Abstract

Background: Public stigma against depression contributes to low employment rates among individuals with depression. Contact-based educational (CBE) interventions have been shown to reduce this public stigma.

Objective: We investigated the ability of our Virtual Reality Antistigma (VRAS) app developed for CBE interventions to reduce the stigma of depression.

Methods: Sixteen medical students were recruited and randomized 1:1 to the intervention group, who used the VRAS app (VRAS group), and the control group, who watched a video on depression. The depression stigma score was assessed using the Depression Stigma Scale (DSS) and Attitudinal Social Distance (ASD) questionnaire at pre- and postintervention. Feasibility was assessed in both groups and usability was assessed only in the VRAS group after the intervention. A qualitative study was performed on the acquisition of knowledge about stigma in both groups based on participants' answers to open-ended questions and interviews after the intervention.

Results: The feasibility score was significantly higher in the VRAS group (mean 5.63, SD 0.74) than in the control group (mean 3.88, SD 1.73; $P=.03$). However, no significant differences were apparent between the VRAS and control groups for the DSS (VRAS: mean 35.13, SD 5.30; control: mean 35.38, SD 4.50; $P=.92$) or ASD (VRAS: mean 12.25, SD 3.33; control: mean 11.25, SD 1.91; $P=.92$). Stigma scores tended to decrease; however, the stigma-reducing effects of the VRAS app were not significant for the DSS (pre: mean 33.00, SD 4.44; post: mean 35.13, SD 5.30; $P=.12$) or ASD (pre: mean 13.25, SD 3.92; post: mean 12.25, SD 3.33; $P=.12$). Qualitative analysis suggested that the VRAS app facilitated perspective-taking and promoted empathy toward the patient.

Conclusions: The CBE intervention using virtual reality technology (VRAS app) was as effective as the video intervention. The results of the qualitative study suggested that the virtual reality intervention was able to promote perspective-taking and empathy toward patients.

KEYWORDS

major depressive disorder; depression stigma; virtual reality; contact-based educational intervention; virtual patient

Introduction

Major depressive disorder (depression) is a severe medical illness accounting for more than 15 million disability-adjusted life years [1]. Individuals with depression must deal with the illness itself and the stigma (misconceptions) associated with depression [2]. One of the causes of stigma is a lack of knowledge about depression [3]. Stigmatization by the public, reflected in attitudes such as “people complaining of depression are weak,” is known as public stigma [3], whereas internalizing such public stigma and viewing oneself as “weak” (self-devaluation) is known as self-stigma [4,5]. Public stigma contributes to a low employment rate of patients with depression and self-stigmatization by patients [2]. Self-stigma impedes help-seeking [6]; thus, reducing public stigma toward patients with depression is crucial. Like the general public, health care providers may also stigmatize patients, such as viewing depression as a sign of personal weakness. Such stigma can consequently affect the quality of care offered to patients [7,8]. Health care providers thus need to be targeted when addressing issues of stigma surrounding depression.

Many interventions have been conducted to reduce the public stigma of mental illness [7,9,10]. Among these, contact-based educational (CBE) interventions have been shown to reduce stigma against mental illness [10,11]. A CBE intervention, which is based on the intergroup contact theory, uses contact with the stigmatized group to provide knowledge, reduce anxiety, and enhance perspective-taking and empathy toward the stigmatized group to reduce stigma [12].

Two main avenues are available for a CBE intervention: in-person [11] and video-based contact, which is a typical media-based contact [13]. In-person contact requires an actual patient who provides their testimony in a presentation [11,14,15]. However, in-person contact has been conducted less frequently than video-based contact [10] because of the difficulties in recruiting patients [16] and the negative effects of identity disclosure. Moreover, the intervention requires well-trained individuals with a history of mental illness to deliver the presentation [17]. By contrast, video-based contact uses premade videos of patients providing testimonies about their illness [13,18], which is much easier to set up and is more cost-effective to disseminate [19].

In recent years, virtual reality (VR) has been used for intergroup contact, promoting perspective-taking and empathy [20-22]. The usage of VR for intergroup contact also allows researchers to measure and monitor changes in the intergroup interactions in real time [23]. VR has also increasingly been used in the field of mental health [24,25] to reduce anxiety, such as interaction with a virtual spider to help treat arachnophobia (fear of spiders) [26] and interaction with virtual humans to treat social anxiety disorder [27]. In addition, VR has been used to reduce the public stigma of schizophrenia [28-30].

Perspective-taking allows the user to experience a situation from the perspective of another individual, leading to a better

understanding of others, affecting others' evaluations, and enhancing empathy [31,32]. Therefore, it was expected that a CBE intervention using VR for depression stigma may lead to improved knowledge of depression, reduction in anxiety, and an increase in empathy, resulting in an overall reduction in stigma [12].

In this study, we investigated the ability of the Virtual Reality Antistigma (VRAS) app, which was developed for CBE interventions, to reduce the stigma of depression.

Methods

Participants

Participants were recruited online. The study was performed in August 2019. Participants were recruited from the University of Tokyo Graduate School of Medicine and School of Medicine. They were informed about the title and background of the study through the website. Exclusion criteria included a current diagnosis of depression or having a history of depression. No payment or reward was offered or provided for participation in the trial. The trial was completed within 1 month of recruitment.

VRAS App

The VRAS app was developed for Android OS smartphones (Google LLC, Mountain View, CA) to be used with a head-mounted display (HMD). The duration of the VRAS experience was approximately 5 minutes, and the frame rate was set to 60 frames per second to reduce the risk of VR sickness [33].

The VRAS app provides an immersive virtual environment consisting of three sections (Figure 1). The first section was a workplace environment experienced from a third-person perspective, in which the user observed a scene where the patient was scolded by his boss who stigmatized the patient. The purpose was to improve understanding toward depression stigma in a workplace setting from the perspective of a colleague. The second section was a counseling environment experienced from a second-person perspective. The user took on the role of a counselor to ask three questions related to the effect of depression on the life of the patient. The purpose was to educate the user about the symptoms of depression and struggles of the patient. The third section used the first-person perspective; the user assumed the role of the patient and experienced the symptoms of depression and workplace stigma, with the purpose of inducing empathy [34,35].

The VRAS app thus allowed users to interact with a virtual patient with depression from different perspectives. The virtual patient provided testimony about his struggles against depression, as an essential component of CBE interventions [17,36]. Educational messages for the VRAS app include (1) messages about the high prevalence of mental disorders, (2) messages about social inclusion/human rights, and (3) messages emphasizing that the patient is also a human being [37]. All three of these message types have been demonstrated to be helpful in reducing stigma [13,38].

Figure 1. The three sections of the Virtual Reality Antistigma (VRAS) app. (A) User watches the patient being scolded by the boss due to depression stigma. (B) User takes on the role of the counselor in listening to testimonies by the patient. (C) User, as a patient, is scolded directly by the boss.

Video Material

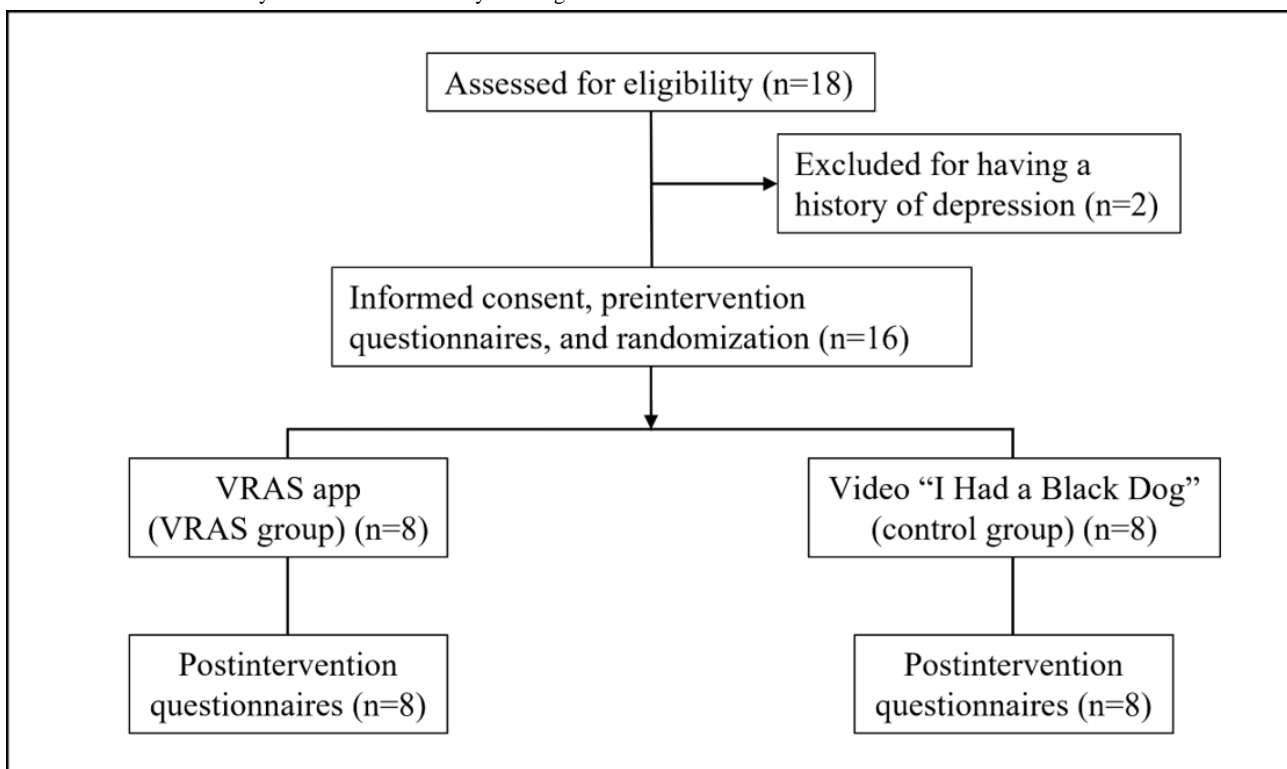

Participants in the control group watched the video “I Had a Black Dog,” written and illustrated by Matthew Johnstone in collaboration with the World Health Organization. The video served as the CBE material, because it showed an animation of a virtual patient, included testimony from the patient about his struggle with depression [17,36], and replaced false beliefs about depression with correct information (“myth-busting”) [17,39]. The video contained educational messages about (1) the high prevalence of mental disorders, (2) social inclusion/human rights, and (3) recovery-oriented practices [37]. These messages have been demonstrated to be effective in reducing stigma [13,38]. This video was of similar duration to the VRAS app (about 5 minutes). The Japanese translation

of the official Japanese picture book “I Had a Black Dog” was used as the subtitle for the video.

Trial Design

This was a randomized, controlled pilot study combined with a qualitative study to compare the effect of the VRAS app and video materials on depression. Participants were randomized 1:1 to the intervention group (VRAS group) or control group (Figure 2). Randomization was performed by randomly allocating a number from 0 to 1 to each participant using Microsoft Excel software. Randomization, enrollment, and assignment of participants were performed by the main experimenter overseeing the trial. Neither the participants nor experimenters were blinded in this study.

Figure 2. Flowchart of the study. VRAS: Virtual Reality Antistigma.

By referring to a previous study using similar scales [40], the sample size was calculated to allow performance of an independent-samples *t* test with a significance level (α) of 5%, power of 80%, mean difference of 0.75, and standard deviation of 0.5. The number of participants required was calculated as eight per group.

The flow of the trial was as follows. The participant first provided informed consent, completed a set of preintervention questionnaires (participant’s knowledge of depression and stigma, Depression Stigma Scale [DSS], and Attitudinal Social Distance [ASD]), and was randomized to the VRAS group or control group. Participants in the VRAS group used the VRAS

app, whereas those in the control group watched the video material. After using the VRAS app or watching the video, the participant immediately completed a set of postintervention questionnaires (DSS, ASD, and feasibility scale for both groups, and a usability scale for the VRAS group only). Participants were required to complete all three sections of the VRAS app. No changes were made to the VRAS app between recruitment and the end of the trial period. The trial was conducted face-to-face with one participant at a time, and only once per participant. The duration of the trial was 30 minutes. Participants in the VRAS group were instructed to stop immediately if they experienced any VR sickness during the VR experience.

Outcomes

The preintervention survey measured participants' knowledge of depression and public stigma, as well as the degree of stigma. To measure the degree of public stigma, we used the following vignette of an individual with depression (the Japanese version was used for this study) [41,42]:

John is 30 years old. He has been feeling unusually sad and miserable for the last few weeks. Even though he is tired all the time, he has trouble sleeping nearly every night. John doesn't feel like eating and has lost weight. He can't keep his mind on his work and puts off making decisions. Even day-to-day tasks seem too much for him. This has come to the attention of his boss, who is concerned about John's lowered productivity.

The DSS was used for participants to describe the individual in the vignette along a 5-point Likert scale; a higher DSS score indicates less stigmatization [40,41]. The ASD (also on a 5-point Likert scale) was used to measure the willingness of participants to have contact with the individual in the vignette; a lower ASD score indicates greater willingness [43].

A feasibility scale was also used to assess the feasibility of the VRAS app and video material as an educational tool. A usability scale was used to evaluate the usability of the VRAS app. Both the feasibility and usability scales were modified from the Web-Based Learning Tool (WBLT) [44] and used a 7-point Likert scale (1=strongly disagree, 4=agree, 7=strongly agree).

Statistical Analysis

A *t* test was applied to the pre- and postintervention results for within- and between-group comparisons. Data were analyzed

using the Python programming language (Python 3.6.9; Python Software Foundation) [45], with the significance level set at $\alpha=.05$.

Qualitative Study

Open-ended questions were provided for participants to answer after the intervention. All questionnaires were self-administered. Participants in both the VRAS and control groups were asked to describe what they understood about stigma against depression after their experience and were told to write "none" if they still did not understand stigma after the intervention. Participants in the VRAS group were asked about their overall impressions on the features of the VRAS app and if there were any features in need of improvement. Participants in the control group were given an opportunity to experience the VRAS app after the experiment and were then interviewed regarding the VRAS app and video material.

The results of the qualitative studies were analyzed using MAXQDA2022 software (VERBI Software, Berlin, Germany) and were coded by two authors (HO and LW) based on the mediators of intergroup contact: "Knowledge acquisition," "Anxiety reduction," "Perspective-taking," and "Empathy" [12].

Ethical Considerations

The study is registered at the University Hospital Medical Information Network Clinical Trials Registry (UMIN-CTR; UMIN000043020). Trial registration was completed retrospectively because ethics approval was obtained from the Research Ethics Committee of The University of Tokyo (approval number 2019099NI) before conducting the trial.

Results

Participant Characteristics

Eighteen students volunteered for this study and disclosed their medical history of depression. Two volunteers were excluded from the study due to a history of depression. The remaining 16 students completed the trial and their data were analyzed. The characteristics of participants at baseline are provided in Table 1. Before the intervention, 50% of participants in the VRAS group and 63% of participants in the control group showed some degree of knowledge about stigma against depression (Table 1). All participants in both groups completed the trial (VRAS app and video).

Table 1. Participant characteristics at baseline (N=16).

DSS Scores

No significant differences between the intervention and control groups were identified for the nine DSS items preintervention ($P=.81$) or postintervention ($P=.92$) (Table 2). In addition, none of the nine items differed significantly between pre- and postintervention. After the intervention, the mean scores for

both the VRAS and control groups tended to increase (suggesting decreased stigma); however, these differences were not significant ($P=.12$ and $P=.15$, respectively) (Table 2). For the VRAS group, a significant decrease in stigma was seen only for the item "People with this problem are unpredictable" ($P=.01$). In the control group, no mean score was significantly different before and after the intervention.

Table 2. Detailed Depression Stigma Scale scores pre- and postintervention.

Item	VRAS ^a group (n=8)			Control group (n=8)		
	Pre, mean (SD)	Post, mean (SD)	<i>P</i> value ^b	Pre, mean (SD)	Post, mean (SD)	<i>P</i> value ^b
1. Person could snap out of the problem	4.00 (1.07)	4.38 (1.06)	.08	4.00 (0.76)	4.13 (0.83)	.69
2. Problem is a sign of personal weakness	4.38 (0.74)	4.50 (0.76)	.60	4.00 (0.76)	4.25 (0.89)	.56
3. Problem is not a real medical illness	4.25 (0.71)	4.38 (0.74)	.35	4.25 (0.89)	4.38 (0.92)	.60
4. People with this problem are dangerous	4.00 (0.76)	4.38 (0.52)	.29	3.38 (0.52)	4.00 (0.76)	.14
5. Avoid people with this problem	4.25 (0.71)	4.25 (0.71)	1.00	4.13 (0.99)	4.38 (0.74)	.52
6. People with this problem are unpredictable	3.25 (0.46)	4.13 (0.64)	.01	3.38 (0.52)	3.50 (0.76)	.69
7. If I had this problem, I would not tell anyone	3.13 (0.99)	2.88 (1.25)	.45	3.25 (0.89)	3.63 (0.52)	.08
8. I would not employ someone with this problem	3.25 (1.04)	3.25 (1.04)	>.99	3.63 (0.74)	3.63 (0.74)	>.99
9. I would not vote for a politician with this problem	2.50 (1.20)	3.00 (1.20)	.17	3.50 (1.07)	3.50 (1.07)	>.99
Total personal stigma	33.00 (4.44)	35.13 (5.30)	.12	33.50 (3.46)	35.38 (4.50)	.15

^bTwo-tailed paired *t* test.

ASD Scores

No significant difference in the mean total ASD score between groups was evident preintervention ($P=.49$) or postintervention ($P=.47$) (Table 3). None of the five items in ASD differed significantly from pre- to postintervention for either group. Tendencies toward a decrease in the mean total score, suggesting increased willingness for contact, were seen in both the VRAS

and control groups, but the differences were not significant ($P=.21$ and $P=.11$, respectively) (Table 3). For the VRAS group, only the score for the item "Make friends with the person" showed a significant increase in willingness after the intervention ($P=.03$). In the control group, no items showed significant differences in mean scores before and after the intervention.

Table 3. Attitudinal Social Distance scores pre- and postintervention.

Item	VRAS ^a group (n=8)			Control group (n=8)		
	Pre, mean (SD)	Post, mean (SD)	<i>P</i> value ^b	Pre, mean (SD)	Post, mean (SD)	<i>P</i> value ^b
1. Move next door to the person	2.88 (0.83)	2.75 (0.89)	.60	2.75 (0.71)	2.38 (0.52)	.20
2. Spend an evening socializing with the person	2.38 (0.92)	2.25 (0.89)	.60	2.13 (0.64)	2.00 (0.53)	.35
3. Make friends with the person	2.63 (0.74)	2.13 (0.64)	.03	2.25 (0.46)	2.38 (0.52)	.35
4. Work closely on a job with the person	2.50 (0.93)	2.50 (0.76)	>.99	2.38 (0.74)	2.00 (0.53)	.08
5. Have the person marry into the family	2.88 (0.99)	2.63 (0.74)	.17	2.63 (0.52)	2.50 (0.53)	.35
Total score	13.25 (3.92)	12.25 (3.33)	.21	12.13 (2.03)	11.25 (1.91)	.11

^aVRAS: Virtual Reality Antistigma app.

^bTwo-tailed paired *t* test.

Feasibility Scale

The perceived feasibility of the interventions was compared between the two groups (Table 4). No significant difference was seen for the items "This intervention provides useful knowledge related to stigma" or "I think this intervention is an appropriate educational tool to learn about depression stigma"

between groups ($P=.17$ and $P=.26$, respectively). However, a significant difference in score was identified for "I understood depression stigma through this intervention," suggesting that participants in the VRAS group had gained a better understanding of stigma against depression postintervention compared to the control group.

Table 4. Detailed scores of the feasibility scale.

Questions	VRAS ^a group (n=8), mean (SD)	Control group (n=8), mean (SD)	P value ^b
1. This intervention provides useful knowledge related to stigma	5.38 (1.06)	4.50 (1.31)	.17
2. I think this intervention is an appropriate educational tool to learn about depression stigma	5.50 (1.31)	4.50 (2.00)	.26
3. I understood depression stigma through this intervention	5.63 (0.74)	3.88 (1.73)	.03

^aVRAS: Virtual Reality Antistigma app.

^bTwo-tailed unpaired t-test.

Usability Scale

Based on a score range of 1 to 7, the mean scores for the items “This VR experience is physically stressful” and “This VR experience is mentally stressful” were 3.13 (SD 1.73) and 2.75 (SD 1.58), respectively, suggesting that users did not find the VRAS experience to be particularly stressful. Participants also did not find the VR experience to be “long” (mean 1.75, SD 0.71) or “boring” (mean 1.75, SD 0.71). The mean score for “I had VR sickness during this VR experience” was 1.63 (SD 1.19), suggesting that users did not experience severe VR sickness using the VRAS app. No technical issues with the VRAS app were reported, and all participants managed to complete the VR experience without any difficulties.

In terms of feedback on features of the VRAS app in need of improvement, participants commented that they hoped to learn about methods to better deal with individuals suffering from depression, a refresher section to reinforce the knowledge gained, more scenarios emphasizing recovery, and scenarios involving family members of the patient.

As for the overall impression of the VRAS app, the following feedback was received from participants: “The VRAS application contains good educational content,” “The usage of perspective-taking from a third-person to a first-person perspective provided a better understanding of depression stigma,” “The scenario seems exaggerated and might not happen in a real-life situation,” “I experienced some delay in movement in the virtual world,” and “I think that the VRAS application would be useful as a training tool for managers.”

Qualitative Analysis

The total number of comments in the VRAS group (n=8) was 33 and that in the control group (n=8) was 6. Three participants in the control group commented “none” related to their understanding of stigma. In the VRAS group, 14 sentences were related to knowledge acquisition, 4 sentences were related to perspective-taking, and 2 sentences were related to empathy. In the control group, 5 sentences were related to knowledge acquisition and 1 sentence was related to empathy; however, there was no comment related to perspective-taking. In both groups, none of the comments was related to anxiety reduction. The other comments in the VRAS group were related to the usability of the VRAS app.

All eight participants in the control group were interviewed on the VRAS experience after the video experience, with two sentences pertaining to knowledge acquisition and one sentence

each pertaining to perspective-taking and empathy, respectively. There was no sentence on anxiety reduction.

Typical comments regarding knowledge acquisition in the VRAS group included “I learned that colleagues and superiors discriminate against patients with depression by viewing them as lazy and weak despite being sick,” “Stigma worsens depression,” and “A lack of knowledge causes stigma.” A typical comment indicating a shift in perspective was “I think I was able to understand the patient with depression better as I was able to experience third, second perspective, and first-person perspectives.” Typical comments on empathy included “I understood people with depression from many angles,” “I can understand the patient from many different perspectives,” and “I realized that the stigma of depression makes it difficult for patients to have their symptoms understood by those around them, and it also makes them feel bad, which worsens their depression.”

In the interviews conducted with the participants in the control group after testing the VRAS app, the following comments were made: “I can understand the patient’s feelings in the VR environment,” “The VR experience was useful to understand the patient’s story,” “VR is better than video because it is more immersive,” and “I can concentrate better in VR.”

Discussion

Principal Results

We compared the effect of the VRAS app developed for CBE interventions with that of a video intervention on reducing stigma related to depression. CBE using the VRAS intervention was as effective as the video intervention. The qualitative study suggested that the VRAS intervention generated more empathy for patients with depression by shifting users’ perspectives to that of the patient.

In the following, the results are discussed in accordance with the mediators of intergroup contact for reducing public stigma mentioned above (ie, knowledge acquisition, anxiety reduction, perspective-taking, and empathy).

Knowledge Acquisition

Although there was a decrease in stigma after the intervention in the VRAS group, the difference was not statistically significant. We speculate that this may be due to the educational content of the VRAS app. As the VR experience was limited to approximately 5 minutes to reduce the risk of VR sickness [33], we included only educational messages designed to reduce stigma [13,38], such as messages about the high prevalence of

mental illness and social inclusion/human rights, as well as “see the person” messages [37]. A recent study also showed that the inclusion of biomedical content (eg, the biological mechanisms underlying mental illness, including neurotransmitters such as dopamine and serotonin) could reduce stigma [46]. Thus, the knowledge gained from the VRAS experience may have been insufficient to reduce depression stigma.

To ensure that the participants had a similar background and knowledge of depression, only medical students were enrolled in this study. Biomedical content may have been particularly relevant to improve the effectiveness of the VRAS app in this population. The lack of such content may have affected the stigma scores. However, the optimal educational content to reduce stigma is controversial [47]. In any case, providing knowledge appropriate to the participant is essential [48]. We believe that VR technology can accomplish this, because it enables cost-effective modification of educational content to fit the demographic characteristics of the user.

The results of the qualitative study suggested that the VRAS group acquired knowledge about stigma more readily than the control group. This may be attributed to the fact that the VRAS app deepened the user’s understanding of stigma by allowing them to meet the virtual patient in a virtual world and experience their behavior and speech in environments similar to the real world. In addition, the participants in the VRAS group commented that the different perspectives of the VRAS app enhanced their understanding of stigma, which was reflected by the results of superior knowledge acquisition in the VRAS group. The usage of the VRAS app for the CBE intervention also overcame some of the difficulties such as ethical issues associated with face-to-face interactions with patients.

Anxiety Reduction

None of the comments from the participants indicated a reduction in anxiety. A prior study using VR to reduce the stigma of schizophrenia showed a reduction in stigma only for participants who liked the person encountered, suggesting that a more positive evaluation of the virtual patient may lead to a reduction in anxiety [28]. However, because schizophrenia and depression have different symptoms, we did not measure the anxiety level of the participants.

Perspective-taking and Empathy

An advantage of VR interventions is the incorporation of perspective-taking to stimulate empathy. Perspective-taking and empathy have been suggested to be helpful in reducing stigma toward others [12,31,32]. The VRAS app utilized a third-person perspective to provide a short example of stigma, a second-person perspective to allow the user to learn about the struggles of patients with depression, and a first-person perspective to put the user “in the shoes” of a patient to understand the experience of having depression and being stigmatized. From the results of the qualitative analysis, it was suggested that the VRAS experience was able to induce empathy and perspective-taking in the participants. However, the total task duration of 5 minutes may have been insufficient to enhance the empathy required, as reflected by the nonsignificant reduction in stigma. Although the optimal duration of intergroup

contact is contentious and requires further research [23], VR is immersive and may be a suitable tool to assist in inducing empathy in a short duration.

Usability of the VRAS App

Hardware issues also affected the results of this study. The high latency in the virtual world may have negatively affected knowledge acquisition, undermining the effectiveness of the VRAS app. In the qualitative study, some participants commented that they experienced a delay in movement in the virtual world. Latency is defined as the delay before data transfer begins after an instruction to enact transfer. A latency of >50 milliseconds has been reported to lead to unpleasant VR experiences by reducing the sense of presence in the virtual world [49]. This may have undermined the learning effectiveness of the VRAS app [50]. The VRAS app was developed for use with Android OS smartphones and an HMD; however, smartphones are generally inadequate for VR apps because of latency issues [51]. The VRAS app had an average latency of approximately 70 milliseconds, which may have degraded the user experience and negatively impacted learning [52].

All participants managed to complete the entire VR task without any issue. Although the VRAS app had high latency, we improved its usability by restricting the duration to about 5 minutes to reduce the risk of VR sickness. Frame rate has been shown to affect performance more than latency [53]. We therefore developed the VRAS app to run at approximately 60 frames per second, which is considered sufficient [33].

Regarding the usability of the VRAS app, most participants did not find the VR experience to be physically or mentally stressful, or overly long, and none of the participants experienced VR sickness. Participants also did not find the VR experience to be boring or tedious. This may be due to the scenario design of the VRAS app in which participants interacted with the patient in different roles through the three sections. Interaction within a virtual world has been shown to improve user engagement with the learning materials and to make learning more enjoyable [54].

Limitations

To our knowledge, this is the first randomized controlled pilot study combined with a qualitative study aiming to reduce the stigma of depression via a CBE intervention using VR technology compared to a video intervention. This study had several limitations. First, the participants and instructor were not blinded, which may have affected motivation. Second, the sample size was small; thus, further, larger studies are needed to validate the effectiveness of the VRAS app. Third, the baseline level of depression stigma in this study was low; therefore, the app should be tested in a population with a higher level of stigma. Fourth, the VRAS app focuses on the workplace environment; scenarios involving environments such as schools and the home are needed to expand its scope. Fifth, the duration and content of the video materials were similar, but not identical, to those of the VRAS app. Therefore, the validity of the video control needs to be examined. Sixth, because no suitable feasibility scale for this intervention type has been reported, we

adapted items from the WBLT rating scale to create our scale, which needs to be validated in further studies.

Conclusions

The CBE intervention using VR technology (VRAS app) was as effective as a video intervention. The qualitative study

suggested that the VR intervention was able to enhance empathy for patients, attributed to the perspective-taking. Further research with a larger number of participants is warranted.

Acknowledgments

We would like to express our gratitude to Professor Norito Kawakami for his advice regarding the development of the VR app. We would also like to express our gratitude to Professor Kathleen Griffiths for permission to use the Depression Stigma Scale (DSS).

Conflicts of Interest

None declared. All authors developed the Virtual Reality Antistigma (VRAS) app evaluated in this study.

Editorial note: This randomized study was not prospectively registered, justified by the authors because ethics approval was obtained from the Research Ethics Committee of The University of Tokyo (approval number 2019099NI) before conducting the trial. The editor granted an exception of ICMJE rules for prospective registration of randomized trials because the risk of bias appears low. However, readers are advised to carefully assess the validity of any potential explicit or implicit claims related to their primary outcomes or effectiveness, as the lack of registration means that authors could change their outcome measures retrospectively.

Abstract

Background: Limited access to mental health care services due to provider shortages, geographic limitations, and cost has driven the area of mobile health (mHealth) care to address these access gaps. Reports from the Cohen Veterans Network and National Council for Behavioral Health show that in states where mental health care is more accessible, 38% of people still do not receive the care they need. mHealth strategies help to provide care to individuals experiencing these barriers at lower cost and greater convenience, making mHealth a great resource to bridge the gaps.

Objective: We present a mixed methods study to evaluate user experiences with the mental mHealth service, Cope Notes. Specifically, we aimed to investigate the following research questions: How do users perceive the service in relation to stigma, impact of the intervention, and perceived usefulness? How do users rate the Cope Notes service and SMS text messaging along various dimensions of acceptability? What is the relationship between Cope Notes SMS text message ratings, user personality, and coping strategies? What are user perspectives of leveraging ubiquitous sensing technologies to improve delivery and provide tailored content?

Methods: We performed qualitative interviews with Cope Notes users (N=14) who have used the service for at least 30 days to evaluate their experiences and usefulness of the service. These interviews were coded by 2 raters (SLK and JL), and the interrater reliability was calculated with SPSS (IBM Corp) at 61.8%. In addition, participants completed quantitative measures, including a user experiences survey, personality inventory (Big Five Inventory-10), and coping assessment (Brief Coping Orientation to Problems Experienced).

Results: We derived 7 themes from our qualitative interviews: Likes or Perceived Benefits, Dislikes or Limitations, Suggested Changes, Stigma or Help Seeking, Perceptions of Ubiquitous Sensing, Cultural Sensitivity, and Alternative mHealth Resources. Exploratory analyses between acceptability ratings of Cope Notes and personality factors showed statistically significant positive relationships between seeing oneself as someone who is generally trusting and acceptability items, the most significant being item 7 (*I fully understood the sentiment behind Cope Notes Messages*) with ($r_{s(10)}=0.82, P=.001$). We also found statistically significant relationships between acceptability and Brief Coping Orientation to Problems Experienced items, with the strongest positive correlation between participants strongly endorsing coping by accepting the reality that an event has happened and acceptability item 7 ($r_{s(8)}=0.86, P=.001$).

Conclusions: Our study found that Cope Notes subscribers appreciate the service for reframing their mental wellness with statistically significant correlations between personality and acceptability of the service. We found that some users prefer a more

personalized experience with neutral to positive reactions to a potential companion app that continuously monitors user behavior via smartphone sensors to provide just-in-time interventions when users need it most.

Introduction

Limited Access to Care

Mental health service access is scarce for many populations across the globe [1]. With many communities experiencing mental health provider shortages, funding limitations, geographic isolation, and stigma toward seeking mental health services, mobile phone interventions enhance service access due to their convenience, lower cost, and privacy [2]. At the National Institute of Mental Health's 2018 Mental Health Services Research Conference, Dr. David Mohr of Northwestern University's Feinberg School of Medicine declared mobile phone interventions "the next big thing" for research regarding mental health services [3]. Although specific mobile interventions, such as mobile health (mHealth) apps and SMS text message systems, have shown to be effective in enhancing access to mental health services [4], a host of unresolved questions remain, including potential impacts on stigma, user acceptability, and other technological components such as ubiquitous sensing technologies that aim to automate emotion recognition in real time without the user's intervention. Identifying what is known and resolving what is unknown about these topics is critical in guiding next steps in research.

Understanding the Problem: Mental Health Treatment Gap

The mental health treatment gap is a well-known phenomenon for stakeholders, especially researchers, providers, and consumers. The World Health Organization reports that "the gap between people needing care and those with access to care remains substantial, and coverage for effective treatment remains extremely low" [5]. Furthermore, this trend is far reaching; worldwide, 76% to 85% of the individuals with mental health disorders do not receive the treatment they need, particularly in low- and middle-income countries [6]. Similarly, the Cohen Veterans Network and National Council for Mental Wellbeing found that although nearly 56% of American adults seek treatment for themselves or others, 38% of American adults must wait over a week to receive services [7]. They also found that even in states where services are more accessible, >38% of people do not receive the services they need. These alarming statistics are attributed to a variety of barriers to care that must be resolved to improve service access.

Barriers to Care

As outlined by the World Health Organization, coverage for mental health services remains a global concern [5]. According to the 2016 Commonwealth Fund's Annual International Health Policy Survey, 15% of US adults in need of mental health services could not afford them, and these rates were similar in

France (21%) and Norway (16%) [8]. Studies similarly indicated poor insurance coverage and cost as the top barrier to care for >42% of the population [7,9]. Data for low- and middle-income countries suggest that mental health expenditure across all countries is US \$2 per year capita, and low-income countries report it as <25 cents [10]. The sources of funding for mental health services in low- and middle-income countries occur in the following order: *out-of-pocket expenditure by patient or family, taxes, social insurance, and private insurance* [11,12]. Furthermore, these data underscore the funding concerns across low- and high-income countries and highlight the importance of enhancing access to lower cost mental health interventions on a global scale.

An additional challenge that dissuades service access is the limited availability of mental health providers. The World Health Organization reports that the average ratio of mental health providers to need is approximately 9 per 100,000 [13]. This ratio is especially problematic given 1-in-7 people worldwide have one or more mental health condition [14]. In all, 77% of the counties in the United States experience a severe shortage of mental health providers, and the demand for providers is estimated to increase during and after the COVID-19 pandemic [15]. More specifically, the Health Resources and Services Administration [16] shares that the "United States is reported to have a shortage of over 10,000 full time mental health practitioners (psychiatrists; clinical, counseling, and school psychologists; substance abuse and behavioral disorder counselors; mental health and substance abuse social workers; mental health counselors; school counselors) by the year 2025." This severe deficit in mental health practitioners may lead to other access issues, such as long wait lists, billing restrictions, transportation challenges, a lack of culturally competent care, and a lack of anonymity, all which are outlined as problematic for rural settings in particular [17]. This manuscript discusses the alternative of mHealth interventions as a viable solution to such barriers to care.

mHealth Interventions: A Potential Solution

First coined approximately 10 years ago, mHealth interventions refer to the delivery of health services via mobile or wireless devices [18]. Common mobile mental health interventions are in the form of mobile apps, but can also include SMS text message components [19] and ubiquitous sensing [20]. SMS text message interventions rely on SMS text messages, which are a form of mobile communication that is fast, reliable, efficient, and highly accessible to the general population. Ubiquitous sensing refers to the use of wireless sensors that are embedded in mobile phones to continuously monitor the activities of mobile phone users to infer, for example, the user's emotional or mental state [21]. In the context of mental health

mHealth interventions, ubiquitous sensing can be particularly useful in the delivery of SMS text messages as it could enable delivery of content when users need them most. For example, inertial sensors (motion and force), physiological sensors (heart rate or dermal activity), and ambient sensors (light) have been shown to capture data indicative of mood changes [22], which could be leveraged for prompt delivery of just-in-time text message interventions (TMIs) [23]. A recent study evaluating a TMI found the approach to be a feasible and acceptable method of delivering psychological treatments [24]. Feasibility and acceptability are 2 implementation outcome measures that help researchers understand if a service is satisfactory (acceptable) or successfully usable (feasible) [25]. Feasibility is a criterion that relates to the practicality, whereas acceptability is a criterion relating to personal judgment [25]. In the context of mHealth interventions, feasibility may examine the ease in performance of an app, and acceptability may examine if the intervention fits an individual's needs. Examining such measures can help facilitate maintenance of TMI and ubiquitous mHealth interventions. Given >20 billion SMS text messages are sent out every day worldwide [26] and nearly 33% of Americans reported to prefer text messaging to all other forms of communication [27], the investigation of SMS text messaging and mHealth apps, their implementation outcome measures, and their impact on mental health outcomes is well justified.

Understanding the Effectiveness of mHealth Interventions

Despite SMS text messaging being a rather new modality for mHealth, studies have already demonstrated the positive impact of TMIs on health behaviors on a global scale. An instance of this is Text4Mood, a TMI service that sends supportive text messages written by mental health therapists daily to subscribers exclusively in Alberta, Canada. This service provides immediate access to an intervention for patients who may have limited access to care, free of charge. After surveying >4000 subscribers, >80% of respondents felt Text4Mood increased hope of managing daily issues, 77% improved management of depression and anxiety, and 75% felt more connected to a support system. Overall, 83% of participants felt Text4Mood improved their general well-being [24]. Although these outcomes suggest the effectiveness of TMI as interventions, the influence of ubiquitous sensing on such mHealth intervention outcomes is less studied. Research in this area also indicates challenges with poor study quality and reproducibility, variability of data types, characteristics of participants, environments, and privacy [28]. As a result, we present these sensors and additional service delivery components, such as the implementation outcome measures, acceptability, and usability, to the participants of this study to gain insight on perceptions as it relates to the app Cope Notes, an SMS text message-based mHealth resource, as a just-in-time intervention.

Overview of Cope Notes

Cope Notes is an SMS text message-based support program that sends daily messages to a subscriber [29]. Currently, these text messages are sent daily at a random time with the aim of increasing the recipient's mental wellness and providing peer support. The goal of these messages is to increase positive

thought patterns and build healthy emotional tendencies of subscribers. This program resembles an ecological momentary intervention (EMI), which delivers real-time information to patients during their everyday lives. A total of 13 other EMI programs designed to address anxiety symptoms in patients exist currently [30]. Similar to Cope Notes, these programs attempt to improve symptoms through mobile technology-based psychoeducation, but only 2 deliver similar intervention-based SMS text messages [31].

Cope Notes differs from other SMS text messaging-based behavioral interventions, such as Text4Mood, because of the founder's personal lived experience with mental illness which enabled him to create an authentic program that resonates with subscribers in search of additional support [32]. Cope Notes aims to use evidence-based approaches, including positive psychology, stigma reduction messaging, and cognitive restructuring, to impact users' mental well-being, as well as encourage help seeking skills in potential users through peer support. By specifically applying SMS text messaging to these concepts, Cope Notes stands as a unique addition to existing intervention programs.

This Study

Apart from certain elements seen in Text4Mood, such as text messages based on principles of cognitive behavioral therapy to target mood and anxiety and promotion of mental well-being [33], no other behavioral health mHealth interventions discussed in the existing literature incorporate SMS text messaging to promote positive mental health self-management using a combination of cognitive restructuring, positive psychology, and stigma reduction. The purpose of this research study is to understand user experiences with Cope Notes as an SMS text messaging-based, mental health, self-management intervention. By understanding the experiences of Cope Notes subscribers, this mixed methods study [9] will facilitate the future application of these findings to other text message-based interventions through a phenomenological lens and advance findings surrounding SMS text messaging-based mHealth. We also aim to identify the current acceptability and usability of Cope Notes to improve similar mHealth services and close the gap in literature as it relates to stigma and how personality influences mHealth use and outcomes in mental wellness. Although in this study we do not investigate the application and use of ubiquitous sensing as it applies to SMS text messaging-based mHealth, we aim to uncover user perceptions of ubiquitous sensing in this space. We view ubiquitous sensing as a potential future innovation of the Cope Notes intervention and have used this research as an opportunity to assess the acceptability of this potential application in future research and development activities. Specific research questions we sought to answer with this study include the following:

1. How do Cope Notes users perceive the service as it relates to stigma, impact of the intervention, and perceived usefulness?
2. How do Cope Notes users rate the Cope Notes service and text messaging along various dimensions of acceptability?
3. What is the relationship between Cope Notes message ratings, user personality, and coping strategies?

4. What are user perspectives of ubiquitous sensing technologies, including integration of ubiquitous sensing for the improvement in the timeliness of the intervention and quality of tailored content?

Methods

Ethics Approval

This study was approved by the University of South Florida's (USF) Institutional Review Board (Pro00040410).

Study Design

To answer our research questions which guided this mixed methods study, we partnered with the USF Morsani College of Medicine (MCOM) and the chief executive officer of Cope Notes to facilitate convenience sampling strategies. We aimed to include 15 participants in the study as this number was deemed large enough to expect to achieve saturation in the themes emerging from the interviews [34]. We collected qualitative and quantitative data separately, and the quantitative component consisting of inventories collected after qualitative interviews was assessed. Qualitative data collection included (1) a demographic questionnaire and (2) qualitative interviews to inform the first and fourth research questions in the aforementioned list. The first quantitative measure evaluated a (3) user experience survey and addresses our second research question. The remaining quantitative data collected, that is, (4) a personality inventory and (5) coping assessment, provided a means to evaluate our third research question in the aforementioned list. Following data collection, we analyzed the qualitative and quantitative data using ATLAS.ti and SPSS (version 26.0; IBM Corp), respectively. The quantitative aspects of the study are used to inform and enhance the themes and patterns that emerged in the qualitative data and SPSS.

Recruitment and Sample

Inclusion criteria required participants to be aged ≥ 18 years and subscribed to Cope Notes for at least 30 days. Exclusion criteria

included not being able to read or speak English. Partnership with the chief executive officer of Cope Notes and USF MCOM guided our recruitment strategies. First, the partnership with Cope Notes allowed a text message to be sent out to subscribers asking whether they would be interested in participating in the study. The USF MCOM partnership provided medical students access to a 30-day Cope Notes subscription as a wellness resource during a time of high stress—the study period before the students' board exam. These gift subscriptions helped us gain additional participants. Recruitment strategies for medical students included sending out emails requesting participation in the study and verbally sharing information about the study in person at lectures. Volunteering subscribers were contacted via email to schedule in-person, Skype, or telephone interviews depending on their preference and availability. All participants provided informed consent before the commencement of the study and were compensated a digital gift card worth US \$15 for their participation. A total of 14 participants were included in this study; 9 (64%) were recruited through the Cope Notes partnership, whereas 5 (36%) were recruited through the MCOM. All data for this study were collected from June 2019 to December 2019.

Qualitative Study Design

Qualitative interviews were conducted to learn more about user experiences with the Cope Notes service, unearth perceptions on privacy and acceptance related to ubiquitous sensing, and gather thoughts pertaining to mental health stigma. Coupled with the interviews, the demographic questionnaire in [Multimedia Appendix 1](#) helped categorize experiences shared by participants—providing context to the outcomes and trends seen in the interviews. Live interviews were conducted using a semistructured interview guide ([Textbox 1](#)) and were audio recorded. The interviews lasted no more than an hour and on average lasted approximately 35 minutes, including completion of the demographics survey, and were transcribed verbatim using a secure web-based transcription service.

Textbox 1. Comprehensive list of interview questions from the qualitative interview guide.

Interview questions
1. What did you like or dislike about Cope Notes?
2. If you responded to any of the texts, describe your experience.
3. Would you recommend any changes or additional functionality to Cope Notes?
4. How do you feel about the delivery strategy of randomly timed messages?
5. Would you recommend any changes to the current delivery strategy?
6. We are considering creating a companion app that you could run in the background on your phone that would gather data using your phone's sensors. What do you think about this?
7. Here are some examples of the data we would collect from smartphone sensors and how it would allow us to predict levels of stress, anxiety, or depression. Do you have any reactions to this?
8. If Cope Notes has been helpful for you, in what areas of your life has it been helpful?
9. Can you recall the most and least helpful texts you received from Cope Notes; why were these the most or least helpful?
10. How do you feel about the cultural sensitivity of Cope Notes?
11. How does knowing the founder of Cope Notes has lived experience with mental illness change your experience or impression of Cope Notes?
12. How do you think that Cope Notes might affect stigma surrounding mental illness?

Quantitative Study Design

Quantitative Components and Measures

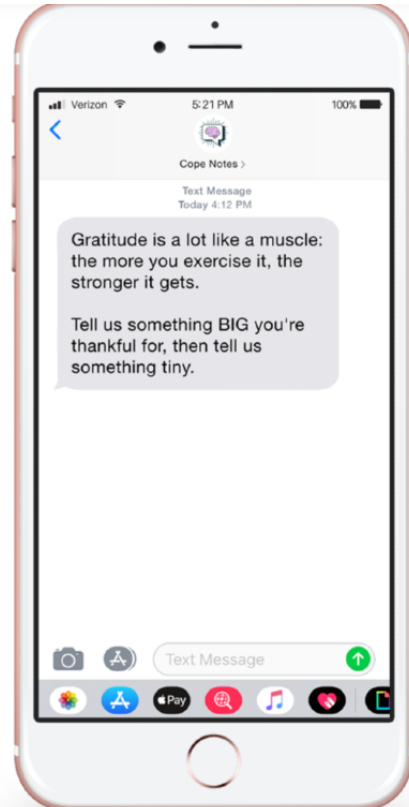

The quantitative component of this study consisted of a user experience survey, a personality inventory, and an inventory of coping strategies. The user experience survey served to directly measure how impactful certain elements of Cope Notes are perceived by participants. The personality inventory and coping assessment was used to extract possible connections between interactions and perceptions of the Cope Notes service and

specific characteristics regarding the participants who engaged with the service. In this way, the quantitative aspects of the study are used to enhance the analysis of patterns that are present in our qualitative results. All quantitative measures were delivered securely and electronically through the Qualtrics survey software, and participants completed the surveys independently without the support of a researcher. Quantitative measures are presented in [Multimedia Appendix 2](#). Examples of Cope Notes messages received by participants are presented in [Figures 1 and 2](#).

Figure 1. Example of an SMS text message that subscribers receive from the Cope Notes service encouraging cognitive reframing.

Figure 2. Example of an SMS text message that subscribers receive from the Cope Notes service encouraging reflection.

User Experiences Survey

The participants were asked to rate Cope Notes on several dimensions approximating the acceptability of the program, including (1) relevance to the user's own life, (2) timing of delivery, (3) how much reflection the texts elicited, (4) how much positive or negative emotion the texts elicited, (5) the user's understanding of the text's sentiment, (6) how much the texts promoted cognitive restructuring and coping, and (7) how much the texts inspired users to share the message with others. A total of 6 items were created in consultation with the chief executive officer of Cope Notes. The internal consistency of the 7 items used in this study was Cronbach $\alpha=.874$, demonstrating sufficient reliability [35]. Items on the survey were answered on a 7-point Likert scale (7=strongly agree). The participants were instructed to rate their level of agreement with a series of statements regarding the content (corresponding to the domains listed) of Cope Notes messages received over the past 30 days. An example item from this scale was, *Cope Notes messages were relevant to my life as a whole, regardless of when they were received*. This measure is available in [Multimedia Appendix 2](#). Because of the exploratory nature of this preliminary investigation of Cope Notes acceptability, we did not use a psychometrically validated instrument to assess user experiences; however, existing research with a similar goal of assessing the acceptability of a TMI adopted a similar methodological approach [24,33].

Personality Inventory

Personality was measured using a short 10-item version of the Big Five personality inventory, the Big Five Inventory (BFI)-10 [36]. This scale was evaluated against the BFI-44 and the

Neuroticism, Extraversion, and Openness to experience Personality Inventory-Revised for reliability and validity. BFI-10 scales retain significant validity and reliability, making it a reliable measure for use in this study. The BFI-10 is a shortened version of the original BFI with 44 items. The BFI-10 was created to decrease the required assessment time carried out by researchers. This measure includes 2 items for each of the 5 dimensions of the Big Five—openness, conscientiousness, extraversion, agreeableness, and neuroticism.

Coping Assessment

Coping was measured using the Brief Coping Orientation to Problems Experienced (COPE) inventory [37], which has also demonstrated good reliability and validity [38]. Brief COPE is an abbreviated version of the original COPE Inventory, a questionnaire that assesses a broad range of coping strategies. Brief COPE contains 14 two-item subscales rather than the original 60-item inventory. The reduced multidimensional measures of coping in response to stressors are analyzed separately as follows: (1) self-distraction, (2) active coping, (3) denial, (4) substance use, (5) use of emotional support, (6) use of instrumental support, (7) behavioral disengagement, (8) venting, (9) positive reframing, (10) planning, (11) humor, (12) acceptance, (13) religion, and (14) self-blame [39].

Results

Sample Characteristics

Of the 14 participants, 10 (71%) identified as White, 2 (14%) identified as Middle Eastern or Arab American, 2 (14%) identified as Asian American or Asian, 1 (7%) identified as Black or African American, and 1 (7%) identified as Pacific

Islander. Half of our sample (7/14, 50%) identified as male, and 43% (6/14) identified as female. It was noted that 71% (10/14) of the individuals had consulted a mental health professional (psychologist, psychiatrist, etc) for challenges regarding their mental well-being (eg, emotional, behavioral, and cognitive), and 64% (9/14) had a diagnosis of a mental illness. Of that 64% (9/14), participants specified being diagnosed with clinical depression, anxiety, bipolar depression, and attention deficit disorder. In all, 29% (4/14) of the participants reported not

receiving a diagnosis of a mental illness. [Table 1](#) provides an overview of the participant characteristics, which were obtained through the demographic survey. On average, participants had been active Cope Notes subscribers for 190 (SD 194) days. The minimum requirement for participation in the study was at least a 30-day subscription, whereas the earliest subscriber had a 700-day long subscription at the time of their interview. The demographic survey completed by participants is available in [Multimedia Appendix 1](#).

Qualitative Findings

Overview

The qualitative interview data were analyzed by 2 independent coders (SLK and JL) using structured coding methods following a narrative analysis approach within the ATLAS.ti program [40]. The study team derived overarching themes of interest driven by our research questions (ie, Likes or Perceived Benefits) and minor themes that emerged during the coding process (ie, customized delivery strategy). Interrater reliability,

the percentage agreement between the 2 coders (SLK and JL) calculated using Cohen κ in SPSS, was 61.8%, showing substantial rater agreement [41]. [Table 2](#) displays the 52 minor codes and how they are organized into 7 overarching themes: Likes or Perceived Benefits, Dislikes or Limitations, Suggested Changes, Stigma or Help Seeking, Perceptions of Ubiquitous Sensing, Cultural Sensitivity, and Alternative mHealth Resources (see [Multimedia Appendix 3](#) for definitions of the 52 minor codes). Disagreements were resolved through discussion and coming to a consensus as a team.

Table 2. Themes, code frequency, and number of participants reporting each code. Most frequent codes per theme are provided below. See [Multimedia Appendix 3](#) for definitions of all 52 minor codes (N=14).

Theme and code	Code frequency	Participants, n (%)
Likes or perceived benefits^a		
1	122	14 (100)
2	66	12 (86)
3	50	14 (100)
4	24	9 (64)

^eMost frequent code: other mHealth or therapy.

^fMost frequent code: positive reaction.

^gMost frequent code: neutral cultural impact.

Theme 1: Likes or Perceived Benefits

When asked about Cope Notes, users generally found Cope Notes to be helpful and supportive:

Cope Notes to me is exactly like somebody saying “hello” to somebody. “How are you doing?” [Participant 6]

Cope Notes would come in and really help me focus on what I could control, and what I couldn't, and what was important. [Participant 7]

All participants voiced a preference for convenience, including passive, low effort, and low time commitment resources that were simple to use:

I think it's a quick tool and it doesn't really take that much effort. That's what I like about it. [Participant 3]

...text messages, which is about as easy as it gets. [Participant 1]

Of the 14 users, 12 (86%) noted that Cope Notes encouraged positive reframing of their mental wellness, and 13 (93%) stated that they liked the random message timing:

I like that it comes at different times of day...[the messages] have been helpful to me, good reminders. [Participant 9]

It's just a nice little way to recenter my thoughts in the middle of the day...I like that they come in randomly, not at the same time every day. [Participant 7]

All users (14/14, 100%) said that they liked the variety of topics, as well as the subject depth, that Cope Notes delivered to them. Some users (4/14, 29%) felt the messages even triggered awareness, self-reflection, and mindfulness when it came to their everyday interactions:

Cope Notes is great because it gives you something to think about and to reflect on. [Participant 3]

Theme 2: Dislikes or Limitations

A common dislike was the invariance of message length:

...message length was always...standardized. [Participant 1]

Of the 14 users, 6 (43%) found that the tone of some of the texts seemed more off-putting rather than encouraging, and in some cases, not sufficiently engaging:

Some [text messages] are instructional which to me felt kind of weird. [Participant 2]

It was just quotes. I saw other people got more interactive [messages]. [Participant 4]

In all, 50% (7/14) of the participants also noted that the timing of some messages came too late or too early in the day to be viewed as helpful:

It would come so late that I was already asleep. [Participant 4]

In total, 14% (2/14) of participants also stated that Cope Notes was “too expensive” as follows:

I'm not sure I would pay \$10 a month for it...when life was crazy, I would pay a little bit more. [Participant 3]

In addition, a user experienced multiple text threads instead of a consistent conversation thread of daily messages and found that to be cumbersome:

For me it was always from a different number, so my inbox was [a] whole bunch of Cope Notes. [Participant 4]

Theme 3: Suggested Changes

The most common suggested change, recommended by 64% (9/14) of users, was to include more interactive media, such as inspirational wallpapers or images:

I'm more of a visual person...that would kind of enrich the experience. [Participant 2]

Users also suggested variability in the length of text messages to make it less robotic. Similarly, another popular suggestion made by 29% (4/14) of participants was the ability for a user to choose the time frame of delivery, as well as the type of content received on a day-to-day basis:

I prefer to be able to set it at a time that I feel like I need it most...I'm like, okay, it's 4:15 [and] I haven't received my message yet. But I know that it is coming somewhere along in the afternoon. [Participant 8]

A user suggested the ability to bookmark text messages that they wanted to remember, whereas 50% (7/14) of the users requested an increase in 2-way interactions:

Ooh [if] you can favorite things...have a favorite quote to come back [to]. [Participant 3]

[I'd prefer] a personalized [response] for sure, if it was automated, I probably wouldn't respond. [Participant 11]

Theme 4: Stigma or Help Seeking

Although the consensus reported by 86% (12/14) of users was that Cope Notes could assist in stigma reduction, participants

raised 2 alternative opinions worth noting. First, some (5/14, 36%) participants stated that upfront knowledge of the Cope Notes founder's lived experience with mental illness could deter those who are label avoidant. Label avoidance occurs when someone avoids people or places that might prime a stigmatizing label such as mental illness. In other words, people may shy away from receiving mental health services (continuing or initiated services) due to fears of being associated with the negative stigma surrounding mental illness. As such, using the founder's public background of lived experience as a selling point of this service may discourage others from using Cope Notes to avoid stigma.

