis was conducted in a precise, consistent, and exhaustive manner by ensuring the credibility, transferability, dependability, and confirmability of our analysis, as well as the use of audit trails [47]. To check for credibility, peer debriefing was adopted to provide an external check on the research process, as well as referential adequacy, which allows for the checking of preliminary findings and interpretations of raw data [48]. Transferability was established by involving sexual health experts from diverse tribal regions to ensure generalizability of results [49]. Dependability was achieved by ensuring clear documentation and traceability of results [49]. All 3 criteria led to confirmability, along with a clear explanation of the analytical framework used in the study. Finally, keeping records of the raw data, field notes, and transcript for clear reporting of the data all contributed to an audit trail (ES Halpren, *Auditing Naturalistic Inquiries: The Development and Application of a Model*, unpublished doctoral dissertation, 1983).

Results

Main Themes and Subthemes

Experts' opinions were structured according to 5 main themes: (1) competing community priorities during COVID-19; (2) moving to web-based programming: skills, training, support; (3) recruiting youth; (4) challenges for implementation in a household environment; and (5) recommendations to overcome implementation challenges. These themes are complementary, connected, and should be considered holistically for the development, dissemination, and implementation of online sexual health programs for AI/AN youth, specifically during the COVID-19 pandemic. The themes and subthemes are presented in Textbox 1 (also see Multimedia Appendix 3 for representative quotes).

Textbox 1. Key themes and subthemes identified in the interviews.

Theme 1: Competing community priorities during COVID-19

- Food security and water sanitation measures
- Financial hardship
- Mental health impact
- Focusing on COVID-19 response in clinics and centers
- Sexual health as a secondary concern

Theme 2: Moving to web-based programming: skills, training, support

- Adaptation of programs to the online platform
- Lack of sufficient time and staff support in the stressful adaptation process
- Youth missing a 1-on-1 connection

Theme 3: Recruiting youth

- Using social media platforms for youth outreach
- Differences in the online program youth participation rate
- Distribution of flyers in community locations

Theme 4: Challenges for implementation in a household environment

- Challenge of youth program participation from a home environment
- Low bandwidth and network connectivity issues
- Dealing with youth internet access

Theme 5: Recommendations to overcome implementation challenges

- Building partnerships with schools and community organizations for program adaptation and implementation
- Adopting a holistic approach when addressing sexual health in American Indian and Alaska Native (AI/AN) communities
- Adopting a systematic and culturally responsive approach for effective virtual program delivery
- Community and youth engagement for the success of virtual sexual health programs

Competing Community Priorities During COVID-19

Food Security and Water Sanitation Measures

The impact of COVID-19 on food security and water sanitation in AI/AN communities led sexual health experts to shift their roles toward food relief and building water sanitation stations. An expert highlighted the hidden food insecurity crisis in AI/AN households that is rarely mentioned in the news (Int1, where "Int" refers to "interview"). Another participant shared that there is a struggle in some households to find baby formula, which encourages AI/AN mothers to breastfeed their infants (Int2-P3, where "P" refers to "participant"). Hand-washing stations provided running water to take care of the necessary hygienic procedures during COVID-19 (Int4).

> *I mean, the food insecurity, I feel like we never hear about that on the news. But, um, the food insecurity is a major, major issue, like meeting the basic needs of households has been a primary thing that I've been hearing from…from Native communities and…and others, you know, that they're…they're either doing contact tracing, or they're doing food relief.* [Int1]

> *And we've also been building hand-washing stations. So, like I was saying earlier, people don't have running water. And you can ask people to wash their hands; if they don't have running water, they need to save that water to drink and to clean themselves and to, you know, cook their food. So, we've been creating hand-washing stations that we've also been delivering to our various partners.* [Int4]

Financial Hardship

Of the 8 experts, 4 (50%) highlighted the financial hardship AI/AN families are struggling with as a result of the COVID-19 pandemic (Int1, Int4-Int6); 1 (25%) of them expressed the financial burden caused by COVID-19 on AI/AN parents and youth because youth had to exchange the opportunity to participate in a sexual health program with the need to find a job to support their families (Int1). A participant also reflected on the long-standing economic inequities that became more apparent during the pandemic (Int4).

> *They have to deal with food insecurity and, like, unemployment, so the kids have to help their parents; that is a national dilemma, right, you know…everybody sort of, kind of everything sort of*

> *falling away. But the basics, you know…and you know, it's an unfortunate thing about this pandemic, is it's really just shedding a light on long-standing inequities and deep-seated inequities between groups in this country. And you know, it's really just shining light on that. And hopefully, some good will come of it.* [Int4]

Mental Health Impact

Many participants expressed concerns regarding youth's mental health during the pandemic. Based on her experience, 1 (12.5%) expert described the detrimental mental health impact of COVID-19 on youth due to the stress, anxiety, and worries associated with the unknown duration of the pandemic and the severity of the disease (Int2-P2). The lack of stability and the loss of elder lives were devastating at a community level (Int3, Int4). An additional concern was having youth feeling "zoom fatigue" as they also complete their schoolwork online (Int3). An expert emphasized the need to support youth since even though they seem to be handling the pandemic well, a spike in mental health conditions is emerging among this population (Int5). Another warned about the trends in youth mental health impacts over the next decade (Int6).

> *And I think, we're at real risk of, like, a widespread mental health crisis for young people, for teens, particularly. So, we cannot…we cannot not address that, like young people's lives are at stake when it when it comes to a time like this. So that would be like mental health piece is 1 of…my number 1 thing to do would be to build competence in how to do this and be really, really thoughtful about how you plan and prepare and deliver your programming.* [Int1]

> *And we've all kind of heard this; like zoom fatigue is such a thing where you're just on video calls all day, and you're exhausted. So, we didn't want this to be 1 more thing that a kid has to do that it's something that they want to do.* [Int3]

Focusing on COVID-19 Responses in Clinics and Centers

A common subtheme across all interviews was the shift in clinic focus away from providing core public health services toward COVID-19-related relief efforts. A participant explained how their Tribal Epidemiology Center pivoted to deal with the COVID-19-related testing and contact tracing, whereby all project-related staff were helping manage the COVID-19 surge in AI/AN communities rather than focusing on youth sexual health programs (Int3). Hesitancy to seek sexual health care during the COVID-19 pandemic was pointed out by an expert in the Northwest, as people did not want to increase their risk of exposure in small clinic spaces for regular checkups (Int2-P3). An expert shared about the switch to telehealth platforms to increase youth access to sexual health programs; however, accessibility differed across tribes (Int6).