Second, 86% (12/14) of participants acknowledged that Cope Notes assisted them with reflecting on shared previous experiences and perceptions of stigma that they could tie to preferred styles of peer support:

[Cope Notes] doesn't allow the opportunity for stigma to kind of present itself, because it's applicable across the board. [Participant 7]

I think it's really totally helping people remove the stigma of mental health issues. It's normalizing that most of the population have issues with mental illness. [Participant 12]

Participants also stated that Cope Notes may encourage some users to find more professional forms of mental health treatment, although some were not sure which of their peers would intentionally seek professional mental health services:

I could see people picking something more light, like Cope Notes, before trying...medical attention type coping mechanisms. [Participant 2]

I don't trust counselors...[Cope Notes] is kind of like a nice little...a form of counseling. [Participant 1]

Theme 5: Perceptions of Ubiquitous Sensing

We asked participants to consider the use of a companion app as a complement to the traditional Cope Notes SMS text message service. The app's functionality, that of which reflects a ubiquitous sensing-like paradigm, was explained to participants in plain language as follows. The app would use the embedded sensors (participants were also provided with this information during their interview; [Textbox 2](#)) in the user's smartphone to gather information about the user's surroundings and how the user interacts with their device. These data would then be used as input to a machine learning algorithm trained to identify distinct patterns in the user's behavior to predict instances where the user might be upset, stressed, or expressing otherwise concerning behavior. Such an app would run in the background on the user's smartphone, and based on the prediction from the algorithm, trigger an SMS text message intervention to be sent to the user, providing timely support when users need it the most.

Textbox 2. Sensor descriptions presented to users accompanying the interview questions on a Cope Notes companion app.

Sensor descriptions

- Your smartphone's hardware consists of a variety of sensors that can gather information from your environment.
- These sensors work together in a continuous and transparent fashion to process that information into something meaningful for you.
- For example, if you use an app for tracking your daily runs, the accelerometer sensor is used for tracking that movement. Researchers have been studying sensor data for many reasons; one of these reasons is to predict abnormal activity (eg, you skipped one of your morning runs), which may correlate with certain moods such as stress or anxiety. The items below are some examples of sensor data that might be collected to predict your stress and anxiety level.
- What are your reactions to these items and this form of data collection?
- Calling and text messaging activity can include data such as the partial phone number of the receiver, time of the call, and length of the call. Research has shown that call and text messaging patterns may be associated with anxiety.
- The screen's status (ie, on or off) and the light sensor (which measures the light source around you) can be used to approximate your sleeping patterns, a known indicator of stress.
- When surrounded by other devices, your smartphone may be able to detect them via Bluetooth technology. Thus, the number of devices detected by your smartphone may provide an approximation of your social context.
- GPS and Wi-Fi sensor information are excellent for approximating location. Studies have shown that location patterns provide valuable insight regarding mood.
- The accelerometer and gyroscope sensors detect speed and rotation and are thus commonly used for recognizing physical activities. When unusual, your activities may be an indication of a potential problem.
- The microphone's gathering of sound information can be processed at a high level for recognizing various sound sources, like wind or motorized transport, to be used for approximating your environment.
- Similar to call logs, app logs track your use of mobile apps and other statistics such as when an app is installed or opened. This information can provide insight into your interests and overall use of the device.

Most participants were neutral (8/14, 57%) or responded positively (10/14, 71%) to the idea of the app providing more timely interventions according to need:

If someone's stressed out, I think a great thing is to have someone to just give them...[a] nugget of wisdom. [Participant 1]

I think that would just be a great enhancement, as a resource! [Participant 8]

In all, 50% (7/14) of the users were concerned that other users may be concerned about privacy, whereas 64% (9/14) of participants had concerns about the collection of data themselves:

It's a little big brother-y, I think is what people think. [Participant 7]

I think this also might be perceived by a lot of people as an intrusion of their privacy. [Participant 10]

Many participants (6/14, 43%) mentioned specific sensors that they had a negative reaction to (ie, call logs and microphone). As a remedy, participants suggested allowing users to select which sensors the app could access:

Let people pick which data to allow the app to use. [Participant 2]

Meanwhile, only 14% (2/14) of participants were opposed to using the sensors owing to their personal privacy concerns:

I actually would not be interested in that...Yeah, it's a privacy issue. [Participant 13]

I definitely struggle with like the microphone gathering information, listening...I don't think I'd

leave that up to my phone, my phone data to gauge [my behavioral patterns]. [Participant 14]

Furthermore, 43% (6/14) of participants were unsure of the abilities of the app or underlying machine learning algorithm to predict times when a user may be stressed or needs support:

It'd be interesting to see how well it worked and how accurate it was. [Participant 9]

Theme 6: Cultural Sensitivity

When asked about cultural sensitivity, participants responded in a generally neutral (9/14, 64%) to positive (6/14, 43%) manner:

I haven't ever come across anything that seemed like it was directed or misdirected. [Participant 7]

Participants did note that most statements made in the messages received referenced Western culture related references:

References to a famous person...someone in another country may not [know them]. [Participant 1]

Theme 7: Alternative mHealth Resources

Another theme that was recognized was the comparison of Cope Notes to other mobile mental wellness resources. In all, 36% (5/14) of participants compared this text message program to the meditation mobile app Headspace or the gratitude journal mobile app Three Good Things:

Three Good Things is very unique and individual, right? And it's also very active, so you...unlike Cope Notes, you can't ignore it, it requires you to put in

something, it's not just a message that comes and you read it. [Participant 10]

A participant also compared it to Autonomous Sensory Meridian Response videos, which are web-based videos that include sensation inducing audio triggers. Cope Notes was also compared with Early Alert, a text message mental wellness check program designed for professional health students. However, users distinguished that these programs were for specific parts of mental health whereas Cope Notes was more encompassing:

I think it's easier. In general, to get to more people with Cope Notes than you can with Not A Therapist. [Participant 15]

Quantitative Findings

We conducted exploratory analyses using descriptive statistics and correlations. Specifically, the quantitative survey data were analyzed through descriptive statistics using SPSS. We were interested in the mean user ratings of Cope Notes' acceptability as well as how personality and coping strategies might relate to user ratings. Table 3 provides the means and SDs of participant ratings of Cope Notes acceptability along 10 dimensions. The sample size for each item varies as participants were given the option to respond that the question was not applicable. In addition, not all participants completed the quantitative survey. Responses to the survey were obtained from 12 of the 14 (86%) participants who provided qualitative interviews. Higher scores (scores could range from 0=not applicable to 7=strongly agree) represent more agreement with each of the acceptability items.

Table 3. Means and SDs of acceptability rating items of the Cope Notes service (N=14).

Acceptability rating items	n (%)	Mean (SD)
1. Cope Notes messages were relevant to my life as a whole, regardless of when they were received.	12	6.25 (1.06)
2. Cope Notes messages came at a relevant time in my life.	12	6.08 (1.38)
3. Cope Notes messages were not relevant to my life at all.	5	2.20 (0.45)
4. I think of Cope Notes messages often, and remembering them helps me face new situations.	11	5.73 (1.42)
5. Cope Notes messages provoked a positive feeling.	12	6.08 (0.90)
6. Cope Notes messages provoked a negative feeling.	4	2.00 (0.00)
7. I fully understood the sentiment behind Cope Notes messages.	12	6.08 (1.16)
8. Cope Note messages helped me view myself or my situation differently.	12	6.08 (1.08)
9. Cope Notes messages helped me deal with or relieve pressure or stress.	12	6.00 (1.47)
10. I have shared Cope Notes messages with others or posted them on a social networking site.	10	6.00 (1.25)

Exploratory analyses of the relationship between acceptability ratings and personality factors as measured by the BFI-10 revealed several significant correlations. Spearman correlations indicated a statistically significant positive relationship between seeing oneself as someone who is generally trusting and acceptability items 4 ($r_{s(9)}=0.71, P=.01$), 5 ($r_{s(10)}=0.75, P=.005$), 7 ($r_{s(10)}=0.82, P=.001$), and 10 ($r_{s(8)}=0.71, P=.02$). There was also a significant positive correlation between perceptions of oneself as someone who does a thorough job and acceptability item 8 ($r_{s(10)}=0.80, P=.01$).

Examining relationships between Brief COPE items and acceptability ratings revealed a statistically significant negative correlation between receiving emotional support from others and acceptability item 1 ($r_{s(8)}=-0.80, P=.006$) and 9 ($r_{s(8)}=-0.79, P=.006$). The active coping strategy of taking action to make things better was significantly positively related to acceptability item 8 ($r_{s(8)}=0.72, P=.02$). Endorsement of the coping strategy of saying things to let one's unpleasant feelings escape was significantly negatively related to acceptability item 5 ($r_{s(8)}=-0.66, P=.04$) and 7 ($r_{s(8)}=-0.70, P=.03$). Participants who strongly endorsed the coping strategy of doing something to think less about their problems (eg, going to movies, watching television, reading, daydreaming, sleeping, or shopping) were significantly less likely to strongly endorse acceptability items

5 ($r_{s(8)}=-0.74, P=.01$) and 7 ($r_{s(8)}=-0.75, P=.01$). Participants strongly endorsing coping by accepting the reality that an event has happened also strongly endorsed acceptability items 5 ($r_{s(8)}=0.69, P=.03$), 7 ($r_{s(8)}=0.86, P=.001$), 9 ($r_{s(8)}=0.67, P=.03$), and 10 ($r_{s(6)}=0.84, P=.009$). Finally, endorsement of using the coping strategy of expressing negative feelings was significantly positively related to acceptability item 8 ($r_{s(8)}=0.67, P=.03$).

Discussion

Principal Findings

In general, Cope Notes users found Cope Notes to be helpful and supportive. Specifically, users spoke about Cope Notes functioning to help them refocus on aspects of their lives over which they had control. Users liked that Cope Notes is a low-effort tool and that it is easy to use and saw Cope Notes helpful for managing stigma and normalizing mental illness. Users also framed Cope Notes as a low-intensity intervention [42] that may lead to seeking professional mental health care later. Users reported that Cope Notes helped with reframing their mental wellness and liked the random timing of the messages. These positive reactions to Cope Notes are confirmed by the high levels of acceptability endorsed through the

quantitative survey asking users to rate the messages on the 10 dimensions of acceptability.

On the other hand, Cope Notes users disliked the standard message length and occasionally disliked the tone of a text message. Some (3/14, 21%) users did not like the early morning or late-night delivery of a text. Some (2/14, 14%) participants also felt that the subscription cost was too high. Changes suggested by users included requests for more media-based and engaging texts, an option to select the time of message delivery, and a more personalized experience. Users generally had a positive or neutral response to the use of ubiquitous sensing, which might aid in bringing about such changes. No specific concerns were expressed about the cultural sensitivity of Cope Notes, though it was noted that Cope Notes seems to be targeted toward Western cultures. We also found that users compared Cope Notes to other mHealth interventions; however, they viewed Cope Notes as targeting mental health more broadly than other products. The goal of our qualitative inquiry was not to generalize these findings but instead to gain understanding of the experiences of users of this SMS text messaging mHealth self-management resource.

There were several personality traits that were significantly related to the acceptability ratings of Cope Notes. Seeing oneself as generally trusting and acceptable was positively related to remembering the Cope Notes messages and using them to face new situations, positive feelings provoked by the Cope Notes texts, fully understanding the sentiment behind the texts, and sharing the Cope Notes messages with others or on social media sites. These relationships seem to reflect the notion that those who trust others may be more likely to place trust in the content of the texts, thereby experiencing a positive reaction to the texts and a desire to share them with others [43,44]. Perceptions of oneself as doing a thorough job was positively related to responding that the Cope Notes texts helped the user to view themselves and their situation differently. This too seems reasonable as those who may have thoroughness as a personality trait may be more likely to process and use the information contained in the text messages [45]. These findings regarding personality provide insight into the types of users who may be more likely to find Cope Notes, or similar SMS text messaging-based interventions, as an acceptable tool for coping, and may also inform the modification of the intervention to appeal to a broader range of personality types.

The coping strategy of receiving emotional support from others, as measured by the Brief COPE, was negatively related to viewing Cope Notes messages as relevant to one's life and using the messages to help deal with pressure or stress. This may suggest that Cope Notes would be most acceptable to those who lack emotional support from others in their immediate environment. Coping styles of taking action to make things better was positively related to using the messages to help change one's views of themselves or their situation. This was a logical finding as both are active forms of coping, also referred to in the existing literature as problem focused coping [46]. There was a negative relationship between endorsing positive feelings provoked by Cope Notes and fully understanding the sentiment of the text and the coping strategy of saying things to let one's negative feelings escape. Perhaps those users who

vent more are less likely to experience a positive response to a nonverbal text message and therefore may be less likely to exert effort to understand the message. Those participants who endorsed the coping strategy of doing things to distract themselves from their problems were also less likely to experience positive feelings from Cope Notes messages or understand the message's sentiment. This finding might reflect the idea that the passive receipt of a text is less likely to emotionally impact those who prefer such active coping strategies and therefore less likely to inspire an effort to understand message content. Participants who endorsed coping by accepting the reality of an event also endorsed positive feelings evoked by Cope Notes, understood message sentiment, used Cope Notes to relieve pressure or stress, and shared the messages with others. Many of the Cope Notes texts are rooted in positive psychology strategies such as mindfulness and acceptance and therefore users who tend to cope in this way may be particularly likely to have a positive experience with Cope Notes. Taken together, these findings may inform targeting of the Cope Notes customer segment as well as modifications of the Cope Notes intervention or content of texts to respond to a broader range of coping styles. Despite the scarcity of similar investigations to compare findings, in summary, we found that those with active coping tendencies, or those who are more likely to receive outside emotional support are less likely to feel positively impacted by Cope Notes. However, participants who are more likely to cope through nonverbal approaches are more likely to embrace Cope Notes. We continuously received feedback from participants who were more concerned about internet safety and privacy regarding the possibility of a companion app from a group think perspective. Individually, participants were not as concerned about privacy and security as they believed other possible users to be.

Comparison With Previous Work

Text4Mood is a similar SMS text messaging-based program that sends supportive texts each day to users located in North America who text the word *mood* to a specific number. This program is designated for those who are currently on a wait list to receive services or have *difficulty accessing service due to geographic barriers* [24]. Text4Mood can also provide psychological support for those currently enrolled in individual or group counseling. For US \$5.40, users can access this service for 6 months at no additional charge.

Text4Mood differs from Cope Notes as it is marketed for users who are in the process of receiving treatment directly from a provider, whereas Cope Notes does not require users to pursue direct care. The geographic boundaries and price points also differ; Text4Mood is only available to users in North America, whereas Cope Notes does not have any geographic limitations and the subscription ranges from US \$6.99 to US \$9.99 per month (depending on the type of subscription purchased). Users of Cope Notes and Text4Mood both reported positive benefits to their overall mental well-being after extended use of both services.

Cope Notes is also similar to EMIs, as previously referenced in the Introduction section. Heron and Smyth [30] identified 27 EMIs for different health conditions, 6 of which focused on

addressing symptoms of anxiety. None of these interventions, including the 6, used SMS text messaging [30]. A more recent meta-analysis of EMI interventions meant to augment mental health and positive psychological well-being, which included some SMS text messaging–based interventions, found that EMIs were effective (medium effect sizes) for improving anxiety, depression, perceived stress, acceptance, relaxation, and quality of life [47]. However, none of the illness self-management SMS text messaging–based EMIs reviewed in the literature to date attempt to integrate cognitive restructuring, positive psychology, and stigma reduction messaging, and none involve a component of peer support, making Cope Notes an innovative addition to the existing menu of available EMIs for mental illness and its evaluation concerning effectiveness and acceptability, a novel and timely addition to research literature in mHealth.

Limitations

The small sample size for our quantitative survey limits our ability to gain an understanding of the relationship between personality and coping styles and the acceptability of the Cope Notes program on a broader scale. Despite our efforts to recruit a large, heterogenous sample, ultimately our relationship with the USF MCOM for recruitment yielded a significant portion of research participants, which could have implications regarding the generalizability of this work. However, we also aimed to reach a more representative population of the Cope Notes users via an SMS text message blast sent to subscribers. It is also possible that the demographic information present in our sample is largely representative of Cope Notes subscribers. Regarding the sample size, we continued to recruit participants until we noticed a clear pattern of qualitative data providing repetitious information. After reviewing the data from the first 14 participants, we then determined we had reached saturation through repeated emerging themes and ended the recruitment stage.

We did detect some statistically significant and potentially meaningful relationships that could be used to target the Cope Notes audience segment and modify the program or message content; however, additional research with a larger sample size is called for to gain a more accurate picture of those who might be more likely to benefit from Cope Notes and SMS text messaging–based interventions in general.

Conclusions

Affordability, limited numbers of mental health providers, stigma, and other factors limiting accessibility to or willingness to seek mental health services are well known. These barriers to care are exacerbated by the effects of the COVID-19 pandemic, further increasing the demand for accessible mental health support [48,49]. mHealth interventions are one way to enhance the accessibility of mental health services, although all forms of mHealth interventions, such as SMS text messaging–based interventions, are understudied [50]. Understanding the effectiveness of mHealth resources, such as SMS text messaging–based intervention Cope Notes, for improving and facilitating mental health self-management services is more important now than ever before.

The presented mixed methods study found subscribers of Cope Notes to appreciate the service for refocusing and reframing their mental wellness, with noted statistically significant correlations between specific personality traits and acceptability of the SMS text messaging–based service as evaluated via qualitative interviews, coping assessment, personality inventory, and a user experiences survey. However, we also found that some users preferred a more personalized experience with Cope Notes, with a potential for a companion app equipped to continuously monitor user behavior to identify moments of distress as a viable solution. Despite touching on ubiquitous sensing in this way, investigating an actual implementation of ubiquitous sensing was not an objective of this study. Findings of this study regarding participant personality and coping styles and Cope Notes ratings indicate potential avenues for future research on coping styles and personality as mediators of acceptability of text-based mental health interventions. It is important to note that Cope Notes is not a replacement for professional mental health treatment but instead a supplement for professional forms of treatment. Through these findings, other researchers can gain more understanding to how SMS text messaging may be received by others, even outside of behavioral interventions. Future research will include a more refined focus on the possibility of using ubiquitous sensing in text message–based interventions for mHealth purposes.

Abstract

Background: The use and sharing of patient-generated health data (PGHD) by clinicians or researchers is expected to enhance the remote monitoring of specific behaviors that affect patient health. In addition, PGHD use could support patients' decision-making on preventive care management, resulting in reduced medical expenses. However, sufficient evidence on the use and sharing of PGHD is lacking, and the impact of PGHD recording on patients' health behavior changes remains unclear.

Objective: This study aimed to assess patients' engagement with PGHD recording and to examine the impact of PGHD recording on their health behavior changes.

Methods: This supplementary analysis used the data of 47 postpartum women who had been assigned to the intervention group of our previous study for managing urinary incontinence. To assess the patients' engagement with PGHD recording during the intervention period (8 weeks), the fluctuation in the number of patients who record their PGHD (ie, PGHD recorders) was evaluated by an approximate curve. In addition, to assess adherence to the pelvic floor muscle training (PFMT), the weekly mean number of pelvic floor muscle contractions performed per day among 17 PGHD recorders was examined by latent class growth modeling (LCGM).

Results: The fluctuation in the number of PGHD recorders was evaluated using the sigmoid curve formula ($R^2=0.91$). During the first week of the intervention, the percentage of PGHD recorders was around 64% (30/47) and then decreased rapidly from the second to the third week. After the fourth week, the percentage of PGHD recorders was 36% (17/47), which remained constant until the end of the intervention. When analyzing the data of these 17 PGHD recorders, PFMT adherence was categorized into 3 classes by LCGM: high (7/17, 41%), moderate (3/17, 18%), and low (7/17, 41%).

Conclusions: The number of PGHD recorders declined over time in a sigmoid curve. A small number of users recorded PGHD continuously; therefore, patients' engagement with PGHD recording was low. In addition, more than half of the PGHD recorders (moderate- and low-level classes combined: 10/17, 59%) had poor PFMT adherence. These results suggest that PGHD recording does not always promote health behavior changes.

patient-generated health data; engagement; health behavior change; postpartum women; health data; health informatics; pelvic health

Introduction

Background

According to the Office of the National Coordinator for Health Information Technology, patient-generated health data (PGHD) is defined as health-related data created, recorded, or gathered by or from patients (or family members or other caregivers) to help address a health concern [1,2]. In 2018, the term PGHD was introduced into the Medical Subject Headings thesaurus [3]—a controlled and hierarchically organized vocabulary produced by the National Library of Medicine for indexing, cataloging, and searching of biomedical and health-related information—and the term became widely known. PGHD in paper form have been used in the past, but the development of digital health innovations has enabled the collection of a large amount of electronic PGHD easily through mobile phones, wearable devices, and several types of sensors. The use and sharing of PGHD by clinicians or researchers is expected to not only enhance the remote monitoring of specific behaviors that affect patient health, but also support patients' decision-making on preventive care management, resulting in reduced medical expenses [4]. However, sufficient evidence on the use and sharing of PGHD in clinical settings is lacking [5], and the impact of PGHD recording on health behavior changes remains unclear [6-8]. Previous studies have incorporated PGHD techniques into multicomponent interventions. A scoping review [9] reported that multicomponent interventions used the following techniques to motivate users for PGHD recording: the provision of rewards and incentives, goal setting, reminders, feedback, social support, and entertainment elements such as gamification. Given the complexity and diversity of multicomponent interventions, it is difficult to evaluate the effect of PGHD recording, and there is no conclusive evidence that it improves health behavior [9,10].

Our Previous Study

We conducted multicomponent interventions with reminder emails for pelvic floor muscle training (PFMT) to manage urinary incontinence (UI), in which users manually recorded the number of pelvic floor muscle contractions (PFMCs) performed as PGHD [11]. Daily reminder emails for PFMT were sent to the postpartum women's smartphones for 8 weeks, and the number of PFMCs performed was recorded on a website via smartphone. Our results showed that this multicomponent intervention improved PFMT adherence (implementation rate and the number of times implemented per day and per week) and reduced the incidence of UI [11]. PFMT is a simple exercise to strengthen the muscles of the pelvic floor—participants contract and relax the pelvic floor muscle repeatedly—and it effectively treats and prevents UI [12,13]. However, it is difficult to maintain PFMT adherence in patients with only verbal instructions and leaflets [14,15]. Although our multicomponent intervention was expected to improve PFMT adherence, problems arose because the participants were not recording the

number of PFMCs performed as PGHD every day as instructed by the researchers.

Additional Rationale for This Study

Many users of digital behavior change interventions (DBCIs) that use technologies such as the internet, telephones, mobile phones, and environmental sensors [16] do not use these technologies as intended by researchers, and the number of users declines over time [17,18]. The attrition of DCBI users may impact the effectiveness of the interventions. Therefore, "effective engagement" that is sufficient to achieve the intended outcomes should be established [16,19]. Engagement with DBCIs is conceptualized as two synthetic constructs, "engagement as behavior" (eg, the extent of use of DBCIs or their components) and "engagement as subjective experience" (eg, intrinsic interest and enjoyment), and it is a dynamic process that is expected to vary both within and across individuals over time [20-22]. A scale for assessing engagement with DCBI has recently been developed [20,21]. It has been suggested that, by assessing engagement, researchers can determine when and how to tailor interventions to the individual, supplement with human support when needed, and identify the components required for intervention design [19,23].

Goal of This Study

We conducted a supplementary analysis of the PFMC data stored on the server of our previous study [11]. This study aimed to assess patients' engagement with PGHD recording (ie, "engagement as behavior") and participants' usability of PGHD recording (ie, "engagement as subjective experience"). Furthermore, we aimed to examine the impact of PGHD recording on health behavior changes in PFMT adherence among PGHD users who recorded their PFMCs consistently using latent class growth modeling (LCGM).

Methods

Recruitment and Sample

The participants were postpartum women who had delivered from January to August 2014 at an obstetric clinic in Osaka Prefecture, Japan, which performs approximately 600 deliveries per year, and had been assigned to the intervention group of our previous study [11]. The inclusion criterion of our previous study [11] was postpartum women with a smartphone and the exclusion criteria were participants with a history of pelvic surgery and cerebral infarction, as well as those with current hypertension, diabetes, hemorrhage, cystitis, neurological disease of the urinary system, chronic cough, and diuretic use. For postpartum care, a midwife provided the participants with verbal instructions on how to perform PFMT as detailed in a leaflet. The PFMT regimen included 3 sets of 6 PFMCs every day (ie, a total of 18 PFMCs per day), and the training duration was at least 8 weeks.

Data Inclusion and Exclusion

This study used the data of 47 postpartum women who had been assigned to the intervention group of our previous study [11] for managing UI. There were no exclusion criteria, and no data were excluded from analyses.

Study Design

This research is a supplementary analysis of our previous study, which improved PFMT adherence and reduced the number of postpartum women with UI. A detailed description of the study has been published in full [11]. In our previous study, participants received PFMT reminder emails via smartphone every day for 8 weeks, which contained a URL link to a website for manually recording the number of PFMCs performed.

Ethics Approval

This study uses data collected during our previous study [11], which was approved by Osaka University Medical Science Department of Health Ethics Committee (approval number 268).

Evaluation Outcomes

Data collected by the above procedure were classified into the following four categories: (1) participants' demographic characteristics, including age, BMI before pregnancy, weight gain during pregnancy, and their child's birth weight; (2) the number of participants who recorded their PGHD (ie, PGHD recorders); (3) each participants' status of PGHD recording; and (4) weekly mean number of PFMCs performed per day among those who recorded it continuously. The participants' usability of PGHD recording was evaluated after the 8-week intervention period with the question "Was it difficult to record the PFMCs every day?" The participants responded on a 5-point Likert scale ("Strongly agree," "Agree a little," "Neither agree nor disagree," "Disagree a little," or "Strongly disagree"). Furthermore, comments on the participants' usability of PGHD recording were collected with the prompt: "Please comment on your experience of recording PFMCs on our system in the free-text field." Participants voluntarily answered these two questions about usability. These data were encrypted using Secure Sockets Layer to prevent leakage of personal information during transmission and were stored on the server through the website. All data were downloaded in .csv format.

Statistical Analysis

The participants' demographic characteristics were described as continuous variables (reported as median values with IQRs) and categorical variables (reported as number of cases with percentages). To assess engagement with PGHD recording during the intervention period, a graph was plotted with the number of PGHD recorders on the y-axis and the number of

days on the x-axis, and the approximate equation of the curve was calculated. To visualize each participant's status of PGHD recording during the intervention period, a figure was created with gray-shaded cells indicating the days that a given participant recorded PGHD and the numbers within cells denoting how many PFMCs were performed that day. On the y-axis, participants are arranged based on the total number of times that PFMCs were recorded and the total number of PFMCs performed during the intervention period. Based on the lower asymptote that was obtained from the approximate curve, 17 participants (IDs 1-17) were classified as the high-engagement group and the remaining participants (IDs 18-47) were classified as the low-engagement group. Fisher exact test and Mann-Whitney *U* test were used to examine the differences in each group. To evaluate PFMT adherence among the 17 participants in the high-engagement group, the weekly mean number of PFMCs performed per day was calculated. To determine the model fit, we employed entropy and the Bayesian Information Criterion, and to determine the model number of the weekly mean number of PFMCs performed per day, we employed the Lo-Mendell-Rubin likelihood ratio test and the bootstrap likelihood ratio test [24,25]. LCGM is a statistical method that uses specific combinations of observed variables and can be used to identify groups of people with similar characteristics. Additionally, LCGM can determine individual phenotypes by identifying subgroups that follow similar trajectories over time [26]. LCGM in eHealth research is commonly used to determine potential trajectories and groups of engagement with DBCIs [27-33]. In this study, we used LCGM to determine PFMT adherence. The usability of PGHD recording was determined by organizing the participants' comment data into qualitatively and inductively meaningful groups and calculating the number of cases and percentages for each group. A *P* value of <.05 was considered statistically significant for all analyses. LCGM analyses were performed using Mplus (version 8.6; Muthen & Muthen). Other analyses were conducted using JMP PRO software (version 15.1.0; SAS Institute Inc).

Results

Participants' Demographic Characteristics

The participants' demographic characteristics are shown in Table 1. The percentage of participants with UI at the baseline was 6% (3/47). The median age of the participants was 34 (IQR 31-36) years and 70% (33/47) were multiparous women. For BMI before pregnancy and weight gain during pregnancy, 72% (34/47) and 57% (27/47) of the participants were in the normal range, respectively. For child's birth weight, 98% (46/47) of the participants reported birth weight of less than 4000 g.

Table 1. Comparison of demographic characteristics of participants having high and low engagement with patient-generated health data recording.

Characteristic	Total participants (N=47)	Engagement with PGHD ^a		P value
		High (n=17)	Low (n=30)	
UI ^b at baseline, n (%)	3 (6)	1 (2)	2 (4)	.99 ^c
Age (years), median (IQR)	34 (31-36)	34 (32-37)	33 (30-36)	.21 ^d
Multipara, n (%)	33 (70)	14 (30)	19 (40)	.20 ^c
BMI before pregnancy (kg/m ²), median (IQR)	20 (19-21)	20 (18-21)	20 (19-21)	.96 ^d

^aPGHD: patient-generated health data.

^bUI: urinary incontinence.

^cFisher exact test.

^dMann-Whitney U test.

Engagement With PGHD Recording

Engagement with PGHD recording is shown in Figure 1. The number of PGHD recorders was the highest at 3 days after the start of the intervention (31/47, 66%) and the lowest at 42 days (14/47, 30%). The approximate curve of the number of PGHD recorders (*y*) and the days (*x*) during the intervention period was calculated by the following sigmoid curve formula:

In the approximate curve, there was an inflection point at 14.2 days (95% CI 11.1-17.3; *P*<.001), with the upper asymptote at 29.9 participants (95% CI 27.2-32.6; *P*<.001) and the lower asymptote at 17.0 participants (95% CI 16.4-17.6; *P*<.001), and

an *R*² value of 0.91. The percentage of PGHD recorders during week 1 of the intervention was constant at 64% (30/47) and then decreased rapidly from week 2 to week 3. After week 4, 36% (17/47) of the participants continued to record the number of PFMCs performed until the end of the intervention.

Figure 2 shows each participant's status of PGHD recording. IDs 1 and 2 (2/47, 4%) completed PFMC recording every day. Conversely, IDs 44-47 (4/47, 9%) never recorded any data. High engagement with PGHD recording was observed for IDs 1-17 (17/47, 36%) and low engagement was observed for IDs 18-47 (30/47, 64%). A low number of participants recorded their PFMCs consistently. No significant difference was observed in baseline UI, age, birth history, BMI before pregnancy, weight gain during pregnancy, and birth weight between the two groups (Table 1).

Figure 1. Engagement with patient-generated health data recording.

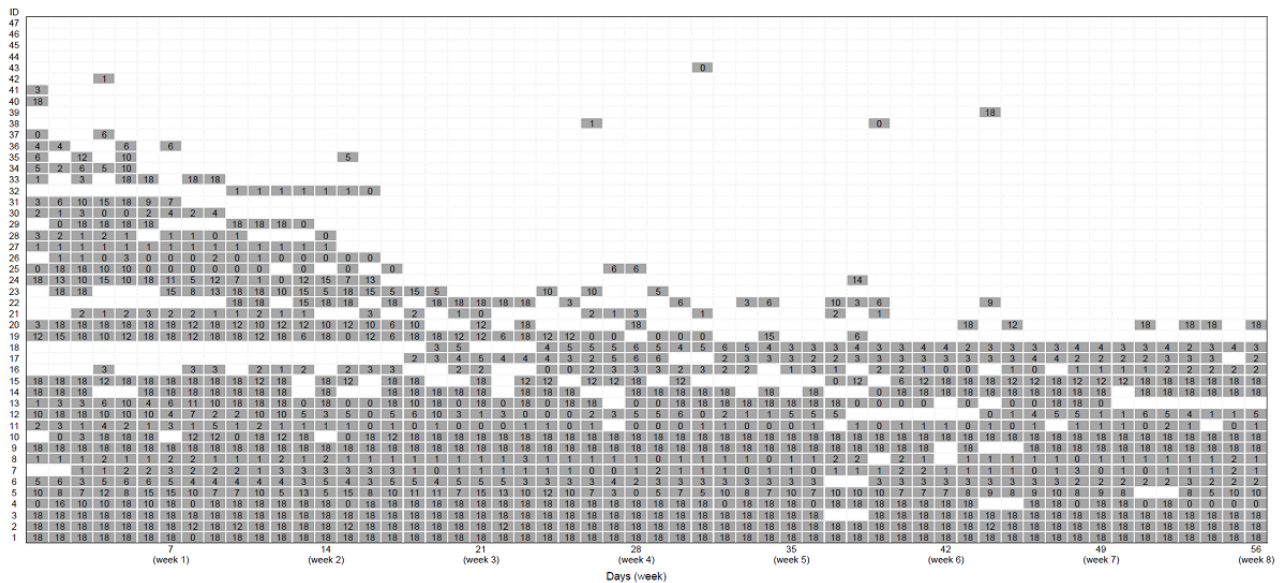

Figure 2. Status of patient-generated health data recording.

The Impact on Health Behavior Changes

Table 2 shows the model information obtained through LCGM for the PFMT adherence of the high-engagement group. The value of entropy of the 2-class model was 0.911 and that of the 3-class model was 1.000, indicating that the high-engagement group could be subdivided into 2 or more groups. No significant difference was found in the Lo-Mendell-Rubin likelihood ratio test and the bootstrap likelihood ratio test; however, the Bayesian Information Criterion was small, indicating a better fit in the 3-class model than the 2-class model. Finally, the 3-class model was selected. A 4-class model could not be produced.

The 3-class model produced latent trajectories that corresponded to the weekly mean number of PFMCS performed per day. The following groups were defined: “high” for PGHD recorders who started with high PFMT adherence levels (7/17, 41%; Figure 3); “moderate” for PGHD recorders who started with moderate PFMT adherence levels (3/17, 17.6%; Figure 3); and “low” for PGHD recorders who started with low PFMT adherence levels (7/17, 41%). Of the 17 participants who continued to record data until the end of the intervention, 10 participants were in the moderate- and low-adherence groups, indicating that overall PFMT adherence was poor. Table 3 shows the characteristics of the 3 groups by PFMT adherence level.

Table 2. Model information by number of classes obtained through latent class growth modeling.

Test	Number of classes	
	2	3
Percent per class	41/59	41/18/41
Entropy	0.911	1.000
Bayesian Information Criterion	592.6	590.0

^fPGHD: patient-generated health data.

Usability of PGHD Recording

After the intervention period, some participants (27/47, 57%) answered questions about the usability of PGHD recording (Table 4). The number of responses was approximately equal for both high (15/27, 56%) and low (12/27, 44%) categories of engagement with PGHD recording. Furthermore, a significant difference between the level of engagement with PGHD recording and usability was found ($P=.01$, Fisher exact test), indicating that those who found PFMC recording difficult had low engagement with PGHD recording. The total percentage

of participants who answered "Strongly agree" and "Agree a little" to the question "Was it difficult to record the PFMCs every day?" was 37% (10/27).

Uncategorized comments by the participants were as follows: "By reporting the number of times, I felt as if I was being watched for not being lazy, and I think I was able to continue," "I did not report PFMCs, but I was able to perform them every day," "When I receive emails three times a day, the importance of emails gradually decreased for me, and I wish I could set the number of times emails were sent individually," and "At first, I was motivated, but I tended to skip halfway through."

Table 4. Usability of patient-generated health data recording.

Discussion

Principal Findings

In this study, we examined patients' engagement with PGHD recording integrated into a multicomponent intervention and evaluated the impact of PGHD recording on their health behavior changes. The following findings were obtained. First, engagement with PGHD recording might be low. This could be because the number of PGHD recorders declined over time, as indicated on a sigmoid curve. Moreover, a small number of participants recorded PGHD continuously (17/47, 36%). Second, PGHD recording may not promote health behavior changes. This was suggested by the overall poor PFMT adherence observed (10/17, 59%).

Comparison With Prior Work

Eysenbach [17] has hypothesized that fluctuations in the number of users and dropouts in digital health can be classified into Phases I-III in “sigmoid attrition curves.” Phase I is the stage where users initially stay because of curiosity, Phase II is the stage where the number of users decreases rapidly (ie, the stage where the users' expectations are not met), and Phase III is the stage where “hardcore” users stabilize. We derived a “sigmoid attrition curve” from the obtained data, which aligned with Eysenbach's attrition hypothesis. However, not all attrition curves for fluctuations in the number of users and dropouts in digital health are sigmoidal. The app-based intervention for diabetes prevention used by Fukuoka et al [34] for obese adults at risk for type 2 diabetes incorporated a core curriculum consisting of PGHD recording (daily steps), reminders, and face-to-face sessions, with the proportion of PGHD recorders declining in a linear function from approximately 80% at the start of the intervention to approximately 40% over the 20-week intervention period. Similarly, Carter et al [35] have reported interventions for weight loss in overweight volunteers using a smartphone app that included PGHD recording of food diaries and physical activity, sending SMS text messages to reinforce health behaviors, and feedback on the recorded physical activities in combination with face-to-face group sessions with

the number of PGHD recorders declining progressively in a linear function from 43 recorders at the start of the intervention to 7 recorders (16%) over the 6-month intervention period. In either study, the attrition curve was not mathematically derived, and a sigmoid curve was not obtained. The shape and slope of these attrition curves are reportedly dependent on the age and sex of the PGHD recorders [36], the type of PGHD [37,38], the lack of relative advantages over digital health for users, usability (complexity), trial settings (such as trial management or reminders by researchers), and user attributes [17]. Possible reasons for the small number of PGHD recorders in this study include the following usability issues: 37% (10/27) of users felt that PFMC recording was burdensome, and those who found PFMC input difficult had low engagement with PGHD recording. In addition, 22% (6/27) of the users mentioned that “it was difficult to secure time for training while raising children” in the usability comments, which may be partly due to the participants of this study being postpartum women who were busy with childcare, had no time to perform PFMT, and could not record the number of PFMCs performed. In this study, PGHD recorders abruptly decreased from week 2 to week 3, which may be an appropriate time period to reinforce individualized interventions with personal support for users. In addition, since the number of participants who recorded PGHD stabilized after week 4, it is desirable to perform the intervention evaluation after this period. Thus, analyzing and understanding changes in the number of users and dropouts is important to enhance the efficacy of the intervention.

PFMT adherence in the 17 participants who recorded PGHD continuously could be clearly categorized into 3 latent classes. The moderate- and low-level classes (combined: 10/17, 59%) were considered to have poor PFMT adherence, and the weekly mean number of PFMCs performed per day was low even in PGHD recorders. In the present analysis, data that were not recorded as PGHD were treated as missing data. The comment “I did not report PFMCs, but I was able to perform them every day” by some participants suggests that some of those who did not record PGHD actually performed PFMT without recording it; thus, we considered an input of 0 for PFMCs performed as

invalid. Accordingly, PFMT adherence may have been higher than shown in the data. However, as PFMT is a muscle-strengthening exercise, a minimum number of contractions and consistent practice (for at least 8 weeks) are both required. Therefore, treatment and prevention of UI cannot be expected unless the PFMT adherence pattern is similar to that of the high-level class drawn by LCGM.

Even users who showed high engagement with PGHD recording did not necessarily adhere to the PFMT regimen as instructed. These data suggest that PGHD recording may not promote health behavior changes. One of the PGHD usability comments was “By reporting the number of times, I felt as if I was being watched for not being lazy, and I think I was able to continue.” A previous study [23] reported that PGHD recording leads to positive attitudes among users, such as increased awareness of health behaviors. However, in our study, the finding that less than half of the users adhered to the PFMT regimen as instructed suggests that although PGHD recording may have a promotive effect on the users’ awareness of changing their health behavior, it might not be sufficient to promote health behavior changes. Steinberg et al [39] implemented an intervention combining recording of the previous day’s steps as PGHD, feedback on the recorded number of steps, and group sessions in women with a BMI ≥ 25 kg/m². Of the 26 participants in the intervention group, 8 stopped recording PGHD during the intervention period, and the proportion of participants who recorded PGHD, which was approximately 80% at the start of the intervention, gradually declined to approximately 25% during the 24-week intervention period. They also reported that there was no correlation between the rate of PGHD recording during the intervention period and the number of steps as a measure of change in health behavior. Although it has been reported that PGHD recording is independent of health behavior changes, there is a possibility that intervention studies have been conducted and analyzed on the assumption that PGHD recording promotes health behaviors. Few studies have shown the impact of PGHD recording on health behavior outcomes, and the evidence is still lacking. Recently, it has been reported that effective use patterns of multicomponent interventions might differ across users, and that users do not always have to use all of the intervention elements [40]. In addition, the possibility that PGHD recording itself may lead to lower engagement for health behavior changes cannot be ruled out [9]. Based on previous studies and our results, clinicians and researchers must understand that all users who record PGHD in multicomponent

interventions do not necessarily adhere to health behavior changes.

Limitations

There are 3 limitations of this study. First, the sample size was too small to clearly demonstrate associations between PGHD recording and health behavior changes. One reason for the small sample size is that participants did not receive explicit instructions that they had to record PGHD, which was a component of the system, at the time of study participation. The participants recorded, or did not record, PGHD at their own discretion. Therefore, those who did not consider the PGHD recording of their PFMT necessary might not have continued PGHD recording. When participants use a multicomponent system, such as the one in our study, it is difficult to ensure that all components are used. Despite this limitation, this is one of the few studies that used LCGM to evaluate PFMT adherence, a measure of health behavior change, and investigated the impact of PGHD recording on health behavior change. Therefore, we believe that this case study will lead to a larger-scale survey. Second, the intervention in this study was a multicomponent intervention combining PGHD recording and PFMT reminder emails; as such, the effect of PGHD recording alone could not be evaluated. However, it is commonly accepted in PGHD research that evaluation of PGHD recording alone is difficult because it is an integral part of multicomponent interventions. In the future, a research design that can evaluate the impact of PGHD recording alone on health behavior changes needs to be established. Third, the number of PFMCs performed as a measure of PFMT adherence is a self-reported outcome and could not be confirmed. Therefore, systemic errors could occur as a result of participants reporting an inaccurate number of PFMCs performed. Given this limitation, the results must be carefully interpreted.

Conclusions

The number of users who recorded PGHD in a multicomponent intervention declined over time in a sigmoid curve. A small number of users recorded PGHD continuously, and users felt that PGHD recording was burdensome. Therefore, PGHD engagement was found to be low. In addition, more than half of the PGHD recorders had poor PFMT adherence. These results suggest that PGHD recording may not always promote health behavior changes. Clinicians and researchers must understand that users who record PGHD in multicomponent interventions do not necessarily adhere to health behavior changes.

Acknowledgments

The kind cooperation of all the participants is gratefully acknowledged. This study was supported by a Grant-in-Aid for Young Scientists (B), grant A227922240, from the Ministry of Education, Culture, Sports, Science and Technology. We thank Dr Tomoharu Sato (Department of Biostatistics & Data Science, Graduate School of Medicine, Osaka University) for providing expert advice on statistics.

Abstract

Background: Mobile apps are not only effective tools for promoting health to teenagers but are also useful for engaging teenagers in participatory research on factors that influence their health. Given the impact of food marketing messages on teenagers' food attitudes and consumption choices, it is important to develop effective methods for capturing the food advertisements targeted at this population to assess their content.

Objective: The aim of this study was to test the feasibility and usability of a mobile app, "GrabFM!" ("Grab Food Marketing!"), designed for teenagers to facilitate monitoring of self-identified targeted food marketing messaging.

Methods: A mixed methods approach, including quantitative user response rates and qualitative focus group discussion feedback, was used in the evaluation process.

Results: A total of 62 teenagers (ages 13-17) completed GrabFM! app pilot testing over a 7-day data collection period. Teenagers submitted a total of 339 examples of food marketing, suggesting high feasibility for the app. Participants also took part in focus group discussions about their experience, providing positive feedback on usability, including ease of use and design aesthetic appeal.

Conclusions: The GrabFM! app had high feasibility and usability, suggesting its efficacy in capturing accurate data relevant to the teenage population's experience with food marketing messaging.

KEYWORDS

mHealth; mobile app; teenager; adolescent; monitoring; participatory research; feasibility; usability; food marketing; food advertising

Introduction

Current research around mobile health (mHealth) and teenage populations focuses on health promotion via behavioral change interventions [1-6]. This includes studies employing the use of mobile technology to allow for self-monitoring of diet and exercise [7,8]. Indeed, mobile technology offers unique opportunities to access and collect data from the everyday lives of teenagers on topics that influence their health. Specifically, in light of growing evidence of the impact of food marketing messages on teenagers' food preferences, attitudes, and

consumption [9,10], it is important to learn more from this group about the food messaging they see and engage with.

To date, research that partners with teenagers to document the food marketing messages that they encounter has not used mobile app technology to empower teenagers to engage in self-reporting. Such participatory research instead uses body cams [11-14] and eyeglass cameras [15] to capture food marketing messaging that teens may be exposed to, but not necessarily *notice* or *engage* with (ie, identify as relevant). Using an mHealth approach, the project detailed in this article uses an evidence-based mobile app called "GrabFM!" ("Grab Food

Marketing!’”), which was designed for teenagers to facilitate self-reporting of targeted food marketing messages. This project thus addresses gaps in current participatory research on food advertising’s reach and persuasive content with respect to teenagers. This study further adds to knowledge about the mHealth elements (ie, mobile app user experience) and participatory methods (ie, data collection procedures) that facilitate the monitoring of health-related data for teenagers.

Reviews of existing literature show that mobile apps are an effective method for reaching teenagers when it comes to health promotion [16], and specifically for self-monitoring of health-related behaviors [17]. This is facilitated by increasing levels of smartphone accessibility among teenagers, and their familiarity and ease with new technologies [16,18]. The acceptability of smartphone use in different social settings for teenagers also contributes to their comfort level in their use for self-monitoring [7].

Current literature on the development of teen-oriented mHealth apps offers important insights into their assessment. A recent systematic review on the quality of mHealth apps for teenagers identified common rating criteria, including ease of use, visual appeal, interactivity, and degree of customizability [16]. Such criteria are commonly explored under the umbrella concepts of *feasibility* (ie, suitability to perform the intended tasks) and *usability* (ie, quality of user experience) [7,18]. Both feasibility and usability are directly relevant to the current study, in which a teen-oriented evidence-based mobile app was created to facilitate the self-identification of food marketing messaging to teenagers. Following an mHealth approach to evaluation, the aim of this study was to explore the app’s feasibility and usability for identifying teen-identified targeted food marketing messages. More broadly, this study contributes to gaps in knowledge around the persuasive power (ie, specific techniques

or strategies used to persuade) and platforms of exposure of teen-targeted food marketing. Findings on the app’s feasibility/usability are important for both researchers engaging in mHealth behavioral interventions, as well as those exploring the use of mobile apps for participatory health-related research.

Methods

App Design Process

The mobile app was developed iteratively with app developers (alongside an expert in app privacy and security) beginning in 2018 over a period of 3 years. Figure 1 outlines the basic steps involved in project development. The goal was to create a mobile app user experience that would allow teenagers (ages 13-17) to easily capture examples of food and beverage marketing (both online and in their physical environments using screenshots/photos and to tag those images with identifying information. The app content was informed by a scoping review of existing literature on identifying teen-targeted food marketing, highlighting relevant platforms and indicators (ie, marketing techniques) [19], and was assessed for appropriateness by a group of teenagers (n=17) in focus group discussions. Additionally, a small group of teenagers (n=5) provided feedback on the app’s visual design (ie, color, imagery) during the development process. App design elements include: a detailed tutorial (that launches automatically upon first opening the app), main interface for data submission (ie, upload screenshot/access camera functions, text fields, and preset lists of options for entering identifying metadata), an image library (with ability to select “favorite images”), and daily push notifications once a day for 7 days (beginning after first use of the app). The app was developed in both iOS and Android versions to accommodate a variety of devices.

Figure 1. Flow chart of GrabFM! mobile app development.

Ethics Approval

This study was approved by the University of Calgary Conjoint Faculties Research Ethics Board (REB19-0020).

Sample and Study Procedure

A mixed methods approach was used, including participatory data collection and focus group discussions. Teenagers between the ages of 13 and 17 were recruited between January and May 2021 from schools (via school boards and research team member networks with principals and teachers), community groups, and sports teams. Principals, teachers, and other group leaders were contacted via email by the study team and invited to participate with their group. Given the low-risk nature of the study and the age of the participants, participants provided their own consent (with additional parental consent where required by schools). Once registered (through a secure website), participants were provided with a unique user code to gain access to the app after download (to their own device) from Apple App Store or Google Play Store. Participants then used the app for a 7-day period to submit self-identified examples of teen-targeted food marketing. Data submission involved the following steps: upload screenshot or take a photo of a food marketing example, and then input (1) the brand, (2) food type (independent text fields), (3) platform (ie, communication channel) where the example was found (selected from a preset list of 16 options, including “other” text

field to add additional platforms), and (4) content “tags” indicating the teen-targeted marketing techniques used (selected from a preset list of 10 options, including “other” text field to add additional tags) [20].

Following the 7-day data collection period, the teenagers took part in focus group discussions to provide feedback on app usability (ie, likes and dislikes regarding functionality, appropriateness of evidence-based content, and barriers and facilitators to user engagement). Focus groups were conducted online due to restrictions around COVID-19 requiring limited in-person contact, using a semistructured moderator’s guide to facilitate discussion. Three researchers facilitated the process (Zoom meeting host/tech facilitator, moderator, and note-taker). Focus groups were recorded in Zoom, transcribed verbatim, and analyzed for themes by two researchers using Nvivo 12 software.

Analysis

App feasibility was defined as the suitability of the app to perform the required tasks (ie, to engage and sustain participant engagement over the use period) [21]. This was measured quantitatively via response rates (as tracked through backend data), which were used for descriptive statistics [22]. App usability was defined as perceived ease of use and enjoyment of use [21,23]. Usability was examined through qualitative data

from focus group discussions and presented in a descriptive summary [23]. Additionally, a qualitative approach was used to allow the teenagers to provide more in-depth responses regarding their experiences using the app for self-initiated data collection [23]. A thematic analysis was performed on the focus group discussion data to identify emerging themes.

Results

Participant Characteristics

Sixty-two teenagers used the app for a 7-day period between January and May 2021 (in small groups, with rolling time

frames). Five participants were excluded from the sample due to incomplete submissions (ie, missing indicators/tags or images), leaving a sample size for app use of 57 teenagers. Teenagers also took part in focus group discussions upon completing the 7-day data collection period using the app. Seven 1-hour mixed-gender discussion groups were conducted between January and May 2021. A total of 47 teenagers provided feedback on their experience using the GrabFM! app in the discussion groups (note that the sample size is smaller for the focus group discussions, as some of the participants from the app data collection phase study were unavailable to participate in the focus groups). [Table 1](#) provides a breakdown of participant demographics in terms of gender and age.

Table 1. Participant demographics.

Characteristic	App testing group, n	Focus groups, n
Gender		
Girl	39	30
Boy	17	17
Gender nonconforming	1	0
Age (years)		
13	23	15
14	18	20
15	9	9
16	5	2
17	2	1

Feasibility

Overall, 339 self-identified examples of food marketing were submitted, suggesting high levels of feasibility for the app. Over the 7-day data collection period, an average of 6 ads per participant were submitted (range of 1-15 ads overall), with the exception of one outlier who submitted 47 ads.

Usability

In the focus groups, teens reported high levels of usability. In general, they reported positively on overall ease of use (“smooth to run” [boy, age 14], “it was simple” [boy, age 14], “everything was labeled” [girl, age 15]), including easy image uploading (“easy to set and easy to upload” [girl, age 14], “loaded very fast” [boy, age 14]). They also provided positive feedback on the app’s esthetics (“The app itself looked nice” [boy, age 14], “I liked the color” [girl, age 14], “It’s very bright and vibrant” [girl, age 13]).

A few teens expressed difficulty in initially understanding how the app functioned (despite the fact that the tutorial was set up to launch automatically upon first opening of the app): “I didn’t know if I was supposed to take pictures of what I saw—had seen—in real life or what [else] I had to do before that. I couldn’t find the tutorial” (boy, age 14). Roughly one third of the participants also commented on the notifications feature with mixed impressions, including both positive (“I got daily notifications and they were helpful” [girl, age 14]) and critical (“I turned it on but I didn’t get any” [girl, age 13]) reviews.

Finally, although most of the participants perceived the evidence-based list of platforms and indicators to be complete, a few additions were suggested for both platforms (Twitch [girl, age 13], Spotify [girl, age 16], Radio [girl, age 17], and Pinterest [girl, 14]) and indicators (ie, marketing techniques: trendy [girl, age 14; girl, age 14], sports [girl, age 13], and filters [girl, age 14]).

Discussion

Principal Findings

This pilot study suggests that the GrabFM! app is feasible given the sustained engagement by participants across the 7-day data collection period. Overall, the app’s usability was also highly rated in terms of ease of use and appeal of aesthetics. Good usability was also reflected in the high rate of complete data submission by participants; only 8% (n=5) of users were eliminated for missing information. This was an important outcome, as one of the central goals in developing the GrabFM! mobile app as a research tool was to allow for effective in-field data capture. As noted in the mHealth monitoring literature, self-reporting in-field is preferable as it does not require user recall, which can be unreliable [18].

Thus, to mitigate data loss based on incomplete submissions, and in light of the focus group feedback on unclear functionality, the results of this study highlight the need for comprehensive onboarding instructions (an external tutorial reinforcing the in-app tutorial) to ensure that all participants understand the

procedure for accurate data collection. Further, given the importance of accurate data capture, the mixed feedback from the focus groups on the notification feature suggests the need to shift from manual settings (originally designed to allow for choice of start date) to automatic settings (one push notification per day for 7 days once the app is opened). Additionally, it is beneficial to instruct participants to set a daily timer on their phones as a reminder for data collection [24]. This will serve as a reinforcement mechanism.

In the focus group discussions, teenagers were asked to provide their own recommendations to increase teen buy-in to app use. Most of the suggested facilitators for buy-in revolved around gamification features such as rewards/points/prizes, monetary value on ad submissions, achievements/badges to unlock levels, competing against peers, linking to social media networks (increasing likes/friends/followers), and daily goals. Such features underline the importance of engagement strategies and social feedback mechanisms for teenagers when it comes to self-monitoring activities as noted in previous studies [6,16,25].

While gamification features (ie, goals/targets as behavioral motivators) are not directly relevant to the GrabFM! project given the app's primary purpose as a data collection tool, these teen-identified facilitators to user engagement are useful for researchers developing mHealth interventions to promote attitude and behavior changes in relation to food/diet for teenagers, about which research remains limited [2,4,26]. Differences in gamification features aside, the important common feature of mHealth monitoring apps (eg, for dietary intake or physical activity levels) and the GrabFM! data collection app is the goal of facilitating self-monitoring (in the form of digital diary keeping) to increase user awareness around particular types of health-related information [17]. Indeed, although not explicitly designed as an intervention tool, the

GrabFM! app promotes increased awareness of targeted food messaging, suggesting the need to further explore its educational potential in line with more traditional mHealth apps.

Strengths and Limitations

The GrabFM! smartphone app is an innovative mHealth tool that is evidence-based, its content having been derived from the literature on monitoring teen-targeted food marketing messages. Further, the design/user experience was developed iteratively in conjunction with the app developer expressly for the teenage user to facilitate accurate data collection, along with careful considerations of privacy and security. However, it is important to note that this is a proof-of-concept pilot study with a small sample; as such, the feasibility and usability of the GrabFM! app will be further tested in the full project rollout currently underway with a much larger group of teenagers. Additionally, it is important to note that the content of the food marketing data collected during this pilot study is outside of the scope of this paper, which has been analyzed previously [20].

Conclusion

Mobile apps are not only an effective method for promoting health to teenagers but are also useful tools for engaging this population in participatory research around factors that influence their health. This study used an mHealth approach to monitoring health-related information using a smartphone app that positions teen participants as experts in the identification of relevant food marketing messages that target them. Both the feasibility and usability of the GrabFM! app were found to be high with teenagers, suggesting its efficacy in capturing accurate data relevant to the teenage population's experience with food marketing. These findings set the stage for use of the GrabFM! app in a broader study to provide important insights into the reach and content of targeted food marketing to teenagers as revealed in their self-identified data.

Abstract

Background: Mothers who identify as Black or African American are more likely to report depressed moods in late pregnancy and early postpartum and have the lowest rates of human milk feeding compared with all other racial groups in the United States. Internet interventions offer the potential to extend preventative and supportive services as they address key barriers, particularly for those navigating the complex and vulnerable early postpartum period. However, there is limited evidence on the feasibility of such interventions for preventing perinatal mental health disorders and improving human milk feeding outcomes in Black mothers.

Objective: This pilot study aimed to assess the feasibility and preliminary findings of a web-based cognitive behavioral therapy-based internet intervention, with and without human milk feeding education and support, to prevent perinatal depression and promote human milk feeding in Black mothers.

Methods: Participants were Black-identifying individuals between 20 and 28 weeks of pregnancy with human milk feeding intention and mild to moderate depressive symptoms (Patient Health Questionnaire scores 5-14). Participants were randomized to either *Sunnyside*, a 6-week cognitive behavioral therapy-based web-based intervention, or *Sunnyside Plus*, which included additional education and support to promote human milk feeding. Assessments occurred at baseline, third trimester (end of antenatal treatment), 6 weeks postpartum (end of postpartum treatment), and 12 weeks postpartum. The primary focus of this randomized pilot trial was the feasibility and preliminary outcomes of mental health and human milk feeding.

Results: A total of 22 tertiary-educated participants were randomized. The mean number of log-ins was 7.3 (SD 5.3) for *Sunnyside* and 13.8 (SD 10.5) for *Sunnyside Plus*. Scores of depression and anxiety measures remained below the clinical threshold for referral to treatment in both groups. All the participants initiated human milk feeding (18/18, 100%). Most participants reported at least some human milk feeding at both 6 and 12 weeks postpartum (6/7, 86%; 11/11, 100%, or 10/10, 100%, for *Sunnyside* and *Sunnyside Plus*, respectively).

Conclusions: The results suggest that tertiary-educated Black mothers at risk for perinatal depression and who intended to human milk feed were receptive to and satisfied with a web-based cognitive behavioral therapy-based internet intervention, with

and without human milk feeding education and support. Preliminary findings indicate that both *Sunnyside* and *Sunnyside Plus* interventions have the potential to affect symptoms of depression, anxiety, and human milk feeding outcomes.

breastfeeding; chestfeeding; perinatal; depression; anxiety

Introduction

Background

Mental health disorders are among the most common complications during pregnancy and in the first 12 months after childbirth [1-3]. Research suggests that the prevalence of perinatal anxiety disorders is at least 17% and that approximately 7% to 20% of individuals experience clinical depression at some time during the perinatal period [4-6]. Perinatal mental health disorders make it difficult to function and care for oneself and for an infant. In fact, maternal mental health is considered an important underlying factor associated with barriers and reduced rates of human milk (HM) feeding intent, initiation, exclusivity, and continuation [1-3,7].

HM feeding is considered the ideal form of infant feeding because of its extensive benefits for the lactating person and infant. All major health and professional organizations recommend exclusive HM feeding for the first 6 months of a child's life, with continued HM feeding in combination with appropriate complementary foods for at least 1 to 2 years [8-10]. However, despite the benefits, recommendations, and high rates of intention to HM-feed, overall rates within the United States continue to be low [11]. There are many known barriers to reaching HM feeding goals, including painful or difficult latch, concerns about milk supply, lack of professional lactation support, unsupportive social and cultural norms, inadequate parental leave policies, and maternal mental health difficulties [12-16].

Certain barriers are disproportionately experienced by Black individuals, many of which stem from historical and continued oppression, systematic racism, social injustices, and structural violence. For example, Black mothers often receive limited education and differential treatment from providers regarding HM feeding information and encouragement [12]. National data show that non-Hispanic Black mothers have the lowest rates of HM feeding initiation and continuation at 6 and 12 months postpartum compared with all other racial groups in the United States. [11] In addition, Black mothers are more likely to report depressed mood in late pregnancy and early postpartum than White mothers, even after adjusting for income and education, distinguishing between the effects of race and socioeconomic status [17].

The relationship between maternal mental health and HM feeding outcomes is bidirectional; mental health disorders can make HM feeding more challenging, and difficulty with HM feeding may predict depression and anxiety [18-22]. Therefore, it is important to consider both when designing interventions to improve these outcomes. Cognitive behavioral therapy (CBT),

which focuses on identifying and changing unhelpful thoughts and behaviors, has been shown to be effective in preventing perinatal depression [23]. Interventions that extend across pregnancy and postpartum and offer individualized support from professionals and peers have been shown to be successful in improving both mental health and HM feeding outcomes [24,25]. In addition, intervention components shown to improve these outcomes among Black mothers include a positive representation that enhances and normalizes HM feeding in an encouraging way, content that addresses gaps in support (eg, building a support network, advocating for oneself in the hospital, preparing for a successful return to school or work, and enhancing HM feeding self-efficacy), and professional and timely HM feeding support that continues into the postpartum period [12,26-28]. Although many effective intervention strategies exist, access to these programs can be a barrier, especially for those navigating the complex and vulnerable early postpartum period.

The internet offers great potential in extending preventative and supportive services to individuals in the perinatal period as it addresses several key barriers to success. Digital technology interventions, which include the use of web-based content and interactions, SMS text messaging, and social media, have been effective in reducing depressive symptoms and improving HM feeding outcomes [29,30]. Black mothers report that social media, for example, is a practical, convenient, and valuable way of obtaining HM feeding information and support, feeling connected with people who have overlapping lived experiences, and improving self-efficacy [31,32]. However, there is limited evidence on the feasibility of such interventions for preventing perinatal mental health disorders and improving HM feeding outcomes in Black mothers.

Objective

The previously studied *Sunnyside* intervention is a web-based CBT-based internet program used to manage mood during the perinatal period. Findings from the pilot study showed that intervention use and satisfaction were high among participants, and symptoms of depression decreased from midpregnancy to 6 weeks postpartum [33]. To further study the relationship between mental health and HM feeding, we developed *Sunnyside Plus*, which is built upon *Sunnyside* and also includes HM feeding education and support. Therefore, the objectives of this study were 2-fold. First, we examined the feasibility of *the Sunnyside Plus* by measuring adherence to the intervention, usability, and acceptability. Second, we tested the preliminary mental health and HM feeding outcomes of *Sunnyside Plus* compared with those of *Sunnyside*.

Methods

Study Design and Participants

This randomized pilot trial used a comparative effectiveness research approach to compare 2 active treatments, *Sunnyside* [33] and the newly developed *Sunnyside Plus*, on maternal mental health and HM feeding outcomes among Black individuals with mild to moderate depressive symptoms upon study enrollment who intended to HM-feed their child. Although HM feeding can include the use of donor HM, in this study, HM was provided directly from the lactating parent at their breast or chest or via their expressed milk.

Participants were recruited through advertisements placed on Ovia Health [34], a nationwide web-based pregnancy forum and internet-based application, between June 12, 2020, and September 15, 2020. Inclusion criteria were as follows: (1) pregnant and between 20 and 28 weeks of gestation, (2) aged ≥ 18 years, (3) Black or African American, (4) intending to HM-feed their child, (5) self-reporting mild to moderate depressive symptoms (Patient Health Questionnaire [PHQ]-8 score of 5-14), (6) access to a broadband internet connection, and (7) proficiency in the English language. Exclusion criteria were as follows: (1) pregnant with multiples; (2) visual, hearing, voice, or motor impairment that would prevent completion of the study procedures; (3) diagnosed with a major depressive episode, psychotic disorder, bipolar disorder, dissociative disorder, substance use disorder, or other diagnoses for which participation in this trial was either inappropriate or dangerous based on self-report; or (4) currently receiving treatment (medication or psychotherapy) and having an intention to resume antidepressant medication after birth (ie, those who discontinued their medication during pregnancy). Those interested were directed to a brief web-based screener to assess their eligibility.

Ethics Approval

Qualifying individuals provided electronic consent to participate. All procedures were approved by the institutional review board at the University of Illinois Chicago (UIC; IRB approval number: 2019-0519).

Study Procedures

Following consent, qualifying individuals were immediately directed to complete the baseline assessment surveys that were provided via a REDCap (Research Electronic Data Capture; Vanderbilt University) link; study data were collected and managed using REDCap electronic data capture tools hosted by the UIC [35,36]. Participants were then randomized in a 2:1 allocation ratio to either *Sunnyside Plus* or *Sunnyside* using a block randomization method with a web-based randomization service provider, Sealed Envelope [37]. A 2:1 randomization allocation was used to gain more feasibility insights and experience with the *Sunnyside Plus* intervention component, which had not been previously studied.

All participants, regardless of group allocation, completed an initial engagement session to review the components and expectations of the study and ensure access to the treatment websites. The engagement session took place through the Cisco WebEx Meeting Center, a Health Insurance Portability and Accountability Act-compliant videoconferencing web application. Once completed, the web-based intervention began. Follow-up assessments using REDCap took place following the completion of 6 weeks of web-based lessons during pregnancy (third trimester) and at 6 and 12 weeks postpartum. A brief assessment of HM feeding continuation and exclusivity (yes or no reply) was performed on a weekly basis via SMS text messaging (SimpleTexting [38]) from 1 to 6 weeks postpartum. Participants received a US \$20 Amazon gift certificate after completing each assessment.

Interventions

Overview

Starting between 20 and 28 weeks of gestation, the participants began the 6-week web-based intervention (*Sunnyside* or *Sunnyside Plus*). After the birth of their baby, the intervention was continued for 6 weeks postpartum. The intervention components for each group are listed in Table 1 and described in the following sections.

Table 1. Overview of intervention components.

^cHM: human milk.

^dN/A: not applicable.

Sunnyside

The *Sunnyside* intervention is a web-based intervention (a website with didactic material and tools) targeting skills to manage mood during and after pregnancy [33]. *Sunnyside*

comprises 6 weeks of web-based lessons during pregnancy and web-based booster sessions at 2, 4, and 6 weeks postpartum. The intervention website was based on CBT and interpersonal therapy principles and comprised 12 learning modules covering basic skills (eg, behavioral activation and cognitive

restructuring). Tools to assist in learning and implementing skills were associated with each learning module. The Feel Tool (ie, mood rating and feelings entry) encouraged participants to rate their mood each time they visited the site to obtain a better sense of their day-to-day feelings. The Think Tool (ie, thought record) was used to track one's thoughts and discern between helpful and harmful thinking. Participants tracked their daily behaviors, identified patterns, and planned future positive activities using the Do Tool (ie, activity scheduling or monitoring and goal setting). In this study, participants were given unlimited access to the web intervention content that comprised lessons and tools and were encouraged to use the site at least twice weekly as new modules become available (every 3-4 days). The web-based lessons that were to be completed during pregnancy required approximately 40 to 60 minutes per week for 6 weeks. The web-based lessons completed during the first 6 weeks postpartum required approximately 10 to 20 minutes per week for 6 weeks. The UIC Center for Clinical and Translational Science Technology Core was responsible for hosting and maintaining the site.

Sunnyside Plus

Sunnyside Plus is built upon *Sunnyside* but also includes additional education and support to promote HM feeding. Education and skill promotion for HM feeding was provided during the 6 weeks of web-based lessons during pregnancy and then continued through 6 weeks postpartum. This postpartum support involved weekly web-based lessons, text support messages, and video support calls with a lactation specialist. The research team requested that at least 2 lactation support calls take place; however, beyond that, support was provided on an as-needed basis determined by the participant. Importantly, the participants had the option to choose who provided lactation support from a racially diverse team. Text support messages were sent using SimpleTexting [38], a user-friendly text-marketing software. Frequency of messages tapered from 3 to 1 message per week during the first 6 weeks postpartum. The SMS text message content included HM feeding encouragement and a reminder of the web-based lactation support.

Intervention components shown to improve mental health and HM feeding outcomes among Black mothers were central to the intervention design and development. These included Black feminist thought as a theoretical foundation—an acknowledgment that Black mothers experience life at the intersection of multiple oppressions, positive and nurturing representation of Black mothers' HM feeding, and culturally relevant professional HM feeding support across pregnancy and postpartum [26,28]. For both groups, modules specific to anxiety and HM feeding during the COVID-19 pandemic were included in the intervention content.

Measures

Overview

The primary focus of this randomized pilot trial was feasibility (adherence to and satisfaction with the intervention) and preliminary outcomes on depression and anxiety symptom severity and HM feeding initiation, continuation, and

exclusivity. Participants' sociodemographic data, parity, pregnancy-related variables, HM feeding history, mental health history, and birth-related variables were also measured. The outcomes were largely assessed using standardized measures or established questions from national sources (eg, the Centers for Disease Control and Prevention [CDC] National Immunization Survey and CDC Pregnancy Risk Assessment Monitoring System questionnaire).

Adherence

Adherence to the web-based intervention was measured by the number of log-ins to the site during the intervention period, lessons read, and tools completed. Adherence to text and video call interactions was measured by the number of weekly text question responses and the number of lactation video calls completed within the first 6 weeks postpartum.

Usability and Acceptability

The Usefulness, Satisfaction, and Ease of Use (USE) questionnaire [39] was designed to measure satisfaction (eg, "It is pleasant to use."), usefulness (eg, "It makes the things I want to accomplish easier to get done."), ease of use (eg, "I can use it successfully every time."), and ease of learning (eg, "It is easy to learn to use it.") on a Likert scale ranging from 1=*strongly disagree* to 7=*strongly agree*. Higher scores indicate greater usability and acceptability.

Depression and Anxiety Symptoms

The PHQ-9 [40] comprises 9 scored items and 1 unscored item, which reflect overall functioning and impairment because of depressive symptoms. The PHQ-9 uses a Likert scale to determine the frequency of experienced depressive symptoms over the past 2 weeks ranging from 0=*not at all*, 1=*several days*, 2=*more days than not*, and 3=*nearly every day*. Higher values correspond to greater frequency. Scoring the PHQ-9 is simple and efficient. The measure yields only one score, which is determined by summing the positively endorsed items (1-3) at the noted values. PHQ-9 scoring interpretations are as follows: 1 to 4=*minimal*, 5 to 9=*mild*, 10 to 14=*moderate*, 15 to 19=*moderately severe*, and 20 to 27=*severe* depressive symptoms. Owing to the large anticipated volume of respondents to our national web-based recruitment effort, the 8-item PHQ, which does not include an assessment of suicidality, was used for eligibility screening. It would have been out of our team's ability to efficiently contact and evaluate all persons who might have expressed suicidal intent or plan and who were not enrolled in the study.

The Inventory of Depression and Anxiety Symptoms (IDAS) [41] is a 64-item measure of depression (including a 20-item General Depression Scale) and anxiety symptoms that has been validated in postpartum mothers. The IDAS was developed specifically in response to a National Institute of Mental Health initiative to provide a more sensitive measurement of depression and its symptom dimensions (eg, dysphoria, lassitude, insomnia, suicidality, and appetite loss) for use in clinical trials. The IDAS uses a Likert scale ranging from 1=*not at all* to 5=*extremely*. The 20-item General Depression Scale was used in this study, with an overall range from 20 to 100. Higher scores represent greater depressive symptoms.

The Generalized Anxiety Disorder (GAD-7) questionnaire [42] is a 7-item measure that assesses anxiety symptom severity using a frequency Likert scale. The values of the scale are 0=*not at all*, 1=*several days*, 2=*more than half the days*, and 3=*nearly every day*. Higher values correspond to greater frequencies. The measure yields only 1 score (0-21), which is determined by summing the positively endorsed items (1-3) at the noted values. The GAD-7 interpretations are as follows: 0 to 4=minimal, 5 to 9=mild, 10 to 14=moderate, and 15 to 21=severe anxiety symptoms.

HM Feeding Outcomes

The Infant Feeding Practices Study 2 [43] was developed by the Food and Drug Administration in collaboration with the CDC to collect data on infant feeding practices used by US mothers. For the purposes of this project, we used the Prenatal Questionnaire to assess infant feeding intent, HM feeding knowledge, and self-efficacy.

The Prenatal Breastfeeding Self-Efficacy Scale (PBSES) was developed by Wells et al [44] in 2006 to assess perceived HM feeding self-efficacy during pregnancy. The scale comprises 20 items with ranges on a 5-point Likert-type scale from 1=*not at all sure* to 5=*completely sure*, with an overall range from 20 to 100. Higher scores indicate greater levels of prenatal HM feeding self-efficacy.

The Breastfeeding Self-Efficacy Scale–Short Form was developed by Dennis and Faux [45] to measure postpartum HM feeding self-efficacy using a theoretical framework from the Social Cognitive Theory by Bandura. The instrument has 14 items and uses a 5-point Likert-type scale, with responses ranging from 1=*not at all confident* to 5=*always confident* and overall scores ranging from 14 to 70. Higher scores indicate greater levels of HM feeding self-efficacy.

Initiation, exclusivity, and duration of HM feeding were assessed during the postpartum period using questions from the CDC National Immunization Survey. Weekly assessments of duration and exclusivity were also performed via SMS text messages.

Statistical Analyses

Statistical analyses were performed using R software [46]. This study used a repeated measures design with 2 intervention groups (*Sunnyside* and *Sunnyside Plus*). Data were examined to assess for outliers. Descriptive statistics were obtained by computing means and SDs for continuous variables and frequencies for categorical variables. Significance testing for within- and between-group differences in mental health and HM feeding outcomes were assessed; however, this feasibility study was not powered for these types of analyses; therefore, our data are largely presented descriptively. These results should be interpreted with caution because of the small sample size. Differences in the baseline characteristics between the intervention groups were assessed using an independent 2-sample *t* test (continuous variables) and Fisher exact test (categorical variables). The intervention feasibility data, including adherence to the intervention, usability, and acceptability, were assessed using descriptive statistics.

Results

Eligibility Screening

In total, 1618 individuals (an average of 17 per day) completed the web-based screener across a 3-month period. Of these 1618 respondents, the mean age was 30.9 (SD 3.3) years, 539 (33.3%) were identified as Black or African American, 1171 (72.3%) intended to HM-feed, and the mean PHQ-8 was 6.2 (SD 4.7). Approximately 4.45% (72/1618) of individuals met the inclusion criteria. The major factors for exclusion were race and the estimated gestational age (EGA). Of the 1618 respondents, 874 (54.01%) of respondents identified as White. Only 38.44% (622/1618) of the respondents had an EGA between 20 and 28 weeks, which was the inclusion criterion for this study. Most had an EGA of <20 weeks (971/1618, 60.01%). Of those who qualified based on the eligibility screener, 31% (22/72) individuals were randomized and received the intervention; those who were not randomized were ultimately not interested in participating, unable to contact, or lost to follow-up. Further details are provided in [Figure 1](#).

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram.

Participants

A total of 22 tertiary-educated Black pregnant individuals in their second trimester (mean EGA 22.6 [SD 2.5] weeks) participated in this US-based study. The mean age of the participants was 30.4 (SD 3.9) years. Most participants were married or partnered and cohabiting (17/22, 77%), employed full-time (13/22, 59%), or had private health insurance (16/22, 73%). All participants attended at least some college degree (12/22, 55%) or held a graduate or professional degree (10/22, 45%). Just over half (12/22, 55%) of the participants reported an annual household income of \geq US \$51,000, with the average household size being 2.5 (SD 1). Maternal prepregnancy BMI (kg/m^2) was calculated from self-reported height and prepregnancy body weight. When data from medical records were available, we explored the differences between self-reported and medical record data and found no differences.

Over half of the participants (14/22, 64%) had obesity. The mean PHQ-9 score at baseline was 6.6 (SD 2.9), with most participants having mild depressive symptoms (15/22, 68%). The mean GAD-7 score was 6.05 (SD 4.7), with most patients having none to mild symptoms of anxiety (16/22, 73%). Most participants were nulliparous at enrollment (14/22, 64%). Regarding HM feeding-related variables, approximately one-quarter of participants reported being HM-fed themselves as an infant (6/22, 27%), most had no prior HM feeding experience (17/22, 77%), and most intended to HM-feed exclusively for at least the first few weeks postpartum (19/22, 86%). The PSES score at baseline was 81 (SD 14.1), and the average HM feeding duration goal was 13.7 (SD 5.7) months. The participants in the intervention groups did not differ significantly in any baseline characteristics, suggesting that the random assignment-generated groups were equivalent at baseline (Table 2).

Table 2. Baseline sample characteristics by intervention group (N=22).

Attrition

Approximately 78% (7/9) of *Sunnyside* participants and 77% (10/13) of *Sunnyside Plus* participants completed the study through 12 weeks postpartum. Approximately 9% (2/22) of participants (1 from each intervention group) withdrew from the study after the baseline assessment. One of the *Sunnyside*

participants did not complete the third trimester follow-up assessment but continued with the study. One of the participants in the *Sunnyside Plus* group did not engage in the web-based intervention or complete the assessments and was therefore withdrawn by the research team after the baseline assessment. Approximately 9% (2/22) of additional participants (1 from each intervention group) were considered lost to follow-up

during the postpartum period; their mood scores did not differ from those who completed the study.

Site Use

Adherence to the web-based intervention was measured by the number of log-ins to the site during the intervention period, number of lessons accessed, and number of tools completed. [Table 3](#) shows site use data. The mean number of log-ins across the 6-week intervention plus booster sessions was 7.3 (SD 5.3) for *Sunnyside* and 13.8 (SD 10.5) for *Sunnyside Plus*. Within the *Sunnyside* group, the average number of lessons accessed during pregnancy (from a total of 13) was 10.1 (SD 3.5) and

during postpartum (from a total of 3) was 1.6 (SD 1.3). Within the *Sunnyside Plus* group, the average number of lessons accessed during pregnancy (from a total of 13) was 9.7 (SD 4.1) and during postpartum (from a total of 9) was 2.6 (SD 3.3). Approximately 67% (6/9) of *Sunnyside* participants and 58% (7/12) of *Sunnyside Plus* participants completed at least 50% of the available lessons. The average number of tools used was 11 (SD 6.6) for *Sunnyside* and 25.8 (SD 27.8) for *Sunnyside Plus*. Participants in the *Sunnyside Plus* group used the activity tool more than those in the *Sunnyside* group ($P=.03$). All other site uses were similar between the groups, with no additional differences found.

^b $P=.03$.

^cN/A: not applicable.

Text and Video Call Interactions

Mean number of weekly HM feeding text question responses across the first 6 weeks postpartum was 5.4 (SD 1.1) for *Sunnyside* and 5.2 (SD 1.3) for *Sunnyside Plus*. Approximately 56% (5/22) of participants in *Sunnyside* and 46% (6/13) of participants in *Sunnyside Plus* completed all 6 weekly text questions. Response rates were similar between the groups, and no differences were found. Participants in the *Sunnyside Plus* group were offered web-based lactation support. The mean number of video calls completed during the first 6 weeks postpartum was 2.8 (SD 2). The number of calls ranged from 0 to 7. One of the participants declined to receive lactation support. The results are presented in [Table 3](#).

Usability and Acceptability

At the third trimester follow-up (after completion of the 6-week antenatal web-based intervention), scores on USE subscales ranged from 1 (strongly disagree) to 7 (strongly agree). Mean

scores for the participants in the *Sunnyside* group were 5.3 (SD 1.3) for usefulness, 5.1 (SD 2.1) for ease of use, 5.1 (SD 2.3) for ease of learning, and 4.9 (SD 1.9) for satisfaction. Mean scores for the participants in the *Sunnyside Plus* group were 4.9 (SD 1.2) for usefulness, 5.9 (SD 1.1) for ease of use, 6.2 (SD 1.1) for ease of learning, and 5.3 (SD 1.5) for satisfaction.

At 6 weeks postpartum, the scores on the USE subscales also ranged from 1 (strongly disagree) to 7 (strongly agree). Mean scores for the participants in the *Sunnyside* group were 4.9 (SD 1.4) for usefulness, 5.4 (SD 1.3) for ease of use, 5.5 (SD 1.5) for ease of learning, and 4.7 (SD 0.7) for satisfaction. For participants in the *Sunnyside Plus* group, mean scores were 5.1 (SD 1.4) for usefulness, 6 (SD 1.3) for ease of use, 5.8 (SD 1.3) for ease of learning, and 5.1 (SD 1.5) for satisfaction. The data are provided in [Table 4](#). Overall, the usability and acceptability scores in this trial were slightly higher than those in previously published pilot data on *Sunnyside* [33].

Table 4. Usability and acceptability^a.

Perinatal period and usability	<i>Sunnyside</i> (n=7), mean (SD)	<i>Sunnyside Plus</i> (n=11), mean (SD)
Third trimester		
Usefulness	5.3 (1.3)	4.9 (1.2)
Ease of use	5.1 (2.1)	5.9 (1.1)
Ease of learning	5.1 (2.3)	6.2 (1.1)
Satisfaction	4.9 (1.9)	5.3 (1.5)
6 weeks postpartum^b		
Usefulness	4.9 (1.4)	5.1 (1.4)
Ease of use	5.4 (1.3)	6 (1.3)
Ease of learning	5.5 (1.5)	5.8 (1.3)
Satisfaction	4.7 (0.7)	5.1 (1.5)

^aUsefulness, ease of use, ease of learning, and satisfaction were measured using a Likert scale ranging from 1=*strongly disagree* to 7=*strongly agree*. Higher scores indicated greater usability and acceptability.

^bn=10 for *Sunnyside Plus*.

Birth Outcomes

Total gestational weeks at birth, provider type, and mode of birth did not significantly differ between the groups. Mean EGA at birth was 38.7 (SD 1.3) and 38.3 (SD 1.7) for *Sunnyside* and *Sunnyside Plus* participants, respectively. A reported 71% (5/7) and 73% (8/11) of participants in *Sunnyside* and *Sunnyside Plus*, respectively, received care under an obstetrician rather than a midwife. Approximately 43% (3/7) of *Sunnyside* and 64% (7/11) of *Sunnyside Plus* participants had a cesarean birth.

Depression and Anxiety Symptoms

Mental health outcomes are presented in [Table 5](#). No differences between or within the groups were detected on any of the mental health outcome measures. In both intervention groups, mean PHQ-9 scores across all follow-up visits remained <10, which is the clinical threshold for referral for treatment [40]. Mean IDAS scores remained relatively consistent across all follow-up visits for *Sunnyside* and *Sunnyside Plus*. In both intervention groups, mean GAD-7 scores across all follow-up visits remained <10, which is the threshold for moderate to severe symptoms of anxiety [42].

Table 5. Mean mental health outcome measures at each visit and mean change from baseline to the third trimester and to 6 and 12 weeks postpartum (N=22).

Outcomes over time	<i>Sunnyside</i> (n=9)			<i>Sunnyside Plus</i> (n=13)

HM Feeding

Prenatal HM feeding outcomes were examined using descriptive statistics (data not shown). The mean intended HM feeding duration at baseline (midpregnancy) was 12.7 (SD 6.2) months for *Sunnyside* participants and 14.3 (SD 5.5) months for *Sunnyside Plus* participants. Among all participants, 86% (19/22) intended to HM-feed exclusively for at least 5 to 6 months. Baseline prenatal HM feeding self-efficacy (PBSES) scores were 77.3 (SD 14.3) for *Sunnyside* participants and 83.5 (SD 14) for *Sunnyside Plus* participants. The PBSES scores increased slightly for all participants from baseline to the third trimester.

Postpartum HM feeding outcomes are shown in [Table 6](#). All participants initiated HM feeding treatment (18/18, 100%). At 6 weeks postpartum, 57% (4/7) of *Sunnyside* and 91% (10/11) of *Sunnyside Plus* participants reported HM feeding exclusively. At 12 weeks postpartum, 57% (4/7) of *Sunnyside* and 80% (8/10) *Sunnyside Plus* participants were exclusively HM feeding. Any HM feeding at 6 weeks postpartum was reported by 86% (6/7) of *Sunnyside* and 100% (11/11) of *Sunnyside Plus* participants. Similarly, any HM feeding at 12 weeks postpartum was reported by 86% (6/7) of *Sunnyside* and 100% (10/10) of *Sunnyside Plus* participants. No differences were detected in the postpartum HM feeding outcome measures between the groups.

Table 6. Comparison of postpartum human milk feeding outcomes between intervention groups.

Discussion

Principal Findings

This study describes the feasibility and preliminary findings of a novel CBT-based internet intervention to prevent perinatal depression and promote HM feeding in Black mothers with mild to moderate depressive symptoms and intention to HM-feed. Although both active treatment groups aimed to target skills to manage mood, the newly developed *Sunnyside Plus* intervention used evidence-based practices to promote and actively support the HM feeding.

Feasibility

Participants for this study were enrolled within a relatively short recruitment period (3 months) of indicating interest in the study intervention. Relatively low attrition rates in the *Sunnyside* group (2/9, 22%) and in the *Sunnyside Plus* group (3/13, 23%) through 12 weeks postpartum in a population of individuals within the perinatal period and who indicated mild to moderate depressive symptoms suggested adherence to the intervention. Further adherence was shown through participant interactions with the site through log-ins, lessons accessed, and tool use and with the study team through SMS text message responses and lactation support calls. Adherence to the web-based intervention indicates that Black individuals who are in the perinatal period are willing to use an individual intervention program that involves engagement with a website and interactions via SMS text messaging and video calls. To improve adherence, future research efforts using the *Sunnyside* intervention should consider adding biweekly support calls with participants to remind them of the intervention components and resolve any potential access issues. Usability scores suggested an overall positive user experience for both the pregnancy and postpartum sections of the intervention.

Depression and Anxiety Symptoms

After completion of the intervention at both 6 and 12 weeks postpartum, no participants in this at-risk sample met the criteria for postpartum depression. This is in line with results from the previously published pilot data on *Sunnyside* [33]. Other studies have shown a 13% prevalence rate of postpartum depression among individuals in the first year postpartum [6] and a 17% prevalence rate among at-risk individuals in the absence of an intervention [47]. Overall, the levels of perinatal anxiety symptoms remained low among the participants. Given the adverse impact of perinatal mental health disorders on both the mother and infant, including reduced rates of HM feeding [3], the overall low levels of depression and anxiety symptoms among all participants were encouraging.

HM Feeding

In the United States, 80% of mothers intend to HM-feed in some capacity, and of those, >85% intend to exclusively HM-feed for at least 3 months; however, only one-third (32%) of mothers achieve their intended HM feeding goals [48]. In this study of individuals who intended to HM-feed in at least some capacity, intended HM feeding exclusivity and duration were high among all participants at baseline. Postpartum HM feeding self-efficacy, defined as the confidence in one's ability to effectively HM-feed, is thought to play an important role in the relationship between postpartum depression and HM feeding [19,49-52]. Not only is high self-efficacy associated with lower levels of depressive symptoms [45,50,51] but also with longer HM feeding durations [50,51]. In this study, prenatal HM feeding self-efficacy was high among all participants, and scores increased after completion of the antenatal portion of the intervention.

According to the National Vital Statistics System, the US cesarean birth rate in 2019 was 32% [53]. Overall, 56% (10/18) of the participants in this study had a cesarean birth, which is almost double the national rate. Medical interventions during birth, including cesarean birth, may make it difficult for mothers

to reach their HM feeding goals [15]. Across both intervention groups, 100% (22/22) of participants initiated HM feeding. The HM feeding initiation rate among Black individuals in the United States is 60% [54]. At 6 weeks postpartum, a greater percentage of *Sunnyside Plus* participants exclusively HM-fed than those in *Sunnyside* (10/11, 91%, vs 4/7, 57%, respectively). At 12 weeks postpartum, a greater percentage of *Sunnyside Plus* participants exclusively HM-fed than those in *Sunnyside* (8/10, 80%, vs 4/7, 57%, respectively). Most participants reported at least some HM feeding at both 6 and 12 weeks postpartum (6/7, 86%; 11/11, 100%, or 10/10, 100%, for *Sunnyside* and *Sunnyside Plus*, respectively). These rates are higher than that of research showing an 81% prevalence rate of any HM feeding at 6 weeks postpartum [51]. High rates of exclusive and continued HM feeding at 6 and 12 weeks further underscore the positive clinical impact of both intervention groups.

Strengths and Limitations

There are several strengths of this study. The design of the intervention offers a novel approach for preventative and supportive care within the perinatal period, one that extends across pregnancy and postpartum, involves various interface options (ie, website, text, and videoconferencing), and acknowledges the logistical challenges of physically seeking care as parents of a newborn. In addition, participants consistently used all aspects of the intervention in both pregnancy and the postpartum period, suggesting interest in and satisfaction with this design of care. To reduce the race-mediated power differential, the lactation specialist team included Black and White individuals. When support was provided by a White lactation specialist, we acknowledge that race-of-interviewer effects may have been present.

This study had several limitations. Although the recruitment response was high, with an average of approximately 17

respondents each day during the 3-month recruitment period, the use of a convenient internet sample may have led to a bias toward higher education levels. In addition, our recruitment method through Ovia Health might not have been the best route, given the characteristics of those using the platform, and future projects should consider other recruitment routes. The major factors for exclusion were race and EGA. Future recruitment efforts should target internet-based applications used by those who identify as Black or African American. In addition, a system that allows for future rescreening might capture those who meet all inclusion criteria, except for the current EGA. As a small pilot study, this trial was not powered to reliably detect small significant differences or associations. The results should be interpreted with caution, and a larger trial is needed to verify these outcomes. Furthermore, the primary outcome data were based on self-report assessments, which may introduce recall bias. Finally, with no true control group, we relied on outside data to compare the rates of mental health and HM feeding outcomes.

Conclusions

The results of this study suggest that tertiary-educated Black mothers at risk for perinatal depression and who intended to HM-feed were receptive to, engaged with, and satisfied with a web-based CBT-based internet intervention, with and without HM feeding education and support, spanning from midpregnancy through 6 weeks postpartum. Preliminary findings indicate that both *Sunnyside* and *Sunnyside Plus* interventions have the potential to affect symptoms of depression, anxiety, and HM feeding outcomes. Future studies should include a larger sample size and a longer follow-up period to better understand the differences between groups and examine the continued impact across the postpartum period.

Acknowledgments

The authors would like to thank Jo Ann Allen, a registered nurse with a master's of science in nursing and International Board Certified Lactation Consultant, for her collaboration and implementation of the web-based lactation support calls.

Conflicts of Interest

PM served as a consultant for Pfizer, Mithra and Balchem and is on the advisory board for Astellas, Bayer, Johnson&Johnson, Alloy, Midi Health and Estrigdnix. She has equity in Alloy, Midi Halth, and Estrigenix.

Abstract

Background: Health-promotion interventions incorporating wearable technology or eHealth apps can encourage participants to self-monitor and modify their physical activity and sedentary behavior. In 2020, a Calgary (Alberta, Canada) recreational facility developed and implemented a health-promotion intervention (Vivo Play Scientist program) that provided a commercially available wearable activity tracker and a customized eHealth dashboard to participants free of cost.

Objective: The aim of this study was to independently evaluate the effectiveness of the Vivo Play Scientist program for modifying physical activity and sedentary behavior during the initial 8 weeks of the piloted intervention.

Methods: Our concurrent mixed methods study included a single-arm repeated-measures quasiexperiment and semistructured interviews. Among the 318 eligible participants (≥ 18 years of age) registered for the program, 87 completed three self-administered online surveys (baseline, T_0 ; 4 weeks, T_1 ; and 8 weeks, T_2). The survey captured physical activity, sedentary behavior, use of wearable technology and eHealth apps, and sociodemographic characteristics. Twenty-three participants were recruited using maximal-variation sampling and completed telephone-administered semistructured interviews regarding their program experiences. Self-reported physical activity and sedentary behavior outcomes were statistically compared among the three time points using Friedman tests. Thematic analysis was used to analyze the interview data.

Results: The mean age of participants was 39.8 (SD 7.4) years and 75% (65/87) were women. Approximately half of all participants had previously used wearable technology (40/87, 46%) or an eHealth app (43/87, 49%) prior to the intervention. On average, participants reported wearing the activity tracker (Garmin Vivofit4) for 6.4 (SD 1.7) days in the past week at T_1 and for 6.0 (SD 2.2) days in the past week at T_2 . On average, participants reported using the dashboard for 1.6 (SD 2.1) days in the past week at T_1 and for 1.0 (SD 1.8) day in the past week at T_2 . The mean time spent walking at 8 weeks was significantly higher compared with that at baseline (T_0 180.34 vs T_2 253.79 minutes/week, $P=.005$), with no significant differences for other physical activity outcomes. Compared to that at baseline, the mean time spent sitting was significantly lower at 4 weeks (T_0 334.26 vs T_1 260.46 minutes/day, $P<.001$) and 8 weeks (T_0 334.26 vs T_2 267.13 minutes/day, $P<.001$). Significant differences in physical activity and sitting between time points were found among subgroups based on the household composition, history of wearable

technology use, and history of eHealth app use. Participants described how wearing the Vivofit4 device was beneficial in helping them to modify physical activity and sedentary behavior. The social support, as a result of multiple members of the same household participating in the program, motivated changes in physical activity. Participants experienced improvements in their mental, physical, and social health.

Conclusions: Providing individuals with free-of-cost commercially available wearable technology and an eHealth app has the potential to support increases in physical activity and reduce sedentary behavior in the short term, even under COVID-19 public health restrictions.

Introduction

Background

Daily participation in physical activity provides numerous benefits, including enhancing physical and mental health and reducing the risk of chronic disease [1]. Despite these benefits, individuals report barriers to maintaining regular physical activity routines such as lack of time, confidence, and money, and unsupportive physical and social environments [2-5]. However, physical activity interventions offer individuals opportunities to initiate, maintain, and modify their physical activity routines [6,7]. Moreover, evidence suggests that sedentary behavior (eg, sitting) can negatively impact health independent of physical activity levels [8,9]. Sedentary behavior is defined as any waking behavior that has a relative energy expenditure ≤ 1.5 metabolic equivalents (METs) while in a sitting, reclining, or lying posture [10]. Physical activity interventions with and without specific components that target sedentary behavior can reduce sedentary time [11]. The current Canadian 24-Hour Movement Guidelines recommend accumulating sufficient physical activity, reducing prolonged sitting and sedentary behavior, as well as obtaining adequate sleep regularly, regardless of age [12,13].

Physical activity interventions incorporating wearable activity trackers (eg, smart watches, fitness trackers, and pedometers) that allow users to quantify self-movement offer wearers immediate behavioral feedback and movement data that can support them in modifying current or future physical activity levels [14-17]. This evidence is encouraging given the growth in the popularity of commercial wearable trackers among consumers for monitoring physical activity and fitness [16,18-21]. Moreover, wearable trackers are often coupled with eHealth (including mobile health) apps on smartphones or other screened devices that provide users with complementary detailed information about behavior patterns (eg, duration and intensity of physical activity, sedentary time, sleep, and energy expenditure), biometrics (eg, heart rate, blood oxygen saturation, and body temperature), and geographical location or global positioning [21,22]. Data from wearable trackers and eHealth apps can support the setting and achievement of behavioral goals, facilitate social comparison or competition, and incorporate individual- or group-based activity through synchronous or asynchronous behavioral challenges. Wearable trackers and eHealth apps can also provide automated

personalized health-promotion messages or movement notifications that motivate or nudge users to undertake more physical activity or less sedentary behavior [16,17,23-26].

Interventions involving the use of commercially available wearable activity trackers have found positive effects on physical activity [15,17,24,26,27] and weight status [26,28] among adults, including clinical and healthy populations [15,17,27]. Moreover, wearable activity trackers and eHealth apps can reduce sedentary time [29]. Wearable activity trackers can encourage immediate, synchronous changes in physical activity and sedentary behavior [17,24]. Barwais et al [24] found that even over a short period (ie, 4 weeks), participants enrolled in an intervention incorporating the daily use of a wearable activity tracker and receipt of personalized device-informed messaging and prompts significantly increased their volume of walking; increased light-, moderate-, and vigorous-intensity physical activity; and reduced their sedentary time. The most effective physical activity interventions involving wearable technology may include those that incorporate concurrent use of a wearable activity tracker and an eHealth app [17].

Vivo Play Scientist Program

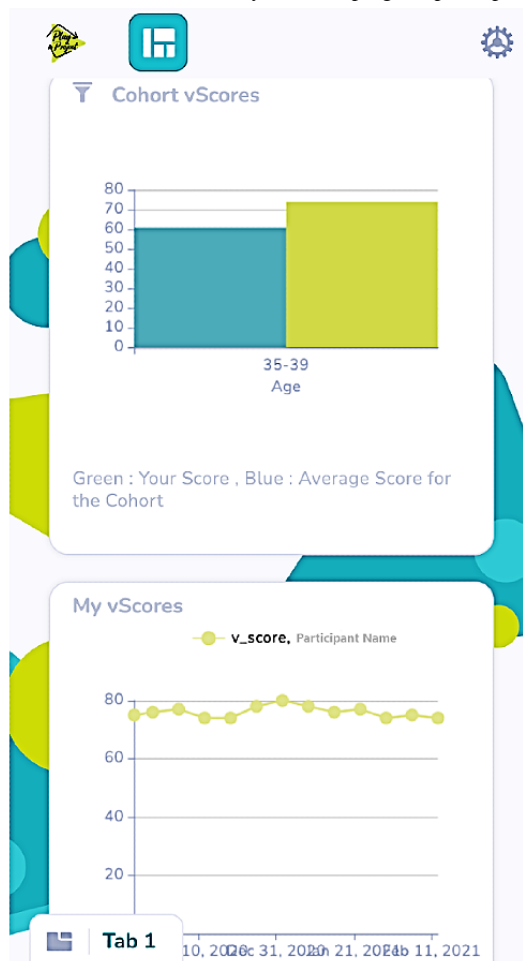

Community-based health-promotion programming provides a vital and cost-effective strategy for increasing physical activity [30] because of the ability to reach large and diverse populations. Recreational facilities that engage in this type of programming typically include diverse offerings of activities and services, and are therefore well-positioned to deliver physical activity programs to their surrounding catchment communities. Our study focuses on an evaluation of what could be considered an innovative community-based health-promotion program, *The Vivo Play Scientist (VPS) program*, offered by a large North Central Calgary recreational center with approximately 6500 members (Vivo for Healthier Generations). Vivo, established in 2004, is a charity that operates the Centre for Well-being and Innovation lab. Vivo offers a mix of family-based and community-delivered physical activity and play programming to surrounding neighborhoods (eg, park-based play events and take-home play kits). Between November 2020 and March 2021, the VPS program was piloted and independently evaluated by our team. Vivo developed and implemented the VPS program with the aim of increasing physical activity and reducing sedentary behavior. The program involved providing participants, free of charge, with a wearable tracker with integrated syncing technology (Garmin Vivofit4) and access to

an eHealth dashboard to support self-monitoring of physical activity and sedentary behavior. The program strategy appeared to align with social cognitive theory [31,32] and control theory [33], both of which recognize the importance of self-monitoring and progress feedback to inform behavior modification and reinforce monitored behaviors. The VPS program was implemented under COVID-19 public health restrictions. The public health restrictions in place during the VPS program included social gathering limits in private and public spaces and occupant capacity limits for businesses. Moreover, recreational facilities, including indoor children's play centers and indoor playgrounds and fitness and sports facilities, were closed from November 27, 2020, to March 8, 2021. Mandatory masking and physical distancing were also in effect throughout the program and working from home was recommended.

The VPS program was advertised on the Vivo website, social media (Facebook and Twitter), and via an email list of clientele affiliated with the facility. The program offered volunteering individuals and families (with a child aged 5-17 years) with a wrist-worn activity tracker (Garmin Vivofit4; approximate value US \$80) and access to a customized eHealth dashboard at no financial cost to participants. Participants also had access to the Garmin Connect platform for processing the data captured by the Vivofit4 accelerometer, which provides summaries of physical activity and other metrics (ie, step count, distance travelled, intensity minutes, energy expenditure, and sleep). This platform also offers opt-in physical activity and step challenges, and provides options for setting personalized step goals. Vivofit4 includes a function that over time automatically monitors activity levels and assigns a daily step goal, and a function that notifies the wearer to move after an extended period of inactivity. The customized Vivo eHealth dashboard was developed by White Whale Analytics [34] and provided the health analytics platform, which incorporated a score (ie, vScore Health) supported by Vivametrica data [35]. The vScore is derived from a proprietary algorithm that combines the step count from Vivofit4 along with the participant's age, sex, height, and weight. Higher vScores [35] reflect better health, and the dashboard provided sex- and age-informed normative values. Participants could share and compare their vScores with other household members participating in the program. On the dashboard, participants could view their current week's vScore,

a historical trend of vScores for each member of their family as a line chart, as well as a comparative bar chart of their vScore to that of their age group within the cohort (see Figure 1). The vScores range between 0 and 100, and include health rankings based on cut-off points (poor, 0-49; fair, 60-62; good, 63-73; very good, 74-85; excellent, 86-100). Although the vScore appears to have face validity, there is limited evidence pertaining to its predictive validity in relation to behavior change and health outcomes. A 12-week intervention involving a small clinical sample of middle-aged women (N=36) that included the use of a wearable activity tracker and access to Vivametrica performance data found a median increase of 9% in daily step counts; however, this change was not statistically significant [36]. The authors (including the founder of Vivametrica) reported that 28% of the participants did not access the Vivametrica output data and the majority of those who accessed this information did so fewer than five times during the intervention [36]. Vivo hypothesized that the access to behavior feedback from the eHealth dashboard, Garmin Connect, and Vivofit4 would motivate participants to modify their physical activity and sedentary behavior.

Participants who registered for the program received written instructions and attended an on-boarding video conference call regarding the use and syncing of Vivofit4, Garmin Connect, and the eHealth dashboard, along with information to assist them in interpreting the vScore. Participants were encouraged to wear Vivofit4 during all waking hours and to synchronize Vivofit4 with Garmin Connect and the dashboard once per week. However, participants did not receive instructions on how often they should access Garmin Connect or the dashboard and what information or outputs they should consult, nor did they receive any prescriptive behavioral goals or targets to achieve in relation to physical activity or sedentary behavior. Participants could use or explore all or any functions within Vivofit4, Garmin Connect, or the dashboard (eg, setting up movement reminders, signing up for challenges, joining activity communities, sharing activity progress, sharing vScores, and tracking sleep). The intention of the VPS program was to offer access to the wearable tracker and eHealth dashboard, and allow participants autonomy in deciding how best to use these tools to support their own physical activity goals.

Figure 1. Screenshot of the dashboard information available to Vivo Play Scientist program participants.

Study Aim

This study is part of a larger research project evaluating the feasibility and effectiveness of the VPS program. A concurrent mixed methods research approach was used to evaluate the effectiveness of the VPS program for modifying physical activity and sedentary behavior in the initial 8 weeks of its implementation.

Methods

Ethics Approval

The University of Calgary Conjoint Health Research Ethics Board approved the study (REB20-1218).

Study Design and Recruitment

We undertook a concurrent mixed methods single-arm repeated-measures design with semistructured interviews. Volunteers were screened for eligibility and registered in the VPS program with the assistance of Vivo staff. Eligible participants had access to the internet, resided in a North Central Calgary neighborhood, were ≥ 18 years of age, and had a current email address. Multiple members of a single household could participate in the VPS program; however, only one self-selecting adult per household could participate in the program evaluation. Eligible registered participants ($N=318$) were sent a recruitment email with study information, consent form, web link to a

baseline online questionnaire, and identification number to access the online questionnaire. Among those sent a recruitment email, 153 participants completed the baseline questionnaire. A subset of participants were invited to undertake a postprogram semistructured interview via telephone or video conference. The semistructured interviews provided supporting data for the quantitative results [37]. To capture a range of different perspectives and a sample that was diverse in age, gender, ethnicity, education level, employment, and income characteristics, we recruited the interview participants using a maximum-variation sampling approach [38]. The interview sample included those who had and had not completed the 8-week VPS program.

Data Collection

The online questionnaires were delivered using the Qualtrics platform (Toronto, Canada) and were administered at baseline (T_0), 4 weeks (T_1), and 8 weeks (T_2). To increase compliance, for each questionnaire completed, participants received entry into a prize draw to win one of two CAD \$500 (~US \$400) gift cards. The questionnaires captured information, including sociodemographic characteristics, perceptions and use of wearable technology and eHealth apps, physical activity cognitions (eg, attitudes, self-efficacy, perceived barriers and benefits), and self-reported physical activity and sedentary behavior. This study included a subset of variables from the questionnaires, specifically self-reported physical activity and

sedentary behavior, history of using wearable technology and eHealth apps, and sociodemographic characteristics. Each questionnaire took 20-30 minutes to complete.

The telephone-based semistructured interviews were 30-45 minutes in duration. Participants who completed the interview received a CAD \$25 (~US \$20) gift card as a token of appreciation. An interviewer, trained in qualitative research methods, asked several open-ended questions regarding participant experiences of the VPS program, including the use of Vivofit4, Garmin Connect, and the eHealth dashboard; the effect of the program on their physical activity and health; and recommendations for improving the program. Given our interest in exploring the effectiveness of the program for modifying physical activity and sedentary behavior, we focused on responses to the following six interview questions: *Which features of the Vivofit4 were most or least useful to you in supporting your physical activity? Which features of Garmin Connect were most or least useful to you in supporting your physical activity? Which features of Vivo Play Scientist Health Dashboard were most or least useful to you in supporting your physical activity? What have you discovered about your physical activity and health as a result of participating in the program? Have you noticed any changes in your behavior since the start of the program? How has your usage of the device changed since you first received it?*

Quantitative Variables

Frequency of Using Vivofit4 and the eHealth Dashboard

At the 4-week (T_1) and 8-week (T_2) surveys, participants reported how many days in the past week and the usual amount of time per day they had used Vivofit4 and the dashboard. In addition to reporting days of VivoFit4 wear and dashboard use as continuous outcomes (both of which had skewed distributions), we categorized Vivofit4 use to capture participants who had used the wearable activity tracker on most days (ie, ≥ 4 days/week vs < 4 days/week). Data presented in the dashboard were automatically updated weekly; therefore, we categorized frequency of use into ≥ 1 day/week versus < 1 day/week.

Physical Activity

At the baseline (T_0), 4-week (T_1), and 8-week (T_2) surveys, physical activity was measured using the International Physical Activity Questionnaire Short-Form (IPAQ-SF). The IPAQ-SF has acceptable reliability and validity [39]. Minutes of walking, moderate-intensity physical activity (MPA), and vigorous-intensity physical activity (VPA) in the past week were captured. We applied the IPAQ-SF scoring protocol to correct for overreporting of physical activity minutes and to estimate total weekly physical activity incorporating the relative intensity (MET) of each activity (ie, MET [minutes/week]=[VPA minutes \times 8 METs]+[MPA minutes \times 4 METs]+[walking minutes \times 3.3 METs]) [40,41]. Accumulating 30 minutes of moderate-to-vigorous physical activity (MVPA) most days provides health benefits in adults [42]. In each survey (T_0 , T_1 , and T_2), a single item captured the number of days in the past week that the participant accumulated at least 30 minutes of MVPA (ie, sport or exercise, brisk walking or cycling

for recreation, or to get to and from places, but excluding occupational activity and housework) [43]. This measure of sufficient MVPA has acceptable test-retest reliability and concurrent validity in relation to other single-item measures of physical activity [43].