> *And through our partnerships with [the Indian Health Service] (IHS), we've also been asked to help them with other COVID-related efforts. So, some of that, but all that work is new, and not necessarily what our team was doing prior to COVID. And it's constantly changing, and in flux…that both of the communities that we work with the most closely, there have been weeks where we have our team back, and it's almost as if, you know, it's not COVID, staff attendance, and availability, but then, you know, the surge…and we lose some of our staff members to necessary COVID-related work.* [Int3]

Sexual Health as a Secondary Concern

Of the 8 experts, 5 (62.5%) reported that sexual health moved from a community-wide health priority to a secondary concern due to challenges imposed by COVID-19 at the mental, economic, and nutritional levels. In addition, 1 (12.5%) participant expressed the need for a holistic approach to sexual health as people are prioritizing their basic needs and ensuring that all their family members are safe (Int2-P2). In terms of prioritizing needs, an expert emphasized the importance of relationship building by reframing messages in an informal context (Int6).

> *And now we're seeing a federal response saying here is a curriculum, a list that can be utilized for some of these programs. I think what's interesting is that it's just not the silo of physical sexual health. It's more holistic—mental health, social health, cultural health, and physical health.* [Int2-P2]

Moving to Web-Based Programming: Skills, Training, Support

Since the start of the COVID-19 pandemic, the majority of in-person and hybrid sexual health education programs had to be adapted to online learning platforms. Experts discussed major challenges faced in the delivery of virtual programs from their own perspective and from the youth's and communities' perspectives. The challenges were most apparent among experts adapting and translating health education programs to virtual platforms for the first time (Int3-Int5).

Adaptation of Programs to the Online Platform

Of the 8 participants, 1 (12.5%) described the challenge of trying to figure out how to coordinate with schools to plan and deliver virtual sexual health programs for youth while managing their ongoing hybrid learning platform (Int1). Other experts expressed struggling to identify which program components to keep, since most activities were designed for in-person delivery (Int3, Int4). A concern shared by most experts was ensuring that the adaptation process was not completed hastily to ensure they met youth's needs (Int1-Int4). In addition, 2 (25%) experts indicated that the in-person sessions were too long when adapted to the virtual platform and had to be shortened to ensure youth engagement throughout the session (Int3, Int4). Furthermore, 1 (12.5%) expert shared that a lot of adaptations needed to be made even for programs that used the online platform for content delivery, since these programs had a physical component to some extent prior to the COVID-19 pandemic (Int3).

> *It can be very quick to open up a Zoom account and get started on Zoom, right? You can do it in minutes. But that doesn't mean that you're prepared to*

implement a program online. So, I think that 1 of the challenges is that people are going to, I think, initially hastily put their programs together, and they're not going to be good. And they're not going to actually meet the needs of young people. [Int1]

You know, very quickly, we had to start adopting our own programming for virtual settings, and, you know, kind of identify which components of our work we're going to get [to] continue happening in community settings, because most of our tribal clinics closed, our tribal schools closed, public schools closed. So, kind of being in touch with our tribal health educators and our clinic staff to see which services and programs were continuing, what was being paused, what priorities they had for moving forward and trying to respond to those. [Int2-P1]

Lack of Sufficient Time and Staff Support in the Stressful Adaptation Process

Experts described the adaptation process as stressful for staff due to the limited time frame available. Of the 8 experts, 1 (12.5%) disclosed that staff were begging for support because meeting young people's needs was substantial during the pandemic. Another highlighted the gap in resources provided for employees working from home (Int5). In addition, 2 (25%) experts from the collective interview (Int2) described the process as "trial and error" due to the time constraints tribal employees encountered while becoming "Zoom savvy" for virtual programs. A common subtheme shared by all experts was the need for continuous staff training to get acquainted with the online platforms and software available to maximize youth learning and engagement. Participants believed that professional development is needed to help staff feel equipped to navigate virtual platforms (Google Classroom, Zoom, Jamboard, etc; Int3).

Secondly was how to coordinate our schedules and utilize a virtual platform such as Zoom and become Zoom savvy for us as professionals, and I can tell you, I think we've talked about it, we've been more busy now in a virtual setting than we have when we were in the office. [Int2-P2]

So, although some of these were presented in person, there was a lot of adaptation to go online, and what that looked like, so a lot of trial and error, a lot of challenges, and a lot of different avenues of communication and having to be also creative and also still innovative, too. [Int2-P3]

We had to incorporate an entire tech training on how to use Zoom and how to use, like, the internet to do a lot of things. And I mentioned our team, our paraprofessionals, which means they're from the community, but they may not always have all of the skills. So, for us, training is really important to make sure that we're helping our team members reach their best potential so they can do all of these things. [Int3]

Youth Missing a 1-on-1 Connection

Of the 8 experts, 4 (50%; Int3-Int6) emphasized that youth were missing the 1-on-1 connection established in in-person programs. Therefore, experts had to delete or modify online activities to engage youth as much as possible. The in-person component was pointed out as an integral part of the AI/AN culture (Int6).