Sedentary Behavior

Two items captured sedentary behavior at baseline (T_0), 4 weeks (T_1), and 8 weeks (T_2). One item from the IPAQ-SF measured the usual time spent sitting (ie, at work, at home, during course work, traveling by motor vehicle, and for leisure) in the last 7 days [39]. Another item captured leisure-based screen time: "In an average week, how much time per day do you usually spend watching television or other screen-based electronic devices outside your workplace (eg, video games, computer games, DVD/movies, internet, email, texting, smartphone)?" A similar item has been used previously to measure leisure-based screen time in Canadian adults [44-46]. We modified the item to also capture contemporary sedentary activities (eg, use of mobile technology).

Sociodemographic Characteristics

Sociodemographic characteristics, including age, sex, ethnicity, household income, employment status, education, marital status, number of dependents in the household, dog ownership, and composition of household members participating in the intervention (ie, one adult only, multiple adults only, one adult and children, or multiple adults and children), were also collected at baseline (T_0).

Analysis

Descriptive statistics (means, standard deviations, and frequencies) were calculated for the sample characteristics. Most outcome variables were nonnormally distributed (positively skewed); therefore, we applied nonparametric statistical tests. All physical activity (weekly minutes of walking, MPA, VPA, total physical activity, and sufficient daily MVPA) and sedentary behavior (daily minutes of sitting and screen time) outcomes were analyzed using the Friedman test to compare the differences in mean rank across the three time points (T_0 , T_1 , and T_2). Using the significant results in the Friedman tests ($P < .05$), we undertook a priori comparisons employing Wilcoxon signed-rank tests to identify statistically significant differences in outcomes between time points relative to baseline (ie, T_0 vs T_1 and T_0 vs T_2). To reduce the chance of type 1 error, pairwise differences from the planned comparisons were considered statistically significant based on an adjusted $P < .025$. In addition, we assessed for effect modification by comparing gain scores (ie, $T_2 - T_0$) for physical activity and sedentary behavior outcomes between subgroups (ie, adults-only participating households vs households with child participants; ever used vs never used a wearable tracker; and ever used vs never used an eHealth app) using Mann-Whitney U tests and stratified analysis (Friedman tests with Wilcoxon signed-rank tests for planned comparisons) to determine if group responses to the intervention were heterogeneous from the beginning (T_0) and to the end of the intervention (T_2). Quantitative analysis was performed using SPSS version 24.

Audio data collected during the semistructured interviews were transcribed verbatim and analyzed using thematic analysis [47]. Qualitative data were organized and analyzed using NVivo version 12. Three researchers (JP, DG, and PKDB) coded the data and identified the themes. Member checking, peer review, and an audit trail were employed as strategies to enhance the trustworthiness of the qualitative results. Triangulation of the quantitative and qualitative results was undertaken during the interpretative phase of the findings.

Results

Sample Characteristics

The flow of participants through the study is shown in Figure 2. The analytical sample included 87 participants with complete data for all three surveys (T_0 , T_1 , and T_2). Excluded participants ($n=66$) did not participate in all three surveys, had incomplete data, or were members of the same household. Sociodemographic characteristics and baseline physical activity and sedentary behavior were similar between the analytical sample and excluded cases, with the exception that excluded cases had a lower proportion of participants reporting an income of CAD \$80,000-119,999 (US \$65,000-94,999) per year (13.6% vs 37.9%, $P<.001$) and a higher proportion reporting they did not know or refused to answer (28.8% vs 10.3%, $P=.003$). The semistructured interviews were conducted with 23 participants (18 women, 5 men; aged 22-56 years).

Our sample consisted mostly of participants who reported being female, having a university education, being non-Caucasian, working full or part time, married or common-law, and not owning a dog (Table 1). Over one-quarter of households had gross annual incomes of at least CAD \$119,999 (US \$94,999)/year. The mean age of participants was 39.4 years and the mean number of children <18 years of age in the home was 1.8.

Almost half of all participants reported prior use of a wearable tracker (40/87, 46%) or eHealth app (43/87, 49%). On average, participants reported wearing Vivofit4 for 6.3 (SD 1.7) days in the past week at T_1 and for 6.0 (SD 2.2) days in the past week at T_2 . Most participants reported using Vivofit4 ≥ 4 days/week (T_1 : 93.1% [$n=81/87$] and T_2 : 87.4% [$n=76/87$]). On average, participants reported usually wearing Vivofit4 for approximately 12.5 hours/day at T_1 (mean 751.2, SD 201.7 minutes) and T_2 (mean 756.8, SD 211.9 minutes). The median usual wear time was 840 minutes/day at both T_1 and T_2 . On average, participants reported using the eHealth dashboard for 1.6 (SD 2.1) days in the past week at T_1 and for 1.0 (SD 1.8) day in the past week at T_2 . Approximately half of the participants reported using the dashboard ≥ 1 day/week (T_1 : 54.0% [$n=47/87$] and T_2 : 47.1% [$n=41/87$]). Approximately two-thirds of participants were from households where at least one adult and one child participated in the program with the remainder being from households with no children participating (Table 1).

Quantitative Findings

Changes in Physical Activity (Pooled Analysis)

Compared to that at baseline, the mean time spent walking at 8 weeks, but not 4 weeks, was significantly higher ($P=.005$)

with no statistically significant differences found between baseline (T_0) and the other time points (T_1 and T_2) for the other physical activity outcomes, including weekly minutes of MPA, VPA, and total physical activity, and frequency (days) of sufficient MVPA (Table 2).

Table 2. Differences in self-reported physical activity and sedentary behavior at baseline (T₀), 4 weeks (T₁), and 8 weeks (T₂) (N=87).

Variable	Friedman test		T ₀ , mean (SD)	T ₁ , mean (SD)	T ₂ , mean (SD)	P value within-subject effect (time) ^a

^fMVPA: moderate-to-vigorous physical activity.

Changes in Physical Activity (Effect Modification)

None of the physical activity gain scores was significantly different between those with and without prior wearable tracker experience, suggesting a similar effect of the intervention for both groups. Time spent walking among those with prior wearable tracker experience was significantly ($P = .03$) different between the time points, but none of the planned comparisons reached significance ($P > .025$; Table 3).

A significant difference in walking gain scores was found between those with and without prior eHealth app experience (T₂-T₀, $P = .04$), suggesting that the effect of the intervention was different between the two groups. Compared to that at baseline, participants with no prior eHealth experience increased their minutes of walking at 8 weeks ($P < .001$) with no significant difference over time found among those with prior eHealth experience (Table 4).

We found a significant difference in walking gain scores between individuals from households with only adults versus households that included children participating in the program (T₂-T₀, $P = .04$), suggesting that the effect of the intervention was different between the two groups. Significant differences were found in walking between baseline and 4 weeks ($P = .02$) and 8 weeks ($P < .001$) only for individuals from households that included children participating in the program. We also found a significant increase in total physical activity at 8 weeks compared to baseline ($P = .01$) among this same group (Table 5). However, the total physical activity gain scores were not significantly different from T₂ to T₀ ($P = .16$), suggesting that the effect of the intervention was similar between individuals from households that included only adult participants and individuals from households that included child participants (Table 5).

Table 3. Differences in self-reported physical activity and sedentary behavior at baseline (T₀), 4 weeks (T₁), and 8 weeks (T₂) according to history of activity tracker use (N=87).

Changes in Sedentary Behavior (Pooled Analysis)

Compared to that at baseline, the mean time spent sitting was significantly lower at 4 weeks ($P < .001$) and 8 weeks ($P < .001$), respectively. However, there were no significant differences in daily screen time between time points (Table 2).

Changes in Sedentary Behavior (Effect Modification)

We found no significant differences in sitting or screen time gain scores between those with and without prior wearable tracker experience, suggesting a similar response to the intervention in both groups. Among participants with prior wearable tracker experience, time spent sitting was significantly lower at 4 weeks relative to that at baseline ($P = .002$) (Table 3).

Similarly, we found no significant differences in sitting or screen time gain scores between those with and without prior eHealth experience. However, compared to that at baseline, the mean time spent sitting was significantly lower at 4 weeks ($P < .001$) and 8 weeks ($P = .004$) among those with prior eHealth experience only (Table 4).

No significant differences were found in sitting or screen time gain scores between individuals from households with only adults versus households that included child program participants. Nevertheless, we found significant differences over time in sitting among those from households with child participants (T₀ vs T₁, $P < .001$; T₀ vs T₂, $P = .002$) (Table 5).

Qualitative Findings

Overview

Three themes associated with behavior change in response to the VPS program emerged from the interviews: *Increased Physical Activity*, *Reduced Sedentary Behavior*, and *Other Health Benefits*. During interviews, participants described how the VPS program including the wearable activity tracker, eHealth dashboard, and Garmin Connect had supported their physical activity, sedentary behavior, and provided other health benefits during the 8-week intervention (Textbox 1). Saturation was obtained, with responses emerging from interviews often being repeated by different participants.

Textbox 1. Themes, subthemes, and representative quotes reflecting participants' experiences during the Vivo Play Scientist program.

<p>Increased physical activity</p> <p><i>Changes in awareness, motivation, and behavior</i></p> <ul style="list-style-type: none"> • “I’m paying attention to how many steps I take and if I took a certain amount each day. I’ve even included [walking] instead of taking my 30-minute lunch break.” [female, 41 years] • “I’ll set goals for myself quietly that no one knows about. I’m accountable to myself if I don’t do it. [It’s] a way to motivate myself.” [female, 43 years] • “This is a physical motivator for me because I look at it, it’s like, ‘Oh crap. I didn’t get my step count’.” [female, 54 years] • “I know how active I am, it [the VScore] shows on the graph, as a family graph and individual. It gives you an indication of how you are doing.” [male, 36 years] <p><i>Negative impacts of using wearable technology</i></p> <ul style="list-style-type: none"> • “I stopped using a fitness tracker, was because I was finding it was taking the enjoyment out of exercise. Because I was getting too focused on how I compared to other people.” [female, 36 years] <p><i>Changes in family physical activity</i></p> <ul style="list-style-type: none"> • “It’s worked really well for my son, because it got him to actually want to walk more. He wants to be more active because he wants to get his steps in. He wants to get a badge.” [female, 52 years] • “It’s been really positive, especially with COVID. Because we were pretty housebound, the kids haven’t been able to go and play with their friends and stuff like that. It’s been a good incentive to go out and just explore and get active.” [female, 39 years] • “We’re looking at the average of our household, how we’re doing as overall health. As a family, this [the dashboard] is really helping us to understand, ‘Hey, what can we do together next time on a weekend?’ That helped us with our planning our activities together. So we were planning a little bit more what kind of activities we can try at home to do it together or taking turns doing it.” [female, 39 years] • “I’ll say to my wife... ‘What’s up with your VScore being on a 50, whereas even of our children are hovering around the high 60s low 70s and myself in the mid-70s at any given time?’ Right? I’ll say well then we as a family collectively have to help mom or help my son make up for that dip in the following weeks. I’ll just simply tell the family during dinnertime like ‘Someone scored low, we won’t mention who. Someone better start moving’.” [male, 41 years] <p>Reduced sedentary behavior</p> <ul style="list-style-type: none"> • “Because my work is mostly like 8 hours work, and I’m sitting all the time...when I get these beeps I actually will move. So it gives me a chance to take breaks too.” [male, 36 years] • “With the Garmin watch on, I would feel more inclined to maybe just take a break from my studying or from my work and go and play with them for 5 or 10 minutes.” [female, 23 years] • “I think as a whole, all those features, like track your steps every day, the dashboard and the challenges, the badges, which actually give you a little push to do it every day. The nudges that it gives you, that you need to move, they all help as a whole to motivate you to be more active.” [male, 36 years] <p>Other health benefits</p> <p><i>Enhanced mental well-being</i></p> <ul style="list-style-type: none"> • “I found that if I didn’t do enough activity, my emotional state was worse. If I have higher, more activity, more like if I’m running or doing just more, higher intensity workouts, it’s for me, I have a better day. My whole mood is much, much better.” [female, 52 years] <p><i>Health education opportunity for children</i></p> <ul style="list-style-type: none"> • “It’s a matter of encouraging something that I would hope that they would keep as a lifestyle thing...keeping in mind that I am raising kids that will someday be adults and hopefully to transmit to them a mentality that includes physical fitness in their lives.” [female, 41 years]

Increased Physical Activity

For many participants, using the wearable activity tracker and dashboard increased awareness of their own physical activity, which motivated them to improve their behavior. Many participants described how the step count displayed on the wearable tracker motivated them to be physically active and how they used this information as a benchmark with which to compare their personal goals and progress. Few participants described how the dashboard and vScore supported their

physical activity. Those who participated in the program with other household members, including with children, described how the program supported increases in their personal physical activity via spending more time being active as a family. Families who participated together in the program used their tracked steps and vScore to hold members accountable to improving their personal and family’s overall physical activity levels. However, for some participants, especially those who were already active or who experienced physical barriers (eg, poor weather and facility closures due to the COVID-19

pandemic) described the program as having little impact on their physical activity. Some participants even commented that certain aspects of the program such as the comparison of activity levels with others detracted from the enjoyment of undertaking physical activity.

Reduced Sedentary Behavior

Similar to physical activity, participants described how the program, and notably the wearable tracker, had increased awareness about their own sedentary behavior (Textbox 1). Participants commented that “move” prompts or notifications from the wearable tracker, as well as just wearing the device, encouraged them to break up periods of sedentary behavior such as sitting with movement activity and “nudged” them to be active.

Other Health Benefits

While not the main aim of the VPS program, participants perceived that their mental as well as physical and social health had improved as a result of participating (Textbox 1). Several participants recognized that their physical activity positively contributed to their sense of mental well-being, stress level, and sleep quality. For example, one participant described how her mood and mental state appeared to be related to her physical activity levels. Some participants noticed reductions in their weight, while others enjoyed the increased family interactions that resulted from participating as a household in the program. A few participants also perceived the program as an opportunity to educate their children about the importance of physical activity, fitness, and health.

Discussion

Principal Results

The aim of this study was to evaluate the effectiveness of a community-focused physical activity intervention designed and implemented by a local recreational facility that incorporated wearable and eHealth technology. Congruent with previous evidence [14-17], the quantitative and qualitative findings from our 8-week evaluation suggest that providing participants with a free-of-cost wearable activity tracker (Vivofit4) and access to a customized eHealth dashboard has the potential to both improve physical activity via increases in walking and to reduce sedentary behavior via discouraging sitting. Specifically, during the 8-week intervention, participants, on average, increased their walking time by approximately 73 minutes/week and reduced their sitting time by approximately 67 minutes/day. An increase in walking of this magnitude has the potential to protect against all-cause and cardiovascular-related mortality and chronic disease [48-50]. Given that a 60-minute increase in sitting time has been found to be associated with an increased risk of cardiovascular disease (4%), cancer (1%), and all-cause mortality (1%) [51], this reduction in sitting time also has clinical relevance. Despite increases in the total physical activity, MPA, VPA, and MVPA, and decreases in screen time during the intervention, none of these changes reached statistical significance. Nevertheless, participants described that wearing Vivofit4 and accessing the dashboard motivated them to monitor and modify their physical activity and sedentary behavior. These

findings highlight the usefulness of wearable technology and eHealth apps in supporting physical activity behavior change in the short term [16,17,23-26]. Importantly, the VPS program appeared to be effective despite being implemented under the COVID-19 public health restrictions.

Our evaluation of the VPS program only included adults; however, Vivo offered the program to individuals and families. The program design was relatively minimalistic. Apart from offering participants with a free-of-cost commercially available wearable tracker and access to the customized eHealth dashboard, the program included no other formal intervention components (eg, no health-promotion messages or reminders such as push notifications, exercise classes, counseling sessions, or group activities) to encourage behavior change. The use and application of feedback from Vivofit4 and the dashboard was self-determined by participants, and participants received no advice as to *how* or by *how much* they should modify their behaviors. Notably, the frequency of accessing the eHealth dashboard among our participants was low (approximately 1 day/week), which is consistent with a previous study using a similar dashboard provided by Vivametrica [36]. However, allowing multiple members from the same household to participate in the VPS program may have had an unintended positive consequence on the effectiveness of the program for some individuals. During interviews, individuals described how participating in the program as a family or with other household members (especially with children) encouraged changes in physical activity and sedentary behavior. This finding aligns with previous evidence suggesting that the social environment can influence physical activity in adults [52,53] and children [54,55]. Participants described the VPS program as providing household members with opportunities to increase physical activity via competition, sharing of behavioral data, developing shared behavioral goals (eg, contributing to a household averaged vScore), motivation, and opportunities to help other household members achieve their personal behavior goals. Our quantitative findings demonstrated that adults from households that included children participating in the VPS program significantly increased their walking by approximately 123 minutes/week and their total physical activity by 553 MET-minutes/week, and decreased their sitting time by 80 minutes/day. Congruent with our findings, Schoeppe et al [56] observed an increase of 45 minutes/day among children and 26 minutes/day among parents in self-reported MVPA during a 6-week multicomponent family-centered intervention that included wearable trackers and family-focused physical activity strategies (eg, family challenges and leader boards). Parental support (eg, motivating and educating), behavior modeling, and shared activities are important for encouraging physical activity in children [55,57,58]. Our findings suggest that interventions that include wearable and eHealth technology together with strategies that can encourage family engagement may be beneficial for improving physical activity and even sedentary behavior among adults.

Participants with and without prior wearable tracker experience had a similar response to the VPS program in terms of changes in physical activity and sedentary behavior. Our data did not allow us to differentiate among those with prior experience into

current and former wearable tracker users. Other studies have found differences in current physical activity levels, perception of influence on physical activity, sociodemographic characteristics, health conditions, length of wearable tracker use, and reasons for using wearable trackers between current and former users [59-61]. Importantly, our findings suggest that the effectiveness of the program appeared independent of prior wearable tracker experience, at least in the short term. However, the novelty of the eHealth dashboard might have had a positive impact on behavior [62]. Participants with no prior eHealth experience reported increases in weekly walking during the 8-week intervention, whereas no changes were observed in those with prior eHealth experience. There is no clear explanation for this finding. Speculatively, those with prior eHealth experience may have been less sensitive to the changes observed in the vScore or possibly they were already using preferred alternative eHealth apps. Adults who positively assess an eHealth app and are resolute in achieving their health goals may be more likely to continue using the app, whereas those who negatively assess an eHealth app but are determined to achieve their health goals may be more likely to switch to another app [63].

While the aim of the VPS program was to increase physical activity and decrease sedentary behavior, participants experienced other benefits. In addition to being more cognizant of their behavior patterns, some participants became more aware of how their levels of physical activity were associated with their sense of well-being and mood. Others derived benefits in terms of improved sleep and perceived reductions in weight. Elsewhere, people reported perceived changes in their sleeping and eating patterns due to using wearable trackers [60]. Moreover, reductions in weight and lipid profiles, and perceived increases in well-being have been found among older adults with chronic medical conditions after 12 weeks of receiving a free wearable tracker [64]. Our results are also supported by findings elsewhere suggesting that in addition to higher physical activity (MPA, walking, and total physical activity) and less sedentary time, current users of commercially available wearable trackers report better sleep quality and quality of life than nonusers [65]. Interventions involving wearable and eHealth technology should consider measuring a range of physical and mental health outcomes, in addition to physical activity and sedentary behavior, to better understand the potential effects on overall health and well-being.

Limitations

Wearable trackers and eHealth apps range in the functions they offer and the ways in which they encourage or support behavior change (eg, movement prompts, behavior goal-setting, goal achievement notifications, data sharing) [66]. Thus, the effects of Vivofit4 and the vScore on physical activity and sedentary behavior found in our study may not generalize to other wearable or eHealth technologies. Nevertheless, our findings tend to be aligned with previous evidence suggesting that wearable activity trackers support improvements in physical activity and sedentary behavior [16,17,23-26]. Participants volunteered for the program and therefore may reflect a highly motivated and healthy population, limiting generalizability. Desires to maintain or improve fitness, weight, and quality of life are motivating factors associated with the use of fitness

applications [62]. Moreover, the effectiveness of the VPS program for improving walking and sitting may have been amplified due to participants having more time or seeking opportunities to undertake physical activity during the COVID-19 pandemic public health restrictions. Notably, only about half of the eligible individuals who registered for the program participated in the evaluation. Individuals registered but who did not participate in the study may have been less motivated to be physically active, knowing that their behavior would be monitored by our team. Moreover, we cannot rule out Hawthorn bias, whereby some participants may have been more inclined to use the wearable tracker and change their behavior knowing that their physical activity, sedentary behavior, and level of use of the device would be measured over the course of the program.

Our single-arm study design did not include a control group that would have allowed competing explanations of our findings to be eliminated (eg, self-selection, history, statistical regression, experimental mortality). However, the inclusion of qualitative data provided explanations in support of our quantitative results, thus adding robustness to our findings. Despite the shortcomings of our quasiexperiment, our findings support the short-term increases in physical activity and steps consistently found by randomized controlled trials of interventions using wearable trackers alone or in combination with other components [67]. We did not have access to device and dashboard data; thus, we relied on self-report data collected using questionnaires. Self-report measures are known to provide bias estimates of physical activity [68]. We are not able to generalize our findings beyond the 8-week observation period. In previous studies, former wearable tracker users reported wearing their devices for only about 5 months [59,60]. This may suggest that other intervention components (eg, check-ins, reminder emails or telephone calls, support groups) would be needed to support adherence in using wearable trackers during longer interventions. The effects of using wearable and eHealth technology on physical activity and sedentary behavior over the long term require further investigation.

Conclusions

The use of wearable activity trackers and eHealth apps may lead to improvements in walking and reduction in sitting time, and could enhance physical and mental well-being. Importantly, the VPS program demonstrated the potential to positively influence physical activity in the short term despite the challenge of being implemented under COVID-19 public health restrictions. Implementation of physical activity interventions that include wearable and eHealth technology could be an option for recreational facilities as they face challenges in delivering recreational programming to families during pandemic lockdowns and capacity restrictions. Future research may consider investigating the cost-effectiveness and sustainability of providing free-of-cost wearable and eHealth technology to participants as a stand-alone intervention for increasing physical activity and reducing sedentary behavior. Moreover, future studies are needed to determine which populations may derive the most benefit from stand-alone interventions that provide free-of-cost wearable and eHealth technology. Recreational facilities that provide free-of-cost commercially available

wearable trackers together with customized eHealth apps as part of community-focused health-promotion interventions have the potential to support increases in physical activity and reduce sedentary behavior in the short term.

Acknowledgments

Funding support for this study was provided by the Canadian Institutes of Health Research (FDN-154331) and Vivo for Healthier Generations Society. Vivo is a charitable enterprise in Calgary, Alberta, on a mission to raise healthier generations in that city and beyond. In addition to operating a local recreation center, Vivo undertakes research and innovation that is focused on developing, testing, and scaling novel healthy living interventions with the community.

Abstract

Background: Depression and anxiety frequently coexist with chronic musculoskeletal pain and can negatively impact patients' responses to standard orthopedic treatments. Nevertheless, mental health is not routinely addressed in the orthopedic care setting. If effective, a digital mental health intervention may be a feasible and scalable method of addressing mental health in an orthopedic setting.

Objective: We aimed to compare 2-month changes in mental and physical health between orthopedic patients who received a digital mental health intervention in addition to usual orthopedic care, those who received usual orthopedic care only (without a specific mental health intervention), and those who received in-person care with a psychologist as part of their orthopedic treatment plan.

Methods: In this single-center retrospective cohort study involving ancillary analysis of a pilot feasibility study, 2-month self-reported health changes were compared between a cohort of orthopedic patients who received access to a digital mental health intervention (Wysa) and 2 convenience sample comparison cohorts (patients who received usual orthopedic care without a specific mental health intervention and patients who received in-person care with a psychologist as part of their orthopedic treatment plan). All patients were 18 years or older and reported elevated symptoms of depression or anxiety at an orthopedic clinic visit (Patient-Reported Outcomes Measurement Information System [PROMIS] Depression or Anxiety score ≥ 55). The digital intervention was a multi-component mobile app that used chatbot technology and text-based access to human counselors to provide cognitive behavioral therapy, mindfulness training, and sleep tools, among other features, with an emphasis on behavioral activation and pain acceptance. Outcomes of interest were between-cohort differences in the 2-month longitudinal changes in PROMIS Depression and Anxiety scores (primary outcomes) and PROMIS Pain Interference and Physical Function scores (secondary outcomes).

Results: Among 153 patients (mean age 55, SD 15 years; 128 [83.7%] female; 51 patients per cohort), patients who received the digital mental health intervention showed clinically meaningful improvements at the 2-month follow-up for all PROMIS measures (mean longitudinal improvement 2.8-3.7 points; $P \leq .02$). After controlling for age and BMI, the improvements in

PROMIS Depression, Pain Interference, and Physical Function were meaningfully greater than longitudinal changes shown by patients who received usual orthopedic care (mean between-group difference 2.6-4.8 points; $P \leq .04$). Improvements in PROMIS Physical Function were also meaningfully greater than longitudinal changes shown by patients who received in-person psychological counseling (mean between-group difference 2.4 points; $P = .04$).

Conclusions: Patients who received a digital mental health intervention as part of orthopedic care reported greater 2-month mean improvements in depression, pain interference, and physical function than patients who received usual orthopedic care. They also reported a greater mean improvement in physical function and comparable improvements in depression, anxiety, and pain interference compared with orthopedic patients who received in-person psychological counseling.

Introduction

Background

Symptoms of depression and anxiety commonly coexist with chronic musculoskeletal pain. When this occurs, traditional mental health treatments are less effective in reducing psychological impairment, and traditional musculoskeletal treatments are less effective in addressing physical symptoms [1-5]. Specifically within the field of orthopedic care, pre-existing symptoms of depression or anxiety are associated with poor outcomes, such as worse postintervention physical functioning, increased postoperative opioid use, and reduced return-to-work rates [6-8]. Awareness of this phenomenon is growing, but mental health screening and intervention is still not considered a standard part of orthopedic care [9]. Barriers include orthopedic providers' lack of time and available mental health resources to offer; patients' financial resources, transportation, time, and stigma-related barriers to seeking mental health care, especially in person; and a national shortage of qualified mental health providers [9-11].

A digital mental health intervention is a promising tool to improve access to mental health care because it is not affected by many of the barriers that limit in-person care. That is, providers can easily refer patients to a digital resource because it is not limited by physical location or wait times, and patient challenges related to transportation, time, and fear of stigma are reduced and, in some cases, eliminated by enabling access to care without requiring travel to an in-person provider [12,13]. Furthermore, in a single-arm prospective pilot study, we demonstrated that delivery of a digital mental health intervention (Wysa) within an outpatient orthopedic care setting is feasible and preliminary effectiveness analyses are promising [14].

Outside the orthopedic setting, existing evidence supports the effectiveness of digital mental health interventions, but the effect size varies depending on the comparison arm, for instance, an inactive "usual care" or waitlist control group, or an active "gold standard" in-person counseling treatment group [15-17]. Therefore, the literature repeatedly calls for more comparison between digital mental health interventions and real-world treatment alternatives, both in the general population of people with symptoms of depression and anxiety and in those with coexisting symptoms of chronic pain [12,18-21]. To further understand the potential for introducing a digital mental health

intervention within the context of orthopedic care, clinical improvements observed in our pilot study need to be compared to improvements made by comparable patients who received usual orthopedic care (without a dedicated mental health intervention) and by patients who received in-person mental health care as part of their orthopedic treatment plan. This added information would provide insight regarding whether a digital mental health intervention provides added clinical benefit compared with usual orthopedic care, and if so, whether that benefit is less than, equivalent to, or even superior to in-person mental health care that is offered in a similar setting.

Objective

The purpose of this study was to compare 2-month changes in mental and physical health between orthopedic patients who received a digital mental health intervention (Wysa) in addition to usual orthopedic care, those who received usual orthopedic care only (without any specific mental health intervention), and those who received in-person care with a psychologist as part of their orthopedic treatment plan. We hypothesized that compared with patients who received usual care, orthopedic patients who were also provided a digital mental health intervention would report greater improvements in mental and physical health at a 2-month follow-up. Additionally, we hypothesized that compared with orthopedic patients who established in-person care with a psychologist, orthopedic patients who were provided a digital mental health intervention would report comparable improvements in mental and physical health at a 2-month follow-up.

Methods

Study Design

This was a retrospective study that involved ancillary analysis of data collected from a single-arm pilot feasibility study and other existing medical record data (ClinicalTrials.gov NCT04640090) [14]. All patients were evaluated within the orthopedic department of a single tertiary care academic medical center (Washington University) in the United States between 2017 and 2021.

Ethics Approval

Washington University institutional review board approval was obtained prior to data collection (IRB #202005219).

Participants

General Eligibility Criteria

All study participants were adults aged 18 years or older who presented to a nonoperative subspecialty-trained orthopedic provider for evaluation and management of musculoskeletal pain. As part of usual care, all patients who present to the orthopedic department of the study institution complete Patient-Reported Outcomes Measurement Information System (PROMIS) Depression and Anxiety measures prior to clinician evaluation. Only patients who self-reported elevated symptoms of depression or anxiety, as defined by scores of 55 or above on either measure or both measures, were eligible.

Digital Mental Health Intervention (Wysa) Cohort

The primary cohort of interest included patients who enrolled in a single-arm, prospective cohort, pilot feasibility study in which they received 2 months of complimentary access to a digital mental health intervention (Wysa), in addition to their usual orthopedic care. The intervention and this cohort have previously been described [14]. In brief, Wysa is a multi-component mobile app based on the principles of cognitive behavioral therapy, mindfulness, and motivational interviewing [22-24]. It includes an artificial intelligence-based “chatbot” conversational agent and text-based access to human “coach” counselors who have master’s degrees in psychology. A commercial version of the app exists, but for the pilot study, additional novel features were incorporated to specifically tailor the experience for people with chronic pain. Additional features were based on the principles of behavioral activation and pain acceptance [25-30]. These patients were recruited for the pilot study between December 8, 2020, and July 14, 2021. Patients who were planning to start in-person psychological treatment were excluded from the pilot study, and only 51 of 61 (84%) enrolled patients who completed 2-month PROMIS follow-up assessments were eligible for this ancillary analysis. While the majority of patients engaged with the intervention multiple times during the study period [14], lack of engagement with the intervention was not an exclusion criterion.

Usual Orthopedic Care Cohort

The Wysa cohort was compared to a “usual orthopedic care” cohort, which was a convenience sample of patients who presented to the same orthopedic clinics as those who enrolled in the prospective Wysa study but on days during which recruitment for the Wysa study was not occurring. In these clinics, “usual orthopedic care” most commonly includes physical therapy, medications (eg, nonsteroidal anti-inflammatory drugs, oral steroids, and neuropathic pain medications), and steroid injections, as appropriate. Other less commonly recommended procedures include radiofrequency ablation, manual massage, and acupuncture. These patients could have been presenting for a new or follow-up evaluation (just like in the Wysa cohort), but their orthopedic management plan could not have included any dedicated mental health management, such as counseling or a digital intervention. Furthermore, follow-up PROMIS Depression and Anxiety scores had to be documented in the medical record between 1 and 3 months after the initial evaluation. If scores from multiple dates

were available, the scores closest to a 2-month follow-up duration were selected for analysis. Patients who presented for an acute injury or a procedure were excluded. Patients in this cohort were identified consecutively via a reverse chronological medical record review until a sample size of 51 patients (matching the Wysa cohort) was reached. As a result, the baseline clinic date for patients in this cohort spanned September 16, 2021, to December 10, 2021, with a mean follow-up time of 56 (SD 9) days.

In-Person Psychological Counseling (“Gold Standard”) Cohort

The Wysa cohort was also compared to a “gold standard” cohort that received in-person psychological counseling as part of the orthopedic treatment plan. This was also a convenience sample of patients who presented to the same orthopedic clinics as those who enrolled in the prospective Wysa study. However, as part of their orthopedic treatment plan, they initiated in-person psychological counseling with a licensed clinical psychologist having over 20 years of experience. The psychologist delivered cognitive behavioral therapy, motivational interviewing, and mindfulness and deep breathing training, as indicated, during treatment sessions. This unique service was available through a lifestyle medicine-based center within the study institution’s orthopedic department [31]. The center’s purpose is to help patients manage musculoskeletal conditions by addressing underlying lifestyle habits and biopsychosocial comorbidities that contribute to musculoskeletal pain. To be eligible for this study, patients in this cohort had to have completed their evaluation with the psychologist within 2 weeks of completing baseline PROMIS Depression and Anxiety measures, and they had to have completed at least one follow-up session with the psychologist prior to the follow-up date designated for this study. For patients with PROMIS scores at numerous time points, scores obtained closest to the initial psychology evaluation and to a 2-month follow-up duration were selected for analysis. Patients were identified consecutively via a reverse chronological medical record review until a sample size of 51 patients (matching the Wysa cohort) was reached. As a result, the baseline clinic date for patients in this cohort spanned August 21, 2017, to September 20, 2021, with a mean follow-up time point of 62 (SD 19) days later.

Variables

As previously described, PROMIS scores from the Wysa cohort were collected prospectively during the pilot feasibility study. The rest of the data from all 3 cohorts were obtained from a medical record review of information collected as standard care during patients’ clinical encounters. All data extraction from patients’ medical records was performed by a single study team member (AJL). Patients’ self-reported mental and physical health was measured using the PROMIS Computer Adaptive Test (CAT) Adult Depression v1.0, Anxiety v1.0, Pain Interference v1.1, and Physical Function v2.0 measures [32-36]. PROMIS scores were normalized to the general US population, with a mean of 50 and SD of 10. Higher scores represent “more” of the domain [37]. For example, high scores on PROMIS Depression are unfavorable, but high scores on PROMIS Physical Function are favorable. Descriptive variables collected

included demographics (age, sex, race, ethnicity, and Area Deprivation Index [38,39]), BMI, pain location and duration, and medical history (hypertension, hyperlipidemia, heart disease, lung disease, diabetes, sleep apnea, depression, and anxiety).

Outcomes

The primary outcomes were the between-cohort differences in 2-month longitudinal change in PROMIS Depression and Anxiety scores. The secondary outcomes were the between-cohort differences in 2-month longitudinal change in PROMIS Pain Interference and Physical Function scores. Minimum clinically meaningful effect sizes were a priori set to match thresholds used in the pilot feasibility study, which were determined from previously published literature in conservatively managed orthopedic patients with chronic musculoskeletal pain. Minimum meaningful effect sizes were defined as at least 3.2 points on PROMIS Depression, 3.0 points on PROMIS Anxiety, 2.0 points on PROMIS Pain Interference, and 2.2 points on PROMIS Physical Function [40-42]. Between-cohort differences in baseline descriptive variables were examined, as well.

Statistical Analysis

Univariate descriptive statistics per cohort were calculated for all baseline study variables. Differences between the “digital mental health intervention” cohort and each of the 2 comparison cohorts (“usual orthopedic care” and “in-person psychological counseling”) were calculated as either mean differences via Welch 2-sample *t* tests or percentage differences via 2-sample *t* tests for equality of proportions with Yates’ continuity correction. Average within-person changes in PROMIS scores in each cohort were calculated using paired *t* tests. Comparisons of the 2-month change in PROMIS scores between the “digital mental health intervention” cohort and each of the 2 comparison cohorts were assessed with linear mixed models. Mean longitudinal changes in health were estimated via slope coefficients, and comparisons of slopes were tested with time by cohort interaction terms. Initially, age and BMI (as a marker for metabolic health) were added to the models as covariates

because these baseline characteristics were different between cohorts. However, these adjustments failed to alter the models in a statistically or clinically meaningful way, so unadjusted models are reported. Missing baseline descriptive data were omitted from relevant analyses. One participant in the “in-person psychological counseling” cohort was missing the follow-up PROMIS Depression score. Median imputation was performed for this single value. Significance was a priori set at $P < .05$. The sample size for each cohort was set to match the available sample size of the Wysa cohort. Data were collected using Research Electronic Data Capture (REDCap) [43,44], and statistical analyses were performed using R (v4.0.2, R Core Team).

Results

Patient Characteristics

Of the 153 patients included, the mean age was 55 (SD 15) years (range 18-86 years), and 128 (83.7%) were female. Compared with the cohort that received usual orthopedic care, patients who received the digital mental health intervention (Wysa) had a higher prevalence of sleep apnea (14/51, 27% vs 5/50, 10%; percent difference 18%, 95% CI 1%-34%; $P = .05$), but otherwise, had similar demographic, musculoskeletal, and medical characteristics (Table 1). Compared with the cohort that received in-person counseling, patients who received the digital mental health intervention were somewhat younger (mean age 53.2 vs 59.5 years; mean difference -6.4 years, 95% CI -12.0 to -0.4 ; $P = .03$), were less likely to have low back pain (28/51, 55% vs 42/51, 82%; percent difference -28% , 95% CI -47% to -8% ; $P = .006$), had a lower BMI (indicative of obesity; mean 29.1 kg/m^2 vs 38.1 kg/m^2 ; mean difference -9.0 , 95% CI -12.1 to -6.0 ; $P < .001$), and had a lower prevalence of both hypertension (21/50, 42% vs 36/47, 77%; percent difference -35% , 95% CI -55% to -14% ; $P = .001$) and sleep apnea (14/51, 27% vs 28/50, 56%; percent difference -29% , 95% CI -49% to -8% ; $P = .007$). There were no meaningful between-cohort differences in the proportion of patients who had a documented diagnosis of depression or anxiety.

^dThe national Area Deprivation Index is a neighborhood-level measure of social disadvantage based on a person's US Census Block Group [38,39].

^eSome patients reported multiple pain locations.

Primary Outcomes: Mental Health

On average, patients who received the digital mental health intervention showed clinically meaningful improvements in PROMIS Depression (mean longitudinal change -3.5 points, 95% CI -5.9 to -1.1 ; $P=.006$) and Anxiety (-3.7 points, 95% CI -5.9 to -1.4 ; $P=.002$) scores at the 2-month follow-up, whereas patients who received usual orthopedic care did not show clinically meaningful improvements in these measures, and patients who received in-person psychological counseling only showed meaningful improvements in PROMIS Depression scores (-3.8 points, 95% CI -5.9 to -1.6 ; $P=.001$) (Table 2).

Furthermore, patients who received the digital mental health intervention showed meaningfully greater mean improvements in PROMIS Depression (but not Anxiety) scores than patients who received usual orthopedic care (mean between-group difference -4.8 points, 95% CI -7.6 to -1.9 ; $P=.001$), and there were no statistically significant or clinically meaningful between-group differences in longitudinal improvements in PROMIS Depression or Anxiety scores between patients who received the digital mental health intervention and those who received in-person psychological counseling (Table 3; Figures 1 and 2). Adjusting for age and BMI did not have a statistically or clinically meaningful effect on these results.

Table 2. Mental and physical health changes (measured by the Patient-Reported Outcomes Measurement Information System) across a 2-month follow-up in the 3 cohorts of patients ($n=51$ for each patient cohort).

PROMIS ^a domain ^b	Baseline score, mean (SE)	2-month follow-up score, mean (SE)	Within-group longitudinal change, mean (95% CI)	<i>P</i> value
Depression				
Digital mental health intervention	58.2 (6.8)	54.7 (8.7)	-3.5 (-5.9 to -1.1)	.006
Usual orthopedic care	54.0 (7.1)	55.3 (6.6)	1.3 (-2.9 to 0.4)	.12

^aPROMIS: Patient-Reported Outcomes Measurement Information System.

^bClinically meaningful effect sizes are defined as at least 3.2 points for PROMIS Depression, 3.0 points for Anxiety, 2.0 points for Pain Interference, and 2.2 points for Physical Function [40-42].

^cAll bivariate analyses involve comparisons with the “digital mental health intervention” group.

^dOne participant in the “in-person psychological counseling” cohort was missing the follow-up PROMIS Depression score. Median imputation was performed for this single value.

Figure 1. Mean longitudinal change in Patient-Reported Outcomes Measurement Information System (PROMIS) Depression scores over a 2-month follow-up in patients who, as part of orthopedic care, were provided a digital mental health intervention (Wysa) (n=51) (green circles), received usual orthopedic care (n=51) (blue triangles), or received “gold standard” in-person care with a psychologist (n=51) (purple squares). The triangle within a circle signifies a between-cohort difference in the longitudinal change between the digital mental health intervention cohort and usual orthopedic care cohort. Error bars represent standard error.

Figure 2. Mean longitudinal change in Patient-Reported Outcomes Measurement Information System (PROMIS) Anxiety scores over a 2-month follow-up in patients who, as part of orthopedic care, were provided a digital mental health intervention (Wysa) (n=51) (green circles), received usual orthopedic care (n=51) (blue triangles), or received “gold standard” in-person care with a psychologist (n=51) (purple squares). Error bars represent standard error.

Secondary Outcomes: Physical Health

On average, patients who received the digital mental health intervention showed clinically meaningful improvements in PROMIS Pain Interference (mean longitudinal change -2.8 points, 95% CI -5.2 to -0.4; $P=.02$) and Physical Function (3.3 points, 95% CI 1.3 to 5.4; $P=.002$) scores at the 2-month follow-up, whereas patients who received usual orthopedic care or in-person psychological counseling in conjunction with usual orthopedic care did not show meaningful improvements in these measures (Table 2). Furthermore, patients who received the

digital mental health intervention showed meaningfully greater mean improvements in PROMIS Pain Interference scores than patients who received usual orthopedic care (mean between-group difference -2.6 points, 95% CI -5.1 to -0.2; $P=.04$), and they showed meaningfully greater mean improvements in PROMIS Physical Function scores than patients in either comparison cohort (mean between-group differences 2.4-2.7 points; $P=.02$ to $.04$) (Table 3; Figures 3 and 4). Adjusting for age and BMI did not have a statistically or clinically meaningful effect on these results.

Figure 3. Mean longitudinal change in Patient-Reported Outcomes Measurement Information System (PROMIS) Pain Interference scores over a 2-month follow-up in orthopedic patients who, as part of orthopedic care, were provided a digital mental health intervention (Wysa) (n=51) (green circles), received usual orthopedic care (n=51) (blue triangles), or received “gold standard” in-person care with a psychologist (n=51) (purple squares). The triangle within a circle signifies a between-cohort difference in the longitudinal change between the digital mental health intervention cohort and usual orthopedic care cohort. Error bars represent standard error.

Figure 4. Mean longitudinal change in Patient-Reported Outcomes Measurement Information System (PROMIS) Physical Function scores over a 2-month follow-up in orthopedic patients who, as part of orthopedic care, were provided a digital mental health intervention (Wysa) (n=51) (green circles), received usual orthopedic care (n=51) (blue triangles), or received “gold standard” in-person care with a psychologist (n=51) (purple squares). The triangle within a circle signifies a between-cohort difference in the longitudinal change between the digital mental health intervention cohort and usual orthopedic care cohort. The square within a circle signifies a between-cohort difference in the longitudinal change between the digital mental health intervention cohort and “gold standard” in-person psychological counseling cohort. Error bars represent standard error.

Discussion

Principal Findings

To understand the potential benefit of introducing a digital mental health intervention in the context of orthopedic care for patients with coexisting symptoms of depression or anxiety, it is necessary to understand (1) the added clinical benefit of this intervention compared with usual orthopedic care, and (2) the clinical benefit of this intervention relative to the benefit achieved via usual orthopedic care supplemented by in-person counseling with a psychologist. In this retrospective cohort study, compared with patients who received usual orthopedic care, patients who also received a digital mental health intervention reported meaningfully greater 2-month mean improvements in depression (mean PROMIS between-group difference -4.8 points, 95% CI -7.6 to -1.9 ; $P=.001$), pain interference (-2.6 points, 95% CI -5.1 to -0.2 ; $P=.04$), and physical function (2.7 points, 95% CI 0.5 to 5.0; $P=.02$). Compared with patients who initiated in-person psychological counseling as part of their orthopedic treatment plan, patients who received a digital mental health intervention reported a meaningfully greater mean improvement in physical function (2.4 points, 95% CI 0.2 to 4.7; $P=.04$) and comparable improvements in depression, anxiety, and pain interference. These between-group differences were present even after controlling for baseline between-group differences in age and BMI.

Strengths and Limitations

This study adds clinical context to our previously reported finding that it is feasible to deliver a digital mental health intervention in the setting of orthopedic care [14]. In other words, the primary strength of this study is the comparison of

outcomes between orthopedic patients who received a digital mental health intervention, a “usual care” cohort, and a “gold standard” in-person psychological counseling cohort, especially because psychological counseling is still rarely prescribed in the context of orthopedic care.

The primary study limitations relate to the retrospective design and between-cohort baseline differences. Nonrandomized study designs have inherent limitations that can affect results. These include possible selection bias, differential attrition, regression to the mean, effects by unmeasured confounding variables (eg, concomitant orthopedic and mental health interventions), potential undetected interaction effects, and temporal/historical bias. Because patients who received the digital mental health intervention were actively enrolled into the research study while comparison cohorts were retrospectively selected as convenience samples, the digital intervention cohort could have been subject to healthy participant bias (in which increased activation in their health care could have contributed to greater health-related improvements). Furthermore, only 51 of 61 participants who completed 2-month follow-up measures in the digital intervention prospective study could be included in this longitudinal analysis, which also could have contributed to healthy participant bias. Additionally, the “usual orthopedic care” cohort could have been biased toward patients who were not showing satisfactory improvements and therefore returned to the clinic for a follow-up visit to determine the next steps. Similarly, it is possible that patients who received in-person psychological counseling as part of their orthopedic treatment plan had more “treatment-resistant” symptoms than patients in the other cohorts because in our experience, patients who choose this biopsychosocial lifestyle medicine approach to orthopedic care report feeling “at the end of their rope” and have often already tried many standard orthopedic treatments. A

difference-in-differences quasiexperimental design was adopted, rather than propensity score matching, so that baseline between-group differences could be explored and because the number of potentially eligible patients for the in-person psychological counseling cohort was limited. Nevertheless, the vast majority of baseline characteristics were not significantly different between the cohorts, and baseline PROMIS scores for the digital intervention cohort were comparable (and at times worse) than the comparison cohorts, which would suggest that the digital intervention cohort was not experiencing less severe symptoms at baseline. While worse baseline scores provide more “room to improve,” the digital intervention cohort did not have worse baseline scores for any of the between-group differences that were found to be statistically significant.

Finally, generalizability is a limitation of this single-center study conducted at a tertiary care center. In order for a digital mental health intervention to be feasibly offered in an orthopedic setting, clinical providers need to support the initiative, and mental health screening needs to be a standard part of a patient’s evaluation, as is the case at the study institution.

Comparison With Prior Work

Our findings are consistent with previous large randomized controlled trials and meta-analyses that have demonstrated the effectiveness of digital interventions for improving symptoms of depression, anxiety, and even pain-related impairment in people with chronic pain who have been recruited from pain management clinics, primary care clinics, and community/internet referral sources [20,21,45-47]. To our knowledge, though, this is the first study to specifically evaluate the effectiveness of a digital mental health intervention that was introduced in the setting of an orthopedic clinic, which is not typically a setting where mental health is a focus. We find it encouraging that, similar to studies of participants among the general population, orthopedic patients who received a digital mental health intervention reported favorable mental and physical health outcomes compared with those who received no active mental health treatment and at least comparable outcomes to those who initiated in-person care with a psychologist [15-17,48]. Our results add to the body of literature showing that the *impact* of pain on a person’s daily functioning and quality of life (ie, pain interference) can be improved by cognitive behavioral techniques, such as cognitive restructuring and addressing maladaptive thought patterns, regardless of the person’s level of physical function [49,50]. However, it was

somewhat surprising that patients in this study who received usual orthopedic care did not make meaningful improvements in physical health. This could be related to (1) the inherent characteristics of nonoperative orthopedic patients who have multiple orthopedic clinic visits within a span of 2 months (eg, to address persistently bothersome symptoms), and (2) the difficulty of treating chronic pain (many years), especially when the interplay between mental health and chronic pain has not been sufficiently addressed. Nevertheless, it is encouraging that patients who received the digital mental health intervention made physical, as well as mental, health improvements even when the usual orthopedic care cohort did not.

Directions for Future Study

Further investigation regarding the effectiveness of incorporating a digital mental health intervention into orthopedic care should include (1) a longer follow-up duration because depression and anxiety are chronic conditions; (2) dedicated evaluation of the intervention’s impact on sleep because pain and insomnia reciprocally affect each other and because digital cognitive behavioral interventions can be effective for insomnia [51-53]; and (3) more detailed information regarding concomitant orthopedic and mental health interventions, which are pursued during the intervention period. To obtain further insight, a fully powered, prospective, randomized controlled trial is needed.

Conclusions

Patients who received a digital mental health intervention as part of their orthopedic care reported greater 2-month mean improvements in depression, pain interference, and physical function than patients who received usual orthopedic care without any specific mental health intervention. They also reported a greater mean improvement in physical function and comparable improvements in depression, anxiety, and pain interference compared with patients who initiated in-person psychological counseling as part of their orthopedic treatment plan. These differences met clinically meaningful thresholds and suggest that when orthopedic patients endorse elevated symptoms of depression or anxiety, incorporation of a digital mental health intervention into orthopedic care may improve patients’ physical and mental health outcomes relative to standard orthopedic care. Furthermore, improvements may be comparable to those achieved on incorporation of in-person psychological counseling. These retrospective findings warrant further investigation using a prospective randomized design.

Acknowledgments

This study was funded by a Washington University/BJC HealthCare Big Ideas innovation grant. Work on this study was also supported by the National Institutes of Health (NIH) (K23AR074520) and the Doris Duke Charitable Foundation (ALC), and use of Research Electronic Data Capture (REDCap) was supported by a Clinical and Translational Science Award (CTSA) Grant (UL1 TR000448) and a Siteman Comprehensive Cancer Center and National Cancer Institute (NCI) Cancer Center Support Grant (P30 CA091842). The authors have no other financial disclosures. The study team purchased participant access codes for Wysa’s novel version tailored for people with chronic pain (which is not commercially available). Wysa provided participants’ deidentified app usage data to the study team free of charge. Data were linked to individual users via randomly generated codes, and only Washington University study personnel had access to the participant keys. No personally identifiable data were shared with Wysa by the study team or vice versa. The content of this manuscript was written solely by the study authors, independent of Wysa.

Authors' Contributions

AJL contributed to follow-up data collection and writing of the manuscript. MJS performed the statistical analysis and contributed to writing the manuscript. DMH contributed to participant recruitment, data collection, and editing of the manuscript. JPM and PAA contributed to the statistical methods, data presentation, and editing of the final manuscript. ALC conceived of the study idea, supervised the entire project, and contributed to writing the final version of the manuscript.

Abstract

Background: The rise of digital methods and computational tools has opened up the possibility of collecting and analyzing data from novel sources, such as discussions on social media. At the same time, these methods and tools introduce a dependence on technology, often resulting in a need for technical skills and expertise. Researchers from various disciplines engage in empirical bioethics research, and software development and similar skills are not usually part of their background. Therefore, researchers often depend on technical experts to develop and apply digital methods, which can create a bottleneck and hinder the broad use of digital methods in empirical bioethics research.

Objective: This study aimed to develop a research platform that would offer researchers the means to better leverage implemented digital methods, and that would simplify the process of developing new methods.

Methods: This study used a mixed methods approach to design and develop a research platform prototype. I combined established methods from user-centered design, rapid prototyping, and agile software development to iteratively develop the platform prototype. In collaboration with two other researchers, I tested and extended the platform prototype in situ by carrying out a study using the prototype.

Results: The resulting research platform prototype provides three digital methods, which are composed of functional components. This modular concept allows researchers to use existing methods for their own experiments and combine implemented components into new methods.

Conclusions: The platform prototype illustrates the potential of the modular concept and empowers researchers without advanced technical skills to carry out experiments using digital methods and develop new methods. However, more work is needed to bring the prototype to a production-ready state.

digital bioethics; digital humanities; digital methods; computational methods; empirical bioethics; research platform; digital health; bioethics; digital platform

Introduction

Empirical bioethics is an interdisciplinary research field attracting researchers with various backgrounds [1]. Software development skills and similar know-how are often not part of their expertise. However, inquiries in the field of empirical

bioethics can rely heavily on computational tools (the textual analysis of millions of tweets, for example). From the 1990s, social scientists have recognized the internet as a valuable research subject and data source, and have adapted their methods and tools to novel digital phenomena [2,3]. This recognition has resulted in novel digital methods, which Snee et al [4] define

as “the use of online and digital technologies to collect and analyse research data.” Novel disciplines emerged, such as computational social science, which leverages computational capabilities to collect and analyze big data, to study social behavior [5].

The development of these methods has spawned a variety of digital tools. One example is the network visualization software Gephi [6]. Gephi imports different data formats and provides functionality to researchers through a graphical user interface. Researchers can use this software to compute basic network statistics, such as network density and average shortest path length. Network visualization features build the core of Gephi, allowing researchers to explore and manipulate large networks. Gephi is open source, and can integrate plugins, enabling software developers to extend the functionality.

Alongside the maturation of digital methods, advances in computer science, especially machine learning, have resulted in an abundance of software libraries. One example is Hugging Face, a Python library that provides state-of-the-art natural language processing (NLP) resources [7]. Hugging Face allows researchers to program their own NLP pipelines; for example, to enable analysis of the sentiment of tweets. In contrast to Gephi, Hugging Face is a collection of resources used by developers to write software programs. It does not offer a graphical user interface or out-of-the-box workflows for researchers without programming experience. One advantage of such a library is that developers have a great deal of control over how to use the resources, which can also be easily combined with resources from other libraries.

In light of these new developments and tools, and in collaboration with other researchers, I conducted several empirical bioethics experiments using digital methods, hereinafter referred to as “digital bioethics.” My collaborators

and I encountered two major issues over the course of these experiments: (1) the need for technical expertise to set up tools and adapt them to each experiment, and (2) the need for technical expertise to develop new methods. In my observation, finding ad hoc expertise can delay projects and make it more difficult for researchers to conduct digital bioethics experiments. If researchers could easily access tools and seamlessly integrate them into their research projects without the assistance of software developers, they might be more inclined to practice digital bioethics.