We have had some Zoom sessions where there are, you know, siblings together with their parent, and there's a couple kids, but their original program, you know, kids are in groups, and they're doing all these fun activities, and they're laughing, and they're really engaged. It's very much like an interactive process. And so, you know, some of the activities that were like that originally—that we knew we couldn't do on Zoom—we either took out or modified. [Int4]

But for tribal communities, the in-person part is such a major piece. And I don't see that changing in any capacity. I do think that the virtual piece will be really amped up, and I think it will be smoothed over quite a bit [of time]. [Int6]

Recruiting and Retaining Youth

Using Social Media Platforms for Youth Outreach

Based on the 2020 nationwide Youth Health Tech Survey [50] mentioned by 1 (12.5%) of the 8 participants, certain social media platforms were identified as preferred channels by AI/AN youth to receive sexual health messages and lessons (Int6). A participant pointed out that facilitators used their personal social media to reach out to youth and families in their community. One expert also mentioned that social media facilitated recruitment during the pandemic, since social messaging was popular among youth (Int2-P2). Another expert emphasized the effective role of social media in allowing lesbian, gay, bisexual, transgender, and questioning (LGBTQ) youth to open up about their sexual health and body image in a positive manner due to the support received from the online platform (Int2-P3). All experts stated that TikTok is less often used to reach youth than are Instagram, Facebook, YouTube, and Twitter. We R Native, a multimedia health resource for Native youth, has a large and growing presence on social media. Instagram and Facebook were the main channels used by We R Native to promote sexual health resources during the pandemic, due to their popularity and national reach. Since then, they have seen expansive growth on TikTok, too—addressing healthy relationships, condoms, STI testing, and birth control with an "indigenous" lens.

Differences in the Online Program Youth Participation Rate

Recruitment and retention of youth for online sexual health program participation was reported as problematic by 2 (25%) of 8 experts (Int5, Int6). Most health educators relied on schools to locate participants and increase recruitment and retention rates (Int5). However, since the start of the pandemic, schools were shut down, and more youth sought mental health services rather than focusing on their sexual health (Int6). A participant described the negative impact of school shutdown due to COVID-19 on youth recruitment for online sexual health

programs. Schools were considered a major hub for recruitment and created an organized structure for outreach efforts (Int1). Parents are also more comfortable when their youth participate in school-based curricula rather than having an outside organization deliver the program (Int1). Most AI/AN villages and reservations are considered remote, which renders schools a hub for recruitment purposes (Int3).

> *I think the programs that are going to be successful at recruitment is programs that are operating through a school. It's much harder already; like some of my teams in the Midwest have been trying to get the young people together, and they're just now getting to the point. And it's because school has created this, like, sort of organizing opportunity, like kids are having a more structured day than what they have over the summer. And in the early days of the shutdown.* [Int1]

> *Yeah, there's definitely…the recruitment and the retention in a virtual setting…versus an in-person implementation. Yes, there is a dramatic difference. Only because of the fact that, you know, that we're trying ourselves as an organization, and educators trying to find resources and tools that they can implement, if they were to implement a [curriculum], trying to adapt that. The upside that we're seeing is an uptick in our social messaging for youth. That's a very popular resource.* [Int2-P2]

Distribution of Flyers in Community Locations

Prior to the COVID-19 pandemic, in-person recruitment was highlighted as 1 of the most effective ways to reach out to AI/AN communities and inform them about the program. A participant indicated that there still needs to be an in-person component to ensure high engagement and excitement about the program despite the restrictions imposed by the pandemic (Int3). Operating through channels available in the community facilitated getting the word out about programs and overcame the challenge of limited network connection and bandwidth (Int1).

> *That's 1 of the effective ways. I mean, flyers in a place that people are still going, in some of the smaller Native communities. There may be people [who] actually go and visit a bulletin board, or they go and visit, like, something in a primary building. Or especially, where the food pickups are happening…a flyer on a bulletin board or a flyer in a location like that can be a good tool for getting the word out.* [Int1]

Challenges for Implementation in a Household Environment

Challenge of Youth Program Participation from a Home Environment

Another challenge discussed by experts (Int3-Int6) was youth's compromised participation in online sexual health programs from their households due to conflicting parent schedules, sharing equipment with siblings, and being surrounded by family members when learning about sexual health. Unreliable internet connections and the limited access to computers in rural AI/AN households have been described by 1 expert as an ongoing "digital divide" (Int2-P2). Many youths do not have access to computers at home or have to share their laptops with their entire family, which makes it harder to participate in virtual sexual health programs (Int3, Int5, Int6). Additionally, 1 of the main program delivery challenges discussed by these experts was having youth in unsafe households (physical and sexual abuse) to participate in such programs, as well as parents perceiving sex as a taboo topic. Delivering these programs through schools helped overcome these barriers, because health educators did not have to worry about conservative parents monitoring the programs' content. As a participant pointed out, even in virtual clinical visits, health care providers are asking whether youth are in a safe place to discuss their health concerns (Int1). Some programs are even including parents in sessions to increase parent-youth communication and appease their fears about having their kids participate in online sexual health programs (Int2-P2, Int3, Int5).

> *But you know, there's lots of need around, you know, with intergenerational families sharing technology. So, you know, maybe the youth was assigned a computer that or, you know, a tablet that did have data on it, but then that youth might have to be sharing it with siblings or the adults. And then also family schedules. So, you know, if there's a family and this youth is supposed to be on a sexual health lesson, but then mom needs to go grocery shopping, just take all the kids with her.* [Int6]

> *So, for instance, young people that are living in homes that aren't safe, and that may be like participating in a sexual health program, in a household where that is not accepted. Whereas a young person could have previously like said, "Oh, my after-school program is, like, [a] spirit club or something," when it was actually a sexual health program. Um, you know, now, if they're doing something at home, they are in a home where other people may see what they're doing and know what they're up to. And in homes that are not safe to do that, that can be a real barrier.* [Int1]

> *But we've also heard collectively what the needs are. And…and that's pretty compelling from the field, infrastructure, needs. You know, there is a digital divide out there. So, not everybody can utilize a computer and a laptop or enroll America in most places. So, that's been pretty compelling.* [Int2-P2]

Low Bandwidth and Network Connectivity Issues

One of the main challenges encountered by experts in the delivery of online sexual health programs is the low bandwidth in rural households and network connectivity issues in tribal communities. It is thus important to be mindful of youth's network connection when designing program activities, because it might take youth some time to connect with their facilitators and ensure a stable internet connection without dropping out of sessions (Int3, Int4). Most youth have reported adequate access to technology resources. However, an expert pointed out the

need to continuously provide technical support for tribes with varying capacity and resources to ensure engagement in virtual programs (Int6).

> *Yeah, I think overall, we know that youth are able to access and have technology resources. And so, if that's the case, then this is the best platform to do it. It's a pretty small number of folks who have absolutely no IT capacity whatsoever; it seems like most tribes, at least, you know, can lend a laptop and a thumb drive. And it's not a perfect scenario. But that's an adaptation that folks are making.* [Int6]

Dealing with Youth Internet Access

Building partnerships with schools was described by a participant as the gold standard due to tribal preference of working with schools to reach youth in remote areas through a streamlined process (Int6). Schools can help resolve the issue of limited internet connection and bandwidth that youth have in their households, which can affect program access and completion (Int4, Int5).

> *And then, at least in schools, they can still access the program and complete everything, and they don't have to worry about [the] internet connection or, like, the bandwidth.* [Int4]

Recommendations to Overcome Delivery Challenges

Building Partnerships With Schools and Community Organizations

All (n=8, 100%) participants emphasized the necessity of building partnerships with schools and community organizations as essential for online program adaptation and implementation during the COVID-19 pandemic. Prior to the pandemic, schools were considered a major hub for youth recruitment and facilitated youth's access to adequate internet bandwidth and computers to participate in virtual sexual health programs [51,52]. However, the pandemic forced health educators to think of alternative ways for maintaining program delivery due to school shutdowns and restrictions on in-person activities [53]. This in turn led educators to adapt lessons for in-person and hybrid delivery [53]. Experts shared the need to collaborate with schools when preparing to transition to online platforms. Partnerships can also facilitate the provision of continuous staff support and training to simplify the adaptation process.

> *You know, parents often do trust what's happening at school a lot more than they trust an outside organization; they're a lot more suspicious of even things like a Boys and Girls Club, you know. So well established, like doing a social good in the world. So yeah, I do think that working in partnership with a school or another bigger organization that can give you a little bit of cover and decrease the suspicion now, you know, the alternative may be true in some Native communities if the institution is a non-Native institution, because there's a lot more suspicion around those types of organizations [than] there might be in White communities, so things like a university [are] not necessarily a great implementation partner in some Native communities that have suspicion around, you know, universities that have historically done research on them.* [Int1]

> *There are collaborations happening between, for example, health, community health, [and] behavioral health departments within a health setting, partnering with their local school, you know, their PE or health teacher, their program, and you know, so you have 2 entities coming together to offer this class. So, that's becoming very popular; it can be done for credit recovery…it could be done just for the sheer fact that this is a tribal school on tribal land that's looking for tribal self, sexual health. Very, very popular. It's the trend.* [Int2-P2]

> *I think that's always the gold standard, too, is that most tribes want to…most programming want to work with schools, because that's the easier way to get to youth and it's a more organized and streamlined process. So, I think that will always be the goal—to collaborate with schools.* [Int 6]

Adopting a Holistic Approach When Addressing Sexual Health in AI/AN Communities

Addressing sexual health holistically was 1 of the major themes emphasized by the interviewed experts in this study. For years, sexual health educators have been emphasizing the need to have a holistic approach to sexual health interventions as STI/HIV prevention interventions were not inclusive of other important adolescent health issues [54-56]. Social and emotional learning, along with physical and mental health issues, must also be addressed in these interventions to promote positive youth development [56]. Since the start the COVID-19 pandemic, downward trends in mental health became apparent in AI/AN communities, due to parental unemployment, food insecurity, and home-based learning with limited social connection [57].

> *If your tribe has behavioral health services, or mental health services, that can support you in integrating those topics into your sexual health program, I think that this is the time to do it, because young people are struggling. And I think our we're at [a] real risk of, like, a widespread mental health crisis for young people, for teens, particularly.* [Int1]

Adopting a Systematic and Culturally Responsive Approach for Effective Virtual Program Delivery

Experts disclosed the benefits of adopting a systematic approach for effective implementation of online programs during the pandemic. Their recommendations included making a leap to identify what is working in AI/AN communities, rather than getting paralyzed just thinking it through; knowing which specific tools are relevant for the program rather than using all available tools and websites; and being patient since program adaptation is a strenuous learning process, particularly during the pandemic, where things are changing all the time. An additional recommendation was the need to have sexual health programs that are reflective and inclusive of the health belief systems of Native cultures and Native traditions since there is

so much to learn from Native cultures when it comes to health and well-being.

> *I think another tip to a part of that was just like, you know, technology can be big and intimidating. I heard a lot of people say that—multigenerational, from the youth all the way to adults. And so, I think it's…it's okay if there's patience, you know; technology's not going anywhere. Even if they feel that they want to get a good grasp of what that looks like, or how to do it. I think it's nice to just kind of get your bearings and then proceed on.* [Int2-P3]

> *I guess some general advice would be to just make the leap. I think sometimes, you get paralyzed by thinking it through. But you just have to act and try to see what's going to work and know that have a flexible approach that you can change things around if things aren't working.* [Int3]

> *I think that there's so much to be learned from Native cultures when it comes to health and well-being. And so, ensuring that programs are inclusive and reflective of that and are rooted in the culture and the community itself [is] really important, really essential. You're not going to get a program off the ground without those things.* [Int4]

Community and Youth Engagement for the Success of Virtual Sexual Health Programs

Interviewed experts emphasized the need to continuously engage youth and community members, to listen to their feedback and carry out the suggested improvements, while considering the impact induced by the pandemic on their overall well-being. Focus groups with program participants and community members can improve program sustainability by highlighting the COVID-19-related challenges that need to be addressed.

> *And what can be helpful for the youth as well as for the adult audience to know, the 1 thing that resonates across the board is—Natives like Natives, you know—we want to see ourselves in the products in the curriculum, in the videos in the messaging, and [in] the theme. And if you tie it back to culture, then that's the tagline—culture is prevention.* [Int2-P2]

> *I think the first thing is, you have to have real community engagement, and willingness and belief that the program is important, and that the program needs to come from the community itself.* [Int4]

Discussion

Principal Findings

This study aimed to (1) better understand the extent to which pre-existing challenges were exacerbated by COVID-19, (2) examine barriers encountered when adapting programs to an online environment, and (3) highlight socioeconomic challenges experienced by youth. Both experts who had extensive experience adapting and translating health programs to online platforms and experts who were going through the process for the first time were interviewed. Such diversity in perspectives allows for a broader exploration of the impact of COVID-19 on the adoption, implementation, and maintenance of youth sexual health programs across different tribal regions in the United States. One of the strengths of this paper is that experts did not restrict themselves to sharing their professional point of view. Rather, they shared the experience of participating in online health programs from the perspectives of youth, parents, and families in tribal communities. Further, they provided advice and recommendations for future sexual health programming, with flexible options for program delivery.