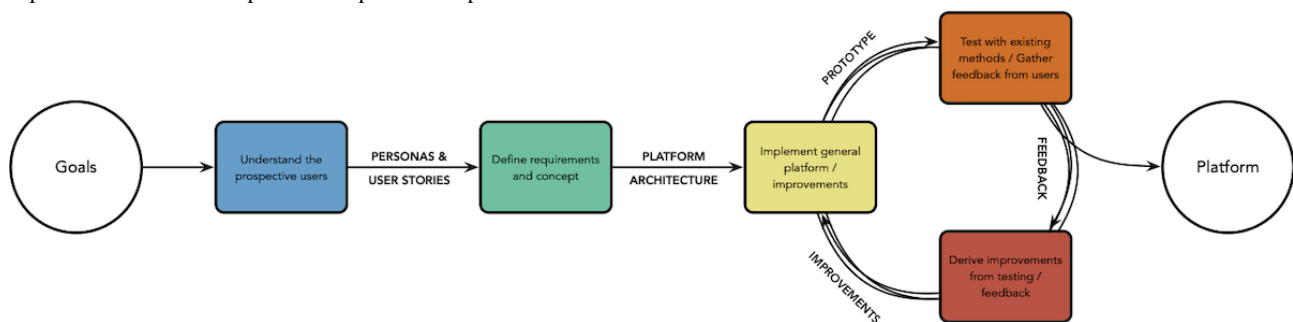

Researchers would still rely on software development skills to develop new tools when fundamentally new functionality is required. However, existing tools might be repurposed, modified, and recombined, if they were built with that objective in mind. Therefore, I aimed to develop a research platform which addresses the two identified issues. In the following, I describe the development process, the resulting research platform prototype, and the learnings from this process.

Methods

Overview

Using a combination of user-centered design [8], rapid prototyping [9], and agile software development [10], I developed a platform prototype that addresses issues (1) and (2) introduced in the *Introduction*. Rather than regarding these issues only as challenges, I translated them into goals, which express an ideal scenario: (A) researchers can easily configure and employ methods provided by the platform for new experiments, and (B) researchers can modify methods and develop new methods, by recombining components of already implemented digital methods. These high-level goals guided the development process, which I describe in the following paragraphs (see [Figure 1](#) for an overview of the approach).

Figure 1. Overview of the methods. The circles represent the start and end points of the development process, and the colored boxes represent the work steps. The three boxes on the right form a prototyping cycle, which I carried out multiple times during the development process. The text in between the steps describes the main inputs and outputs of a step.

Understanding the Prospective Users

The first step of the development process was to create *personas*; that is, abstract individuals who represent typical target users [11,12]. In total, I created four personas (two for each goal [A] and [B]). I defined their attributes such as name, age, gender, and professional background, as well as their personal goals, challenges, and motivations with respect to digital bioethics. I based the personas on my own experience, as well as anecdotal data from colleagues and the empirical bioethics literature [1,13,14], which is common practice when no empirical data

are available. I then derived so-called *epics*, that is high-level narratives of what each persona as a user would want to do on the research platform, and why [15]. The epics incorporated the platform goals (A) and (B) from the perspective of the persona. Finally, I broke down the epics into specific tasks a user might want to accomplish, together with the user’s corresponding motivation [8]. These *user stories* took the form “as a <user> I want to <action> so that <value>,” commonly referred to as the role-feature-reason format [16]. The user stories formed the initial functional requirements for the platform and described

the user-centered features (see [Multimedia Appendices 1 and 2](#) for the personas, epics, and user stories).

Designing the Platform Concept

While the user stories described the intended functionality of the platform, they also had nonfunctional implications for the platform design. For example, if two researchers were working on a project at the same time, the actions of one researcher should not unintentionally override data resulting from actions of the other researcher. I also defined nonfunctional requirements from my past experience with digital bioethics. As an example, training a machine learning model requires significant computational power and is time-consuming. I therefore defined requirements about the performance of the platform and its ability to run such a time-consuming process without blocking other processes. I then designed the high-level platform architecture based on these requirements, using a micro service and micro frontend approach [17-19].

Implementing the Base Prototype

In the final phase of the development process, I used rapid prototyping [9,20] to implement a first functional prototype, and then to iteratively improve the prototype through evolutionary prototyping (ie, continuously improving the same prototype). Initially, I implemented the overall platform without incorporating any specific digital method, focusing on general platform functionality such as data handling and the graphical user interface (GUI). Next, I implemented two digital methods: one from a study examining the web-based data sharing policy landscape [21], and another from a study analyzing themes in tweets about CRISPR [22]. To adhere to goal (B) and the corresponding user stories, I did not implement the methods as one monolithic process, but rather split into functional components. For example, I implemented a data filtering step as an individual component, and not as part of a multi-stage data processing pipeline. The implementation of these methods allowed me to test the platform's conceptual choices and added functionality to the platform prototype at the same time.

Testing and Improving the Prototype in a Real-life Scenario

To test the prototype in a real-life scenario, I collaborated with two researchers (Julia Amann, Joanna Sleight) from the same lab to investigate visual risk communication about COVID-19 on Twitter [23]. I completed multiple prototyping iterations with one researcher (JS) to implement functionality that was necessary for the research, but not yet implemented in the platform. Over the course of the study, I continuously gathered feedback from the researchers about their user experience, defined improvements based on this feedback, and implemented the improvements, forming multiple prototyping cycles (see [Figure 1](#)). The researchers also requested additional features based on their experiences with the platform. I implemented, tested, and improved the requested features in-situ; the researchers used the new features over the course of the study and provided direct feedback, until the features fit their needs precisely. At the conclusion of the visual communication study, the platform prototype contained all components of the study methods.

Results

Overview

The main result of this study is the research platform prototype. It is important to note that the goal of this study was to develop a platform that affords more flexibility to a researcher working with digital methods. Therefore, the main focus of this section is to describe how the platform provides this flexibility, and not how a specific digital method is implemented. In the following, I report the major technical and functional design choices, and describe the main features of the platform (see [Multimedia Appendix 3](#) for screenshots of the platform prototype and descriptions thereof).

Platform Architecture

The platform is implemented as a client-server model, allowing multiple users to work on the same project with all data centrally stored. This model eliminates the peer-to-peer sharing of data sets but imposes security features on the platform. Client-server communication implements the standard HTTPS protocol with Transport Layer Security encryption. Users are authenticated through the Authentication and Authorization Infrastructure [24] provided by most Swiss universities, and can share projects with other authenticated users.

The frontend was realized as a web application using the web application framework Angular [25] to be independent of the user's operating system, and supports browsers compliant with the World Wide Web Consortium's web standards [26]. The backend was built with the Python framework Flask [27] and employs the Python library pandas [28] for data management and core data operations, such as extending data sets with data sent from the frontend and providing dataset previews to the frontend. Packages are managed through a Python virtual environment. An overview of the platform architecture is shown in [Figure 2](#).

The GUI defines the web application's layout and style, such as colors and fonts. A router enables the user to navigate to the different core views that provide the general functionality of the platform. When prompted by the user, the router provides the custom digital method specific views (micro frontends) to the GUI. Two core frontend services facilitate communication with the backend, and are both available to the core view and micro frontends.

The backend's application programming interface (API) allows the frontend to interact with the backend functionality. Through the API, the frontend can load and store information about research projects, handled by the project manager. The actions carried out and the data processed when running a project are coordinated by the service manager, which starts and stops micro services, and reads and writes data. The micro services can store resources (such as images) and results (such as tables or figures resulting from the analysis) as files which can be requested from the frontend through the API. To download a data set from the web application, a user can request the specific data set from the database through the API.

The micro services and micro frontends form the heart of the platform. When a digital method is implemented on the platform,

the method is broken down into smaller units, each fulfilling one specific function. These units are implemented as either an interactive *task* or a fully automated *process*, which can be chained together in a *pipeline*. The tasks and processes both process data, receive different kinds of input, and produce results; for example, a chart illustrating the outcome of a statistical analysis carried out as part of the process. An abstract micro service class and an abstract micro frontend class provide all of the technical functionality necessary to seamlessly integrate new tasks and processes implemented by a developer.

A task consists of a micro service, which carries out operations requested by the user, and a micro frontend, which provides the user with a custom user interface for the task. This interface allows the user to trigger operations of the micro service and to exchange data with it. The user starts a task through the frontend, performs actions through the task-specific interface,

and stops the task once it is completed, all in a synchronous way. In contrast, a process is started by the user, and runs asynchronously until completion. In this context, *asynchronous* means that the user can perform other actions while the process is running, and can even close the web application. This mechanism is intended for time-intensive operations that can continue for multiple hours or days, such as analyzing a large amount of data or training a machine learning model.

All tasks and processes have a specification file, which defines what input data they take, what data they output, what results they produce, and what parameters the user can configure. Thanks to this shared core concept, a user can easily connect and configure tasks and processes. I will explain how this is done, together with the other main features of the platform, in the next subsection.

Figure 2. High-level overview of the platform architecture. The platform is separated into the frontend, with which the user interacts (left), and the backend, which is concerned with data storage and processing (right). The two communicate through HTTPS (dashed line). The micro frontends and micro services provide the functionality of the individual components, which together represent the digital methods. The arrows indicate the direction of communication flow between the elements of the platform.

Main Features of the Web Application

On the starting page of the platform, a user can choose to create a new project by specifying a project name and description, or to open an existing project. A project consists of the project pipeline, data set inspector, and results inspector (see Figure 3A).

The project pipeline is the control center for the project. It displays all processes and tasks carried out during the course of the project, and lets the user start them individually (see Figure 3B). When a new project is created, the user can choose an existing digital method from a collection of implemented methods. The pipeline is then populated with all components (ie, tasks and processes) of that method. The user can configure each task and process to match the context of the current project. The user can also specify which datasets provide the input data for each component, and whether the output data forms a new data set or is appended to an existing one (see Figure 4A).

Alternatively, the user can develop a new method or adapt an existing method by adding individual processes and tasks to the pipeline. These processes and tasks are then connected to components through their input and output data sets (see Figure 4B). If a new method is created or an existing method changed, the user can export the pipeline to the method collection and provide a rationale for the methodological choices in a text field.

The user can ultimately run a project by starting processes and tasks in the pipeline through a click on the respective button.

Two distinct features help a researcher to keep track of the ongoing project. The data set inspector shows all existing data sets for a project, and a preview of the data. This enables researcher oversight, to see that the processes and tasks are functioning as intended. The data set inspector also allows the user to download full datasets for further inspection. Similarly, the results inspector shows all results (such as charts) produced as part of the tasks and processes. The results can also be downloaded from the results inspector.

The last feature I discuss here is the knowledge base. A detailed understanding of how the methods and components work is of great importance for the development and application of digital methods. To address this challenge, each component and method has a detailed description. The description is adapted automatically on the basis of the user's configuration of the component, to reflect the actual pipeline as accurately as possible. These descriptions serve to educate users about available components and methods and help users assess their suitability for a new study design. The descriptions also allow users to verify that the composed pipeline does what they intended it to do and to accurately describe the method; for example, in a scientific publication about a study conducted on the platform.

Figure 3. Main features of the web application. Experiments are organized into projects which offer three main functionalities: the project pipeline where the experiment is run, the data inspector that provides insight into the data sets of the experiments, and the results inspector displaying the results produced by the components (A). The user can populate the pipeline with existing methods, tasks, and processes by adding them from collections (B).

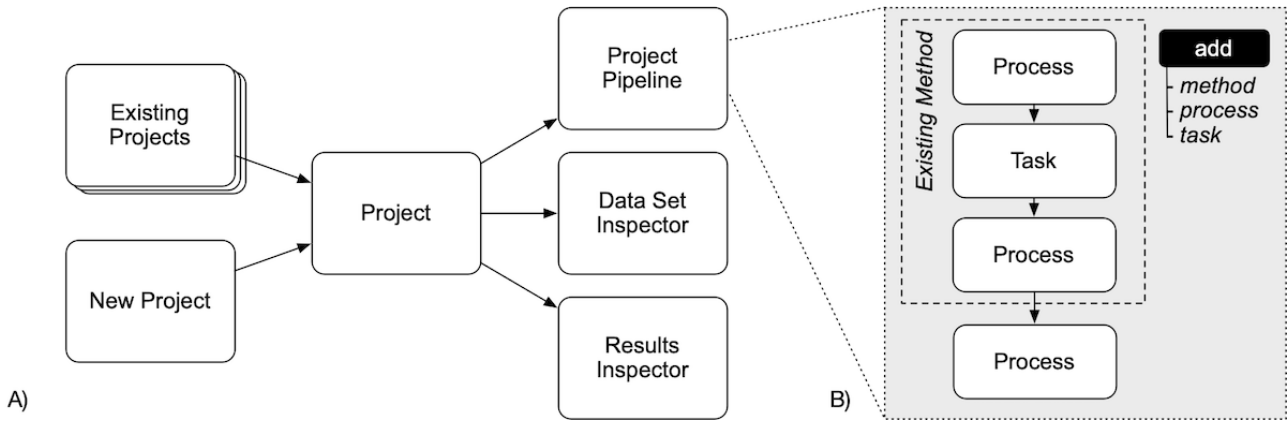

Figure 4. Integration of the components into the pipeline. Components (processes and tasks) are configured by the user. Besides functionality-specific parameters, the user also specifies which data sets provide the input data to each component, and what output data is written to which data set (A). The components' relations to the input and output data sets define the execution sequences, and are reflected in the pipeline (B).

Visual Communication Study

The communication study [23] conducted on the platform prototype during the last phase of the development process exemplifies how researchers can use the platform for their research. Hence, I characterize the project pipeline of the study and describe the procedure the researchers followed on the platform (see Figure 5 for a schematic overview of the pipeline).

The communication study's pipeline consisted of 2 tasks and 23 processes. Some of the process components performed the same function. For example, the statistical analysis at the end of the pipeline employed the same process component type multiple times. However, the components' individual configurations resulted in distinct statistics describing different aspects of the data. The pipeline view (the control center of the project) allowed the researchers to start tasks and processes. When researchers started a task, the platform prompted a custom task interface, which allowed them to carry out each task's specific work. Researchers ran the processes one after another by clicking on the respective button in the pipeline view. It was in this way that data was processed throughout the pipeline. Altogether, the tasks and components formed 7 functional steps (see Figure 5).

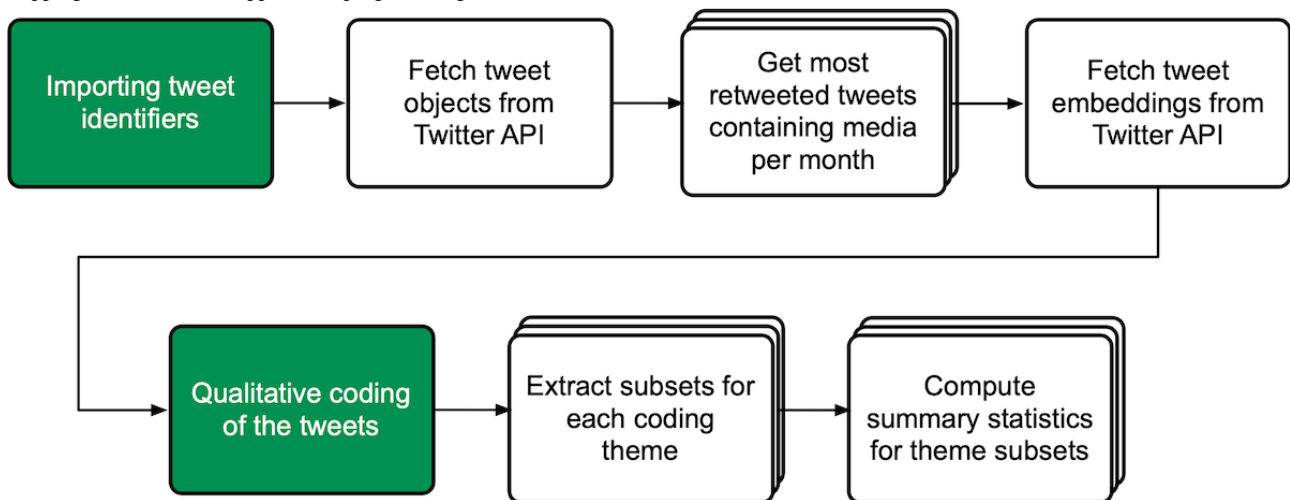

The researchers started their work on the platform by importing the tweet identifiers from a data set they obtained from Crowdbreaks [29], which collects tweets concerning various public health topics. They then ran a process component that

fetches the entire tweet object (eg, tweet text, hashtags, and retweet count) for each tweet identifier from the Twitter API. The subsequent processes filtered the data set to include only tweets that contained visuals and selected the 500 most retweeted tweets per month.

The process that followed fetched tweet embeddings (formatted text snippets) from the Twitter API, which the subsequent task utilized to display the tweets within its custom interface. The task interface offered two views to carry out the qualitative coding, a form of qualitative content analysis [30], representing the researchers' main activity during the study. One view presented the individual tweets and allowed the researchers to select items matching the tweets' characteristics from a predefined codebook specified in the task's configuration (see Multimedia Appendix 3 for a screenshot). A second view displayed a list of all the tweets providing a preview for each tweet, the initials of the coders that coded it, and whether or not it was included in the analysis.

Following the coding task, multiple process components extracted subsets from the coding data set, one subset for each of the 6 coding themes. Finally, 12 process components provided statistical results for all the themes, which created the basis for the researchers' manual inspection and interpretation of the results. The statistical processes also produced basic figures from the statistical results to assist interpretation (see Multimedia Appendix 3 for a screenshot).

Figure 5. Overview of the visual communication study pipeline. The researchers carried out the tasks (in green) while the other elements represent the process components, which automatically carried out functions. Process components with the same or similar functionality are grouped for simplicity (overlapping elements). API: application programming interface.

Discussion

Principal Findings

The study using the prototype to examine visual communication on Twitter [23] demonstrates the potential of the platform design. In accordance with the platform's modular design, I implemented the study method as individual components. For example, the platform provides a component to carry out a qualitative coding of tweets. Now that the study components are available on the platform, the visual communication study pipeline can be used as a template for similar studies. As the functionality of the qualitative coding component is not limited to tweets, it can be used to analyze other content (for example news articles) as well.

The platform prototype offers greater flexibility to researchers without programming skills, when compared with Gephi or Hugging Face. Once a new digital method is implemented on the platform, a researcher can easily configure the method to fit a specific experiment, or adapt an existing method by removing and adding components. Further, a researcher can develop a new method by combining individual components of existing methods. If new functionality is needed, software developers can readily integrate a new component, thanks to the platform's modular architecture.

Enabling researchers to function with greater independence from technical experts might seem counterintuitive for an interdisciplinary endeavor such as digital bioethics. I do not suggest excluding technical experts; my aim is rather to minimize purely implementation-related technical work.

The knowledge feature only emerged during the rapid prototyping phase and illustrates the importance of training and educating researchers new to digital methods. Such a research platform should not only be a tool to develop methods and carry out research projects, but also a means for researchers to acquire skills and expertise necessary for digital methods research.

Limitations

The development of new components can still cause delay for research projects and needs resources from both researchers and software developers. However, the platform can reduce software development work, as researchers can configure and reuse components outside of the specific circumstances for which they were originally developed. Furthermore, if multiple researchers work with the platform and develop methods with this modular paradigm, the methodological flexibility increases, and established computational means can be combined in new ways. Although maintenance and extension of the platform must be performed by technical experts, the application of digital methods in digital bioethics research can scale.

The prototype illustrates the potential of the implemented concept. However, more work is required to obtain to a fully operational research platform that can support a broad community of researchers. Further, I could not test the platform exhaustively owing to the limited number and availability of researchers working with digital methods in bioethics. For the same reason, I could not carry out comprehensive user research during the design phase. In such cases, the use of fictional personas based on limited assumptions, as applied in the platform development, is common practice. In addition, I was able to validate my assumptions and improve the design choices during the rapid prototyping phase at the end.

Conclusions

The platform prototype is a proof of concept, demonstrating how this approach might facilitate digital bioethics research by offering researchers easier access to digital tools and opportunities to expand their methods toolbox. Further research is needed to quantify this effect and to further improve the platform. In addition, substantial investment will be required to build, run, and maintain a production-ready open research platform, for which this prototype serves as a blueprint. While I built this platform to address issues encountered in digital bioethics research, it does support digital methods in general, which are not restricted to bioethics research. Digital methods

find applications in various research fields and, therefore, this platform and its concept are useful beyond empirical bioethics.

Acknowledgments

I thank Julia Amann and Joanna Sleigh for their collaboration and feedback on the platform prototype during the risk communication study, Alessandro Blasimme and Effy Vayena for the collaboration and discussions on earlier digital bioethics projects, and Effy Vayena for her input on this project and manuscript.

Abstract

Background: With the aging of populations worldwide, early detection of cognitive impairments has become a research and clinical priority, particularly to enable preventive intervention for dementia. Automated analysis of the drawing process has been studied as a promising means for lightweight, self-administered cognitive assessment. However, this approach has not been sufficiently tested for its applicability across populations.

Objective: The aim of this study was to evaluate the applicability of automated analysis of the drawing process for estimating global cognition in community-dwelling older adults across populations in different nations.

Methods: We collected drawing data with a digital tablet, along with Montreal Cognitive Assessment (MoCA) scores for assessment of global cognition, from 92 community-dwelling older adults in the United States and Japan. We automatically extracted 6 drawing features that characterize the drawing process in terms of the drawing speed, pauses between drawings, pen pressure, and pen inclinations. We then investigated the association between the drawing features and MoCA scores through correlation and machine learning-based regression analyses.

Results: We found that, with low MoCA scores, there tended to be higher variability in the drawing speed, a higher pause: drawing duration ratio, and lower variability in the pen's horizontal inclination in both the US and Japan data sets. A machine learning model that used drawing features to estimate MoCA scores demonstrated its capability to generalize from the US dataset to the Japan dataset ($R^2=0.35$; permutation test, $P<.001$).

Conclusions: This study presents initial empirical evidence of the capability of automated analysis of the drawing process as an estimator of global cognition that is applicable across populations. Our results suggest that such automated analysis may enable the development of a practical tool for international use in self-administered, automated cognitive assessment.

Introduction

With the aging of populations worldwide, early detection of cognitive impairments has become a research and clinical priority. In particular, early identification of prodromal dementia is essential for providing secondary prevention and disease-modifying treatments [1-4]. The cognitive screening tests most commonly used by clinicians are the Mini-Mental State Examination (MMSE) [5] and the Montreal Cognitive Assessment (MoCA) [6]. Both tests are designed to assess global cognition, and validated cutoff scores are used for detecting impairment [7,8]. One limitation of these tests is that they require administration by trained professionals. According to the World Alzheimer Report published in 2021 [1], 83% of clinicians reported that the COVID-19 pandemic has delayed access to cognitive screening tests. Consequently, self-administered, automated assessment may be more important in situations, like the current COVID-19 pandemic, that impose limitations on in-person evaluation in a clinical setting. Another limitation of these tests is related to issues with their use in multilingual populations, such as cross-linguistic artifacts in translation [1,9,10]. Recently, several nonlinguistic cognitive tests have been investigated to overcome the influence of language differences by mitigating the need for translation [11,12]. In sum, there is a clear need to develop a self-administered, automated assessment tool that can be used internationally, which would greatly increase the accessibility of screening in a variety of settings and populations. This would be particularly important for removing barriers to diagnosis and mitigating the gap between countries in the diagnostic coverage—the rate of diagnosis of dementia was estimated to be only 25% worldwide, with less than 10% in low- and middle-income countries [1].

Drawing ability is a promising means for developing such an automated cognitive assessment tool. Drawing tests have been widely used for screening cognitive impairments and dementia (eg, trail making [13] and clock drawing [14]), and automated analysis of the drawing process has shown that features characterizing the drawing process are sensitive to cognitive impairments and diagnoses of dementia [15-18]. For example, reduction in the drawing speed and increases in its variability, as well as increased pauses between drawing motions, have been reported as statistically significant features for assessment of impaired global cognition [19,20], as well as for detecting Alzheimer disease (AD) and mild cognitive impairment (MCI) [21-24]. Machine learning models based on these drawing features have succeeded in estimating measures of global cognition [25,26] and classifying AD, MCI, and control individuals [23-25,27]. However, there has been little evidence of the capability of automated analysis of the drawing process for assessment of cognitive performance across different populations, even though applicability across the intended

populations is a requirement for machine learning-based health care tools, including those for screening of dementia [1,28,29].

In this study, we evaluated the applicability of automated analysis of the drawing process for estimating global cognition in community-dwelling older adults across populations in different nations. Specifically, we collected drawing data with a digital tablet, along with MoCA scores for assessing global cognition, from community-dwelling older adults in the United States and Japan. We then investigated the associations between the MoCA scores and drawing features across the 2 data sets. Finally, we built a machine learning model that used the drawing features to estimate MoCA scores, and we evaluated the model's generalizability from the US data set to the Japan data set.

Methods

Ethical Review

The study was approved by the University of California San Diego Human Research Protections Program (HRPP; project number 170466) and the Ethics Committee of the University of Tsukuba Hospital (H29-065). All participants provided written consent to participate in the study after the procedures of the study had been fully explained.

Participants

The participants were community-dwelling older adults recruited in San Diego County, California and in Ibaraki prefecture, Japan. For the US data set, the participants were residents of the independent living sector of a continuing-care senior housing community and were recruited through short presentations using an HRPP-approved script and flyer. For the Japan data set, the participants were individuals recruited through local recruiting agencies or community advertisements in accordance with the approved protocol. Both data sets represented subsets of larger cohort studies [24,30]. The participant selection criteria were as follows: (1) English-speaking (for the United States) or Japanese-speaking (for Japan) individuals ≥ 65 years old, (2) completion of the MoCA, (3) no known diagnosis of dementia, and (4) no other diseases or disabilities that would interfere with the collection of drawing data.

Table 1 summarizes the participants' characteristics. We collected and analyzed drawing data and MoCA scores from a total of 92 community-dwelling older adults in the United States and Japan. The US data set included 55 participants aged 67-98 years (female: 39/55, 71%; age, mean 83.4, SD 6.9 years). The Japan data set included 37 participants aged 65-80 years (female: 19/37, 51%; age: mean 73.3, SD 4.5 years). Regarding the demographics, the proportion of female participants did not differ statistically between the 2 data sets ($\chi^2_1=3.63$, $P=.06$), while the age and years of education were higher in the US data set than in the Japan data set (age: $t_{90}=7.79$, $P<.001$; years of education: $t_{90}=5.25$, $P<.001$).

Table 1. Participants' characteristics (n=92).

Characteristics	United States (n=55)	Japan (n=37)	P value
Age (years), mean (SD)	83.4 (6.9)	73.3 (4.5)	<.001 ^a
Sex (female), n (%)	39 (71)	19 (51)	.06 ^b
Education (years), mean (SD)	16.3 (2.3)	13.8 (2.0)	<.001 ^a
Montreal Cognitive Assessment ^c , mean (SD)	24.4 (3.2)	24.4 (2.6)	.98 ^a
Trail Making Test part B time (seconds), mean (SD)	131.9 (65.1) ^d	96.9 (50.1) ^d	.008 ^a
Trail Making Test part B errors, mean (SD)	1.7 (2.5) ^d	0.9 (1.5) ^d	.07 ^a

^aCompared using 2-sided *t* tests.

^bCompared using a chi square test.

^cTotal possible score ranges from 0 to 30.

^dData were missing for 1 participant because of incomplete trials.

Data Analysis

All participants performed the Trail Making Test part B (TMT-B) [13] and MoCA. The TMT-B drawing data were collected using a Wacom Cintiq Pro 16 tablet (sampling rate: 180 Hz; drawing area size: 252 × 186 mm; pen pressure levels: 8192; pen inclination resolution: 1 degree) and custom Windows software that we developed. The software was written in the C# language and was used to capture raw drawing data from the tablet via the Wacom Wintab .NET library (version: 1.2). The raw data consisted of a time series of the pen tip's x- and y-coordinates, the pen pressure, the pen's horizontal and vertical inclinations, and the distance of the pen tip from the drawing surface. All data were captured at the tablet's sampling rate.

The TMT-B was selected as a representative cognitive task that involves drawing motions and is commonly used in clinical practice for screening AD and MCI [31,32]. It requires participants to draw lines that alternately connect a total of 25 numbers and letters in their respective sequences [13]. For the MoCA, we used the original paper-and-pencil version [6] for the US participants and its Japanese version [33] for the Japan participants. The total possible score on the MoCA ranges from 0 to 30, where lower scores indicate lower global cognition. Both TMT-B and the MoCA were administered by neuropsychologists or trained study staff who were blind to the study hypothesis during data collection. The US data set was collected between May 2019 and January 2020. The Japan data set was collected between December 2018 and May 2019.

Next, we extracted drawing features from the drawing data and examined their associations with the MoCA scores. Specifically, we investigated the following 6 automatically extracted drawing features: the drawing speed and its variability, the pressure variability, the variabilities of the pen's horizontal and vertical inclinations, and the pause:drawing duration ratio. These features were selected because they have been reported as significant indicators of changes in cognitive or motor functions [15,16,24,34]. The drawing speed represented the speed of the pen tip on the surface during drawing motions. The drawing speed variability was calculated using the coefficient of variation to remove the influence of the absolute value, as the drawing speed itself was also a feature. For the pressure variability, we

used the median absolute deviation, which is more robust against outliers than the standard deviation. In contrast, the variabilities of the pen's horizontal and vertical inclinations were calculated using standard deviations. The pause:drawing duration ratio was defined as the ratio of the total duration of pauses between drawing motions (ie, between strokes and within a stroke) and the total duration of drawing motions on the surface. Pauses within a stroke were detected when the pen tip remained inside a 0.25-mm radius on the drawing surface for more than 100 milliseconds.

To investigate the associations of each drawing feature with the MoCA scores, Pearson correlation coefficients were computed after controlling for the age, sex, and years of education for the entire data set and for the US and Japan data sets separately. The 3 sociodemographic variables were considered as covariates, because they have been suggested to affect performance on cognitive screening tests, including the MoCA [35]. The following Python 3.8 libraries were used for the correlation analysis: pandas (version 1.2.4), NumPy (version 1.20.1), SciPy (version 1.6.2), and pingouin (version 0.4.0).

We also developed a supervised machine learning model that used drawing features to estimate MoCA scores, and we then evaluated the model's applicability across data sets. The analysis workflow is illustrated in Figure 1A. Specifically, the model was trained on the US data set and tested on the Japan data set. For the machine learning model, we used the random forest algorithm to capture nonlinear relationships, given that nonlinear interactions between drawing features and cognitive impairments were observed in previous studies [23,24]. The random forest hyperparameters in this study were as follows: search range of 2, 3, and 4 for the maximum tree depth; 2, 3, 4, and 6 for the maximum number of features; 1.0, 0.75, and 0.5 for the proportion of the maximum number of samples to train each base regressor; and 2, 3, 4, and 5 for the minimum number of samples required at a leaf node. The number of trees was set to 500, and all other parameters were kept at their default values. The hyperparameters were tuned through 10-fold cross-validation within the training data set. We statistically evaluated the observed performance through permutation testing (1000 iterations) by randomizing the MoCA scores. To better interpret the results, the importance of each feature in the

resultant model was also evaluated using the Shapley Additive Explanations (SHAP) method [36]. Specifically, we compared the mean absolute SHAP values of each feature. The following

Python 3.8 libraries were used to perform the machine learning analysis: scikit-learn (version 0.23.2) and SHAP (version 0.40.0).

Figure 1. Study overview: (A) workflow of the automated analysis in which drawing data were collected with a digitizing tablet and pen, 6 drawing features were extracted from the drawing data, and a regression model for estimating Montreal Cognitive Assessment (MoCA) scores was trained on the US data set and tested on the Japan data set; (B) plot of the drawing speed variability with respect to the MoCA score for the US and Japan data sets, in which each point represents 1 participant and the solid line represents the regression line for the combined data set; (C) plot of the estimated and actual MoCA scores in the Japan data set, in which each point represents 1 participant and the solid line represents the regression line; (D) comparison of the features' importance with standard deviations, as assessed via the mean absolute Shapley Additive Explanations (SHAP) values.

Results

The mean MoCA score was 24.4 (SD 3.0; range for participants: 16-30; possible range: 0-30), and the scores did not differ statistically between the 2 data sets ($t_{90}=0.02$, $P=.99$; Table 1). For the collection of drawing data, each session took an average of 119.7 (SD 64.6) seconds per participant. The mean TMT-B time and number of errors were 117.9 (SD 61.7) seconds and 1.4 (SD 2.2), respectively. The TMT-B time was longer in the US data set ($t_{88}=2.72$, $P=.008$), while the number of errors did not differ statistically between the 2 data sets ($t_{88}=1.82$, $P=.07$). Two participants (US: 1; Japan: 1) could not complete the TMT-B trial. To include them in the analysis, we used features extracted from their partial drawing data.

For the correlation analysis between the MoCA scores and each drawing feature in the entire data set, we found that 4 of the 6 features were significantly associated after controlling for age, sex, and years of education (absolute Pearson $r=0.33-0.49$, $P\leq.002$; see Figure 1B for a correlation example and Table 2

for the full list). With lower MoCA scores, there tended to be higher variability in the drawing speed and pen pressure, a higher pause:drawing duration ratio, and lower variability in the pen's horizontal inclination. As listed in Table 2, these tendencies were also observed when the 2 data sets were each analyzed separately. After correction for multiple comparisons, all the statistically significant correlations remained for the entire data set and the Japan data set (Benjamini-Hochberg adjusted $P<.05$), whereas those for the US data set lost significance (Benjamini-Hochberg adjusted $P>.05$).

The random forest model trained on the US data set could estimate MoCA scores from drawing features for the Japan data set with an R^2 of 0.35 (Pearson r of 0.61, mean absolute error of 1.75, and root-mean-square error of 2.12; permutation test, $P<.001$; Figure 1C). Regarding the importance of each feature in the model, as indicated by the SHAP values, the variability of the pen's horizontal inclination had the highest importance, followed by the pressure variability and the drawing speed variability (Figure 1D).

Table 2. Partial correlations between drawing features and Montreal Cognitive Assessment (MoCA) scores after controlling for age, sex, and years of education.

Drawing features	All (n=92)		United States (n=55)		Japan (n=37)	
	Pearson <i>r</i> (95% CI)	<i>P</i> value	Pearson <i>r</i> (95% CI)	<i>P</i> value	Pearson <i>r</i> (95% CI)	<i>P</i> value
Drawing speed	0.08 (-0.14 to 0.28)	.48	0.09 (-0.19 to 0.35)	.53	0.14 (-0.21 to 0.45)	.44
Drawing speed variability	-0.42 (-0.58 to -0.23)	<.001	-0.33 (-0.55 to -0.06)	.02	-0.58 (-0.77 to -0.31)	<.001
Pause:drawing duration ratio	-0.49 (-0.63 to -0.31)	<.001	-0.32 (-0.55 to -0.06)	.02	-0.73 (-0.86 to -0.53)	<.001
Pressure variability	-0.34 (-0.51 to -0.14)	.001	-0.26 (-0.49 to 0.02)	.07	-0.49 (-0.71 to -0.18)	.003
Variability of pen's horizontal inclination	0.33 (0.13 to 0.50)	.002	0.30 (0.03 to 0.53)	.03	0.38 (0.04 to 0.63)	.03
Variability of pen's vertical inclination	0.17 (-0.04 to 0.37)	.11	0.26 (-0.01 to 0.50)	.06	0.16 (-0.19 to 0.47)	.37

Discussion

Principal Findings

We collected drawing data from 92 community-dwelling older adults in the United States and Japan, and we investigated the associations between features characterizing the drawing process and global cognition as assessed by MoCA. We obtained 2 main findings, as follows. First, we found drawing features that showed consistent trends with respect to the changes in MoCA scores across the US and Japan data sets. Specifically, with low MoCA scores, there tended to be higher variability in the drawing speed, a higher pause:drawing duration ratio, and lower variability in the pen's horizontal inclination. Our second finding was that the automated machine learning model trained on the drawing data in the US data set could estimate the MoCA scores for the Japan data set with an R^2 of 0.35, particularly by leveraging variability-related features. We used drawing data from the TMT-B task in this study, but other types of drawing tasks may have a similar capability. For example, a previous study showed that MoCA scores could be estimated by using pause- and speed-based features from a clock drawing task [26], although the method's applicability across populations was not evaluated. The use of 2 or more tasks will be a promising area of future research for more reliable estimation of global cognition.

Regarding the correlations of drawing features with MoCA scores across the US and Japan data sets, the correlations persisted even after controlling for age, sex, and years of education. In post hoc power analysis, the power exceeded 0.90 with a significance level of .05 (2-sided). The trends were consistent with those observed in previous studies with individuals with impaired global cognition [19,20] or patients with AD or MCI [21-24]. One of our contributions lies in demonstrating consistent trends between drawing features and clinical cognitive scores across 2 different populations by using the same protocol. It is especially notable that the pause:drawing duration ratio and the drawing speed variability have been reported as representative features for use in AD or MCI screening models based on automated analysis of the drawing process [23,24]. To our knowledge, the models in those previous studies were not tested for their applicability across different populations, but our results suggest that these drawing features may help with the application of screening models across populations for international use.

We have presented preliminary evidence suggesting that automated analysis of the drawing process for estimation of global cognition can be applied across populations. We trained the machine learning model on drawing data in the US data set, and we then evaluated its performance on unseen drawing data in the Japan data set. In this context, the model could estimate MoCA scores with an R^2 of 0.35 (Pearson r of 0.61 and root-mean-square error of 2.12). Previous studies investigated models that used a single data set to estimate global cognition from the characteristics of drawing or other types of behaviors such as speech. The performance results for those models included a Pearson correlation coefficient of 0.55 for MoCA on a model using drawing features [26] and a root-mean-square error of 3.74 for MMSE on the best model using speech features in a competition [37]. Our model outperformed those recent results, although there are notable methodological differences in terms of the evaluation method and the sample size, for example. Our model's improved performance might have derived from the use of variability-related features, given that they were ranked as the most important features in our model. Variability-related features in drawing have recently been suggested as a potential marker for motor control deterioration in dementia [19,38,39], but they have rarely been used for estimating cognitive function, and they have not been tested across populations. Our results thus suggest that variability-related features in drawing may be a key behavioral marker for automatic assessment of global cognition across different populations.

With the aging of populations worldwide, there is a growing interest in using digital technology to assess cognitive function in nonclinical settings like the home for early detection of dementia [1]. Examples of such research include approaches using computerized cognitive tests [29,40-42] and using behavioral data such as drawing, speech, and gait data [24,32,43-45]. In either approach, a major challenge is to make the tool suitable for multinational and multilingual populations [1]. In this context, our results suggest that automated analysis of the drawing process may offer a promising approach for developing such a tool for international use.

Furthermore, the approach using behavioral data is expected to support future efforts toward the development of continuous, passive monitoring tools for early detection of dementia from data that can be collected in everyday life [43,45]. For example, multiple studies have demonstrated the feasibility of detecting

cognitive impairments by using daily walking behavior collected from accelerometer sensors in a free-living setting [46-48] and by using daily conversational speech data [49-52]. To our knowledge, no study has investigated the associations of cognitive impairments with daily drawing data that are collected passively in a free-living setting. However, drawing may be a promising behavioral modality for reliable estimation of cognitive impairments: It is a common activity in everyday life, and drawing data can be easily and robustly collected with a commercial-grade device.

Regarding the device used for drawing data collection, previous studies have shown the usefulness of a range of devices, including a mobile tablet with a stylus [53-57], a smart pad [58], and a digital pen [23,26,38]; accordingly, our findings may be applicable to those devices as well. All such devices commonly allow capture of x-and y-coordinates and pressure data at similar sampling rates, and previous studies reported similar associations of pause-, speed-, and pressure-based features with cognitive measures. In a future study, as pen inclination data are not always available, we will need to examine whether a combination of other available data can achieve performance comparable to that of our model. Furthermore, the variability of the device placement (eg, holding the tablet with the nondominant hand) can affect the drawing performance in free-living settings. We will thus need further research in situ for the development of realistic applications.

Limitations

This study had several limitations. First, it was limited in terms of the numbers of participants, drawing tasks, and data sets.

Our findings were based on drawing data from a single task, and the applicability to other types of drawing data thus remains unexplored. In addition, the international applicability of our model was only evaluated between 2 data sets, and the details of how the model performance is influenced by cultural differences have not been thoroughly investigated. Together, our findings have yet to be confirmed with larger samples that provide cross-cultural insights. Second, we did not investigate the participants' sensory and physical functions (eg, eyesight, grip strength), even though those functions might affect drawing performance. Moreover, other residual confounders might exist. Third, the drawing data were collected in a laboratory setting with a tester; accordingly, a future study will need to establish the validity of fully self-administered tasks. Finally, further research will also be needed to obtain a mechanistic understanding of how drawing features relate to the neural changes underlying cognitive impairments.

Conclusions

In summary, we have presented empirical evidence of the capability of automated analysis of the drawing process as an estimator of global cognition that is applicable across populations. Although no causality could be inferred from our results with cross-sectional data, the results nevertheless suggest that automated analysis of the drawing process could be a practical tool for international use in automated cognitive assessment. Consequently, this approach may help lower the barrier to early detection of cognitive impairments in a variety of settings and populations.

Abstract

Background: Inadequate adherence to prescribed immunosuppressive medication regimens among kidney transplant recipients is common, yet interventions are needed to support patients in sustaining adequate adherence to prescribed regimens and achieving optimal transplant outcomes.

Objective: We examined the preliminary fidelity of a transplant center-based, multifaceted adherence monitoring strategy known as TAKE IT.

Methods: The TAKE IT strategy includes: (1) routine, online, monthly patient self-report adherence assessments; (2) care alerts directed to nurses; (3) quarterly reports monitoring tacrolimus values and adherence trends; (4) support tools tailored to specific adherence concerns. A 2-arm, patient-randomized trial is underway at two large transplant centers (N=449). To evaluate the initial fidelity of TAKE IT, we investigated patient uptake of monthly adherence assessments during the course of a 3-month period, whether any disparities emerged, and the nature of any reported adherence concerns.

Results: Among 202 patients randomized and exposed to TAKE IT for 3-months or more, 81% (164/202) completed an adherence assessment, 73% (148/202) completed at least two, and 57% (116/202) completed all monthly assessments. Overall, 50% (82/164) of kidney transplant recipients reported at least one adherence concern over the 3-month assessment period. The most common barriers were classified as regimen-related (eg, regimen complexity), cognitive (eg, forgetfulness), and medical (eg, side effects). Higher-income participants were more likely to complete all surveys compared to lower-income participants ($P=.01$).

Conclusions: TAKE IT demonstrated 81% (164/202) completion of an adherence assessment, 73% (148/202) completion of at least two, and 57% (116/202) completion of all monthly assessments during this brief, initial observation period. Among those that did respond to the online assessments, the majority demonstrated sustained engagement. Additional monitoring modalities could also be offered to meet patient preferences to ensure all patients' medication use can be properly monitored.

Trial Registration: ClinicalTrials.gov NCT03104868; <https://clinicaltrials.gov/ct2/show/NCT03104868>

KEYWORDS

kidney transplantation; medication adherence; fidelity; digital health; patient portal

Introduction

Kidney transplant (KT) recipients require chronic immunosuppression to counteract graft rejection. However, inadequate medication adherence is a major cause of organ (graft) failure, with rates up to 48% post-transplant and even higher among at-risk patients (eg, racial/ethnic minorities, older adults, and those with poor health literacy) [1,2]. Poor adherence to the immunosuppression regimen is particularly high in KT patients (approximately 35%) compared to other organ transplant recipients [3-5]. Though current literature has indicated interventions, such as support tools (eg, reminder systems), monitoring strategies, and continuing education, to improve adherence, studies have largely been underpowered to provide conclusive evidence of their effectiveness [6-13]. Furthermore, medication adherence may be variably evaluated as part of post-transplant care. While immune suppression levels are measured as trough levels and provide a possible proxy indication of adherence specific to immunosuppression regimens, patient-reported assessments of any adherence concerns to the entire regimen one may be taking are not routinely embedded in clinical practice. Previous research has also found that medical staff has difficulty identifying patient adherence problems and factors driving suboptimal adherence [14]. Due to the complexity of factors that influence medication use, which may evolve over time, there has been increasing interest in finding ways to routinely monitor patients' medication experiences and any potential barriers.

Digital health solutions, in particular, have been investigated as potential methods to surveil and address medication adherence [11,15,16]. There has been promising preliminary results and positive attitudes towards mobile health or web-based interventions to support regimen use, although further research is still needed to best understand how to integrate technologies into clinical workflows in an acceptable manner, both for patients and their care teams [17,18].

In 2017, the Transplant Regimen Adherence for Kidney recipients by Engaging Information Technologies, also known as TAKE IT, was launched to address inadequate regimen adherence among KT patients. The TAKE IT trial aims to address patient engagement and self-management with all prescribed medication regimens, not limited to immunosuppressants, by leveraging a web-based patient portal and a transplant centers' electronic health record (EHR) to educate patients on their medication regimen, assist patients in organizing their daily prescription schedule efficiently, routinely monitor medication use, and provide care alerts to transplant center clinical staff when medication concerns are detected to mobilize the care and provide a response tailored to the specific concerns. It should also be mentioned that a prior trial, conducted in Canada and also known as TAKE IT, tested the effectiveness of an intervention to promote medication adherence among adolescent kidney recipients [11].

At the time of writing, TAKE IT is underway as a pragmatic, randomized clinical trial to test its effectiveness, compared to usual care, among diverse KT recipients. Primary outcomes related to medication-taking behaviors and regimen adherence, collected at 6 and 13 months, have now been completed. While evaluations of intervention effectiveness have not yet been performed, in the meantime, we sought, as planned, to examine the initial fidelity of the intervention's ability to engage KT recipients beyond the point of care through the use of monthly invitations to complete brief portal assessments that allowed them to report on their regimen adherence and any specific concerns.

As some patients may lack the technological proficiency to interact with the online portal or may not be comfortable sharing details on their medication-taking behaviors with their healthcare providers, this investigation would inform which patients may not be adequately monitored in this manner. Thus, alternative methods may need to be offered by transplant centers.

Methods

Patients

The TAKE IT trial is a 2-arm, patient-randomized controlled trial conducted at two large tertiary care hospitals (Northwestern University and Mayo Clinic), which have a high volume of KT recipients annually. Patients within 5 weeks to 2 years post-transplant were recruited and were followed for 2 years. In-person baseline interviews were conducted, with telephone interviews given 6 weeks and 6 months post-baseline and in-person interviews at 12 months and 18 months post-baseline.

Study Population

KT patients were eligible if they were 21 years of age or older, within 5 weeks to 24 months of KT, English-speaking, primarily responsible for administering their own medication, owned a cell phone and were comfortable receiving text messages, and had access and proficiency using the internet at home. This time interval of KT eligibility (ie, 5 weeks to 24 months post-transplant) was determined by prior studies indicating that adherence issues persist at different time points post-transplant, including early nonadherence, whether intentional or unintentional, due to regimen complexity, side effects, and health literacy [19-21]. Patients were excluded if they had severe, uncorrectable vision, hearing impairments, or cognitive impairments. For the purpose of this paper, fidelity data from patients in the intervention arm only were investigated.

Intervention

Eligible participants were randomized to either intervention (TAKE IT) or usual care. The TAKE IT intervention is multifaceted and leverages a transplant center's existing resources, including a routine monthly adherence assessment that requests patients to periodically self-report on their medication use. While self-reports of medication use and

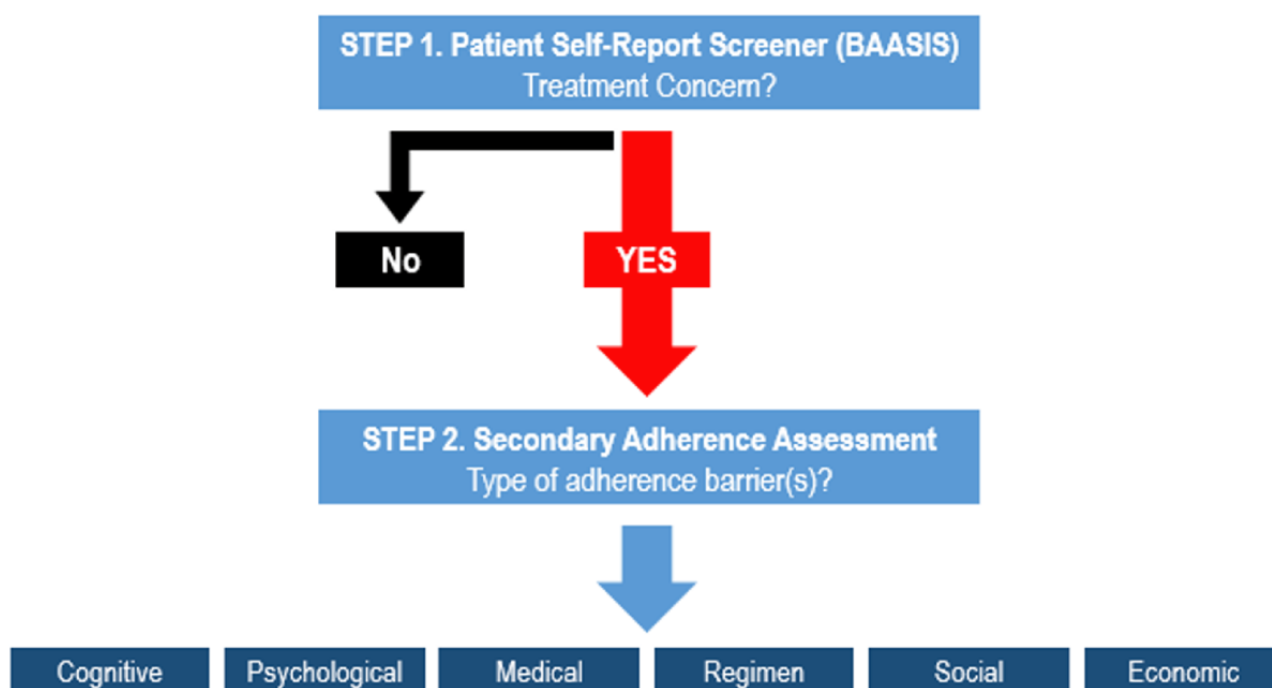

adherence may be biased due to socially desirable responses, more objective measures would be cost-prohibitive for routine use. Further, timely access to pharmacy fill data has also been problematic for most health systems and can also be inaccurate. Although this analysis will focus on evaluating the fidelity of TAKE IT's monthly adherence assessments that request patients to periodically report on their medication use, the intervention strategy also includes additional components: (1) automated care alert notifications via the EHR identifying adherence-related problems to the transplant center nurse coordinator, (2) quarterly adherence reports that automatically calculate patient whole blood tacrolimus levels for transplant nurse coordinators, and (3) standardized protocols for mobilization of appropriate clinicians and staff for appropriate, tailored clinical support of existing transplant center tools to directly target adherence-related concerns identified by the results of routine TAKE IT adherence assessment. Specifically, if an adherence concern were to be identified, the appropriate care team member (eg, nurse, pharmacist, social worker, psychologist, etc.) would be expected to respond. Usual care refers to the normal standard clinical practices in place at either site, immediately post-transplant.

Patients in the TAKE IT intervention report their medication use on a monthly basis via the patient portal. This enables a continuous link between patients and the transplant center beyond routine in-person visits. The monthly, patient-reported adherence assessment includes a two-step approach to first determine a KT recipients' regimen adherence status (adequate vs. inadequate). For this first step, we utilized the validated Basel Assessment of Adherence with Immunosuppressive medication Scales (BAASIS) instrument and a generated coefficient of variance from their last consecutive set of three tacrolimus levels. If patients self-report any adherence concerns

via the BAASIS, they then complete a brief survey of items that capture the more specific nature of the adherence barriers. During this second step, a number of brief assessments seek to "phenotype" the presenting barrier(s) to further inform a transplant center's response and deployment of resources. Thus, the monthly survey not only identifies patients at risk of inadequate adherence but also categorizes the nature of adherence concerns into the following: cognitive, psychological, medical, regimen, social, and economic (Figure 1).

Cognitive barriers include forgetfulness, memory issues, and difficulties concentrating and staying organized. Psychological barriers include low mood (eg, feeling down, depressed, hopeless) and little interest or pleasure in doing things. Medical barriers include side effects and self-reported overall health. Regimen barriers include confidence in taking medication as instructed, the complexity of regimen, missing medications, and taking medications earlier or later than instructed. Social barriers include issues around lack of support from family or healthcare providers. And finally, economic issues included issues around the cost of medications or refills. While not exhaustive, monthly survey items were taken from previously validated measures across these six categories, including self-reported assessments of cognitive complaints (eg, Brief Test of Adult Cognition by Telephone), depression (eg, Patient-Reported Outcomes Measurement Information System Depression subscale), regimen complexity (eg, Medication Regimen Complexity Index), unmet social needs (eg, Tangible Support Survey), and medication trade-offs, a survey assessing difficulties with medication affordability [22-28]. Given the potential risks of inadequate adherence, the study team defined the presence of a "concern" if participants endorsed any single item within the adherence assessment category.

Figure 1. Flowchart of TAKE IT adherence assessment.

Procedure

KT patients were initially screened at both sites. Eligible patients were identified through EHRs. Participants who were eligible and interested in the study were scheduled for a baseline interview around their upcoming clinic visit, where applicable, with written consent obtained at the beginning of baseline interviews. At each site, enrolled patients were randomized by a 1:1 scheme to intervention (TAKE IT) or usual care. Patients complete the baseline interview at the transplant clinic in person. Starting 1-week post-baseline, TAKE IT participants complete the monthly, online, two-step adherence assessment. Any adherence concerns flagged during the monthly assessment will be included in a lab report that is sent to a designated clinic contact at each site immediately after the assessment is submitted. The report contains the patient's identifying information, the nature of the adherence concern reported, and a recommendation for follow-up. The study was conducted in accordance with the approved IRB protocol (STU00204465).

Measurement

To evaluate the initial fidelity of the TAKE IT strategy, we investigated what proportion of participants in the intervention arm completed online adherence assessments and described the prevalence and nature of adherence concerns to date. We restricted the sample for this analysis to only those participants who had received at least 3 consecutive monthly portal surveys, as this would allow us to examine their willingness to repeatedly complete the surveys. Specifically, survey completion over a 3-month timeline was first examined by the number of portal surveys completed (0 to 3 surveys) and then coded as an ordinal variable with 3 levels: 0 surveys completed, 1 or 2 surveys completed, and all surveys completed. The outcome of adherence concerns was categorized as a binary variable (yes/no to any adherence concern) per each of the six categories. The average number of adherence concerns identified from all surveys and the number of participants who flagged for more than two adherence concerns during any survey were also examined.