As described by the key informants, AI/AN youth experienced significant and prolonged disruptions to sexual health education and sexual health services during the pandemic. Many also experienced socioeconomic and mental health challenges, juggling virtual learning while supporting their family's basic needs. There is a need for cross-agency funding opportunities that holistically support the health and development of AI/AN youth [56,58-62]. Many tribes are small, which makes it challenging to apply for issue-specific funding. Holistic funding opportunities will provide tribal health educators with the opportunity to address the social determinants of health and the risk factors leading to adverse health outcomes among AI/AN youth [56].

To better disseminate culturally responsive resources for future program adopters, experts recommended Healthy Native Youth [63], We R Native [64], and iknowmine [65] websites that share resources, tools, and curricula to get people engaged and excited about topics, ideas, and strategies that communities have used to address AI/AN youth sexual health. Even though technological tools can be intimidating at a multigenerational level (youth and adults), experts stressed the importance of being patient with technology, as well as the need for facilitators to have a good grasp of technological tools before moving on with program adoption or implementation.

Collaborative partnerships between AI/AN communities have been reported as an effective strategy to improve program delivery [50]. Successful programs implemented in AI/AN communities have been attributed to all the connections made across different project partners and collaborators [51]. One expert shared that all things are rooted in relationships in Native communities. Another expert emphasized the importance of attending meet-and-greet sessions to learn from the personal experiences of program implementers working in the field. A common recommendation highlighted across interviews was the power gained from leveraging community-mobilizing efforts during the pandemic, along with believing and trusting in the project staff who bring their strengths and talents to the table. As mentioned by 1 (12.5%) of the 8 experts, even though COVID-19 has altered the way sexual health programs are being delivered to youth, patience and perseverance will create the needed answers in these uncertain times.

Findings from this study reiterated the importance of community and youth engagement in the dissemination, adaptation, and evaluation of health promotion programming in Native communities. In a systematic review looking at the elements of a successful implementation framework in indigenous communities, two-thirds of included studies demonstrated high

levels of community engagement from a culture-centered approach, while two-thirds of the studies included structural changes and researcher reflexivity [58]. Similarly, a review of effective youth engagement strategies for mental health and substance use interventions indicated that comment boxes and evaluation surveys as well as primary decision-making authority at every stage of program design, implementation, and evaluation contribute to high youth engagement [59]. Other strategies for youth engagement include having youth sit on boards and committees within an organization and having youth participate as peer support workers [60]. Findings from the included studies emphasized that youth participation in program adaptation established a dissonance between their behavior in using substances and their prevention role adopted through program participation [61]. Additionally, youth participants who were able to better identify with the program content recorded a significant reduction in adverse health behaviors [62].

Limitations

This study has several limitations. Given that participant recruitment was conducted using a nonrandom sampling approach, selection bias cannot be ruled out. However, the purposive sampling approach allowed us to reach a diverse group of sexual health experts across different US regions. The small sample size is attributed to the low response rate to recruitment emails and the hard-to-reach sexual health experts who were likely overburdened with the challenges in program delivery imposed by COVID-19. This is an inherent limitation of the recruitment methodology that was addressed through the detailed descriptions, thoughts, and themes provided by the key informants, along with the diverse demographic characteristics of the sample. Furthermore, the diversity of experts interviewed made it possible to obtain opinions from organizational, field, and academic professionals. Finally, another limitation was having 1 collective key informant interview encompassing 3 key informants who might have influenced each other's opinions; yet the allocation of questions for each participant helped control for any kind of potential biases.

Conclusion

This exploratory, qualitative study examined COVID-19-related challenges in the adaptation and delivery of sexual health programs on virtual platforms. Recommendations for future efforts included building partnerships with schools and community organizations, adopting a holistic approach to sexual health in AI/AN communities, adopting culturally responsive approaches, and engaging youth and community members in the design and delivery of sexual health programs in AI/AN communities. Findings can provide guidance on strategies to follow when selecting or preparing online sexual health programs for AI/AN youth. Future studies should explore the impact of COVID-19 on sexual health programs from the perspectives of youth themselves and empower them to share their own thoughts and recommendations for effective sexual health programs when delivered in hybrid and virtual spaces.

Acknowledgments

We would like to express gratitude and appreciation to all key informants who took the time to share their experience and provide recommendations for other experts in the field.

Abstract

Background: The COVID-19 pandemic has resulted in the closure of schools and may have inadvertently resulted in decreased physical activity for youth. Emerging evidence suggests that school closures due to the COVID-19 pandemic could have hastened the inactivity of youth, possibly due to a lack of structure outside of school and increased access to sedentary activities.

Objective: The purpose of this study was to assess changes in physical activity from pre–school closure (before the pandemic) to post–school closure (during the pandemic) among youth in spring 2020.

Methods: This study used a natural experimental design; youth were enrolled in a physical activity study prior to the lockdown, which was enforced due to the pandemic. The number of device-assessed steps per day and moderate-to-vigorous physical activity minutes per week were measured by using a Garmin Vivofit 4 (Garmin Ltd) accelerometer over 8 weeks. Mixed effects models were used to compare physical activity variables, which were measured before and during the COVID-19 pandemic.

Results: Youth were primarily Hispanic or Latinx (8/17, 47%) and female (10/17, 59%). The number of daily steps decreased by 45.4% during the school closure, from a pre–school closure mean of 8003 steps per day to a post–school closure mean of 4366 steps per day. Daily moderate-to-vigorous physical activity decreased by 42.5%, from a pre–school closure mean of 80.18 minutes per week to a post–school closure mean of 46.13 minutes per week.

Conclusions: Youth are engaging in roughly half as much physical activity during the school closure as they were prior to the school closure. If additional evidence supports these claims, interventions are needed to support youths' engagement in physical activity in the Midwest.

Introduction

The lack of youth physical activity (PA) is a pervasive public health issue. Less than one-quarter of youths aged 6 to 17 years in the United States engage in the recommended 60 minutes of moderate-to-vigorous PA (MVPA) per day [1,2]. Regular PA can improve children's physical health [2] and cognitive performances [3,4]. Physical inactivity can result in being overweight or obese [3] and increase one's risk for cardiovascular disease [5,6] and type 2 diabetes [7], among other negative health conditions. Further, physically active youth

are likely to have better school attendance, grades, classroom behavior, and cognitive function [3,4].

Children spend a substantial amount of time at school, making it an ideal place to embed PA within the day [2]. Youth have been found to be more physically active during the school year than during the summer [8,9], and this pattern is even more pronounced for certain subgroups, such as Hispanic or Latinx youth [9]. One explanation for this may be the structured day hypothesis, which posits that the presence of structure (preplanned, segmented, and adult supervision) may regulate obesogenic behaviors, including physical inactivity and sedentary behaviors, in youth [10].

In March 2020, the World Health Organization declared COVID-19 a pandemic [11]. In response, many schools closed for the academic year 2 months earlier than usual to curb the spread of COVID-19. Students participated in web-based schools for the remainder of the school year. As a result, past research has hypothesized that overall PA would be further reduced due to school closures during the COVID-19 pandemic [12]. Therefore, the purpose of this study was to objectively measure changes in youth PA from before to during COVID-19 pandemic–related school closures.

Methods

Participants

Beginning in January 2020, middle school youth from an urban school district in a Midwest city were recruited to participate in a 2-arm quasi-experimental study. All students in the school district qualified for free lunches [13]. Students from 2 middle schools were recruited to participate as controls, and 2 schools were recruited to participate in an after-school PA and nutrition intervention. The intervention would have provided sports sampling programming, during which 4 sessions of sports instruction would have been provided weekly. The focus sport would have rotated every 2 weeks to provide a variety. Weekly distributions of produce kits that were designed to make at least 1 meal for a family of 5 would also have been distributed. The study activities were planned to continue throughout the remainder of the school year (May 2020) and were planned to resume in fall 2021. During the recruitment process and baseline testing and prior to intervention implementation, schools closed for spring break. Following spring break, the schools remained closed, and students did not return to in-person schools for the remainder of the academic year due to the COVID-19 pandemic. This phenomenon provided a unique opportunity to conduct our natural experimental study. Prior to school closure, baseline data collection (ie, height, weight, and demographics) was completed for 86 youths; 72% (n=62) of these youths were in the control group. Due to school constraints, enrollment for intervention students was slower compared to that for control schools. Students who enrolled in the intervention stayed after school to complete enrollment and baseline testing. During this time, no structured programming had begun in intervention schools. Due to the low intervention enrollment and low dose of the intervention that was delivered, all participants (control and intervention groups) were eligible for inclusion in our analysis.

Instrumentation and Procedures

Each youth was provided with a Garmin Vivofit 4 (Garmin Ltd) to objectively measure PA from February to April 2020. Although it is critical to account for nonwear time in research that involves using consumer activity monitors, there is a lack of consensus on the best approaches for detecting nonwear time. Approaches vary by device manufacturer (eg, Garmin Ltd vs Fitbit LLC) and device model (eg, heart rate is sometimes used but is not measured by the Vivofit 4). Although the most common approaches have been to include all days regardless of wear time (ie, no detection of nonwear) and define valid days based on a minimum step count threshold [14], we used a more rigorous approach in this study, similar to what has been used in some Fitbit-based research [15]. Groups of ≥3 epochs (15 minutes each) with a value of 0 for maximum motion intensity were considered nonwear time. Valid wear days were defined as days for which a participant had ≥8 hours of wear time between 9 AM and 9 PM and ≥500 steps. For each participant, daily data were aggregated at the week level, with a requirement of ≥1 valid day for the week to be included in the analyses. We selected the requirement of ≥1 valid day due to the stringent criteria used for a valid day; however, the mean number of valid days per week was 5.24 (SD 2.21). Weighted weekly values for steps per day and MVPA minutes per day were calculated as follows:

$$([\text{mean of weekdays} \times 5] + [\text{mean of weekend days} \times 2]) \div 7$$

When a participant did not wear the device for ≥1 weekday and ≥1 weekend day in a given week, the weekly value was calculated as a mean of all valid wear days for the week. MVPA was measured by using the Garmin device's automated activity detector. The device automatically measures active minutes when a user runs for at least 1 minute or walks for at least 10 consecutive minutes.

Participants with at least 1 week's worth of data in the 4 weeks prior to school closure and at least 1 week's worth of data in the 4 weeks after school closure were included in the data analyses. The mean numbers of pre–school closure and post–school closure weeks with valid participant data were 2.65 (SD 1.11) and 3.12 (SD 1.17), respectively. This inclusion criterion allowed us to examine multiple time points of PA behavior while also allowing for a larger sample size. After removing participants who did not meet the inclusion criteria, we had 17 participants with valid data. The school closure forced a change in syncing practices; research staff went from syncing youths' Garmin devices weekly at schools to instructing students to sync their Garmin devices to a personal device (ie, a smartphone or tablet) at home. Many of the students did not respond to the research team's efforts to train students on the new syncing practices, which limited the number of participants who had valid data post–school closure to 17 participants. Of these 17 participants, 16 were in the control group.

Ethics Approval

All study procedures were approved by the University of Missouri-Kansas City Institutional Review Board (2017528).

Data Analysis

Descriptive statistics were used to analyze demographic variables. Demographic differences between youth who were included in and excluded from the analyses were assessed by using chi-square tests. Differences in the number of steps per day and MVPA minutes per week from pre–school closure (4-week period) to post–school closure (4-week period) were assessed using 2 mixed effects models (1 for each PA dependent variable). Our models accounted for the nesting of weeks within participants and were adjusted for the number of valid weekday wear days and weekend wear days in each week. A second pair of mixed effects models, which accounted for the nesting of weeks within participants, was used to investigate differences in the number of steps per day and MVPA minutes per week across the 8 study weeks. For these models, the *study week* variable was entered as a categorical fixed effect in addition to the aforementioned covariates. Estimated sample means and CIs were calculated from the models' results and plotted. The restricted maximum likelihood was used in all models to account for missing data. Significance levels were set at $P<.05$. All analyses were conducted with SPSS (version 25; IBM Corporation).