To assess any demographic disparities between participants across survey completion rates, patient characteristics were evaluated through a sociodemographic/health questionnaire. Age, days since transplant, and patient activation (as measured by the Consumer Health Activation Index or CHAI) were assessed as continuous variables. Gender was assessed as a binary variable (male or female). Health literacy was measured through the Newest Vital Sign and coded as a binary variable (inadequate or adequate). Global health was coded as a categorical variable with four ordinal levels: excellent, very good, good, and fair/poor. Ethnicity (ie, Hispanic) was coded as a binary variable (yes or no). Race was assessed as a three-category variable (White/Caucasian, Black/African American, and other). Education was coded as a three-category variable (less than college, some college or technical school, and college graduate). Income was also coded as a three-category variable (<US \$30,000, US \$30,000-US \$49,999, and >US \$50,000).

Analysis Plan

Statistical analysis was conducted using RStudio (version 3.6.1; R Core Team). Appropriate descriptive statistics (eg, percentage, frequency, and median) were performed on all patient variables. Bivariate analysis was conducted to determine if there were any statistically significant demographic disparities between survey completion groups within the intervention arm. For categorical variables, data were analyzed using chi-square tests or Fisher exact test when expected cell counts were less than 5. For continuous variables (ie, age, CHAI scaled, and days since transplant), normality was assessed using the Shapiro test. No continuous variable was normally distributed; thus, bivariate analysis was conducted via Kruskal-Wallis, a nonparametric test that compares medians.

Results

Overview

Of the 449 participants enrolled in the TAKE IT trial, 224 (49.9%) participants were randomized to the intervention arm and analyzed for this investigation. Sociodemographic and clinical characteristics of this subsample are presented in Table S1 in [Multimedia Appendix 1](#). Overall, the median age of intervention participants was 53 years (range 21-76), 58.4% (129/221) were male, and 19.2% (43/224) were African American. The median time since transplantation for these KT recipients was less than a year (202 days, range 23-1,091).

The majority of recipients (148/224, 66.1%) completed the initial online adherence assessment; there were no significant differences between participants who completed or did not complete the initial assessment in age, gender, race, or time since transplantation. However, participants who did not complete the initial assessment had significantly lower education ($P=.02$) and household income ($P=.006$; Table S1 [Multimedia Appendix 1](#)). Among those who did complete it, 34.6% (56/162) had one or more adherence concerns. The most common barriers were classified as regimen-related (25/56, 44.6%), cognitive (15/56, 26.8%), medical (11/56, 19.6%), and psychological (9/56, 16.1%).

Repeat Completion of Monthly Portal Assessments

We investigated repeat completion among 202 (90.2%) participants who had exposure to the intervention for three months or longer and thus had the chance to complete the initial online adherence assessment and 3-monthly follow-up surveys postbaseline. Intervention participants who had not been in the study for at least 3 months (22/224, 9.8%) were excluded from the analysis. Table S1 in [Multimedia Appendix 1](#) provides sociodemographic characteristics of intervention patients exposed for three months or longer, stratified by survey completion. Overall, 81.2% (164/202) completed at least one assessment, and 73.3% (148/202) completed at least two assessments. Most (116/202, 57.4%) participants did complete all three surveys. There were no significant differences in age ($P=.49$), gender ($P=.22$), race ($P=.50$), education ($P=.07$), time since transplant ($P=.94$), health activation ($P=.14$), or health literacy ($P=.30$) between participants who completed no surveys, 1-2 surveys, or all surveys. Overall, participants who completed

all surveys were more likely to have a higher income ($P=.01$) than participants who completed none or just one or two surveys. **Figure 2** provides a flowchart illustrating the participants' detailed completion of each of the monthly adherence assessments in time order.

Half of the intervention participants were at risk for inadequate adherence at some point over the three-month assessment period (**Table 1**). Among participants who completed 1 survey (16/202, 7.9%) versus 2 surveys (32/202, 15.8%) versus all 3 surveys (116/202, 57.4%), the proportion of those flagging for an adherence concern was 43.8% (7/16), 59.4% (19/32), and 48.3% (56/116), respectively. Among all of those who were identified as at risk for inadequate adherence, the average number of

adherence concerns was 1.13, with a range of 1 to 5 adherence concerns. There were 26 (31.7%) participants who flagged for 2 or more adherence concerns. The most commonly reported barriers were cognitive (42/93, 45.2%), regimen-related (26/93, 28.0%), and medical (25/93, 26.9%) due to overall health or medication side effects).

The median time for participants who were sent and completed survey 1 (162/202, 80.2%) to open and return the assessment was 0.88 days (**Table 2**). A total of 51.9% (84/162) of participants completed the survey in less than 1 day, and among these recipients, the median time to return the assessment was 2.86 hours.

Figure 2. Flowchart of participant completion of TAKE IT adherence assessment.

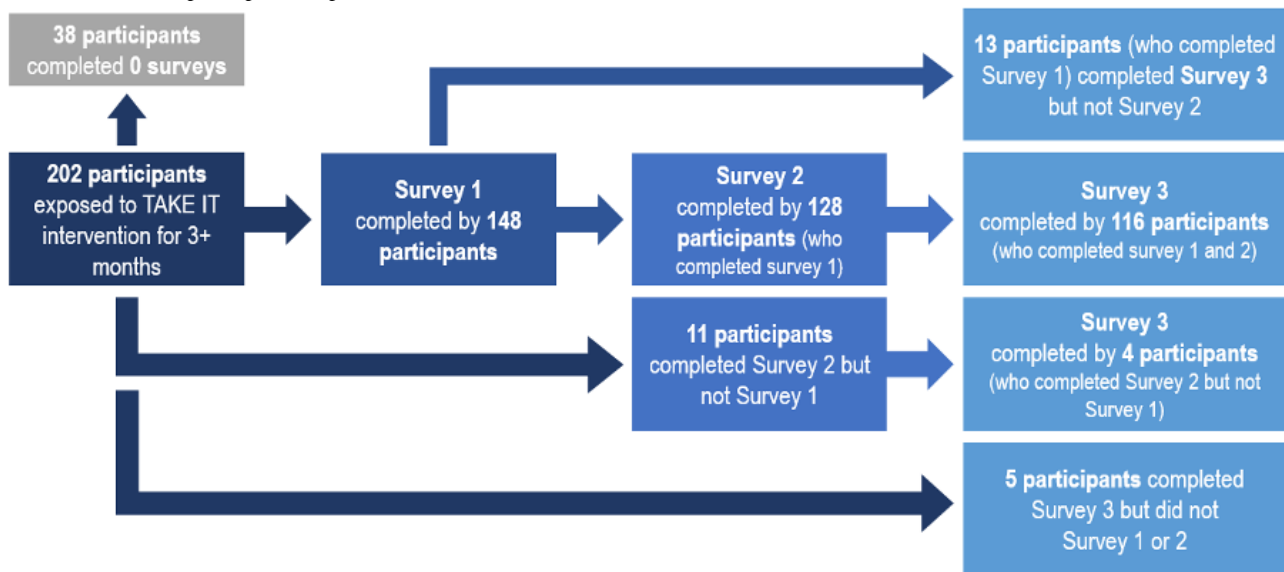

Table 1. Nature of adherence concerns (N=164).^a

Participant characteristics	n (%)
Any adherence concern	
No	82 (50)
Yes	82 (50)
Flagged for 2+ concerns	26 (31.7)
Total adherence concerns	93 (56.7)
Adherence concern type	
Cognitive	42 (45.2)
Regimen	26 (28.0)
Medical	25 (26.9)
Psych	16 (17.2)
Economic	5 (5.4)
Social	4 (4.3)

Table 2. Time between sending survey 1 and completing survey 1 (N=162).

Survey 1 characteristics	Values
Time to completion (days), mean (SD)	2.52 (3.55)
Time to completion (days), median (range)	0.88 (1.22 mins-23.06 days)
Participants completing survey in > 1 day, n(%)	84 (51.9%)
Time to completion (hours), mean (SD)	4.78 (5.86)
Time to completion (days), median (range)	2.86 (1.22 mins-23.17 hrs)

Discussion

Principal Findings

In this diverse sample of KT recipients, there was albeit modest, while relatively high uptake to initially responding to the monthly adherence assessments using the patient portal, yet sustained engagement over the 3-month period among those who did respond with the monthly portal assessment. Of the 202 intervention participants who had the chance to complete the initial online adherence assessment and three monthly follow-up surveys postbaseline, most (n=164/202, 81%) completed at least one assessment, and 57% (116/202) completed all assessments. Further, the flowchart of participants' completion of monthly adherence assessments (Figure 2) illustrated KT patients who demonstrated intermittent engagement (eg, did not complete survey 1 but completed surveys 2 and 3) versus sustained engagement to all monthly assessments. Though this may be due to the study's limitation of a 3-month analysis, this may also point to challenges in survey complexity, patient indifference to completing monthly surveys, or more specific patient-level barriers in survey completion, such as time or forgetfulness. The results of monthly assessment engagement may also suggest that, perhaps, the frequency of assessments may benefit from shifting from monthly surveys to bimonthly or quarterly surveys. In technology-based intervention studies targeting medication adherence in transplant recipients, McGillicuddy et al [29] and Taber et al [30] managed to receive 91% and 98% retention, respectively; however, the McGillicuddy intervention engagement was passive, and both studies were small pilot samples of less than 68 participants in the intervention arm. Trends in sustained engagement to the TAKE IT monthly adherence assessments may be better clarified in future analyses as participants' exposure to the intervention increases.

In addition to high retention, over half of participants (84/162, 51.9%) who were sent the first survey completed the survey in less than one day after the survey was sent to them, suggesting that the monthly surveys may not pose a huge burden on patients. Furthermore, medication adherence concerns assessed by TAKE IT's monthly assessments align with results from a recent study examining barriers to immunosuppressant medication adherence in KT recipients [31]. This same study categorized regimen-specific barriers largely as delaying doses (70/156, 45%) and skipping doses (40/156, 25%), often from daily routine changes or other factors (eg, financial issues). Our study demonstrated a high prevalence of inadequate adherence (82/164, 50%), with adherence barriers targeted around

cognitive, regimen-related, and medical issues (eg, side effects or overall health issues).

We also sought to investigate any differences in the receptiveness of TAKE IT intervention by patient factors. Only lower income was associated with statistically significantly lower uptake in TAKE IT assessments. While the reasons are unclear, it could be speculated that lower uptake of the monthly assessments might be an access issue. If a patient's internet access is primarily through their mobile phone use, it will put participants without a laptop or desktop at a disadvantage. The significance of lower income on assessment uptake may also point to psychosocial trade-offs. For example, a low-income patient may experience more psychosocial stress (eg, working multiple jobs) and not have time to prioritize surveys.

Though low income was the only significant factor in survey completion, it should be noted that non-significant differences were observed in other factors, including health activation, health literacy, global health, ethnicity (ie, Hispanic), and education. Again, reasons are unclear if these point to an access or use issue, but it could be that patients who are not as activated (or motivated) or who have greater difficulty understanding health information (eg, prescription information) because they have lower health literacy or lower education may not be as responsive to monthly adherence surveys. Future studies including a larger transplant sample may be better powered to investigate the impact of health activation, health literacy, and education on study assessment completion.

As of now, there were no significant differences overall in participant characteristics related to known risk factors for medication adherence (eg, age, time since transplant, race). These results are promising and possibly suggest that the TAKE IT intervention might not create further disparities and may provide equitable solutions across patient groups; however, further research should examine whether this strategy can, in fact, work among diverse populations.

Limitations

There were several other limitations of the TAKE IT fidelity analysis. First, analysis was limited to an intervention follow-up of 3 months. Currently, we are unable to assess if the TAKE IT strategy is impactful on changing adherence behaviors or outcomes in the long-term, as active follow-up is ongoing; however, future analyses may elucidate long-term outcomes. Second, TAKE IT assessments are optimized for desktop and laptop use rather than mobile phones. As mentioned above, this potentially poses an access barrier for participants who do not have easy or reliable access to a desktop or laptop. Third, study

participants were recruited from two large tertiary care hospitals, and fourth, intervention excludes participants who do not speak English—both of which limit the generalizability of findings.

Conclusions

Overall, the TAKE IT trial demonstrates 81% (164/202) completion of an adherence assessment, 73% (148/202) completion of at least two, and 57% (116/202) completion of all monthly assessments among diverse patient groups, notably across age, time since transplant, health literacy, and race—a potential benefit in monitoring adherence behaviors among KT recipients and engaging transplant center staff to address at-risk patients. Assessments of medication adherence and potential root causes of poor adherence, including psychological and social determinants, can be captured beyond the point of care via brief, routine online surveys via an EHR patient portal. Such

routine assessments have the potential for earlier detection of adherence concerns between clinic visits without adding to already busy clinical workloads. Future work should focus on deploying adherence support tools tailored to specific adherence concerns and addressing possible disparities in access to this technology-enabled strategy. The goal would be to ensure that both responding to online assessments and deploying support tools can be integrated into existing clinic workflows without burdening clinical staff. Furthermore, ensuring monthly surveys are mobile phone friendly and assessing TAKE IT among non-English speaking populations to clarify why TAKE IT may not be as acceptable to Hispanic populations would be important next steps to improve uptake. Additional work should also include qualitative research for understanding why participants do not complete surveys and evaluating clinicians' perspectives if a patient's nonresponse should be a clinical response in itself.

Acknowledgments

This study was funded by the National Institute of Diabetes and Digestive and Kidney Diseases (grant R01DK110172).

Authors' Contributions

SH, LMC, SSN, SCB, MS, PPR, DPL, and MSW contributed to the study design, statistical analysis, and editing of the paper. AHW and PZ contributed to the data acquisition, performance of the research, and editing of the paper. ESY contributed to the statistical analysis and the writing and editing of the paper. Each author contributed to important intellectual content during manuscript drafting or revision, accepts personal accountability for the author's own contributions, and agrees to ensure that questions pertaining to the accuracy or integrity of any portion of the work are appropriately investigated and resolved.

Conflicts of Interest

SCB reports grants from the National Institutes of Health (NIH), Merck, RRF Foundation for Aging, Pfizer, Gordon, and Betty Moore Foundation, Lundbeck, and Eli Lilly and personal fees from Sanofi, Pfizer, University of Westminster, Lundbeck, and Luto UK outside the submitted work. MSW reports grants from the NIH (National Institute on Aging [NIA], National Institute of Diabetes and Digestive and Kidney Diseases [NIDDK], National Institute of Nursing Research [NINR], National Heart, Lung, and Blood Institute [NHLBI], National Institute of Neurological Disorders and Stroke [NINDS]), Gordon and Betty Moore Foundation, and Eli Lilly, and personal fees from Pfizer, Sanofi, Luto UK, University of Westminster, and Lundbeck. PPR receives investigator-initiated and collaborative grants from Merck, AbbVie, and Gilead to the University of Pennsylvania to support research on transplantation of HCV-infected organs into uninfected recipients, followed by antiviral treatment. PPR is also an Associate Editor for the *American Journal of Kidney Diseases*, consults for VALHealth (management of patients with chronic kidney disease), and provides unpaid consultation to eGenesis, a company developing xenotransplantation technology.

Abstract

Background: Preanesthesia evaluation is a basic practice preceding any surgical procedure, aimed at tailoring individualized anesthetic plans for patients, improving safety, and providing patients with educational knowledge and tools in preparation for the surgery day. In the last 2 decades, eHealth and mobile health (mHealth) settings have gradually replaced part of the face-to-face encounters as the platform for preanesthesia communication between doctor and patient, yielding a range of benefits as demonstrated in recent publications. Nevertheless, there is a lack of studies examining the effectiveness of surgical mHealth apps focusing on the pediatric preanesthetic setting and addressing their usability among families.

Objective: This study describes a dynamic approach for the development process of GistMD's preanesthesia mHealth system, a mobile-based educational and management system designed for the pediatric setting.

Methods: The study was conducted in 4 departments at a 1500-bed quaternary, academic medical center in Tel Aviv, Israel. During the study period, the link to the preanesthesia system was sent via SMS text messages to families whose children were about to undergo surgery. The system included preanesthesia questionnaires, educational videos, downloadable instructions, and consent forms. Continuous collection and examination of usability data were conducted during the implementation term including responsiveness, effectiveness, and satisfaction indicators. The information collected in each stage was used to draw conclusions regarding potential usability gaps of the system and to plan product adjustments for the following period.

Results: During 141 days of implementation, the link to the GistMD preanesthesia management system was sent to 769 families, and product-fit actions were implemented during this term: (1) changing text message scheduling for addressing learnability and accessibility, resulting in a significant increase of 27% ($\chi^2_1=12.65$, $P<.001$) in view rates and 27.4% ($\chi^2_1=30.01$, $P<.001$) in satisfaction rates; (2) reducing the number of screens to increase efficiency and operability, leading to a significant decrease of 8.6% in cases where users did not perform any activity on the system after logging in ($\chi^2_1=6.18$, $P=.02$); (3) conducting a patient-focused campaign in 2 departments aimed at addressing memorability, leading to significant increases in 8 of the 12 usability indicators.

Conclusions: Our results indicate that mHealth product-fit decisions originating from theory-based approaches and ongoing usability data analysis allow tailoring of the most appropriate responses for usability gaps, as reflected in increased use rates and satisfaction. In the case of the preanesthesia management system in the pediatric setting, increased usability conveyed important

benefits for patients and families. This work suggests a framework and study methods that may also be applicable in other mHealth settings and domains.

Introduction

Every surgical procedure that involves anesthesia is preceded by a preanesthesia evaluation session, conducted to develop a plan for anesthesia and assess the potential risks. Generally, it includes 2 essential components. First, to tailor an anesthetic plan for each patient, anesthesiologists conduct the preanesthesia clinical evaluation by gathering information from medical records, physical examinations, and patient interviews [1-3]. This basic practice aims to improve patient safety; in addition, it is important for health care organizations, as it can minimize preoperative costs, operation cancellations, and operating room time loss resulting from managing suboptimal plans [4]. Second, the process is also designed to provide patients with educational knowledge and tools that will enable them to be better prepared for the surgery day and more engaged in the anesthesia process they are about to undergo, facilitating shared decision-making and reducing preoperative anxiety, of which anesthesia is a leading cause [5-10]. The preanesthesia process is particularly important in the pediatric setting as children's anesthesia carries the risk of unique complications, such as respiratory adverse events and involves emotional engagement of the child and its parents, who usually experience significant anxiety and seek to be informed by care providers [11,12].

In the last 2 decades, telemedicine, eHealth and mobile health (mHealth) settings have gradually replaced part of the face-to-face encounters as the platform for preanesthesia communication between doctor and patient [13], and a considerable amount of literature demonstrated the range of benefits resulting from that shift. For example, a study conducted at 4 veteran affairs medical centers in the United States revealed that the electronic consultation system allowing primary care providers and anesthesiologists access to a shared electronic record can improve workflows of anesthesiologists and allow the development of anesthetic plans without face-to-face preoperative visits [14]. Another study conducted in the United States demonstrated that telemedicine screening visits, prior to preadmission testing center appointments, decreased the time spent in hospital on the preoperative day, prevented case cancellations, and highly increased patient experience and satisfaction [15]. Nonetheless, one of the most important values that is addressed using these technologies from a patient perspective is the access to quality care. For instance, a study in Canada, where nearly 15% of the residents live in remote areas, showed that 9 out of 10 patients that live far from the hospital and 8 out of 10 anesthesiologists were highly satisfied with the experience of using telemedicine-based preanesthesia assessment [16]. In fact, similar results were demonstrated among patients from a central area with shorter travel distances and expenses [17]. The vital role of telemedicine capabilities

was well demonstrated during the COVID-19 pandemic [18,19], highlighting the need to keep developing innovative solutions that will provide remote access for the preanesthesia domain, regardless of distance-from-hospital considerations.

Although worldwide smartphone penetration reached 48.3% in 2021 [20] and more than 400,000 mHealth apps are available in app stores [21], mHealth apps in the wide context of surgical and operative settings are increasingly emerging and offer new opportunities for patients [22,23]. The efficacy of these apps was recently measured in several studies that underline the potential role of mHealth platforms in promoting patients' comprehension and readiness prior to surgery, adherence to proper postoperative behavior and patient outcomes [23]. A South Korean study presented a significant increase in patient knowledge regarding surgical safety issues before the operation when using guidance apps [24]. In another study, anxiety and depression scores among patients with breast cancer were significantly lower when they accessed additional information provided by an mHealth app [25]. Postoperative behavior was examined in patients who underwent bariatric surgery and demonstrated a greater tendency to adopt a healthy lifestyle because of using tailored educational apps [26]. Despite the unique need, only a few studies have examined the effectiveness of surgical mHealth apps focusing on the pediatric preanesthetic setting and were designed for parents and their children. Some of these studies have found that preoperative anesthesia education provided by mobile apps can reduce anxiety and improve patient satisfaction [27,28], but, to the best of our knowledge, none of the studies addressed their usability among parents and children. In contrast, there are several examples of usability studies that are intended for health care providers, professional anesthesiologists, facilitating information sharing and management [29-32], or postoperative settings [33]. Leveraging the benefits of mHealth requires families to be highly engaged in using the apps [34]. It is evident that an incredibly low portion of the 400,000 health care apps has been successfully implemented; the total number of worldwide downloads sharply decreased recently, and hospitals can engage only 2% of their patients in mHealth activities [21]. This environment highlights the importance of evaluating mHealth apps via the prism of usability, assuming that one of the reasons that considerable proportions of users, patients, or professionals may not use the apps owing to low-quality or poor user interface (UI) or user experience (UX) components and not necessarily because of their low potential value [34]. The acceptable basic usability characteristics of systems and software products emerged in 1990 and are based on the definition of the International Organization for Standardization that encompasses effectiveness, efficiency, and satisfaction [35,36]. The Nielsen model expanded the conceptualization of usability and included learnability, memorability, and error protection [37]. The 6 main

themes of usability should reflect a variety of subcharacteristics such as UI aesthetics, defined as the degree to which a product or system has attributes that make it easy to operate and control, and the degree to which a product or system can be used by people with the widest range of characteristics [36].

Considering the lack of literature evaluating the usability of mHealth products that are designed for patients and focused on the preanesthesia period in a pediatric setting, this study aims to describe the implementation process of a mobile-based system designed for this purpose.

Methods

Study Objectives

The main objective of the study is to report a dynamic, quick, and timely approach for mHealth product development during its implementation period applied to modify the web-based app to family needs and address usability gaps as quickly as possible. This agile process included ongoing collection of usability data from day 1 and theory-grounded thinking. The secondary aim is to describe the lessons learned and suggest recommendations to increase the usability of these types of systems.

Web-Based App

The mHealth system used in this study was developed through a partnership between an industry vendor (GistMD, Ltd) and a 1500-bed general academic medical center in Israel (Tel Aviv Sourasky Medical Center). The medical center is the largest acute care facility in Israel. GistMD is a digital health company founded in 2018 and develops platforms that enable scalable production of personalized content and media for improving patient education, engagement, and adherence.

The system was designed to address three main functions in the pediatric preanesthesia meeting: (1) providing families and children with personalized education regarding the anesthesia process and the required preparations prior to surgery, (2) performing a remote preanesthesia evaluation possibly avoiding the need for a face-to-face encounter prior to the day of surgery, and (3) giving families the opportunity to download instructions,

consent forms, and other relevant information prior to the day of surgery.

The process includes the following steps. A text message is sent to the families' mobile phones in conjunction with scheduling the surgery for the children and entering minimal demographic data into the system (gender and age group 0-8 or 9-18 years). The message is sent from the medical center and contains a hyperlink for the web-based system. The web-based app is compatible with all types of smartphones. Initially, the guardians are asked to indicate their preferred language for all the content in the app. Currently available languages are Hebrew, English, Arabic, Russian, and Spanish. The app customizes the content according to the medical condition for which the child was referred for surgery and demographics (eg, language, age, gender, and background diseases), displaying highly personalized material. In total, the system's recombination engine can produce 80 different versions of the video, whereas the families can reboot the system at any stage and dynamically adjust the preferences or customize a new version of the video (eg, when different users want to watch the video in different languages). The guardians were also requested to answer a 10-item preanesthesia evaluation questionnaire aimed at identifying patients with a medical background requiring face-to-face evaluation by an anesthesiologist prior to the day of surgery. The questionnaire is an in-house development of the Tel Aviv Medical Center, validated among 200 patients for multilingual versions since 2019. It has become a standard of care at the medical center since the middle of 2020. Immediately after filling out the questionnaire, the family has the option to watch a tailored 5-minute animated video aimed at assisting them to better prepare for the day of surgery. After watching the video, parents can download various documents to review, including the informed consent for anesthesia, written instructions for fasting guidelines before anesthesia, a checklist of documents to bring on the day of surgery, and a list of new onset symptoms that require attention prior to surgery. The family is requested to provide feedback by stating whether the video was helpful or not. As illustrated in [Figure 1](#), the characters and the storyline in the video, as well as the documents, are adjusted according to the combination of demographics entered.

Figure 1. Illustration of various combinations of visual content.

Study Population

Between August 9, 2020, and December 31, 2020, the app was offered to all families whose children were scheduled for surgery in 4 pediatric surgical departments at Dana-Dwek Children's Hospital, the pediatric facility of the Tel Aviv Sourasky Medical Center in Israel. The medical center serves a population of 1 million people from Tel Aviv and the greater metropolitan area, a central location that is typically characterized by higher socioeconomic levels. Dana-Dwek Children's Hospital provides medical services and treatment for children of all ages, from newborns to 18 years of age and approximately 3500 pediatric surgeries are performed at the hospital annually. The 4 departments selected for the study represent approximately 80% of the surgical capacity of the pediatric hospital in the study term and specialize in plastic surgery, urology, orthopedics, and otolaryngology.

Data Collection

Surgery coordinators in the 4 pediatric surgical departments were equipped with an operation interface that supports the web-based app. The operation interface and the web-based app are cloud-based and external to the hospital's information technology infrastructure. After the coordinator scheduled a surgery and the system sent a text message to the guardians of the child, usability data were automatically retrieved for each user without the need for intervention or active collection among families. The collected data were encoded and anonymized, and the personal details of the patients or their family could not be identified.

Ethical Considerations

This manuscript is not considered human subjects research and is not presenting any medical information, and thus does not require ethical approval.

Measurements

Usability indicators measured in this study were focused on the degree of usage of the various functions of the app. All measures were coded as dichotomous variables, with 1 indicating that the users used the function and 0 indicating that they did not. At the basic level, the initial indicator is the responsiveness to logging on to the system, showing whether the users open the link they received in the text message. Similar threshold indicators are common in similar usability tests of apps [34]. At the second level, effectiveness indicators examined whether the users used each further function (filled out and completed the questionnaire, played the video, downloaded the informed consent and the documents with instructions). Additional indicators refer to determining whether users meaningfully and efficiently used the educational function. Previous studies have measured the usability of educational content in health apps by assessing the extent of use, such as the number of modules completed or the average viewing time [26,31]. In addition to the measurement that examined whether the users clicked "play" and started watching the video, meaningful use of the educational function was measured in this study by examining whether the participants viewed 75% or more of the video's total duration. The first 75% of the video was chosen as the cutoff point, as it contains the essential content to be provided to the families, whereas the remaining 25% contains, for example, wishes from the medical staff and credit roll. In this regard, reverse indicators examining underuse of the system

were also measured by examining whether the participants viewed 50% or less of the video's total duration and whether the users accessed the link but did not follow on with any activity. Finally, the satisfaction indicator refers to the user perspective regarding the opportunities that the system suggests. Unlike satisfaction that corresponds to the degree of enjoyability of apps [38], the measure used in this study examined whether it was appropriate for the needs of the participants and was perceived as providing them utility [36,39]. In this study, satisfaction was measured by asking participants, "Do you find the system helpful?" The response options were "Yes" and "No." Answering the question was not mandatory and participants could use all functions without providing an answer.

Procedures

For a quick product-fit process, we applied dynamic and ongoing processes of usability assessment. First, the implementation process for the web-based app was divided into 4 periods, and toward the end of each period, an examination of the usability indicators was conducted. All data were collected automatically, and the information gathered in each stage was used to draw hypotheses regarding potential current usability gaps of the system. Next, up-to-date literature and theories on the usability of software applications and mHealth in particular were reviewed to tailor product adjustments for addressing the gaps in the following period. Table 1 describes the thinking processes that yielded the product-fit strategies and actions taken to address the usability gaps during the market-product fit process in all stages of implementation.

Table 1. Product-fit actions by strategies and related usability gaps.

Period	Cases (N)	Duration (days)	Usability gap	Decision on strategy	Decision on action
1: Launching	286	34	Poor usage rates of basic features	Addressing learnability and accessibility issues by considering the daily habits of end users	<i>Change in text message scheduling</i>
2	56	22	Unsatisfied rates of under-use tendency	Improving efficiency and operability by applying lean and agile thinking for product modification	<i>Reduce number of screens</i>
3	238	54	Usability gaps between different departments	Addressing memorability problems by sending notifications	<i>Family-focused campaign</i>
4: End of implementation	189	31	N/A ^a	N/A	<i>Follow-up and summarizing</i>

^aN/A: not applicable.

Period 1: Addressing Learnability and Accessibility

Identify the Gap

The web-based system was launched on August 9, 2020. At 34 days after the initial distribution, we conducted a preliminary evaluation of its usability indicators. The findings (as specified in the results section below) revealed that although users opened the link for the system and filled out the questionnaire, the usage rates of users who played the video and started watching (33%) and downloading the documents (1%) were extremely low. These poor results led us to conduct a deeper viewing analysis suggesting that although users get the link for the system in the morning (as was the custom at first), more than a third of them preferred to watch the video in the afternoon, and those who watched the video in morning hours tended to watch shorter parts of it.

Choose a Strategy and Tailor the Solution

In the context of usability, learnability should reflect the degree to which the system can be used to achieve the desired goals of learning and reap its benefits. Learnability can be facilitated by integrating the system with the daily life and habits of users, while accounting for the amount of time required for users to perform the process [35,37]; this type of modification can also address the accessibility aspect of usability while allowing more users with the widest range of characteristics and capabilities to use the system [36]. Identifying the gap between the time when users receive the link to the system and their preferred hours to use it in practice led us to conclude that the required

step is to change the hour when the link is sent to users from morning to afternoon, when users are more likely to use the feature and invest more effort for the time-consuming activity of watching the video.

Period 2: Addressing Efficiency and Operability

Identify the Gap

The second period occurred between September 14 and October 6, 2020, and it yielded 56 cases. Toward the end of the period, we re-evaluated the usability indicators and analyzed the underuse trends. As specified in the results section below, although all the usability indicators increased, particularly the rate at which families that opened the link increasing by 10%, we expected that the rate at which users logged into the system by opening the link without any activity would decrease in relation to the high value it showed in the first period, but it remained stable with a high and dissatisfying rate of 11%. The increase in the rate of system logins, alongside the high rate of underuse, led us to hypothesize that users may want to use the system but find it cumbersome and it may be possible to improve UX.

Choose a Strategy and Tailor the Solution

When it comes to software products, the efficiency aspect of usability can be attributed to the stability of the software as well as the quality and aesthetics of the UI that make the product easy to operate and control [35,36]; therefore, user-centered interface designing is strongly related to usability [40,41].

A key strategy for improving usability by simplifying the UX relies on “agile” and “lean” thinking of designing software products [41,42] and mHealth apps in particular [35,43]. Agile and lean design underlines the need to produce high customer value while minimizing the elements that do not provide value for providers or users. From these perspectives, individual functions are implemented in the smallest possible steps [41,44,45]. The solution chosen to mitigate the underuse tendency was reducing one of the screens [46]. Initially, instructions for the family prior to surgery were displayed on a

screen separate from the video player, and the download features of the informed consent and the printable detailed instructions. Users were required to click on a button to move from the first screen to the second. After the modification, all functions were merged into 1 screen, allowing a more compact app whose flow of use is shorter and simpler. All features were accessible to users by just scrolling down. Figure 2 presents screenshots from the app that illustrate the differences between the full version and the simplified one.

Figure 2. Illustration of the differences between the 2-screen and 1-screen versions of the app.

Period 3: Addressing Memorability

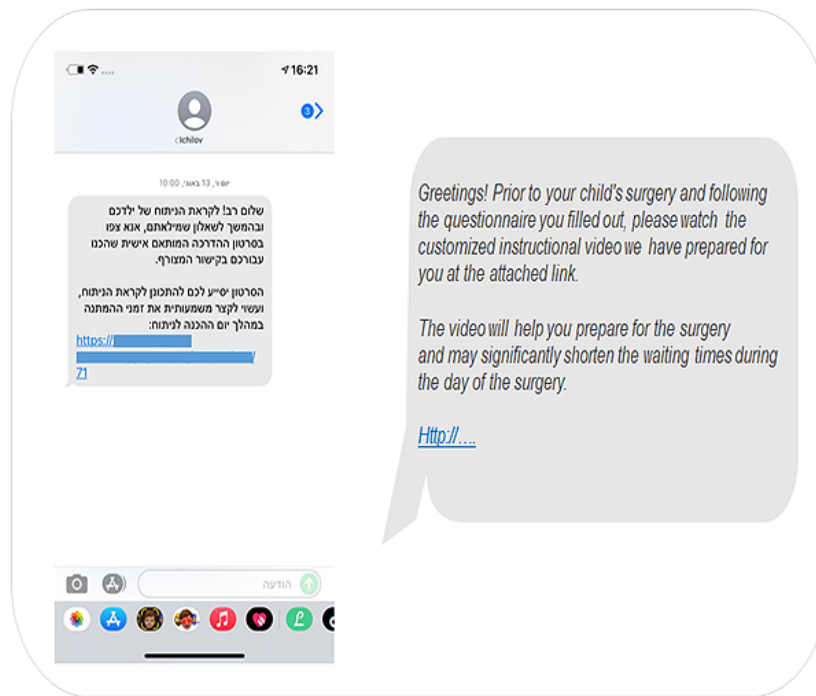

Identify the Gap

After the measures aimed to mitigate the tendency to underuse the system, the third period of implementation took place between October 7 and November 30, 2020, and this yielded 238 cases. In this stage, usability indicators were examined across different departments in the first 3 periods. As specified in the results section, the system performance in 2 departments (C and D) was significantly lower compared to that in the other 2 departments (A and B).

Choose a Strategy and Tailor the Solution

Memorability refers to the level of ease with which users, families in this case, can recall how to use an app even after discontinuing its use for some time [47]. Effective notification management is important for maintaining memorability of mobile apps among users and consequently increasing the usability potential [48]. In practice, departments C and D were targeted in a focused campaign aimed to strengthen memorability and thus increase their usability performance and reduce the gaps between them and departments A and B. Families whose children are about to undergo surgery received telephone and SMS text message notifications regarding the opportunity to use the web-based system and the benefits of using it. Figure 3 illustrates a screenshot of the message.

Figure 3. Illustration of a notification sent to families as part of the campaign.

Period 4: Follow-up and Examining Trends Throughout the Implementation Term

At the end of the implementation term, usability indicators across departments were compared to assess the impact of product-fit actions applied in the third period. In addition, trends related to all usability indicators and with respect to the entire sample were examined. The final implementation period was between December 1 and 31, 2020, and it yielded 189 cases.

Statistical Analysis

SPSS software (version 26; IBM Corp) was used to perform data analysis. To examine the effect of the strategic actions of product fit, chi-square tests were performed for comparing all usability indicators (dichotomous variables) during each of the periods in comparison to the prior periods. The percentage of

users who opened the link was calculated considering all participants to whom a message was sent. The percentage of users with respect to all other usability metrics was calculated only from the total number of users who opened the link.

Results

Sample

During the 141 days of the implementation term, the GistMD preanesthesia system was delivered to 769 families of children who were about to undergo surgery at the Tel Aviv Sourasky Medical Center. The system was initially launched in 4 departments. Table 2 presents the characteristics of the pediatric patients whose families received the link to the system prior to their surgery from the various departments.

Table 2. Patient characteristics by department (N=769).

Characteristic	Department A	Department B	Department C	Department D	Total
Age in years, n (%)					
0-8	66 (67.3)	145 (82.9)	158 (66.7)	70 (27)	439 (57.1)
9-18	32 (32.7)	30 (17.1)	79 (33.3)	189 (73)	330 (42.9)
Gender, n (%)					
Male	67 (68.4)	154 (88)	152 (64.1)	133 (51.4)	506 (65.8)
Female	31 (31.6)	21 (12)	85 (35.9)	126 (48.6)	263 (34.2)

Step 1: Change in Text Message Scheduling

The launch period was between August 9 and September 13, 2020, yielding a total of 286 cases. The initial findings indicate that 227 (79.4%) families received and opened the link provided

by the system, 195 (85.9%) opened the link and responded to the questionnaire, which is the first step in the system's operational flow; however, only 75 (33%) of them played the video and started watching it. Moreover, only 3 (1%) and 4 (1%) families downloaded the informed consent form and the

instructions document, respectively. Finally, the number of users who answered “YES” to the question “Was the system useful to you?” corresponded to only 7% (15/227) of the families who received and opened the link.

The second period was between September 14 and October 6, 2020, and it included 56 families who received the link, with only 89% (n=50) opening it. Chi-square tests showed marginal significance indicating a 9.9% increase in the second period compared to the first one ($\chi^2_1=2.99, P=.06$). However, strong statistical significance was observed for the other usability indicators. First, 30 (60%) of the parents opened the link and played the video, which is an increase of 27% in comparison to the first period ($\chi^2_1=12.65, P<.001$). Second, the proportion of parents who answered the questionnaire but did not watch the video decreased from 52.9% (120/227) in the launching period to 28% (14/50) in the second period ($\chi^2_1=10.14, P=.001$). Third, the download rates of informed consent forms and instruction documents increased by 18.7% ($\chi^2_1=31.96, P<.001$) and 20.2% ($\chi^2_1=32.76, P<.001$), respectively. Finally, 34% (17/50) of the families actively indicated that the system was helpful for them, an increase of 27.4% in comparison to the first period ($\chi^2_1=30.01, P<.001$).

Step 2: Reduce Number of Screens

The third implementation period was between October 7 and November 30, 2020, and it included 238 cases. Results indicate that the families who opened the link without any activity in the system significantly decreased from 12% (6/50) in the second period to 3.4% (7/238) in the third ($\chi^2_1=6.18, P=.02$).

The number of cases in which the video was stopped before reaching its midpoint also decreased from 20% (6/30) to 8.6% (12/140). Chi-square tests demonstrated a marginal significance ($\chi^2_1=3.41, P=.07$). It is noteworthy that all the values of the usability parameters, which increased in the second period, were retained or increased in the third, but without significant differences; for instance, the satisfaction indicator rose from 34% (17/50) in the second period to 42% (88/206) in the third period ($\chi^2_1=0.86, P=.17$).

Step 3: Patient-Focused Campaign

The fourth period was from December 1 to 31, 2020, in which 124 cases were retrieved and analyzed. Table 3 presents usability comparisons across different departments in the first 3 periods. The system performance in 2 departments (C and D) was lower than that in the others (A and B). For example, the link opening rate in department A was 90.8% (59/65), whereas that in department D was only 71% (142/200) ($\chi^2_1=10.47, P<.001$). In addition, the difference in the informed consent download rate between department B (26/129, 20.2%) and department C (13/153, 8.5%) is also significant ($\chi^2_1=8.12, P=.005$).

Considering these gaps, departments C and D were targeted in a focused campaign, and a follow-up examination was performed in period 4. As observed in Table 3, the campaign led to a significant increase in some of the usability indices in departments C and D. However, during the campaign, some of the usability indicators of departments A and B, which were not part of the campaign, decreased, except for 1 (download of informed consent document); the decreases were not significant.

Table 3. Usability indicators before and after the focused campaign across departments.^a

Department	Period 1 (N=238)	Period 2 (N=56)	Period 3 (N=238)	Periods 1 to 3 (N=580)	Period 4 (N=189)	χ^2 (df)	P value
Department A (not targeted during the campaign)	n=8	n=13	n=44	n=65	n=33		
Opened the link (%)	88	92	91	91	100	3.25 (1)	.08
Responded to the evaluation questionnaire (%)	100	67	98	92	91	0.01 (1)	.6
Played the video and started watching (%)	71	58	80	75	73	0.38 (1)	.52

Step 4: Summarizing the Implementation Phase

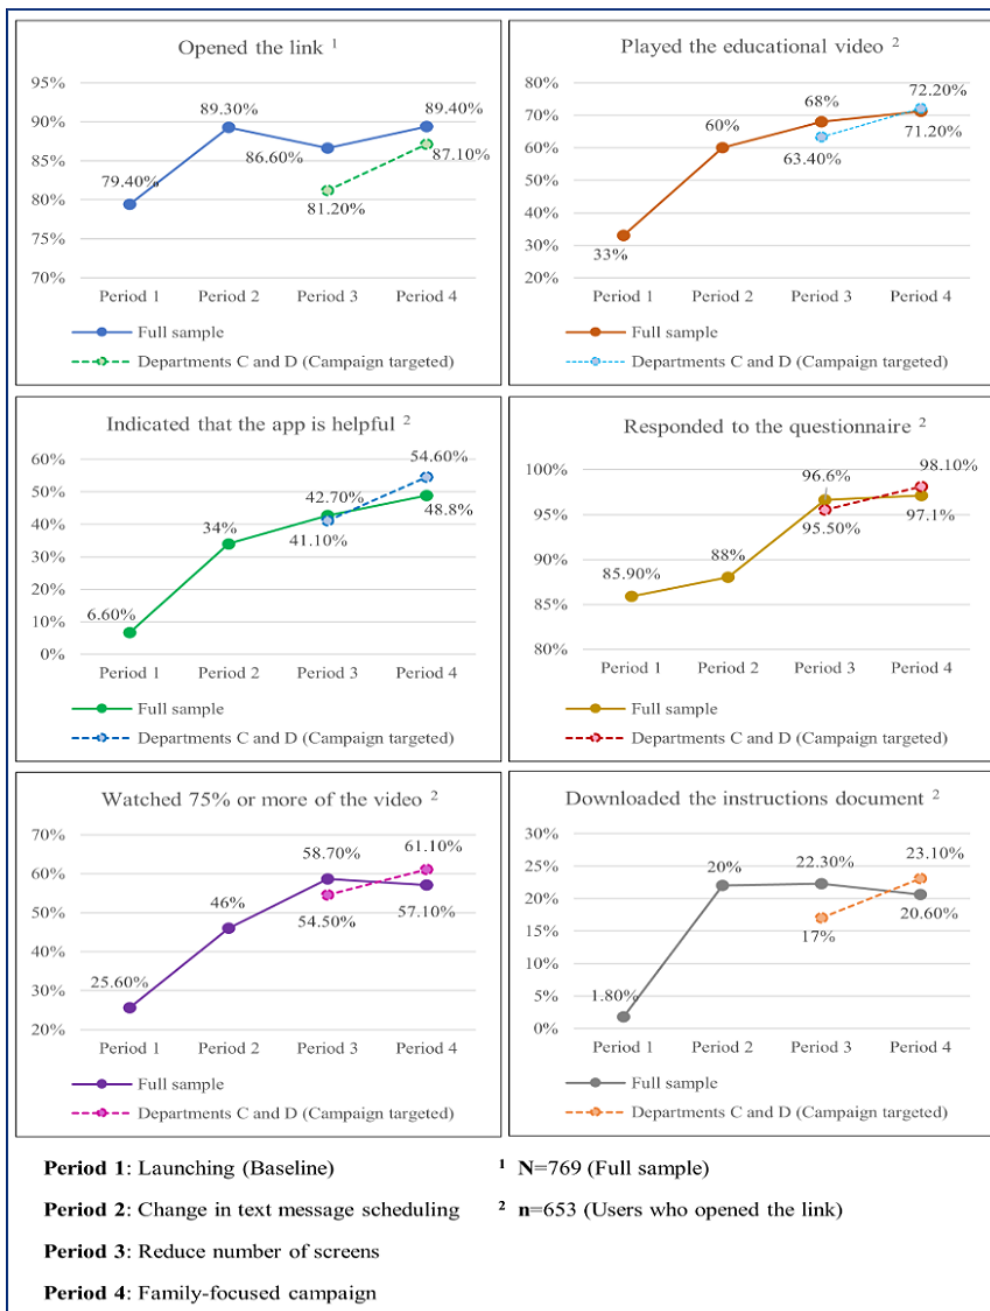

As observed in Figure 4, analysis of the usability data for the entire sample and throughout all the stages of implementation reveals that 4 of the indices peaked in the fourth period (ie, opening the link, responding to the questionnaire, watching the video, and the satisfaction indicator). However, 3 of the indices peaked in the third period.

They demonstrated a slight decrease in the fourth period (ie, watching more than 75% of the video, responding to the

questionnaire, and downloading the instruction document). Further examination of the trends only among the departments targeted during the campaign (C and D) showed that all indicators demonstrated an increase between periods 3 and 4, including those that demonstrated a decrease at the level of the entire sample. All indicators showed overall increases during the implementation period (from period 1 in comparison to the end of period 4). Chi-square tests were performed for examining the differences between indicator values at the end of period 1

and those at the end of the implementation period (period 4), revealing that all were significant at the level of $P<.001$.

Figure 4. Trends in usability indicators throughout all the implementation stages.

Discussion

Overview

eHealth and mHealth platforms are gradually replacing face-to-face encounters for preanesthesia communication and evaluation, underlining their potential to streamline the process that is crucial to ensure successful surgery. Although realizing the potential of these digital solutions depends on adequate engagement among the users (ie, patients, professionals, and caregivers), it is essential to examine their usability indicators and identify barriers that might reduce the likelihood of optimal

use among those who can benefit from these products. Nevertheless, studies addressing the usability characteristics of surgical mHealth apps focusing on the pediatric preanesthetic setting and designed for parents and their children are scarce. To bridge this gap, this study examined the usability of web-based preanesthesia apps that are designed for the pediatric setting and describes a product-fit process during its implementation period. Specifically, we describe 3 product modifications performed to improve the usability of the system, based on insights that emerged from the synergy between existing user data as well as academic and professional theoretical knowledge.

Principal Findings

Our results indicate that choosing a dynamic and theory-grounded approach to product-fit adjustments during the implementation period leads to significant increases in all the usability metrics of the system (see [Figure 4](#)). Each period of the study was characterized by a different gap that was identified and addressed with a tailored response considering the conceptual principles of usability. The first action that aimed to address learnability and accessibility by considering the daily habits of end users (ie, change in text message scheduling) led to higher numbers of users playing the educational video and starting to watch it as well as higher questionnaire completion rates. This finding is consistent with past studies that have shown that patients having the option to receive customized flexible text messages scheduled in their mHealth apps increased their effective usage of these apps [49], and this eventually improved their health outcomes [50]. In the context of the first action taken, existing studies also suggest that users should be directed to use the app at a time that best suits them and implies that the solution should bring together the concept of usability and data science. This broad perspective indicates that proper scheduling of push notifications for smartphones has become a major challenge these days, where users receive large amounts of various information on their mobile device that cause information overload and influence their ability to pay attention to the information that we seek to provide them [51]. The data from this study revealed that users prefer to use the system in the afternoon, which may indicate that there are families with children about to undergo surgery, and they may need time without interruptions for learning and preparing for an emotionally involved event. Alternatively, but not in contradiction, if we choose to “speak about usability,” we will ask ourselves whether the families may want to coordinate app usage at a time when they can do so together with their children to enable them to be engaged in the process.

The second action, aimed to address efficiency and operability by reducing the number of “screens,” was reflected in our collected data indicating reduced instances of app underuse. This finding suggests that interfaces failing to deliver a positive UX may be a barrier to usage for an audience of users who have expressed a willingness to use the app, passed the initial threshold, and clicked on the link. By reducing the number of screens, we tried to apply a lean approach for the app that aimed to provide better customer value using lower capacity; in fact, this approach can present the entire process demonstrated in this study in a different light. In recent years, “lean thinking” demonstrates one of the theoretical meeting points between usability and UX of apps as well as for developing software products using the agile process in which the developers initially release a Minimum Viable Product (MVP) [41]. The UX of the product designed using an agile process will be tested according to the lean approach by receiving user feedback and constantly examining the usability indices of the product [52]. After analyzing the accumulated data, a new cycle will begin, and an updated MVP will be released for users in another agile process. The dynamic process of the app development described in this study also involved cycles of product modifications derived from data analysis of its usability metrics. This iterative scheme

is previously demonstrated in studies that described the development process of mHealth apps and its potential to produce a better product [53] as well as increase its usability [54].

The third action aimed to address the memorability of the app among families and was implemented in response to the data analysis we performed to examine the usability indicators in each of the departments and the findings related to 2 departments that demonstrated low usability performance in comparison to the others. The focused notification campaign was able to bring about a considerable increase in the usability metrics at the departments where we hoped to achieve improvement (C and D). Previous studies have also highlighted the importance of better connectivity between providers and users of mHealth apps; using notifications for this purpose had a positive influence on the product assessment [55] and usability [56].

Although we achieved the desired result, we also found that increases in the metrics for departments A and B were characterized by higher usability indices in the baseline assessment (periods 1 to 3); therefore, these metrics were not targeted during the campaign, where extreme and modest decreases in some of the metrics during the fourth period were observed (See [Table 3](#)). The relatively weak performance in departments A and B at period 4 affected the overall results and can explain the negative trend in the values of the 3 indicators that demonstrated a decrease in the fourth period with respect to the entire sample. Contrary to the overall negative trend, departments C and D showed an increase in all indices (see [Figure 4](#)). These findings suggest that latent usability barriers may emerge when high usability indicators are demonstrated, and this highlights the need to examine usability patterns at diverse levels of analysis, such as tuning the app according to population-specific or department-specific needs. From a different viewpoint, usability may also be improved in groups of already highly engaged users, and this can further motivate them to use the app.

Lessons Learned

There are 2 main lessons to be learned based on our positive experience with the dynamic implementation of the web-based app. First, mHealth product-fit decisions originating from usability data analysis can be reflected in increased app use and satisfaction levels. In a system designed for the pediatric setting, increasing usability involves providing important benefits (ie, education, reducing anxiety) to patients and families who initially expressed a willingness to use the system (ie, logged in and checked its functionality) but did not use it optimally, if at all they used the system. In this study, several cycles of usability analyses were performed followed by product modifications to suit the user requirements. It is possible to link this process to the concepts of agile and lean design and development, but its main strength is different and lies in its inherent ability to facilitate theory-grounded thinking aimed at interpreting data and registering metadata. The combination of the lean design principles, data sciences theory, and conceptualization of product usability characteristics enabled modifications and successful improvements to the app. Second, we realized that satisfactory usability metrics do not necessarily

indicate that product-fit modifications should not be made. In the last action, which included a campaign targeting patients from 2 departments, we did not concentrate product-fit efforts in the 2 departments where we assumed the app performance was good. From the decreased usability indices observed in these departments, we can learn that maintaining usability is an ongoing process that requires deepening of the theory-grounded thinking and efforts to refine the methods of analyzing the data retrieved from the usability patterns of our users.

Study Strengths and Limitations

The present study has 2 main strengths. First, to the best of our knowledge, this is the first study to examine usability of surgical mHealth apps that focused on the pediatric preanesthetic setting and was designed for parents and their children. Addressing the unique needs of children and families prior to surgery is particularly important owing to the emotional involvement in the preparation for the operation and information seeking by the parents. Usability analyses of mHealth solutions are aimed at maximizing the potential of exposure and usage of these solutions among patients and families who need them the most. Second, although most studies examining the usability of apps in the surgical setting relied on small samples, this study is based on comparative examination of 769 cases, thus collecting better quality data for understanding the usability of the app among patients and their families.

The notable limitations of the study concern the sample and its potential lack of representativeness. First, the fact that the system required using smartphones excluded families without access to these devices, or those having low technological orientation or other limitations preventing them from using it in practice. In this context, the reliance on smartphones was chosen to strengthen the elements of personalization and anonymization for the children and their families, which could have weakened if we had expanded the distribution channels of the system. Second, the study was conducted in a medical center in a central metropolitan area that is characterized by high socioeconomic levels, and this may lead to sample bias based on income or education levels. Nevertheless, because no personal information such as socioeconomic status or health literacy was collected from families, we could not control these factors and perform systematic sampling. These constraints might limit the generalizability of our findings and conclusions, but it helped us obtain a broad picture of how the system was used and even yielded statistically significant findings. Finally, because this study was designed to examine a newly launched mHealth system and to apply ongoing, quick, and timely solutions for emerging usability gaps, we did not consider collecting available data because it was time-consuming. These data, such as patient testimonials, may have contributed to the understanding of

system usability. Future studies may be able to leverage knowledge derived in this manner using the approach we have proposed in this study.

Looking Toward the Future

The findings this study yielded the current version of the system, which showed stable usability performance. Therefore, future studies may be conducted with considerably less time constraints. A major aspect that should be addressed in future studies is expanding our toolbox of measurements to assess the usability of future versions of the system, including collection of qualitative feedback from patients before and during implementation of new versions, to gain deep insights about UX and the use of validated questionnaires in the field of usability after implementation. When we think about the desired growth direction of pediatric preanesthesia apps, we believe that increased usage and satisfaction levels of patients should also be accompanied by increased satisfaction levels of hospital personnel. The app that is the focus of this study has high utility for professional anesthesiologists and the hospital management as well as patients and their families, and these aspects have not been addressed here. In our further studies, we would like to examine, for example, the extent to which the system makes it possible to eliminate face-to-face meetings and how this will affect staff satisfaction with the system and the attempt to persuade patients to use the app. We assume that a dynamic, theory-grounded process like the one presented here will be developed, in which we will examine the usability of the app from the perspective of the treating team; this will be added to the knowledge gained from the patients, close the feedback loop, and may also enable autotuning of the system in future.

Conclusions

Usability analysis of mHealth solutions is crucial for maximizing the potential benefits that patients can receive. In this study, we developed a successful dynamic process of usability examination and product-fit adjustments of a preanesthesia app designed for the pediatric setting. A dynamic and ongoing process is suggested for analyzing and interpreting usability data. This process includes timely data collection and using of theory-based thinking to tailor the most appropriate response for addressing usability gaps. Because every change is implemented to address a need arising from earlier usage, this framework may facilitate values such as communication, reliability, and responsiveness that in turn strengthen the appropriateness recognizability of the app from the user perspective. This framework can also potentially be applicable in other mHealth settings and domains. Future studies will be able to refine the method to apply it in different settings and expand the areas of knowledge that will use it.

Acknowledgments

We thank Professor Idit Matot, Director of the Anesthesia, Pain and Intensive Care Division, and Director of General Surgery Division and Professor Ronni Gamzu, Chief Executive Officer of Tel Aviv Sourasky Medical Center, for their support, time, and efforts. This study was supported by a grant from the Israel Innovation Authority.