Results

Demographics

The demographics of the participating youth are presented in Table 1; demographics data are presented separately for youth who were included in and excluded from analyses and are compared for statistical differences. The participants included in the data analysis (n=17) were primarily Hispanic or Latinx (8/17, 47%) and female (10/17, 59%). All participants were in the sixth, seventh, or eighth grade and represented 3 public middle schools. The majority of families (15/17, 88%) reported incomes within low-income limits for the county [16]. No significant differences were reported between those who were included in the analyses and those who were excluded from the analyses.

Table 1. Demographic characteristics of participants who were included in the analyses compared to those of participants who were excluded from the analyses.

Characteristic	Participants included in the analyses (n=17), n (%)	Participants excluded from the analyses (n=69), n (%)	*P* value
Race and ethnicity			.66
Black	7 (41)	22 (32)	
Hispanic or Latinx	8 (47)	33 (48)	
White	2 (12)	9 (13)	
Other or preferred not to respond	0 (0)	5 (7)	
Gender			.78
Male	7 (41)	28 (41)	
Female	10 (59)	39 (57)	
Other or preferred not to respond	0 (0)	2 (3)	
Household monthly income (US $)			.72
≤1000	4 (24)	19 (29)	
1000-2000	4 (24)	23 (35)	
2000-3000	5 (29)	12 (19)	
3000-4000	2 (12)	7 (11)	
≥4000	2 (12)	4 (6)	

PA Findings

Table 2 presents the pre– and post–school closure steps and MVPA data. Participants accumulated a mean of 8003 (SE 369.18) steps per day pre–school closure. This decreased to a mean of 4366 (SE 351.42) steps per day after school closures due to the COVID-19 pandemic, which was a significant decrease ($F_{1,6}=50.17$; $P<.001$). Similarly, MVPA significantly decreased ($F_{1,6}=47.3$; $P<.001$) from pre–school closure (mean 80.18, SE 3.56 minutes/week) to post–school closure (mean 46.13, SE 3.39 minutes/week). Figures 1 and 2 show that the number of steps per day and MVPA minutes per week were fairly consistent across the first 4 study weeks; these decreased during the fifth study week, which coincided with spring break, and remained low during the school closure.

Table 2. Changes in the number of steps and physical activity from pre–school closure to post–school closure (n=17).

Characteristic	Pre–school closure, mean (SE)	Post–school closure, mean (SE)	Percent change	*F* test (*df*)	*P* value
Number of steps per day	8003 (369.18)	4366 (351.42)	−45.4	50.17 (1,6)	<.001
MVPA[a] minutes per week	80.18 (3.56)	46.13 (3.39)	−42.5	47.30 (1,6)	<.001

[a]MVPA: moderate-to-vigorous physical activity.

Figure 1. Mean number of steps per day by study week. Study weeks 1 to 4 depict pre–school closure data, and study weeks 5 to 8 depict post–school closure data. Estimated sample means are presented with error bars representing 95% CIs.

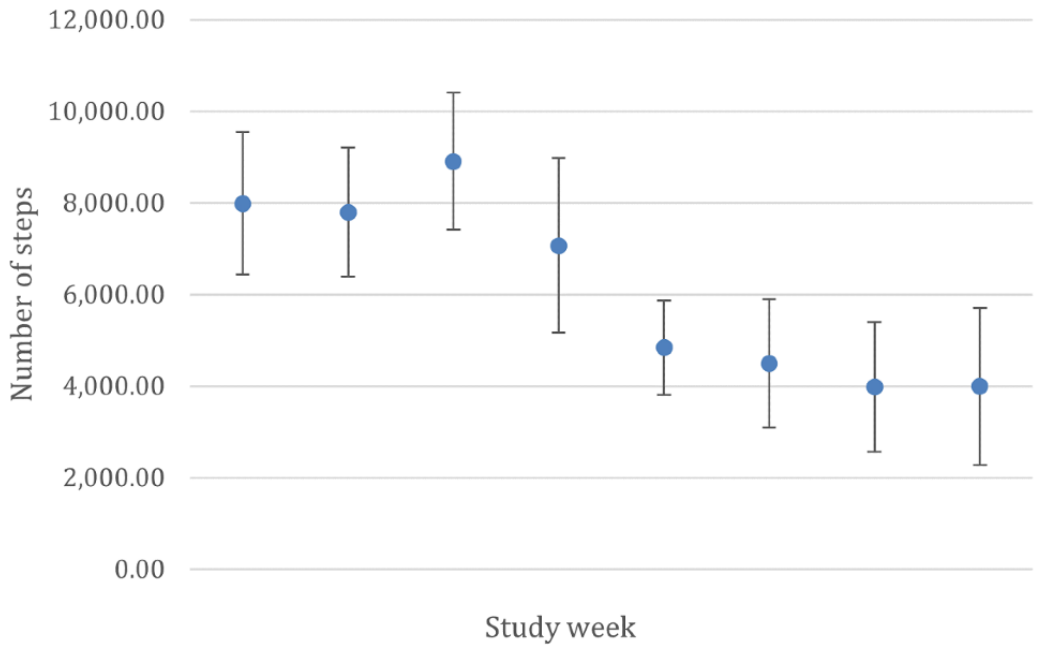

Figure 2. Mean moderate-to-vigorous physical activity minutes per week by study week. Study weeks 1 to 4 depict pre–school closure data, and study weeks 5 to 8 depict post–school closure data. Estimated sample means are presented with error bars representing 95% CIs.

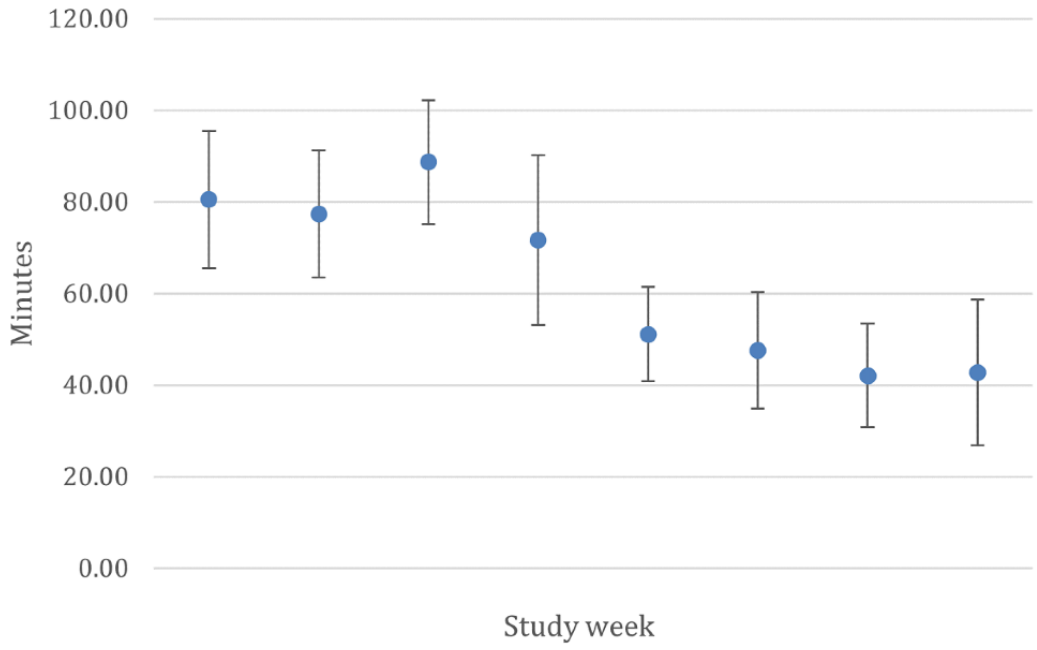

Discussion

Principal Findings

This study aimed to objectively assess the change in youth PA from before to during school closures due to the COVID-19 pandemic. Overall, the sample was small and was comprised of mostly racial and ethnic minority students (15/17, 88%). Similar to findings from a scoping review of other studies conducted in the first year of the COVID-19 pandemic [17], a significant decrease in objectively measured PA was recorded for the participants ($P<.001$). The findings from this study add to the previous literature by providing longitudinal data that spans pre– and post–school closure time points, as the majority of previous studies were cross-sectional and provided no comparison data for PA prior to the pandemic. Moreover, this is the only study, to our knowledge, to use pre– and post–school closure device-based measurements for youth in the United States. The large decrease in PA that we observed in our study may be partially explained by the decreases in PA among racial and ethnic minority groups during school breaks, which are more significant than those among White youth [9]. It appears that the structure and opportunities for movement provided during a web-based school day, at least during the early delivery of web-based schooling, were not sufficient for maintaining PA, as hypothesized in the structured day hypothesis [10].

Childhood obesity and inactivity continue to plague youth in the United States. PA tends to decline during middle school years—a time when recess and physical education requirements often decrease. Additionally, COVID-19 has exacerbated previously identified declines in PA. Schools are still an ideal place for implementing policies and interventions that improve health behaviors because of the significant time spent at school by most youth [2], but new strategies may be needed, particularly when schools are conducting web-based learning. Schools should consider implementing active learning and encouraging movement between classes. Middle school administrators should examine policies regarding physical education requirements and aim to achieve the recommended 225 minutes per week of physical education instruction [18]. Before- and after-school activities are highlighted as key strategies for supplementing youth PA levels [19]. In summary, middle schools need to expand their offerings for increasing PA as students return to in-person learning. This will not only help students achieve prepandemic levels of PA but also help them meet the recommended 60 minutes of PA every day [2].

Although schools have traditionally been a setting for youth to obtain the majority of their recommended PA, the effects of the COVID-19 pandemic suggest that other settings may need to foster a greater proportion of youths' PA. Further, while youth spend more time at home, parents will likely play a more significant role in encouraging PA during the pandemic. However, parents have indicated that they need resources to help them support their child's PA [20]. Web-based, after-school PA programming may be one strategy for increasing PA. Such programming should be tailored to students in middle school, where the activities are fun, involve friends, and include some competition [21]. Lastly, a variety of outdoor activities should be encouraged (eg, nature walks, bike rides, games, etc).

Strengths and Limitations

This study has several strengths. One is its natural quasi-experimental design. Additionally, this study is strengthened by its use of objective measures of PA and offers longitudinal time points that demonstrate the change in PA behavior from before to during the school closures resulting from the COVID-19 pandemic. By using objective measures of PA, participant recall biases were eliminated. Racial and ethnic minority groups are often left out of PA research; this study is strengthened by the participation rates of these groups.

This study also has limitations. The sample for this study was small, and the proportion of participants included in the analyses was also small. There were several days with missing data, which required us to compute weekly means for the number of steps taken. Additionally, we were forced to change the syncing procedures for the Garmin accelerometers due to the school closure. Before the school closure, the research team synced participants' accelerometers at school weekly. After the school closure, we needed youth to register their accelerometers to a personal device, which posed significant issues for consistent data collection, as reflected by our lower number of valid weeks post–school closure. Lastly, social distancing and other precautionary measures that were enforced upon the youth may have impacted other opportunities for PA. Further research with larger sample sizes is needed to confirm our results. Many schools continue to offer web-based learning, and they should be studied to determine if the low PA trends have held consistent.

Conclusions

This study revealed a significant decrease in PA among middle school student participants after the COVID-19–related school closures. As schools remain web-based or continue to have periods of web-based learning, it should be a priority for schools to incorporate regular PA within the school day. Schools and partnering organizations should provide extracurricular PA opportunities, even if they are provided on the web or through other noncontact formats.

Acknowledgments

This project was supported by an award (award number: 1 ASTWH190088-01-00) from the United States Department of Health and Human Services, Office of the Minority Health, and the Office on Women's Health. This paper's contents are solely the responsibility of the authors and do not necessarily represent the official views of the Office of the Assistant Secretary for Health.

Authors' Contributions

AG conceptualized the study, wrote the manuscript, and performed the literature review. JSL conceptualized the study, analyzed the data, and contributed to manuscript writing. KE collected the data and contributed to manuscript writing. CS collected the data and contributed to manuscript editing. RPS oversaw the research efforts. JC analyzed the data and contributed to manuscript writing.