Authors' Contributions

YC and RL contributed to data collection and analysis, and they were the primary drafters of the manuscript, tables, and figures. AB, DR, EA, and ON provided critical inputs regarding the study vision and design. AB, YBS, and DS critically revised the paper for intellectual content. All authors have approved the manuscript for publication.

Conflicts of Interest

YC and RL are employees and equity holders of GistMD. DS, YBS, and ON are advisors and equity holders in GistMD. AB and DR are cofounders of and equity holders in GistMD. EA has no conflicts of interest.

Abstract

Background: The most common dermatological complication of insulin therapy is lipohypertrophy.

Objective: As a proof of concept, we built and tested an automated model using a convolutional neural network (CNN) to detect the presence of lipohypertrophy in ultrasound images.

Methods: Ultrasound images were obtained in a blinded fashion using a portable GE LOGIQ *e* machine with an L8-18I-D probe (5-18 MHz; GE Healthcare). The data were split into train, validation, and test splits of 70%, 15%, and 15%, respectively. Given the small size of the data set, image augmentation techniques were used to expand the size of the training set and improve the model's generalizability. To compare the performance of the different architectures, the team considered the accuracy and recall of the models when tested on our test set.

Results: The DenseNet CNN architecture was found to have the highest accuracy (76%) and recall (76%) in detecting lipohypertrophy in ultrasound images compared to other CNN architectures. Additional work showed that the YOLOv5m object detection model could be used to help detect the approximate location of lipohypertrophy in ultrasound images identified as containing lipohypertrophy by the DenseNet CNN.

Conclusions: We were able to demonstrate the ability of machine learning approaches to automate the process of detecting and locating lipohypertrophy.

KEYWORDS

insulin; lipoma; machine learning; diagnostic ultrasound; lipohypertrophy; diabetes; ultrasound images

Introduction

The most common dermatological complication of insulin therapy for glycemic control in diabetes is lipohypertrophy, which has a prevalence ranging from approximately 25% to

65% in the literature [1,2]. These lesions are characterized by fibrosis, decreased vascularity, and adipose hypertrophy [3] and are likely due to both inflammation and the trophic properties of insulin [4]. These lesions have clinical effects that reach far beyond the skin—some previous works have shown that

lipohypertrophy alters insulin absorption resulting in poor glycemic control and high glycemic variability in persons with diabetes [5-7]. Avoidance of lipohypertrophic sites has also shown to improve glycosylated hemoglobin levels, and current practice recommends the evaluation of these lesions based on either visual inspection or palpation [8,9]. More recent findings have developed clear criteria for detecting lipohypertrophy with ultrasound and have shown that approximately half of these lesions are not detectable by palpation [10,11]. These findings have led to the suggestion that bedside ultrasound can be used as an adjunct to palpation [10], but there are significant barriers to implementing this in standard diabetes clinics since ultrasound imaging is only familiar to and implemented by a small group of diabetes educators or physicians.

The development of machine learning techniques to predict masses in ultrasound images has been an ongoing effort in clinical practice for the past few decades. To assist physicians in diagnosing disease, many scholars have implemented techniques such as regression, decision trees, Naive Bayesian classifiers, and neural networks on patients' ultrasound imaging data [12]. Further, many studies involving ultrasound images have attempted to preprocess the images to extract features. Previous work by Chiao et al [13] has demonstrated that the use of convolutional neural networks (CNNs) with ultrasound images is better than radiomic models in predicting breast cancer tumors [13]. Other recent work has shown success in classifying liver masses into 1 of 5 categories with 84% accuracy, using a CNN model [14]. Recent work looking into the use of various complex image augmentation approaches has shown that the use of generative adversarial networks to generate images to enlarge the data set improve the performance of the eventual model [15], and many such studies [16,17] have confirmed that minimal transformations such as flipping images can result in a higher prediction accuracy.

In an effort to improve the accessibility and efficiency of this method of detection, we have, as a proof of concept, developed a supervised machine learning algorithm to detect lipohypertrophy in ultrasound images using a CNN and a web-based application to deploy the trained models and make accurate predictions on the presence or absence of lipohypertrophy in ultrasound images.

Methods

Recruitment

All images were obtained from research participants who were enrolled in a diabetes education program at an academic center and who had an unknown lipohypertrophy status between July 2015 and March 2017 as part of a previous study of this condition [10]. All research participants were above 19 years of age, had a diagnosis of type 1 or type 2 diabetes mellitus, and were currently being treated with a minimum of 1 insulin injection daily or an insulin pump for at least 2 years. Participants were excluded if they were prescribed a systemic glucocorticoid, glucagon-like peptide-1 agonist, or if they had a nonlipodystrophic dermatological condition extending to the

insulin injection site area. Each image was categorized as positive (lipohypertrophy present) or negative (no lipohypertrophy present) by a radiologist as per previously published criteria in a blinded fashion [10]. Ultrasound images were obtained in a blinded fashion using a portable GE LOGIQ *e* machine with an L8-18I-D probe (5-18 MHz; GE Healthcare).

Ethical Considerations

All research participants gave written consent, and our study protocol received approval by the Human Subjects Committee of the University of British Columbia (H20-03979).

Data Splits

Before beginning any model training, the data were split into train, validation, and test splits of 70%, 15%, and 15%, respectively, followed by some preprocessing steps of manually removing borders from the nonannotated versions of the images. We included all different types of diabetes as 1 set and did not differentiate between patients when splitting, as the histology of these lesions has been found to be independent of the source of insulin or mode of administration [18,19]. In fact, insulin-induced lipohypertrophy does not show any histological specificity, closely resembles hypertrophic cellulite [20], and appears identical to fat nodules due to other etiologies such as corticosteroids [21] or electromagnetic fields [22]. The lesions have been shown to be due to the direct result of the hypertrophic effects of administered insulin with no evidence for a pathogenic role for the insulin antibodies found in type 1 diabetes [23].

Image Transformation and Model Development

Given the small size of the data set, image augmentation techniques were used to expand the size of the training set and improve the model's generalizability. A variety of classic transformations [16,17] were tested, and the model's performance on these augmented data sets were documented at this stage (Figure 1). The augmenting transformations that led to the best performance were adding random vertical and horizontal flipping, randomly changing the brightness between -0.1 to 0.1, and randomly changing the contrast between 0 and 1, each with a probability of 50%. The images in the data set varied in size from 300300 up to 460500. As a result, after the above transformations, all images were resized to a standard common denominator of 300300 pixels by cropping. An example of a transformed image is shown in Figure 1. The augmented data is then used to train a CNN model using transfer learning, a technique using pretrained models on thousands of images, which then allows for retraining of the entire network with our comparatively smaller data set. Based on our literature review, the transfer learning architectures we chose to investigate were the following: VGG16, ResNet50, DenseNet169, and InceptionV3 [24]. Each model was incorporated into our small data set, trained in separate experiments using techniques to optimize the parameters of the model to maximize its ability to learn. To compare the performance of different architectures, the team considered the accuracy and recall scores of the models when tested on our test set.

Figure 1. Final image transformations included random vertical and horizontal flipping and random brightness and contrast adjustment.

Object Detection

In addition, we wanted to implement object detection into our pipeline, giving users the opportunity to visually identify the location of lipohypertrophy being detected by our model. To implement object detection using a popular framework called YOLOv5 [25,26], the team created bounding boxes around the location of the lipohypertrophy masses on the positive training images using the annotated ultrasound images as a guide. Next, using the YOLOv5 framework, the YOLOv5m model was trained for 200 epochs with an image size of 320x320 pixels (as this was what the Application Programming Interface allowed) and a batch size of 8.

Table 1. Research participant characteristics (N=103).

Characteristics	Values
Age (years), mean (SE)	75.0 (11.8)
BMI (kg/m ²), mean (SE)	28.3 (6.1)
Participant with type 1 diabetes, n	8
Number of years on insulin, mean (SE)	9.4 (11.5)
Duration of diabetes (years), mean (SE)	20.7 (6.1)
Glycated hemoglobin (%), mean (SE)	8.0 (1.1)
Total daily dose (units), mean (SE)	48.6 (42.9)
Daily doses, n (range)	2 (1-6)

Results

Our images were obtained from a total of 103 participants, of whom 8% were diagnosed with type 1 and 92% were diagnosed with type 2 diabetes (Table 1). Our data set included 218 negative images (no lipohypertrophy present) and 135 positive images (lipohypertrophy present). Examples are shown in Figure 2.

Each of the potential models (VGG16, ResNet50, DenseNet169, and InceptionV3) were investigated by training them in separate experiments, using our augmented data set.

Figure 2. Some examples of images found in our data set. The top row displays negative images (no lipohypertrophy present) and the bottom row displays positive images (lipohypertrophy present) where the yellow annotations indicate the exact area of the mass. The yellow annotations are only for the reader; the images that the model was trained on were unmarked with no yellow annotations.

As shown in [Table 2](#), all models were able to achieve accuracy scores higher than 0.60 when tested on a holdout sample. When comparing performance of the various models, DenseNet demonstrated the highest accuracy score (0.76), the highest recall or sensitivity score (0.76), and the highest specificity score (0.49), indicating an overall better performance than Inception, VGG16, or ResNet. In addition to better performance, DenseNet also demonstrated a relatively small computational size (30 MB) compared to the other models (Inception, 100 MB; ResNet, 99 MB; VGG16, 547 MB).

With respect to object detection implementation, the YOLOv5m model was able to identify the specific location of lipohypertrophy in test cases, as demonstrated in [Figure 3](#). In order to help a clinician verify the results of our models, YOLOv5m was able to accurately create bounding boxes around lipohypertrophy sites in ultrasound images. As shown in [Figure 4](#), YOLOv5m demonstrated an F1 score of 0.78 at a confidence value of 0.41.

All 4 models (ResNet, VGG16, Inception, and DenseNet) were tested on a holdout sample to produce these accuracy, recall or sensitivity, and specificity results.

Table 2. Model accuracy scores, recall or sensitivity scores, and specificity scores.

Model	Accuracy scores	Recall or sensitivity scores	Specificity scores
DenseNet	0.76	0.76	0.49
Inception	0.74	0.52	0.33
VGG16	0.65	0.19	0.12
ResNet	0.61	0	0

Figure 3. Our final object detection model results on a test sample reveals promising outcomes. The top row indicates the true location of lipohypertrophy, and the bottom row indicates where the model thinks the lipohypertrophy is. The number on the red box indicates the model's confidence.

True labels

Predicted labels

Figure 4. Our results from the YOLOv5m object detection model showcase a successful initial attempt, as shown by our precision (a). Our best F1 score (b) is around 0.78 with a confidence value of about 0.4109. Any higher confidence value causes our recall (c) to suffer dramatically, which was the focus of our optimization.

Discussion

Principal Results

As a proof of concept, we were able to demonstrate the ability of a supervised machine learning algorithm to detect lipohypertrophy on ultrasound images using a CNN, and we were able to deploy this algorithm through a web-based

application to make accurate predictions on the presence or absence of lipohypertrophy in ultrasound images obtained at the point of care. The DenseNet transfer learning architecture outperformed the other architectures tested, suggesting this would be the most appropriate choice to automate the process of detecting and locating lipohypertrophy, a common dermatological complication of insulin injections.

Comparison With Prior Works

Prediction of masses in ultrasound images using machine learning techniques has been an ongoing effort in clinical practice for the past few decades. To assist physicians in diagnosing disease, many scholars have implemented techniques such as regression, decision trees, Naive Bayesian classifiers, and neural networks on patients' ultrasound imaging data [12]. Further, similar to this study, many investigators have used preprocessing techniques to extract features. In fact, Chiao et al [13] demonstrated that CNNs using ultrasound images perform better than other methods (such as radiomic models) in predicting breast cancer tumors. Another recent study showed considerable success in classifying liver masses into 1 of 5 categories with 84% accuracy, using a CNN mode [14]. To our knowledge, this is the first attempt to use CNN techniques to automate the detection of lipohypertrophy, demonstrating the considerable performance of our DenseNet model both in terms of test accuracy and recall (Table 2).

Recent research has delved into various complex image augmentation techniques to generate images [15]; we also found that traditional transformations managed to improve model performance, congruent with the results of this study. Furthermore, other studies [16,17] also confirmed that minimal transformations such as flipping the images led to higher prediction accuracy in their application. DenseNet has also proved successful in similar deep learning applications using small data sets [27], which we suspect is due to its ability to reduce the parameters in a model.

Limitations

Although our project has demonstrated in principle that machine learning can be used to detect lipohypertrophy, there are some key limitations that should be addressed before it can be used in a clinical setting. Given the small size of our data set, more images need to be incorporated into the model before it can be used to direct patient care. Besides, even after the addition of new images, an auditing process should also be developed to ensure that our machine learning model does not propagate any biases that could cause harm to specific patient populations.

Conclusions

Previous clinical studies of lipohypertrophy have demonstrated quite a high prevalence of this condition (greater than half). More importantly, they have demonstrated a significant burden of subclinical lesions in patients with diabetes [10]. This is clinically important both due to the alterations in insulin absorption with injection proximate to a lipohypertrophic lesion [5-7] and the fact that the only treatment for this condition is avoidance [28]. Although our proof-of-concept study was limited by the fact that our model was based on a small number of images, we have successfully demonstrated the development of a model that can automatically detect lipohypertrophy in patients with diabetes. Although more work needs to be done, future studies of models developed on larger image data sets could allow for the development of a rapid, noninvasive, bedside test for subclinical lipohypertrophy that could easily be used by health care professionals unfamiliar with the use of ultrasound technology.

Abstract

Background: In Thailand, the health care system has struggled to cope with COVID-19, resulting in directly observed therapy for tuberculosis being de-emphasized. A video-observed therapy (VOT) system, or more specifically, the Thai VOT (TH VOT) system, was developed to replace directly observed therapy. According to the pilot study, the system needed notifications to improve usability and user compliance. The updated version of the TH VOT system thus enabled LINE (Line Corporation) notifications.

Objective: This study aimed to reassess users' compliance with and the usability of the updated TH VOT system.

Methods: This study was conducted in the Hat Yai and Mueang Songkhla districts in Songkhla Province, Southern Thailand, from September 18 to December 1, 2021. The system was used by not only patients with tuberculosis but also tuberculosis staff, who acted as observers in primary health care settings. Some of the observers used the simulated VOT system instead of the actual system due to the lack of participating patients in their jurisdiction. After 30 days of using the system, VOT session records were analyzed to determine the compliance of the patients and observers. The User Experience Questionnaire was administered to reassess the usability of the system and compare the ratings of the participants with the general benchmark scores of the User Experience Questionnaire. The results were summarized to reveal the degree of user compliance and usability in the following three groups: the patients, actual VOT observers, and simulated VOT observers.

Results: Of the 19 observers, 10 used the actual VOT system, and the remaining 9 used the simulated VOT system; there were also 10 patients with tuberculosis. The patients, actual VOT observers, and simulated VOT observers exhibited about 70%, 65%, and 50% compliance, respectively, in terms of following the standard operating procedures every day. The scores of all groups on all dimensions were well above the average scores. There was no significant difference in any of the dimensional scores among the three groups.

Conclusions: The updated version of the TH VOT system was deemed usable by both the patients and the health care staff. Compliance with the use of the system was high among the patients but moderate among the observers.

Introduction

Thailand—1 of 30 countries with the highest tuberculosis burden, especially multidrug-resistant tuberculosis burden [1]—has been hit hard by COVID-19 for 2 years. The health care system had struggled to cope with COVID-19, resulting in nonemergency services, including directly observed therapy (DOT) for tuberculosis, being de-emphasized [2,3]. This occurred in addition to DOT being widely criticized for its sloppiness [4-8]. Under this constraint, a video-observed therapy (VOT) system, or more specifically, the Thai VOT (TH VOT) system, was developed to replace DOT.

In our pilot study, the system was still not usable for observers in Na Yong District, Trang Province, Southern Thailand. Among the different dimensions of usability, stimulation, which is supposed to motivate users, was the least favorable. About half of the video sessions were sent and observed (37/70, 53%), indicating low compliance among the observers. In order to determine a solution, a qualitative study was conducted, and the observers suggested adding a notification system and an auditor to improve their observation tasks and compliance. The pilot study was also limited by an insufficient sample size and the short duration of users' experience [9].

Based on the aforementioned suggestions, an improved version of the TH VOT system was developed. The updated system was integrated into the DOT programs of primary care units (PCUs) in the Hat Yai and Mueang Songkhla districts in Songkhla Province, Southern Thailand. The tuberculosis staff of PCUs were the observers who monitored the patients in their juristic areas. One auditor exclusively evaluated the observers and gave feedback. This study aimed to reassess users' compliance with and the usability of the updated TH VOT system.

Methods

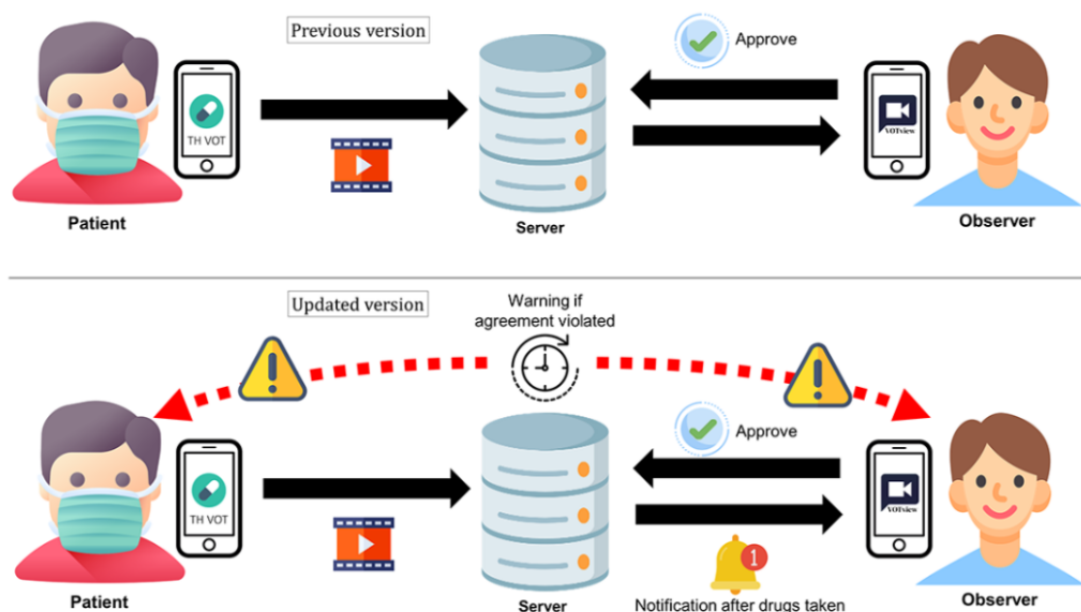

Enabling a Notification System

The LINE (Line Corporation) notification application programming interface had been created as part of our previous study [9]. However, the notification function was disabled at that time for reasons of cost reduction. The LINE notification system is common in Thailand; therefore, the notification function was enabled to improve the user experience dimension of simulation [10].

Details of the LINE Notification System Added in the Standard Operating Procedures

Details were added to the standard operating procedures (SOPs) [9] for the previous version of the TH VOT system with regard to the notification system. The time to take medication was determined and revised, if necessary, by the patients. The LINE notification would pop up on the patients' smartphones if they did not record a video by using the TH VOT app within 30 minutes of the time set for taking medication. The notification alarm would sound immediately after a patient sent a video. Moreover, the notification would also notify an observer to remind the patients to take their medication if this was not done within a predetermined time interval. The system notification would also send a secure link to the observers, which led to the lists of patients under their jurisdictions who did not send a video. The observer could then call the patients by using the "call" buttons on the lists. The auditor would then conduct a daily evaluation of the VOT sessions of the patients and their observers by using the electronic database and judge whether the sessions were completed properly. Feedback on individual performance was then sent to users every weekend. Hence, the notifications for both the patients and the observers could enhance the system, making it more efficient, accurate, and stimulating than the previous version (Figure 1).

Figure 1. A comparison of the previous and improved versions of the TH VOT system. TH VOT: Thai video-observed therapy.

Implementation of the Updated TH VOT System

To obtain a larger sample size of users, the study site was moved to the Hat Yai and Mueang Songkhla districts in Songkhla Province, which has the highest tuberculosis burden in Southern Thailand. The sample size was estimated by using 1 mean sample formula [11] and compared with the general benchmark to test whether the simulation score was above the “good” level (>1.35) [12]. We estimated that the mean simulation score of the User Experience Questionnaire (UEQ) for the observers would be 2 (it was 0.67 in the pilot study), while the SD of the mean score was estimated to be 1. Other aspects of the settings were similar to those of the pilot study’s setting. As there were several PCUs in the study area, 9 and 10 PCUs from Hat Yai and Mueang Songkhla districts, respectively, were randomly selected as the sites of implementation. For each PCU, 1 tuberculosis staff member was assigned to be an observer. Thus, at least 19 observers were required. The number of patients for each observer was flexible, depending on how many patients they could invite for usability testing.

The 19 recruited tuberculosis staff, as the observers, familiarized themselves with the system by following the training that was described previously in the pilot study [9]. In brief, the use of the TH VOT system was explained and demonstrated to the observers. After the training, each observer was assigned to

invite and train the patients with tuberculosis in their jurisdictions by using the TH VOT app. This secondary training step was supervised and approved by the researchers before the actual VOT process was launched. Only patients with pulmonary tuberculosis who were treated during the continuous phase of tuberculosis treatment and had a smartphone were eligible for inclusion. The patients who were scheduled to complete treatment within 30 days were excluded. The recruited patients were scheduled to take medication once per day for 30 days, and they received cellular internet support for using the TH VOT app to record and send a daily video to their observers for 30 days. Each observer had to approve the videos sent by their patients within 24 hours. If an observer could not invite any eligible patient with tuberculosis, the videos that had been recorded in the pilot study would be used instead as part of the simulated VOT system for usability testing. The patients in the videos had consented to being observed by tuberculosis staff in other areas for training purposes. For the observers without patients, daily notifications would be randomly sent without a video 3 days per week to indicate that the automated system inconstantly sent videos like the actual VOT system. On those days, each observer had to press the “call” button in the notification link to remind the patients to send a video. The changes that were made to the system from the pilot study to create the current system are presented in [Table 1](#).

Table 1. Comparison of this study’s setting and the pilot study’s setting.

	Pilot study	This study
Sites	Nayong District, Trang Province	Hat Yai and Mueang Songkhla districts, Songkhla Province
Centers	3 primary care units	19 primary care units
Patients	Real patients with tuberculosis who were treated with an isoniazid-rifampicin regimen and had a smartphone or simulated patients who had a smartphone (village health volunteer)	Real patients with tuberculosis who were treated with an isoniazid-rifampicin regimen and had a smartphone or a simulated video-observed therapy system (automatic video sending)
Observers	Tuberculosis staff from the primary care units were trained with the original instructions	Tuberculosis staff from the primary care units were trained with the updated instructions
Auditor	None	1 auditor for all
Video-observed therapy system	No notification system	LINE notification system added
Duration of observation	14 days	30 days

Ethics Approval

This study was approved by the Human Research Ethics Committee, Faculty of Medicine, Prince of Songkla University (approval number: 64-03618-9). The researchers and deputy province chief medical officer of the Songkhla Provincial Public Health Office came to an agreement for the implementation of the TH VOT system.

Compliance and Usability Assessment

Study Design

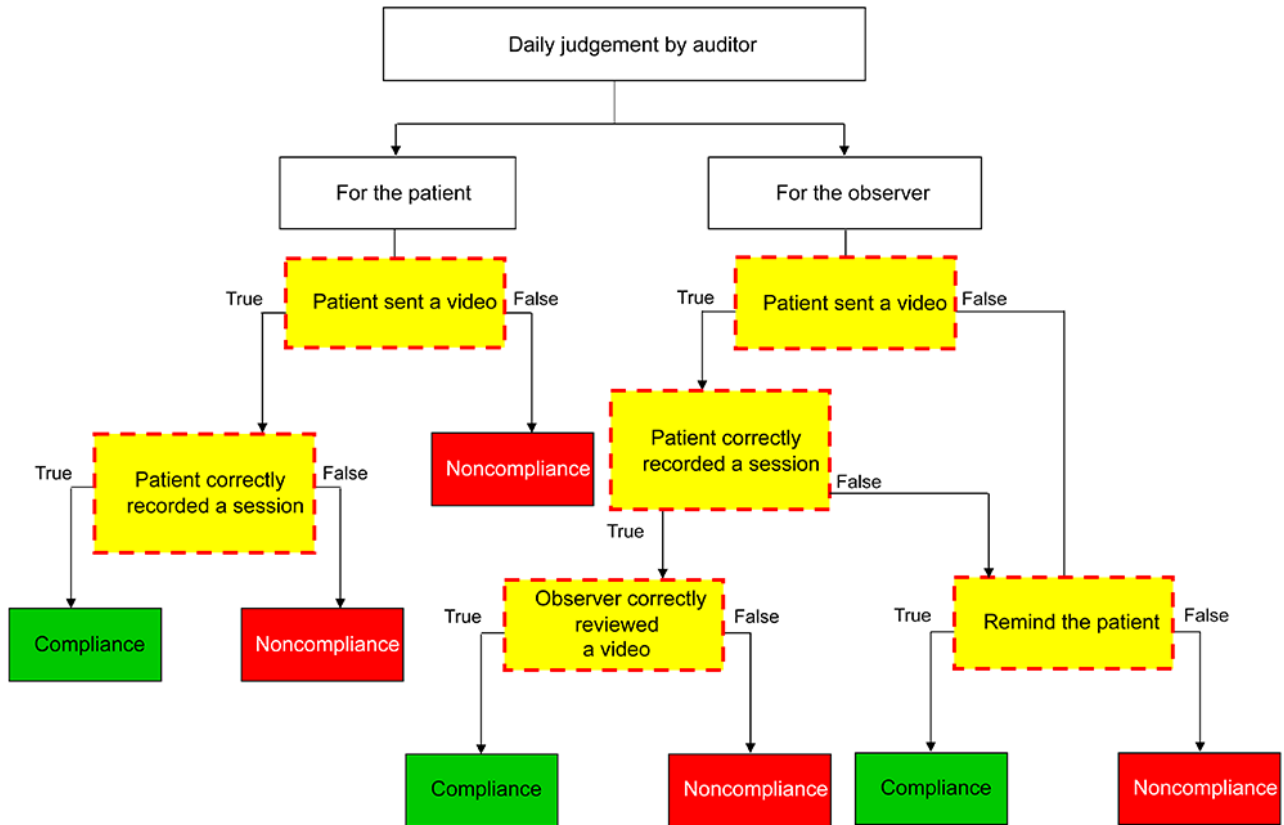

A prospective study was conducted among the aforementioned 19 observers and their patients with tuberculosis. The participants were recruited from September 18 to November 1, 2021. The staff were trained as observers from September 18

to 30, 2021. Then, the staff using the actual VOT system and their patients were trained together and certified by the researchers on November 1, 2021. They were then assigned to use the TH VOT system from November 1 to 30, 2021. A daily VOT session, which was comprised of the patients who were properly taking medication, was recorded in 1 video that was sent to the observer and approved within 24 hours. Then, the compliance of the users was judged by the auditor. Usability was assessed by patients and observers through the UEQ [10].

Data Collection

On each day of the study period, the auditor assessed both the patients’ performance and the observers’ performance by using the SOP. Their assessment was recorded in a system that also contained all of the VOT data, as shown in [Figure 2](#).

Figure 2. Algorithm of the auditor’s judgment.

The SOP for the Assessment of Patient and Observer Compliance by the Auditor

The time unit for the judgment of compliance was “day,” and local times (Greenwich Mean Time + 7 hours) were recorded. The morning began at 12 AM (midnight), and the evening ended at 11:59 PM. However, daily compliance was judged as “achieved” if the patients took their medication and sent their videos before 6 AM the next day. The observer was considered compliant if they reviewed the videos within 24 hours after the videos had been sent. Therefore, the day that compliance was judged for the observer was always 1 day behind that for the patients.

A patient was only considered compliant if their video was sent before the cutoff and the quality of the video passed the following criteria:

1. The patient’s face and the drug tablets or capsules were clearly visible in the video frame.
2. The pills were picked up from the drug plane and put on the tongue.
3. The pills were swallowed along with clear water from a (clear) glass.
4. The tongue was then raised to show the sublingual area and stuck out to show the palate area.
5. Steps 2 to 4 were repeated until all of the pills were completely taken.

The observer was only considered compliant if they did the following to a quality standard: (1) assess whether the patients performed the aforementioned steps, (2) note the number of pills taken by the patient, and (3) make a reminder call if the

patients did not send a video or incorrectly performed any procedure.

All daily VOT session records were automatically registered in the database of the TH VOT system, but only the usernames, dates, and times of the session records, which were confirmed by the auditor, were retrieved for compliance analysis. After 1 month of using the system, all users were administered the validated Thai UEQ [13]. It contained the following six dimensional scales: attractiveness (6 items), perspicuity (4 items), efficiency (4 items), dependability (4 items), stimulation (4 items), and novelty (4 items). The items were developed based on a semantic differential scale ranging from -3 to 3. In this scale, positive terms are given a score of 1, 2, or 3; neutral terms are given a score of 0; and negative terms are given a score of -1, -2, or -3 [10]. All participants were assured that they would be eligible to receive a reward regardless of how they answered the questions. Further, 1 UEQ sheet was sent to each participant by a delivery person in the first week of system use. The participants scored the TH VOT system (ie, via the UEQ) at home and sent the UEQ sheet back to the delivery person at the end of the observation phase. The delivery person put all of the sheets into a concealed box and gave it to the researchers. The UEQ sheets had no identification numbers and only indicated whether a respondent was a patient, an actual VOT observer, or a simulated VOT observer. No one could identify who provided particular responses. The mean UEQ scores of the six dimensional scales were compared with the average and good general benchmark scores [12].

Data Analysis

The users were categorized into the following three groups: patients, actual VOT observers, and simulated VOT observers. The basic characteristics of the users were summarized by using descriptive statistics. For each group of users, the average number of VOT sessions completed within 30 days by a user was estimated by using the mean cumulative function (MCF) of the Nelson-Aalen estimator [14]. The 95% CIs of the MCFs were produced via bootstrapping with 1000 replicates from resampling procedures. Ideally, the MCF value would be 30 if all participants performed sessions every day for 30 days. The mean UEQ scores were aggregated into 4 groups—the UEQ scores of the aforementioned groups of users and those of the overall observers. The UEQ scores were then visualized by using violin plots [15], in which mean scores and SEs were compared against the benchmark line. If the lower limit of the SE was over the reference line, it was determined that the corresponding UEQ score was significantly above the reference scores.

Results

Of the 19 observers, 10 had a participating patient, while the rest of them had no patients and used the simulated VOT system instead. Table 2 summarizes the characteristics of the observers and patients and their VOT-related behaviors. The mean ages of the patients and observers were approximately 50 and 37 years, respectively. The basic characteristics of the observers for the actual and simulated VOT systems were similar. All patients performed VOT in the evening or after midnight and spent about 1 minute recording and sending their videos. The time between the patients' and the observers' sessions varied considerably because different observers viewed the videos at different times. The average time spent reviewing the videos was approximately 1.5 minutes. The notifications for the simulated VOT system were sent to the observers regularly (every day at 7 PM), and the observers responded to the videos shortly after their receipt (no more than 4 hours after receiving the videos). Only videos that showed complete sessions were sent to the observers for the simulated VOT system; thus, their reviews were completed faster (within 1.2 minutes) than those of the observers for the actual VOT system.

Table 3 summarizes descriptive statistics regarding participant compliance over a 30-day period for the three groups. The level of compliance was higher among the patients than that among the observers. Differences in compliance are visualized in Figure

3. Participants' daily compliance, as judged by the auditor, is represented by a dot for each day. The results show that the observers who used the actual and simulated VOT systems gradually disregarded their observation tasks and eventually became noncompliant with the protocol. On the first day, all participants were trained in accordance with the standard instructions [9] and performed a real session correctly. On the second and third days, all patients forgot to show their palate area; thus, their observers were not able to adequately see their compliance. The auditor therefore made calls to remind all participants to not miss this step. Among the 72 instances (patient days) when patients forgot to send a video, there were 32 instances (44%) in which they were reminded by the observers. For the simulated VOT system, observers sent reminders on 40 out of the 123 (32.5%) "bot days" that required a call action. During the study period, there was 1 festival day—*Loy Kratong*—on November 19, 2021, but it did not affect compliance. The days of noncompliance appeared to be random and did not follow a particular pattern for the patients with tuberculosis and actual VOT observers. For the simulated VOT observers, their compliance dramatically dropped due to the COVID-19 situation after November 15, 2021. After this point, the compliance of the simulated VOT observers (who were also tuberculosis staff) diminished, as they were needed to help control SARS-CoV-2 infection due to a lack of health care workers. Although the number of actual VOT observers did not suddenly diminish, it gradually decreased over time.

The 30-day MCFs in the patient, actual VOT observer, and simulated VOT observer groups were 21.79, 19.03, and 14.65, respectively, indicating that the three groups exhibited about 70%, 65%, and 50% compliance, respectively.

Figure 4 depicts the violin plots for each group of users and each dimension of the UEQ. The summation of UEQ scores could range from -18 to 18; however, each participant's scores ranged from 3.58 to 18. The mean of the sum score was 11.89 (SD 3.99), and there were no outliers. The means and SEs are also presented within the violin plots as dots and error bars, respectively. The dotted horizontal lines for each dimension denote a good score (orange) and the average score (blue), which were compared to the general benchmark [12]. The scores of all groups on all dimensions were well above the average scores. Only the scores for the novelty and stimulation dimensions were significantly above the good scores. There was no significant difference in any of the dimensional scores among the three groups and overall observers.

Table 2. Participants' characteristics and their video-observed therapy (VOT) behaviors.

Characteristics and behaviors	Actual VOT (users: n=20)	Simulated VOT (users: n=9)	P value ^a
Patient characteristics and behaviors (n=10)			
Sex, n (%)			— ^b
Female	4 (40)	—	
Male	6 (60)	—	
Age (years), median (SD)	50.6 (13.6)	—	—
Appointment time, median (minimum, maximum)	8 PM (7 PM to 9 PM)	7 PM (7 PM, 7 PM)	—
Lapse time between video appointment and uploading a video (minutes), median (minimum, maximum)	230.20 (104.4, 260.9)	0 (0, 0)	—
Uploading a video daily, n (%)			<.001
Within 1 day	217 (72)	270 (100)	
After midnight	83 (28)	0 (0)	
Upload time within 1 day, median (minimum, maximum)	9:01 PM (7:29 PM, 11:59 PM)	7 PM (7 PM, 7 PM)	—
Upload time after midnight, median (minimum, maximum)	1:13 AM (12:02 AM, 2:01 AM)	—	—
Duration of recording a video (seconds), median (IQR)	56.3 (47.5-66.4)	59.6 (50.3-65.8)	.13
Observer characteristics and behaviors (n=19)			
Sex, n (%)			.99
Female	6 (60)	5 (56)	
Male	4 (40)	4 (44)	
Age (years), mean (SD)	35.9 (4.6)	39.4 (4.8)	.12
Lapse time between video uploading and reviewing (minutes), median (IQR)	322.6 (156.8-678.1)	81.9 (71.6-121.3)	.008
Review time, median (minimum, maximum)	3:46 PM (7:42 AM, 10:51 PM)	8:15 PM (7:02 PM, 10:45 PM)	—
Duration of reviewing a video (seconds), median (IQR)	102.7 (89.5-119.5)	79.4 (70.6-88.9)	<.001

^aP values were calculated by using a Fisher exact test for all categorical variables, a 2-tailed Student *t* test for age, and a Wilcoxon rank-sum test for the duration of recording and reviewing.

^bNot available.

Table 3. Average compliance in video-observed therapy (VOT) sessions completed by a user within 30 days (30-day mean cumulative function [MCF]) for each group.

Participants	Average session compliance of users within 30 days, MCF	Compliance, % ^a (95% CI)
Patients (n=10)	21.79	72.6 (70.0-75.2)
Observers		
Actual VOT (n=10)	19.03	63.4 (60.6-66.3)
Simulated VOT (n=9)	14.65	48.8 (44.2-53.5)

^aPercent compliance was calculated as follows: MCF/30 × 100.

Figure 3. Visualization of the VOT sessions completed by the three groups of users (solid dots). TB: tuberculosis; VOT: video-observed therapy.

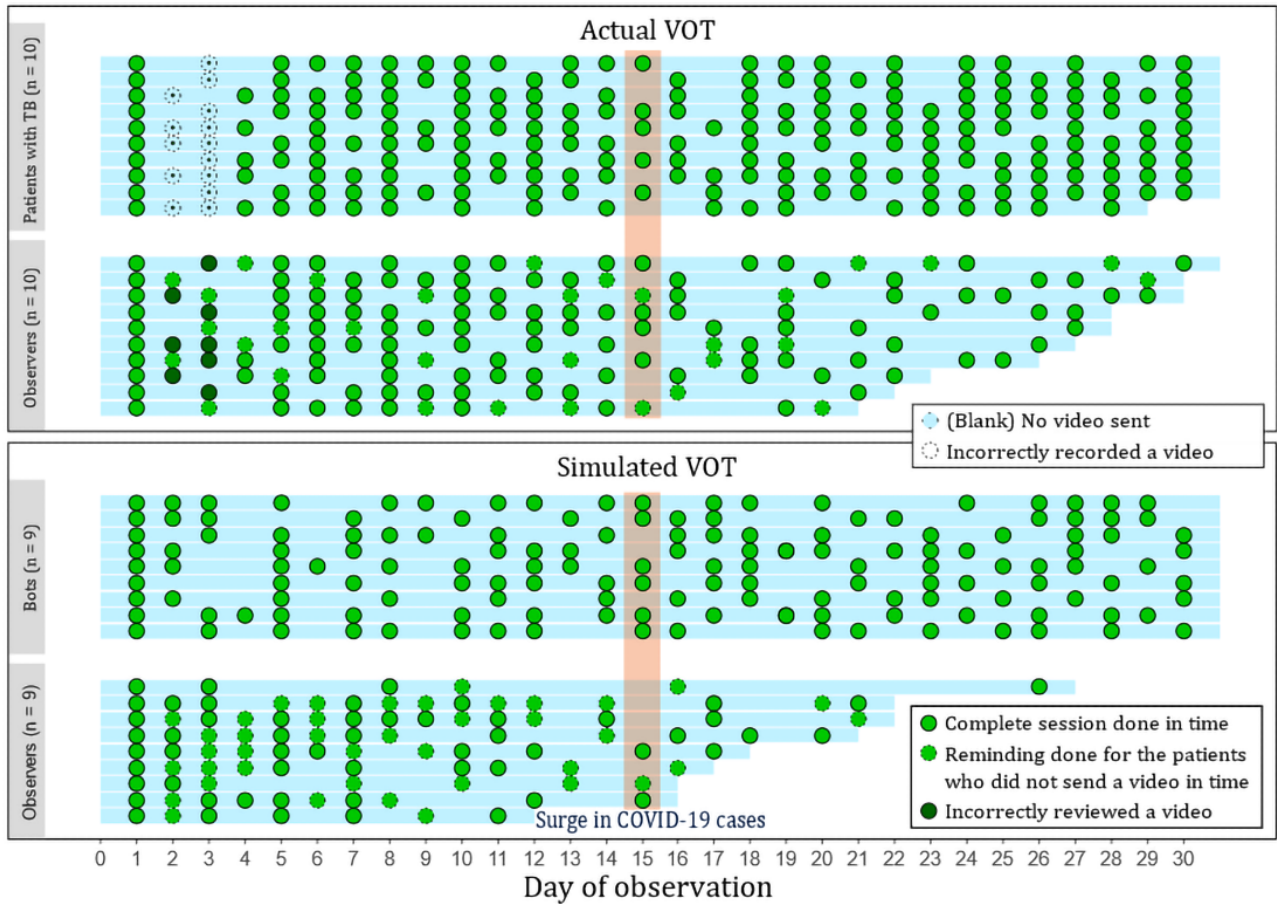

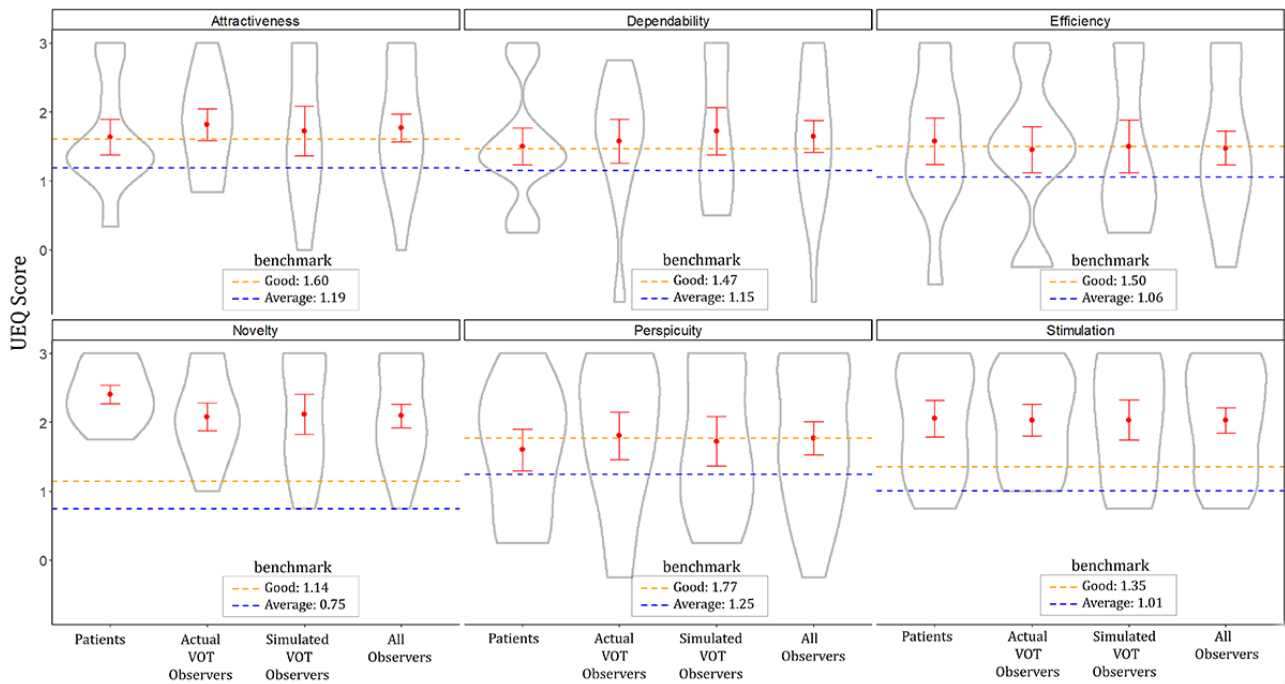

Figure 4. The six dimensions of UEQ assessed by the users within 30 days. UEQ: User Experience Questionnaire; VOT: video-observed therapy.

Discussion

Principal Findings

In the revised version of the TH VOT system, we added a notification and audit system to improve the accountability of users. This study reassessed the usability of the revised version of the system. The usability assessment, which was performed with the UEQ, showed that the system was usable at an above-average level for all dimensions. Good stimulation—the most important aspect in sustaining medication adherence—was achieved. In the actual VOT system, there were no particular patterns in the days that the patients and observers achieved compliance and noncompliance. Among the three groups of users, the patients almost reached the highest amount of compliance (70%). The average level of compliance across all three groups was above 50%. Compliance was easier to achieve for the simulated VOT observers because the simulated VOT videos were sent at a set time each day, as opposed to the actual VOT observers who received patients' videos at varying times. However, the simulated VOT observers' compliance levels sharply dropped when they had other responsibilities (ie, helping to control COVID-19). This did not seem to immediately affect the compliance of the actual VOT system observers, as they tried to continue their observation tasks for the sake of the patients with tuberculosis. However, their compliance did gradually dwindle over time owing to an increase in the number of COVID-19 cases. This was mirrored in many other countries where the level of tuberculosis care decreased due to the burden of COVID-19 [8,16,17].

In comparison to the previous version [9], the improved TH VOT system appeared to improve the compliance of both patients and observers via notifications and audits. The instructions regarding compliance protocols for VOT were meticulously developed to ensure that observers and patients completed all of the necessary steps. For patients, there was a learning curve for maintaining compliance because of the complexity of instructions, as evidenced by the noncompliant videos that were sent on the first few days. However, as time

went by, the patients' compliance was able to be kept at a reasonable level.

Unlike previous studies in the United States and United Kingdom [18,19], the observers in our study context (Thailand) could not be laypeople because of privacy concerns. Due to the shortage of paramedics in PCUs during the COVID-19 pandemic, the staff (observers) had an increased workload, and the traditional DOT program was almost completely ignored. In addition to routine work, the tuberculosis staff were responsible for many other tasks in their PCUs.

According to our previous study [9], all tuberculosis staff said that at best, they could perform DOT twice per month. With its feasible features and audit system, the TH VOT system has the potential to improve tuberculosis treatment monitoring among tuberculosis staff by increasing compliance with the DOT program from almost 0% to at least 50%. If the COVID-19 surge had not taken place, we would have been able to better assess compliance.

The number of participants in this study was too small to be able to evaluate the effectiveness of VOT on tuberculosis treatment outcomes. Hence, a larger-scale study that compares traditional DOT and VOT is needed. In addition, this study did not include a control group, and no medical outcome was assessed; thus, a randomized control trial (VOT vs DOT) is needed.

Conclusion

The updated version of the TH VOT system was considered usable by both the patients and the health care staff. Compliance with the use of the system was high among the patients (about 70%) and moderate among the observers (about 50%-65%). In this study, the reported usability scores showed that the TH VOT system was acceptable. Based on the unanimous above-average scores for all dimensions, we suggest that the system should be studied further and does not need any major changes. A randomized control trial should be conducted to ensure the effectiveness of the TH VOT system for tuberculosis treatment.

Acknowledgments

The researchers would like to sincerely thank all of the tuberculosis staff in the Hat Yai and Mueang Songkhla districts for their engagement in the implementation of the Thai video-observed therapy system. The mobile app's development was supported by the Health Systems Research Institute, Thailand. This study was funded by the Fogarty International Center and the National Institute of Allergy and Infectious Diseases of the National Institutes of Health under award number D43 TW009522. Abstract

Background: Due to the strict measures employed to control the spread of SARS-CoV-2, the extent of COVID-19 goes beyond morbidity and mortality and affects individuals' mental health in the long term.

Objective: This cross-sectional study aimed to investigate the effects of the COVID-19 pandemic on mental health and its contributing factors among older people in Chengmai County, China.

Methods: A web-based survey was administered through WeChat between March and April 2020. Older people (ie, >50 years) from local and foreign community groups completed the survey, which included items on sociodemographic and clinical characteristics, the 7-item Generalized Anxiety Disorder scale (GAD-7), and the 9-item Patient Health Questionnaire (PHQ-9). Independent *t* tests and a multiple linear regression analysis were used to investigate differences between anxiety and depression and the factors associated with these symptoms across the 2 groups.

Results: Overall, 469 responses were received; 119 responses (25.4%) were from male participants and 202 (43.1%) were from those older than 65 years. Of the 469 responses, 245 (52.2%) were from the local community group and 224 (47.8%) from the foreign group. The mean GAD-7 ($P=.003$) scores were significantly higher in the local group. Anxiety was significantly more present in the local group (61/245, 24.9% compared to 35/224, 15.6% in the foreign group; $P=.01$). A total of 6 respondents presented severe anxiety and 2 presented severe depression.

Conclusions: This study demonstrated that both community groups of older adults from the Chinese "Hometown of Longevity" presented anxiety or depressive disorders during the first months of the pandemic. Local community groups presented significantly more mental health disorders, which were associated with a history of previous psychological disorders.

KEYWORDS

mental health; COVID-19; depression; anxiety; aged; aging; older adults

Introduction

SARS-CoV-2 is a novel coronavirus identified as the cause of COVID-19 that emerged in Wuhan, China, in late 2019 and spread worldwide [1]. As of January 17, 2022, approximately 330 million cases have been confirmed worldwide, with 5.5 million deaths [2]. Due to its highly contagious pathogenic nature, safety measures employed by governments worldwide have tried to prevent the spread of COVID-19; these measures include social distancing (ie, limiting social gatherings), avoiding in-person interactions, and lockdowns [3]. Due to these strict measures, the effects of COVID-19 go beyond morbidity and mortality, and the long-term impact on mental health has been heavily discussed in clinical, scientific, and political settings [4-7].

Although COVID-19 can affect persons of any age, older people are particularly vulnerable to serious infection and death [8,9]. This group has been advised to stay indoors, avoid contact with family and friends, limit in-person visits, and have groceries and medicines delivered to their homes or shop during specific hours to reduce their risk of infection [10,11]. Before the pandemic, poor mental health in the elderly community was already considered a serious problem, with approximately 15% of people 60 years and older in the world living with a mental disorder, including anxiety and depression [12]. Given the well-established connections between social interactions and mental health in the elderly [13-16], the safety measures imposed due to COVID-19 may have had a negative impact on the mental health of this group. The mental health of the elderly is very important as it is closely related to their quality of life [17].

In the earlier phases of the emergence of COVID-19, China was the first to impose lockdowns and restrictions on movement and social gathering [18,19]. Chengmai County is a region in the touristic province of Hainan in China [20], famously known as the “Hometown of Longevity” since the life expectancy of its residents is 80 years, and 215 centenarians live in the region [21]. There are, however, 2 different communities of older people in Chengmai County that have different dialects, living habits, and socioeconomic characteristics: the local and the foreign community groups. The foreign group is composed of the so-called migratory birds, which is a colloquial term used to describe people, most often retirees, who reside in other regions of China but spend extended periods in Chengmai County during the winter months. Once COVID-19 restrictions were put into place, many migratory birds were stranded in Hainan. Although the epidemic in China subsided after the implementation of strict containment measures and movement restrictions [22,23], the effects of the COVID-19 pandemic on the mental health of older people from both communities in Chengmai County have not yet been investigated.

Although there are several studies demonstrating the high burden of anxiety and depressive symptoms among older people during the COVID-19 pandemic worldwide [24-30], the trend of anxiety and depressive symptoms has not been investigated in the region of China with the highest life expectancy. Therefore, the aim of this cross-sectional study was to investigate the

effects of the COVID-19 pandemic on mental health and its contributing factors among older people from 2 different communities in Chengmai County, China.

Methods

Ethical Considerations

This work was undertaken by the Xinhua Hospital Affiliated to Shanghai Jiao Tong University School of Medicine, which approved the secondary use of the data for this publication (protocol number XHEC-D-2021-165). Informed consent was obtained from all subjects involved in the study. Participation in the survey constituted voluntary consent to participate. Responses were confidential.

Study Design

This was a cross-sectional web-based study. Data collection was conducted from March 30, 2020, to April 9, 2020, via the web-based survey platform Wenjuanxing. The survey was disseminated through WeChat to local groups of hospital employees, schools, government organizations, and elderly individuals. All survey questions were in Chinese. Participants were asked about their circumstances in the previous month. Researchers were available to answer questions via WeChat or phone. Only 1 survey could be completed per device, and the link was active for 1 month.

Sample

The sample was comprised of 2 communities of older people (ie, 50 years or older) in Chengmai County, China: a local and a foreign group. The local group was composed of people who were born in the region and have lived there since. The foreign group was composed of migratory birds (ie, people who reside in other regions of China but spend extended periods in Chengmai County during the winter months) or people who retired in this region. The exclusion criteria were the following: (1) people with severe cognitive impairments or any conditions that preclude them from being able to understand and agree to participate in the research; (2) people 50 years or older who are not retired; (3) people with severe liver and renal disease, malignant tumors, severe anemia, autoimmune diseases, or a history of acute cerebrovascular accidents; and (4) people unwilling to cooperate with the research protocol.

Measures

The web-based survey consisted of the following measures: (1) participants' clinical and sociodemographic characteristics, namely age, gender, marital status, living situation, educational attainment, fixed financial income, preretirement occupation, internet access, history of previous psychological disorders, and recent psychological trauma; (2) the presence of anxiety disorders measured by the 7-item Generalized Anxiety Disorder scale (GAD-7) [31]; and (3) the presence of depressive disorders measured by the 9-item Patient Health Questionnaire (PHQ-9) [32].

The GAD-7 is a 7-item instrument that measures symptoms of anxiety. Each item is scored on a 4-point Likert scale ranging from 0 (“not at all”) to 3 (“nearly every day”). Scores range from 0 to 27, with higher scores reflecting greater anxiety

symptoms. Cutoff points of 5, 10, and 15 might be interpreted as representing mild, moderate, and severe levels of anxiety, respectively [31,33]. The GAD-7 has shown good reliability and validity in Chinese populations [34,35].

The PHQ-9 is a 9-item instrument that measures depressive symptoms corresponding to the diagnostic criteria for major depressive disorders. For each item, patients are asked to assess how much they were bothered by the symptoms over the previous 2 weeks. Each item is also scored on a 4-point Likert scale ranging from 0 (“not at all”) to 3 (“nearly every day”). Scores range from 0 to 27, with higher scores reflecting greater depression severity. Similar to the GAD-7, cutoff points are scores of 5, 10, and 15, which represent mild, moderate, and severe levels of depression, respectively [32]. The PHQ-9 has been considered valid and reliable to identify depression in the Chinese population [36].

Statistical Analysis

Data were exported from Wenjuanxing to SPSS (version 22; IBM Corp), where the statistical analysis was performed. Descriptive statistics were used to describe participants' socioeconomic and clinical characteristics. Chi-square tests were used to compare the proportions of respondents across the 2 community groups. The normality of the data distribution was tested using the Kolmogorov-Smirnov test. Independent *t* tests were used to investigate differences between anxiety and depressive symptoms across the 2 community groups. To identify the sociodemographic and clinical factors associated with anxiety and depressive symptoms in respondents from the

2 community groups, a multiple linear regression analysis was carried out with GAD-7 and PHQ-9 total scores as dependent variables and the collected demographic and clinical characteristics as independent variables. $P < .05$ was considered statistically significant for all tests.

Results

Respondents

Overall, 469 responses were received, of which 245 (52.2%) were from the local community group and 224 (47.8%) from the foreign community group. The overall sample was predominately elderly (321/469, 68.4% between 55 and 74 years), female ($n=350$, 74.6%), and married ($n=409$, 87.2%); most participants had high educational attainment ($n=328$, 69.9% of the sample had at least a high school degree). In addition, only 9.6% (45/469) of participants lived alone. Table 1 presents the sociodemographic and clinical characteristics of respondents overall and by community group. As described, respondents from the foreign community group were significantly older ($P < .001$), had higher educational attainment ($P < .001$), were more likely to have had a physical labor occupation before retirement ($P < .001$), had more fixed income ($P < .001$), relied more on their own expenses and less on medical allowances to pay for medical costs ($P < .001$), were more likely to live with their spouses ($P < .001$), used social media more often, and were more likely to have a history of mental health disorders ($P < .001$) and psychological trauma ($P = .03$) than respondents from the local community group.

Table 1. Sociodemographic and clinical characteristics for the overall sample and by community group.

Characteristic	Overall sample (N=469), n (%)	Local community group (n=245), n (%)	Foreign community group (n=224), n (%)	Chi-square value (df)	P value
Age group in years					
50-54 years old	96 (20.5)	82 (33.5)	14 (6.3)	77.031 (4)	<.001
55-64 years old	171 (36.5)	63 (25.7)	108 (48.2)

Internet access	339 (72.3)	126 (51.4)	213 (95.1)	111.33 (1)	<.001

^aSymptoms of anxiety or depression or a diagnosis of these conditions was considered a history of mental health disorders for this study.

^bPsychological trauma that occurred in the past 3 months was considered recent.

Presence of Anxiety and Depressive Disorders

Table 2 displays the presence of anxiety (measured by the GAD-7) and depressive disorders (measured by the PHQ-9). Overall, 20.5% (96/469) of respondents presented some levels of anxiety and 19.2% (n=90) presented depression. Regarding the differences between community groups, the mean GAD-7 ($P=.003$) scores were significantly higher in the local group

compared to the foreign one. Anxiety was significantly more present in the local group compared to the foreign group (61/245, 24.9% versus 35/224, 15.6%; $P=.01$). There was no significant difference in the presence of depressive disorders between the groups. Finally, 6 respondents presented scores related to severe anxiety and 2 respondents presented scores related to severe depression.

Table 2. The presence of anxiety and depressive disorders in the overall sample and each community group.

Mental health disorder	Overall sample (N=469)	Local community group (n=245)	Foreign community group (n=224)	P value
Anxiety				
GAD-7 ^a total scores, mean (SD)	2.3 (3.3)	2.7 (3.7)	1.8 (2.8)	.003
Anxiety identified by GAD-7 scores (ie, >5), n (%)	96 (20.5)	61(24.9)	35 (15.6)	.01
Mild anxiety (GAD-7 scores between 5 and 9), n (%)	79 (16.8)	49 (20)	30 (13.4)	— ^b
Moderate anxiety (GAD-7 scores between 10 and 14), n (%)	11 (2.3)	7 (2.9)	4 (1.8)	—
Severe anxiety (GAD-7 scores between 15 and 21), n (%)	6 (1.3)	5 (2)	1 (0.4)	—
Depression				
PHQ-9 ^c total scores, mean (SD)	2.3 (3.2)	2.3 (3.3)	2.4 (3.0)	.73
Depression identified by PHQ-9 scores (ie, >5), n (%)	90 (19.2)	50 (20.4)	40 (17.9)	.48
Mild depression (PHQ-9 scores between 5 and 9), n (%)	70 (14.9)	39 (15.9)	31 (13.8)	—
Moderate depression (PHQ-9 scores between 10 and 14), n (%)	18 (3.8)	9 (3.7)	9 (4)	—

^cPHQ-9: 9-item Patient Health Questionnaire.

Factors Associated With the Presence of Anxiety and Depressive Disorders

The regression models for the local and foreign community groups are presented in [Multimedia Appendix 1](#) and [Multimedia Appendix 2](#), respectively. Results suggest that a history of mental health disorders and psychological trauma are associated with anxiety ($F_{9,235}=2.45$; $P=.01$; $R^2=0.09$) and depression ($F_{9,235}=2.88$; $P=.003$; $R^2=0.10$) in the local community group. In the foreign community group, only having a physical labor occupation before retirement was associated with depressive disorders, although the overall regression model was marginally significant ($F_{9,214}=1.79$; $P=.07$; $R^2=0.07$).

Discussion

This study was conducted to investigate the effects of the early months of the COVID-19 pandemic on mental health and its contributing factors among older people from 2 different communities in a Chinese region with one of the longest life expectancies. During the first months of the pandemic, in 2020, China was the first country that imposed strict restrictions, when little was known about the virus and its effect; therefore, results from this study describe the mental health effects in this scenario. The findings from our study identified that 20.5% (96/469) of respondents presented some levels of anxiety and 19.2% (90/469) presented depression, and anxiety was significantly more present in respondents from the local community group.

It is unanimously agreed that the COVID-19 pandemic has negatively impacted the mental health of different groups, such as health care providers [37-39], people living with disabilities or chronic conditions [5,40-43], pregnant women [44,45], young

people [46], and the elderly [25,27,29,30,47]. Although with different characteristics, activities, routines, and lifestyles, the impacts of COVID-19 on these groups have led to an increase in loneliness, anxiety, depression, insomnia, alcohol and drug use, and self-harm or suicidal behavior [48]. Specifically in the elderly group, there has been an identified increase in loneliness in response to COVID-19 measures [49], which can lead to poor mental and physical health [50], serious illness, and mortality [51,52]. Although we have not assessed loneliness in this study, since only 10% (45/469) of respondents lived alone, it is possible that social interactions with spouses and family members living in the same household helped compensate for the decrease in other social interactions due to COVID-19 restrictions.

Results from this study suggest that a history of mental health disorders and psychological trauma are associated with anxiety and depression in the local community group. Therefore, approaches to help mitigate the negative impact of the COVID-19 pandemic on older people with previous mental health disorders are warranted. Interventions should focus on multiple components, including emotional, spiritual, social, and physical support to meet the various health needs of the elderly [53-55]. Internet-based interventions have demonstrated the potential to support the self-management of mental health conditions and could provide people access to information and tools during COVID-19 restrictions [56-58].

Caution is warranted in interpreting the findings of this study. First, the cross-sectional nature of this study allows no causal interpretation of the results. We are not able to identify if mental health disorders are further aggravated due to COVID-19 restrictions or if the results reflect preexisting differences in mental health. Moreover, we do not know what the delayed effects of COVID-19 in the following months and years are, and if these disorders were aggravated since restrictions continue to take place 2 years after the start of the pandemic. This should

be evaluated in a future study. Second, the generalizability of the results is unknown and may be limited for the following reasons. We do not know how many people received the invitation to complete the web-based survey. In addition, this was a convenience sample, so the results may be biased. Third, although we have used well-established and validated tools to identify anxiety and depressive disorders, the gold standard to establish a clinical diagnosis of a mental disorder is a diagnostic structured interview with a professional. Finally, developing and applying appropriate interventions for mental health during a pandemic is essential. For this reason, future research in this area should focus on the design of appropriate interventions targeting improvements in mental health and the adoption of a healthy lifestyle during COVID-19 restrictions and beyond.

In conclusion, the present study investigated the mental health of older people living in the so-called Hometown of Longevity in China. Results showed that 20% (n/N) of respondents had anxiety or depressive disorders, and there was an association between current mental health status and a history of psychological disorders, highlighting the need to take measures to prevent, identify, and treat mental health problems in this group. Although many studies have been conducted focusing on mental health and COVID-19, the global crisis we are now living in is still new and rapidly evolving. The long-term consequences of this pandemic on mental health should be evaluated and effective mental health interventions should be developed.

Acknowledgments

We thank all the participants and their families, the Elderly Community College, and local hospitals and government organizations for helping with recruitment. This study was supported by a grant from the Science and Technology Commission of Shanghai Municipality awarded to HC (grant 19ZR1433200).

Abstract

Background: Behavioral weight loss programs typically enroll 12-40 people into groups that then suffer from declining engagement over time. Web-based patient communities, on the other hand, typically offer no limits on capacity and membership is fluid. This model may be useful for boosting engagement in behavioral weight loss interventions, which could lead to better outcomes.

Objective: In this study, we aimed to examine the feasibility and acceptability of continuously enrolling participants into a Facebook-delivered weight loss intervention for the first 8 of 16 weeks relative to the same intervention where no new participants were enrolled after randomization.

Methods: We conducted a randomized pilot trial to compare a Facebook weight loss group that used open enrollment with a group that used closed enrollment on feasibility and acceptability in adults with BMI 27-45 kg/m². The feasibility outcomes included retention, engagement, and diet tracking adherence. We described the percentage loss of ≥5% weight in both groups as an exploratory outcome. We also explored the relationship between total volume of activity in the group and weight loss. The participants provided feedback via web-based surveys and focus groups.

Results: Randomized participants (68/80, 85% women) were on average, aged 40.2 (SD 11.2) years with a mean BMI of 34.4 (SD 4.98) kg/m². We enrolled an additional 54 participants (50/54, 93% female) in the open enrollment condition between weeks 1 and 8, resulting in a total group size of 94. Retention was 88% and 98% under the open and closed conditions, respectively. Randomized participants across conditions did not differ in engagement ($P=.72$), or diet tracking adherence ($P=.42$). Participant feedback in both conditions revealed that sense of community was what they liked most about the program and not enough individualized feedback was what they liked the least. Weight loss of ≥5% was achieved by 30% (12/40) of the participants randomized to the open enrollment condition and 18% (7/40) of the participants in the closed enrollment condition. Exploratory analyses revealed that the open condition (median 385, IQR 228-536.5) had a greater volume of engagement than the closed condition (median 215, IQR 145.5-292; $P=.007$). Furthermore, an increase of 100 in the total volume of engagement in the Facebook group each week was associated with an additional 0.1% weekly weight loss among the randomized participants ($P=.02$), which was independent of time, individual participant engagement, and sociodemographic characteristics.

Conclusions: Open enrollment was as feasible and acceptable as closed enrollment. A greater volume of engagement in the Facebook group was associated with weight loss, suggesting that larger groups that produce more engagement overall may be beneficial. Future research should examine the efficacy of the open enrollment approach for weight loss in a fully powered randomized trial.

Introduction

Background

Obesity, a serious risk factor for cardiovascular disease and type 2 diabetes, affects 42.4% of the adults in the United States [1]. Robust evidence supports the efficacy of lifestyle interventions [2], but such interventions require regular in-person visits for 6-12 months, which is inconvenient for many people and a difficult model to scale up. Technology-delivered lifestyle interventions have been developed to address these challenges. Although weight loss outcomes from technology-delivered lifestyle interventions are promising, they still need optimization because weight loss outcomes tend to be lower than those produced by traditional clinic-based interventions [3]. Technology-based interventions are typically delivered via a web-based platform or mobile app in which participants receive counseling, peer support, and multimedia intervention content. Some of these interventions use commercial social media platforms, such as Facebook, because they are free, many people already use them, and some allow users to create private groups [4,5].

Systematic reviews and meta-analyses have revealed promising outcomes of social media-delivered lifestyle interventions [6-10], with modest but significant weight loss [11]. Engagement, defined as any visible activity in the group (eg, posts, comments on posts, *likes*, and poll votes), appears to be an important predictor of outcomes [12-15]. The degree of engagement reported in studies of social media-delivered interventions is highly variable, ranging from an average of once per participant during the entire intervention to 11 times per week per participant during the intervention [12,13,15-21]. Regardless of how engaged the participants are at the beginning of these programs, engagement generally declines over time. For example, in a study of a social media-delivered weight loss intervention, engagement in the first 3 months was significantly higher than that in the last 3 months [18]. The same study found that every 10 posts made by a participant corresponded to a -0.5% weight loss. Similarly, findings from a social media-delivered smoking cessation intervention study revealed that a 1-unit increase in engagement was associated with a 0.56-unit decrease in cigarettes smoked per week [22]. These findings suggest that keeping participants engaged throughout the course of the intervention may improve outcomes. Effective engagement strategies are required to accomplish this goal.

Few studies have tested strategies for increasing engagement in social media-delivered interventions. In our previous study of a Facebook-delivered weight loss intervention, participants were randomized to a condition in which a small number of participants were incentivized to engage daily or a condition that involved no incentivized engagement [15]. Participants in the incentivized condition were unaware of this arrangement until they were debriefed at the end of the intervention. Engagement was higher in the incentivized condition, but this

was driven mostly by an increase in *likes* as opposed to posts and comments, which means that the activity of incentivized engagers did not effectively prompt others to speak up more in the group. This study was not powered to detect group differences in weight loss; however, greater engagement was associated with greater weight loss.

An alternative approach to increasing engagement might be to design web-based lifestyle interventions that are more similar to spontaneously formed web-based patient communities that tend to be highly engaged [23,24]. Web-based patient communities have become increasingly popular on commercial social media platforms, but they have also been developed by commercial digital health companies (eg, WW [formerly Weight Watchers]), nonprofit organizations (eg, the American Diabetes Association), and health care systems (eg, Mayo Clinic Connect) [25]. Web-based patient communities have been created for a wide variety of medical conditions, including diabetes [26], cancer [23], and cardiovascular disease [25]. Many of these communities have thousands of members and a high volume of daily engagement [27]. Spontaneously formed web-based patient communities are different from web-based communities created for behavioral programs, as the latter tend to recruit smaller groups of people who start and finish the program together on specific dates [12,13,17,28]. Spontaneously formed web-based patient communities are also larger and fluid in membership, such that new members can join any time, which allows them to grow quite large over time. Such communities might stay highly engaged because even if some members inevitably disengage over time, new members are always joining and keeping the discussion threads populated, which provides new content to read and respond to all members. Fluidity in web-based communities can result in a greater exchange of information, support, and resources, leading to more innovative knowledge creation among community members [29]. Further, the volume of daily engagement often remains consistently high for long periods, unlike the usual steady decline in engagement observed in short-term (eg, 3-6 months) web-based communities created to implement behavioral programs.

A high volume of engagement seems important for improving the impact of behavioral interventions delivered in web-based communities for 3 reasons. First, Facebook's newsfeed algorithm prioritizes groups that show higher engagement [30]. This means that Facebook users are more likely to see posts in their newsfeeds from a highly engaged group than from a group where only a few members are engaging. Second, a higher volume of posts may simply produce more opportunities for members to engage, receive information and support, and feel connected to each other. Third, highly engaged groups may make engagement easier for timid members who are not comfortable being the first to speak up. In our previous work, we found that in postintervention interviews, participants expressed that they wished more participants engaged and felt uncomfortable being the first to speak up [12]. That said, too

much content from a large community may cause members to feel cognitive overload [31] or make it difficult to find program content. An important difference between organically grown web-based communities and the ones researchers create to deliver behavioral interventions is that the former do not have a feed of behavioral intervention posts by a professional counselor; instead, the content is largely member generated. If web-based communities that are created to deliver behavioral interventions become saturated with participant-generated content, intervention receipt, defined as the degree to which participants saw intervention posts, could be compromised, which could then negatively impact outcomes. Research is needed to determine how to create a web-based community to deliver a lifestyle intervention in which participants are highly engaged but not so much that they feel that other participants' posts impede their ability to follow the program.

Goal of This Study

The purpose of the present *proof of concept* pilot study is to test the feasibility and acceptability of a Facebook-delivered lifestyle intervention that shares the open enrollment feature of organically grown web-based patient communities. As such, once a core set of participants is randomized into a group, enrollment continues to allow new people to join each week. Participants with overweight or obesity were randomized to receive either a Facebook-delivered lifestyle intervention in which enrollment continued for the first 8 of 16 weeks (ie, open enrollment condition) or the same intervention but in a Facebook group that did not continuously enroll participants (ie, closed enrollment condition). Our first aim was to examine retention (ie, percentage of participants providing their weight at follow-up) and acceptability (ie, percentage of participants who would recommend the program to a friend, percentage of participants who did not feel other participants posted too much, and percentage of participants who felt the counselors were responsive) in each condition and overall. We hypothesized that retention and acceptability would exceed our benchmark of 80% in both conditions. We measured acceptability quantitatively and qualitatively in focus groups, where participants were asked what they liked and disliked about the program and their thoughts on the size of their group.

The second aim was to compare the conditions on participant engagement during the intervention. Engagement was conceptualized in 4 ways. The first way was mean total engagement (ie, reactions, comments, posts, and poll votes) per randomized participant during the intervention. The second way was total engagement among all the participants in each condition during the intervention. The third way was total engagement produced by everyone in the group (all participants and counselors). The fourth way was engagement among all participants during the 1 year following the intervention when we left the groups open for participants to use as they wished. We hypothesized that the open enrollment condition would outperform the closed enrollment condition in all 4 metrics of engagement.

Our third aim was to compare the conditions on the number of complete daily diet records, a key behavioral weight loss

strategy, to explore whether an increasingly populated group either motivates or distracts participants from their diet tracking.

Our fourth aim was to compare the conditions on counselors' total engagement. We hypothesized that counselors in the open enrollment condition would engage more than counselors in the closed enrollment condition. This difference will inform future randomized trials on the cost-effectiveness of these intervention approaches.

Our fifth aim was to describe the percentage of weight loss from baseline to 16 weeks and the proportion of participants who lost $\geq 5\%$ of their baseline weight in both conditions. This aim is descriptive because this pilot feasibility study did not have the power to detect significant differences in weight loss between conditions. Our sixth aim was to explore whether the volume of engagement in the Facebook group (ie, posts and comments from participants and counselors) each week was associated with weight loss among randomized participants. This sheds light on whether greater engagement in the overall group is a potential predictor of better outcomes.

Methods

Study Design, Settings, and Participants

This study was a pilot randomized feasibility trial in which 80 participants who were either overweight or obese were randomized into 1 of 2 remotely delivered lifestyle interventions. We recruited adults interested in losing weight via advertisements on the web, at the University of Connecticut, ResearchMatch, and yard sale and neighborhood Facebook groups in 37 states across the United States between June and October 2019. Inclusion criteria included having a BMI between 27 and 45 kg/m², owning a smartphone, being an active Facebook user (ie, comments or posts more than once a week), aged 18-65 years, and having daily internet access. Exclusion criteria were pregnancy, bariatric surgery or plans during the study period, loss of $>5\%$ weight in the past 3 months, pre-existing conditions that precluded physical activity or dietary changes, taking medications affecting weight, inability to walk a quarter mile without stopping, type 1 or type 2 diabetes, Participation in previous weight loss studies led by the principal investigator, inability to attend the orientation webinar, inability to provide consent, and refusal to be audiotaped (focus group).

Participants completed an orientation webinar before randomization, the purpose of which was to educate participants about participating in research, review study procedures, discuss the importance of follow-up data regardless of individual outcomes, and discuss barriers to participation [32]. Upon completion of the webinar, those still interested in participating in the study were mailed a Wi-Fi scale (Fitbit Aria) and asked to provide the staff with log-in information for the scale to record the weights for the assessments. We randomized 80 participants to the 2 conditions and continued to recruit participants for 7 weeks, placing all new recruits into the open enrollment condition. Each week, new recruits were introduced to the group by a counselor in a welcome post on Sunday evening.

Intervention Conditions

Overview

Participants were randomized to either a Facebook group in which new participants were continually enrolled during weeks 1-8 (open enrollment) or a Facebook group that included only the original 40 randomized participants (closed enrollment). In the open enrollment condition, 54 additional participants were enrolled between weeks 1 and 8, for a final group size of 94 (open enrollment additional). Both Facebook groups were led by a registered dietitian, whose role was to provide counseling and support during the program. The dietitians in each group had a junior coleader who assisted them. All counselors completed the web-based Diabetes Prevention Program (DPP) Lifestyle Intervention training.

Facebook-Delivered Lifestyle Intervention

All participants received an identical 16-week lifestyle intervention based on the DPP [33] but modified to be delivered to a private Facebook group. We adapted the DPP content to be appropriate for a web-based setting as described elsewhere [34]. Each participant received an individualized calorie goal that would facilitate a 1 to 2 lb (0.45-0.91 kg) weight loss weekly and was asked to use MyFitnessPal to track their calories daily. They were asked to have the counselor review 2 weeks of their MyFitnessPal records but could request reviews more often as desired. The Facebook group was private, such that only those invited by the study team could join, and the group and all its content were viewable only to the members. Consistent with our previous work [34,35], the lifestyle intervention was delivered through twice-daily posts, with each week's content reflecting 1 DPP module. The DPP goals include (1) calorie tracking based on achieving the calorie goal that corresponds to losing 1-2 lbs a week (0.45-0.91 kg), (2) following a healthy diet consistent with the American Heart Association guidelines [36], (3) getting 150 to 300 minutes per week of moderate or higher intensity exercise, and (4) strength training goal of 2 times per week according to the National Guidelines for Physical Activity [37]. On Mondays in the group, participants were instructed to set 2-3 diet- and exercise-related goals for the week. On Friday mornings, they were asked to report the degree to which their weight had changed in the past week (eg, lost 1 lb), but not their actual weight (eg, 250 lbs). On Sundays, they were asked to report whether they accomplished their diet and exercise goals for the week and if they did not, to engage in problem solving of the barriers. The remaining posts each week were related to that week's DPP module (eg, Get More Active and Cope with Triggers). Throughout the intervention, staff produced weight and engagement reports for counselors to track which participants had not engaged during that week or had not lost weight. This allowed counselors to re-engage participants by tagging them in posts or sending private messages to check on them.

Focus Groups

At the end of the intervention, all participants were contacted by email to schedule a focus group via videoconference. Participants were asked what they liked most and least about the program and their opinions on how to improve various

aspects of the program. The focus groups were recorded and transcribed.

Postintervention Period

At the end of the 16-week intervention, participants in both groups were informed that they may stay in the group for up to a year to continue using the group as they wished to support each other's continued weight loss efforts; however, the counselor would no longer be present. In the final weeks of the intervention, the counselor in each group asked a volunteer to take over the group moderator role for this period. Each group had a volunteer who was willing to take on this role. They were also reminded that the study team would extract engagement data in the subsequent year as part of the research procedure. We tracked engagement in the year following the end of the intervention to see if the entire open enrollment group (randomized and additional) continued to engage to a greater degree than did the closed enrollment group.

Measures

Retention

Retention was assessed by recording the percentage of participants in each condition who completed the 16-week follow-up assessment, which included the final weigh-in and survey.

Acceptability

Participants rated the acceptability of their intervention in the follow-up survey using the following items. First, participants rated how likely they would be to recommend the program to a friend using responses on a 5-point Likert scale from not at all likely to very likely. Second, participants reported what they thought of the amount of posts by other participants in the group using the following response options, "I would prefer that participants did not post at all," "I would prefer fewer posts by participants," "I liked the amount of posts by participants," and "I would prefer more posts by participants." Third, participants reported what they thought of the amount of comments made by other participants in their group using the following response options: "I would prefer that participants did not reply/comment at all," "I would prefer fewer comments by participants," "I liked the amount of comments by participants," and "I would prefer more comments by participants." Fourth, participants rated how responsive counselors were to participants' posts using the following response options, "The counselors were not responsive," "The counselors were somewhat responsive," and "The counselors were very responsive." Finally, we asked participants if they had become Facebook friends with any participants (yes or no), and if so, how many.

Engagement

Engagement was broadly defined as posts, comments, reactions (eg, love, wow, like, angry, and sad), and votes on polls. After the intervention was complete, we extracted the engagement data of the private Facebook groups using the Grytics app, except for poll data, which were extracted manually because Grytics does not extract poll data. We summarized the total number of posts, comments, reactions, and poll votes per randomized participant, as well as per participant (randomized

and postrandomized) during the intervention period. We also calculated total participant engagement in each condition during the year following the intervention. In addition, we calculated the total volume of participant engagement as the total number of posts, comments, and poll votes in each condition (and in each week), and then the total volume of engagement, including that generated by the counselor and all participants in the group. We also summarized the posts, comments, reactions, and total engagement by counselors in each condition.

Diet Tracking Adherence

Diet tracking adherence was defined as the number of days a participant tracked their dietary intake in the MyFitnessPal app. A complete day of diet tracking was defined as any day on which the participants tracked ≥ 2 meals and ≥ 800 kcal per day [21,22].

Weight

Weight was collected at baseline and each week of the intervention via the Fitbit Aria scales the participants received upon enrollment. Participants were advised to weigh themselves in the morning with no clothing and before eating or drinking. The study staff had access to the participant Fitbit accounts during the study and accessed weight values via these accounts. Percentage weight change from baseline was calculated for each participant by subtracting the follow-up weight from the baseline weight and dividing by the baseline weight.

Statistical Analysis

Retention, engagement, diet tracking, acceptability, and weight loss were summarized using descriptive statistics. For variables that were normally distributed, we described distributions using means and SDs. For variables that were not normally distributed, we described distributions using medians and IQRs. We compared engagement and diet tracking by treatment condition using *F* tests or the Mann-Whitney *U* test, as appropriate. This pilot study was not powered for weight loss; thus, statistical tests were not used to compare groups on weight loss [26]. A participant became pregnant during the intervention and was not included in the weight loss outcomes. Four participants (1 in closed enrollment and 3 in additional open enrollment) did not provide follow-up weight; thus, if weight was available within 1 week of the follow-up week, that weight was used (1 participant); otherwise, the baseline weight was used (3 participants). We conducted a conventional content analysis using a data-driven inductive framework [25] of focus group data on acceptability. HT and JD developed a codebook based on themes emerging from participant responses. JD and HT independently coded responses, and discussions were used to achieve consensus on coding discrepancies. The interrater reliability (IRR) and Cohen κ statistics were calculated [27]. We summarized the frequency of the themes.

Furthermore, we performed two exploratory analyses: (1) we summarized the total volume of engagement in each condition in each week and compared the conditions using Mann-Whitney *U* tests and (2) we tested whether the total volume of engagement in the Facebook group each week was associated with weekly weight loss among the randomized participants. To this end, we first used multiple imputation [33] to impute the missing values of weekly weight during the intervention for all randomized participants (excluding the participant who became pregnant). A total of 12.97% (164/1264) observations were missing and thus imputed. We then used the percentage weight change for each participant in each week as the outcome and the total volume of engagement (ie, number of posts, comments, and poll votes from participants and counselors) in the Facebook group in each week as the key predictor of interest and controlled for the treatment condition; week of the intervention; participants' individual engagement in each week (log-transformed); baseline weight; and sociodemographic characteristics such as age, race, gender, and employment status in a linear mixed-effects model [38].

Data management and quantitative analyses were conducted using SPSS Statistics (version 26; IBM Corp). STATA (version 16.0; StataCorp LLC) was used for exploratory analysis of engagement volume and weight loss.

Ethical Considerations

This research was approved by the University of Connecticut Institutional Review Board (H17-215) in October 2017.

Results

Overview

In total, 499 individuals completed the initial screening survey (Figure 1). Among those screened for eligibility, the most common reasons for exclusion were BMI out of range (< 27 or > 45 kg/m²), nonregular Facebook use, $> 5\%$ weight loss in the past 3 months, and unresponsiveness to contact (Figure 1). A total of 80 participants were randomized to the 2 treatment conditions (Table 1). Overall, randomized participants were on average, aged 40.2 (SD 11.2) years with a baseline BMI of 34.4 (SD 5.0) kg/m², 85% (68/80) were women, and 90% (72/80) were non-Hispanic White. The participants were from 34 US states and District of Columbia. A total of 54 participants were enrolled in the open enrollment condition between weeks 1 and 8. Of these 54 participants, a total of 19 (35%) joined during week 1, 7 (13%) joined during week 2, 3 (6%) joined during week 3, 8 (15%) joined during week 4, 7 (13%) joined during week 5, 5 (9%) joined during week 6, 3 (6%) joined during week 7, and 2 (4%) joined during week 8.

Posts or comments on Facebook daily, n (%)	20 (50)	18 (45)	25 (46)	63 (47)

Retention

Retention exceeded the 80% benchmark in both treatment conditions, with 88% (35/40) of randomized open enrollment participants, 98% (39/40) of closed enrollment participants, and 87% (47/54) of additional open enrollment participants, providing complete follow-up data.

Acceptability

Among participants who completed the follow-up survey (121/134, 90.3%), general acceptability ratings exceeded the 80% benchmark in both conditions, such that 92% (36/39) of the closed enrollment participants said they were a little to very likely to recommend the program to a friend, compared with

89% (31/35) of randomized open enrollment participants and 94% (44/47) of the additional open enrollment participants. When asked about the volume of posts by other participants in the group, the benchmark of at least 80% of the participants felt that other participants did not post too much was exceeded, such that 92% (36/39) of the closed enrollment participants said they either liked the amount of posts (30/39, 77%) or wanted more posts (6/39, 15%) by other participants compared with 86% (30/35) of the randomized open enrollment participants who said they either liked the amount of posts (22/35, 63%) or wanted more (8/35, 23%) and 92% (43/47) of the additional open enrollment participants who said they either liked (33/47, 70%) or wanted more (10/47, 21%; [Table 2](#)).

Table 2. Acceptability of post and reply volume by other participants.

	Closed enrollment (n=39), n (%)	Open enrollment, n (%)			All participants (n=121), n (%)
		Randomized (n=35)	Additional (n=47)	All partici- pants (n=82)	
Participant post volume					
I would prefer that participants did not post at all.	0 (0)	1 (2.9)	2 (4.3)	3 (3.7)	3 (2.5)
I would prefer fewer posts by participants.	3 (7.7)	4 (11.4)	2 (4.3)	6 (7.3)	9 (7.4)
I liked the amount of posts by participant.	30 (76.9)	22 (62.9)	33 (70.2)	55 (67.1)	85 (70.2)
I would prefer more posts by participants.	6 (15.4)	8 (22.9)	10 (21.3)	18 (22)	24 (19.8)
Participant reply volume					
I would prefer that participants did not comment/reply to posts at all.	0 (0)	2 (5.7)	1 (2.1)	3 (3.7)	3 (2.5)
I would prefer fewer comments/replies by participants.	2 (5.1)	3 (8.6)	1 (2.1)	4 (4.9)	6 (5)
I liked the amount of comments/replies by participants.	27 (69.2)	25 (71.4)	37 (78.7)	62 (75.6)	89 (73.6)
I would prefer more comments/replies by participants.	10 (25.6)	5 (14.3)	8 (17)	13 (15.9)	23 (19)

When asked about the volume of replies by other participants in the group, the 80% benchmark (ie, 80% not feeling like other participants replied too much) was exceeded such that 95% (37/39) of the closed enrollment participants said they liked the amount of posts (27/39, 70%) or wanted more (10/39, 26%), whereas 85% (30/35) of the randomized open enrollment participants said they either liked the amount of posts (25/35, 71%) or wanted more (5/35, 14%), and 96% (45/47) of the additional open enrollment participants said they either liked the amount of posts (37/47, 79%) or wanted more (8/47, 17%; [Table 2](#)).

When asked to rate the responsiveness of counselors to participants' posts, the 80% benchmark was not met in all groups: although 87% (34/39) of the closed enrollment participants said they were very responsive, only 77% (27/35) of the randomized open enrollment participants and 83% (39/47) of the additional open enrollment participants did so. Finally, when asked if they became Facebook friends with fellow participants, only 3% (1/39) of randomized participants in the closed enrollment and 3% (1/35) of open enrollment conditions had done so, whereas 15% (7/47) of the additional participants in the open enrollment condition had done so. The closed enrollment randomized participant who said yes to this question made 1 new Facebook friend, whereas the open enrollment participant had made 3 new Facebook friends, and of the 7 additional open enrollment participants who made new Facebook friends, 5 (71%) said they made 1 new Facebook friend, and 2 (29%) said they made 2 new Facebook friends.

Participants (118/134, 88.1%) who attended postintervention focus groups provided 165 responses to the question about what

they liked most about the program (IRR=90%; Cohen κ =0.88; [Table 3](#)). The closed enrollment participants (n=37) provided 54 responses, the most common themes of which were sense of community (17/54, 32% responses), program content (16/54, 30% responses), and accountability (9/54, 17% responses). The open enrollment of randomized participants (n=34) provided 42 responses. The most common themes were sense of community (12/42, 29%), followed by accountability (10/42, 24% responses), and program content (10/42, 24% responses). The additional open enrollment participants (n=47) provided 69 responses. The most common themes were sense of community (22/69, 32% responses), accountability (17/69, 25% responses), and program content (15/69, 22% responses). Participants provided 123 responses regarding what they liked the least about the program (IRR=91.1%; Cohen κ =0.89). The closed enrollment participants (n=37) provided 40 responses, the most common themes of which were guidance that was not individualized enough (9/40, 23% responses), calorie tracking (8/40, 20% responses), and difficulty keeping up with the pace of the program (7/40, 18% responses). Randomized open enrollment participants (n=34) provided 37 responses. The top 3 most common themes of responses were difficulty feeling connected to the group (12/37, 32% responses), guidance not individualized enough (11/37, 30% responses), and problems with the technology (5/37, 14% responses). The additional open enrollment participants (n=47) provided 46 responses, the most common themes of which were guidance that was not individualized enough (9/46, 20% responses), calorie tracking (9/46, 20% responses), and difficulty keeping up with the pace of the program (8/46, 17% responses).

Table 3. Postintervention focus group data on intervention acceptability.

	Closed enrollment (n=37), n (%) responses	Open enrollment, n (%) responses		All participants (n=118), n (%) responses
		Randomized (n=34)	Additional (n=47)	
Liked best	54 (100)	42 (100)	69 (100)	165 (100)
Sense of community	17 (31.5)	12 (28.6)	22 (31.9)	51 (30.9)
Accountability	9 (16.7)	10 (23.8)	17 (24.6)	36 (21.8)
Program content	16 (29.6)	10 (23.8)	15 (21.7)	41 (24.8)
Convenience	6 (11.1)	5 (11.9)	5 (7.2)	16 (9.6)
Counselor feedback	6 (11.1)	4 (9.5)	9 (13)	19 (11.5)
Other	0 (0)	1 (2.4)	1 (1.4)	2 (1.2)
Liked least	40 (100)	37 (100)	46 (100)	123 (100)
Difficulty feeling connected to the group	2 (5)	12 (32.4)	7 (15.2)	21 (17)
Not individualized enough	9 (22.5)	11 (29.7)	9 (19.6)	29 (23.6)
Technology problems	6 (15)	5 (13.5)	4 (8.7)	15 (12.2)
Calorie tracking	8 (20)	4 (10.8)	9 (19.6)	21 (17.1)
Pace was too fast	7 (17.5)	2 (5.4)	8 (17.4)	17 (13.8)
Weekly weigh-ins	2 (5)	2 (5.4)	3 (6.5)	7 (5.7)
Need more accountability	2 (5)	1 (2.7)	3 (6.5)	6 (4.9)
Nothing	4 (10)	0 (0)	3 (6.5)	7 (5.7)

Engagement

Among the randomized open enrollment participants, the median total engagement (reactions, replies or comments, and poll responses) over 16 weeks per participant was 77 (IQR 29.5-271.5), which was not statistically significantly different from 116.5 (IQR 29-173; $U=763$; $P=.72$) in the closed enrollment condition (Table 4). Because the additional open enrollment participants were in the group for 8-15 weeks, we could not compare their engagement data to the other groups. As expected, given the difference in the size of the 2 groups, the total volume of engagement from participants per week was higher in the open enrollment condition (n=94; median 229, IQR 129.5-336.5) than in the closed enrollment condition (n=40; median 125.5, IQR 86.5-188.5; $U=64$; $P=.02$). The total volume of engagement from both participants and counselors per week was also higher in the open enrollment condition (median 385,

IQR 228-536.5) than in the closed enrollment condition (median 215, IQR 145.5-292; $U=56$; $P=.007$).

In terms of engagement in the year following the intervention, the open enrollment condition, including both randomized and additional participants (n=94), produced 4.78 times greater total engagement (sum=1266) than the closed enrollment group (n=40; sum=265). In the open enrollment condition, 43% (40/94) of the participants engaged at least once in the subsequent year, compared with 60% (24/40) of participants in the closed enrollment condition ($N=134$; $\chi^2_1=3.4$; $P=.06$). A comparison of all 3 sets of participants (closed enrollment, randomized open enrollment, and additional open enrollment) on the proportion of participants who participated in the year following the intervention revealed no differences (24/40, 60%; 17/40, 43%; 23/54, 43%), respectively; $N=134$; $\chi^2_2=3.4$; $P=.18$).

Table 4. Median total engagement per randomized participant during the 16-week intervention.

	Closed enrollment, (n=40), median (IQR)	Open enrollment randomized, (n=40), median (IQR)	Mann-Whitney U test	P value
Posts	1.5 (0-5)	1 (0-3.5)	758.5	.68
Replies	39 (9.5-73.5)	36.5 (14.5-80.5)	778.0	.83
Reactions	28 (7.5-81.5)	29 (7-134.5)	727.5	.49
Poll votes	12 (5.5-20.5)	10.5 (5-19.5)	763.0	.72
Total engagements	116.5 (28.5-174.0)	77 (29.5-271.5)	763.0	.72

Diet Tracking

Randomized participants (n=40) in the open enrollment condition tracked their diet on a mean of 42.4 (SD 33.0) days out of the 84 days, and participants in the closed enrollment condition (n=40) tracked their diet on a mean of 36.3 (SD 34.7) days, which represented an average of 38% (SD 30%) of possible days for participants in the open enrollment condition and 32% (SD 31%) of possible days for participants in the closed enrollment condition ($F_{1,79}=0.653$; $P=.42$). Because the additional open enrollment participants were in the group anywhere from 56 to 105 days, we could not compare their diet tracking data to the other groups.

Counselor Engagement

In terms of counselor engagement, counselors produced 7653 total engagements in the open enrollment condition, which was

about twice as many as the counselors in the closed enrollment condition, where counselors produced 3618 total engagements (reactions or likes, comments, and posts; Table 5). In terms of counselor reactions or likes, the open enrollment counselors produced 5018 which was 2.27 times higher than the closed enrollment condition counselors who produced 2203 during the intervention. In terms of counselor comments, open enrollment counselors produced 2392 which was approximately twice that of the closed enrollment condition counselors who produced 1153 comments during the intervention. In terms of counselor posts, 224 were prescheduled. In addition, the open enrollment counselors produced 19 other posts during the intervention, and the closed enrollment condition counselors produced 38. On average, each week counselors generated 478.31 (SD 284.57) total engagements in the open enrollment condition and 226.13 (SD 86.69) total engagements in the closed enrollment condition ($U=38$; $P<.001$).

Table 5. Total counselor engagement during the 16-week intervention.

	Closed enrollment, n (%)	Open enrollment, n (%)	Difference between open and closed enrollment (%)
Preprogrammed intervention posts	224 (6.2)	224 (2.9)	0
Other posts	38 (1.1)	19 (0.2)	-100
Comments	1153 (31.9)	2392 (31.3)	+207.5
Reactions	2203 (60.9)	5018 (65.6)	+227.8
Total	3618 (100)	7653 (100)	+211.5

Weight Loss

Over 16 weeks, participants randomized to the open enrollment condition (n=40) lost an average of -6.67 (SD 9.84) pounds or -3.08% (SD 4.28%) of their baseline weight and participants randomized to the closed enrollment condition (n=40) lost an average of -4.47 (SD 9.54) pounds or -1.87% (SD 4.41%) of their baseline weight. In terms of clinically significant weight loss (ie, $\geq 5\%$ of baseline weight), 30% (12/40) and 18% (7/40) of participants randomized to the open enrollment and closed enrollment conditions, respectively, achieved $\geq 5\%$ weight loss. The 54 additional participants in the open enrollment condition lost a mean of 2.8% (SD 4.5%) of their baseline weight and 20% (11/54) achieved $\geq 5\%$ weight loss over a median of 13 (IQR 11-15) weeks they were in the group.

Relationship Between Volume of Engagement and Weight Loss Among Randomized Participants

Participants' individual engagement was the strongest predictor of weight loss; a 100% increase in individual engagement each week was associated with an additional 0.11% weekly weight loss ($P<.001$; 95% CI 0.05%-0.16%). However, the total volume of engagement was also associated with weight loss such that every 100 engagements in the Facebook group each week were associated with an additional 0.1% weekly weight loss for each randomized participant ($P=.02$; 95% CI 0.02%-0.18%), after controlling for individual engagement, treatment condition, time, baseline weight, and sociodemographic characteristics (eg, age, race, gender, and employment status).

Discussion

Principal Findings

The open enrollment approach to conducting a Facebook-delivered weight loss intervention allows members to flow into the group throughout the program, and has the potential benefits of treating more people at once and producing a higher volume of content overall. The possible trade-offs are that members might find the feed too busy or they may be dissatisfied with the amount of attention they receive from the counselor. We tested the feasibility of the open enrollment approach and discovered that it was feasible and acceptable relative to the typical approach to group-based lifestyle interventions, in which a specific number of participants are enrolled all at once and begin and end the program at the same time. We enrolled 54 additional participants in the open enrollment condition over the first 8 weeks of a 16-week intervention, bringing the total group size to 94. Despite the open enrollment group more than doubling in size during the study, the outcomes of retention and acceptability in both conditions exceeded the 80% benchmarks, with the exception that only 77% (27/35) of randomized open enrollment participants felt that the counselors were very responsive. However, 83% (39/47) of the additional open enrollment participants in that group felt that counselors were very responsive. It is possible that some randomized participants perceived a reduction in counselor responsiveness as the group size increased. Despite this, the diet tracking frequency among randomized participants was similar across both conditions, which means that the open enrollment approach did not appear to negatively impact adherence to this key behavioral strategy.

Counselors in the open enrollment condition had just over twice the engagement as the closed enrollment condition, which is consistent with the finding of a greater volume of participant engagement in the open enrollment condition. Interestingly, participants who were enrolled in the open enrollment condition while it was ongoing lost similar amounts of weight as both the randomized participants in that condition and the closed enrollment condition (mean 2.8%, SD 4.5%; mean 3.1%, SD 4.3%; and mean 1.9%, SD 4.4%, respectively), even though they were in the group for a mean and median of approximately 13 (IQR 11-15) weeks. Because this study was not powered to detect group differences in weight loss, a fully powered trial is needed to determine if the open enrollment approach can produce greater weight loss outcomes.

Contrary to our hypothesis, the randomized open enrollment participants did not engage significantly more than the closed enrollment participants did. This means that the greater volume of content in that group did not prompt the original randomized participants to post or reply more often. As such, if open enrollment proved to be more efficacious than closed enrollment for weight loss in a fully powered randomized trial, it would seem unlikely that higher individual engagement would be the mechanism of action. Future studies should explore whether groups differ in terms of intervention content, which can be thought of as both a form of passive engagement and intervention receipt. Although we did not observe group differences in individual engagement, as in previous studies [21], participant engagement was a predictor of weight loss outcomes. The open enrollment condition as a whole had a significantly greater overall volume of engagement (from participants and counselors combined) than the closed enrollment condition, likely because of the larger size of the group. The total volume of engagement in the group each week was also a predictor of weight loss each week, suggesting that a busier group may benefit individual members of that group. Alternatively, this finding could reflect that participants who are more successful with their diet and exercise habits engage more often in those weeks. Regardless, a Facebook group with a higher volume of engagement will rank higher in Facebook's newsfeed algorithm for any given group member, especially for group members who engage regularly [30]. This would result in greater intervention receipt, which could be a possible mechanism of action should a fully powered trial reveal the open enrollment approach to be advantageous for weight loss. Facebook's newsfeed algorithm is also influenced by the extent to which participants engage with each other and even more so if that engagement is with other Facebook friends. A small number of group members ($n=9$) made new Facebook friends, while in the study, and most (8/9, 89%) were in the open enrollment condition. Future research is needed to determine how meaningful interactions among participants in Facebook-delivered interventions can be facilitated.

Although the open enrollment condition had a significantly greater volume of engagement in their group, 86% (30/35) of those randomized to this group and 91% (43/47) of the additional participants in this group said they either liked the amount of posts by other participants or wanted more, and 85% (30/35) of randomized and 96% (45/47) of additional

participants in this group said they either liked the amount of comments by other participants or wanted more. This further supports the notion that a Facebook weight loss group size of 94 is feasible when ushering new participants gradually over time. Notably, 25% (10/39) of the participants in the closed enrollment condition said they would have preferred other participants to comment more, whereas only 13% (5/35) of the randomized and 17% (8/47) of the additional participants in the open enrollment condition said so. A randomized trial of a hybrid web-based weight loss program with monthly in-person groups compared group sizes of 20 and 100 and found no differences in weight loss among groups and high satisfaction in both conditions [39]. This suggests that groups as large as 100 participants do not seem to have deleterious effects on outcomes or feasibility when using web-based or hybrid approaches, regardless of whether participants start at the same time or are continuously enrolled. However, a trial comparing groups of 10 to 30 for an in-person weight loss program found that participants in the smaller groups lost significantly more weight than those in larger groups [40]. In the study, smaller groups had better session attendance, which was a significant predictor of weight loss outcomes. Group cohesion might be stronger in smaller in-person groups versus larger in-person groups because group meetings are the only opportunity to bond when the meetings are in person, and the more people who are in the room, the less time any one participant gets to talk. In web-based weight loss interventions, group cohesion may be less dependent on group size because opportunities for participant interaction are not limited to a single 90-minute weekly meeting; rather, opportunities are available 24/7.

In the postintervention focus groups, participants were asked what they liked the most about the program and in all 3 groups of participants (open enrollment randomized, open enrollment additional, and closed enrollment). The most common response was a sense of community, comprising 28.6% to 31.9% of responses in each group. This is further evidence that a web-based group of 94 people was not too large for participants to feel a sense of community. However, when asked what they liked the least about the program, 32% (12/37) of open enrollment randomized participant responses said they had difficulty feeling connected to the group compared with 5% (2/40) of the closed enrollment participant responses. This suggests that the entry of new participants into the open enrollment group may have disrupted the dynamics for some of the randomized participants; however, far fewer nonrandomized participant responses reflected this (7/46, 15%). Activities that facilitate group cohesion may be useful in larger groups, regardless of whether the participants start at the same time or are continuously enrolled. For example, small breakout sessions, icebreakers, or a buddy system may be used to help group members get to know each other better.

Future research is needed to determine the extent to which web-based weight loss groups can grow while still being feasible and acceptable to the participants. Although open enrollment did not result in the originally randomized participants engaging more than the closed enrollment group, the ability to treat many patients at once certainly has important advantages in terms of scalability; however, this should not be done at the expense of

group cohesion and undue cognitive burden. The open enrollment approach may be more feasible in real-world settings for 2 reasons. First, multiple small groups may become more difficult to manage administratively than fewer large groups, and second, patients will not have to wait until enough people are enrolled to begin treatment. For example, in our study, randomized participants had to wait on average nearly 30 days from when they provided baseline data to start the intervention, because we needed to recruit, screen, and onboard 80 participants before we could randomize them into their groups. An open enrollment approach that allows people to start the program immediately might take better advantage of the heightened motivational state that prompted patients to enroll in the first place. It might also prevent any patient loss that may occur during the waiting period.

Limitations

This study had some limitations. First, the sample was predominantly non-Hispanic White and female; thus, the results may not be generalizable to other groups. Historically, lifestyle interventions have been plagued by low enrollment of men [41]. Future research should explore men's perspectives on participation in behavioral programs on Facebook. Second, weight loss was modest, and the study was not powered to detect group differences in weight loss. Weight loss was similar to other social media-delivered weight loss interventions in similar samples [15,42]. A fully powered trial is needed to establish the efficacy of this intervention approach in weight loss outcomes. Third, this study did not assess the time counselors spent delivering the intervention in each condition, which prevented us from calculating and comparing the cost of conducting each condition. However, we found that counselors in the open enrollment condition had twice as many comments as those in the closed enrollment condition, which indicates that they likely put more time into their group. Future trials should

perform cost-effectiveness analyses to determine if any benefit of the open enrollment approach to a larger group of patients is worth the extra costs associated with the extra time spent by counselors. A previous study found that web-based weight loss intervention cost US \$67.74 per kilogram lost compared with US \$88.31 per kilogram lost in an in-person weight loss intervention, where groups were similarly sized (12-18 participants) [43]. This highlights the importance of further optimizing web-based approaches given that they are more cost-effective than traditional approaches. Even if counselors spent the same amount of time per participant in the larger versus smaller group, open enrollment may still be more cost-effective when treating the same number of people because of the extra time needed in the closed enrollment groups to create additional Facebook groups for each set of 40 people and scheduling posts in those groups. Finally, we did not assess whether the conditions differed in terms of the number of participants who muted notifications from the group, which is a potentially important outcome for studies testing group size. Future studies should assess this because participants might be more likely to mute notifications in a very busy group, and muting notifications could impact intervention receipt and outcomes.

Conclusions

Lifestyle interventions are effective, but traditional delivery modalities (eg, in-person or web-based group meetings) suffer from poor scalability. Web-based approaches that can efficiently serve a large number of patients are needed. We found that the approach of continuously enrolling participants in an ongoing web-based program was feasible and acceptable. Future research should explore the cost-effectiveness of enrolling large numbers of patients in web-based programs using an open enrollment approach that eliminates waiting times and leverages strategies to facilitate group cohesion.

Abstract

Background: To maintain the benefits of a bariatric procedure, patients have to change their lifestyle permanently. This happens within a context of coresponsibilities of health care professionals and their social support system. However, most interventions are focused on the patient as an individual. In this explorative pilot study, behavioral, contextual, and experiential data were gathered to obtain insight on coresponsibility.

Objective: The aim of this study is to explore the use of trackers by patients who have undergone bariatric surgery in a data-enabled design approach.

Methods: Behavioral and contextual data on the households of patients who have undergone bariatric surgery were explored using a smartphone with an interactive user interface (UI), weight scale, activity bracelet, smart socket, accelerometer motion sensor, and event button to find examples of opportunities for future interventions.

Results: A total of 6 households were monitored. Approximately 483,000 data points were collected, and the participants engaged in 1483 conversations with the system. Examples were found using different combinations of data types, which provided the obesity team a better understanding of patient behaviors and their support system, such as a referral to a family coach instead of a dietician. Another finding regarding the partners was, for example, that the conversational UI system facilitated discussion about the support structure by asking for awareness.

Conclusions: An intelligent system using a combination of quantitative data gathered by data tracking products in the home environment and qualitative data gathered by app-enhanced short conversations, as well as face-to-face interviews, is useful for an improved understanding of coresponsibilities in the households of patients who have undergone bariatric surgery. The examples found in this explorative study so far encourage research in this field.

Introduction

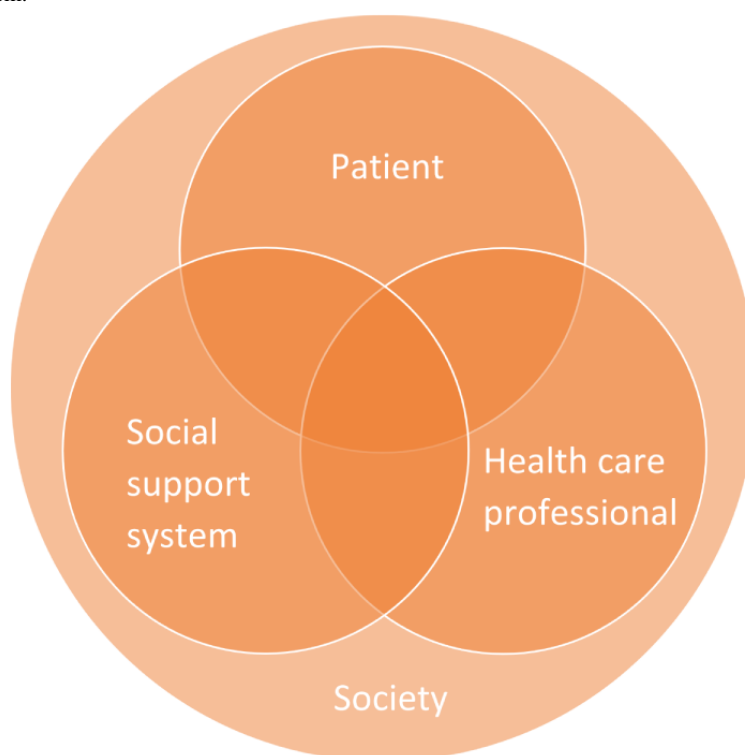

Overweight and obesity are steadily growing into one of the largest threats to human health in this century, as almost 2 in 5

people are overweight worldwide [1]. Bariatric or weight loss surgery has been used to treat patients with morbid obesity for decades with a proven long-term effect [2]. Worldwide, more than 800,000 procedures are performed annually [3]. Key

aspects of a successful treatment include multidisciplinary preoperative screening and postoperative guidance [4-6]. Even though most aftercare programs are focused on the importance of a long follow-up by a dedicated obesity team, and there is increasing knowledge on primary care for long life guidance thereafter, the time and resources used could not be enough for individual patients [7]. Obesity teams gather as much information as possible from the interviews, anamnesis, and group sessions. However, this is time-consuming, subjective, and probably incomplete. Besides lab results for medical follow-ups, other frequently used aids are questionnaires, diet diaries, and exercise tests. As obesity is undoubtedly multifactorial in origin, more sources of data can be useful, for instance, the frequency and duration of exercises and meals. Such information can be useful for the patient and for the obesity team as both have their part in the responsibility to maintain the benefits of a bariatric procedure. Frequently, behavior is influenced by those living with the patient. In most cases this will be a partner, but it could also be parents, children,

housemates, close friends, or even colleagues. This could pose a challenge to successfully change behavior postoperatively, as preoperative behavior is often intertwined with a person's social life. As this behavior is crucial for a successful bariatric intervention, the social support system has a share in this responsibility as well. Connecting these responsibilities within limited time and with limited information is demanding. An answer to this demand could be tracking data from households, using several devices with information originating from the patients, as well as others in the direct social support system. A visualization of these coresponsibilities is suggested in Figure 1 [8,9]. Creating an interactive system with more data for these parties could enhance this coresponsibility and, therefore, improve weight loss and quality of life for a long period. In this explorative study, such an interactive system was created. The aim of this study was to assess the value of an interactive system with tracking data from a household as a social support system for the patients who had undergone bariatric surgery.

Figure 1. Coresponsibility system.

Methods

Ethics Approval

This pilot study was part of a clinical trial entitled “Together in Shape.” Its setup as a therapeutic intervention study was approved by the Philips Internal Committee of Biomedical Experiments, the medical ethical review board of Medical Research Ethics Committees United (MEC-U) and Central Committee on Research Involving Human Subjects (NL63252/100.17), and the local feasibility committee (CZE-2018.06).

Setting and Selection Criteria

The setting was the obesity center of Catharina Hospital where up to 1000 patients are treated annually. Normally, a patient has 27 contacts individually or in group with the multidisciplinary team during 5 years of follow-up. Additional visits or telephone-based consultations are provided whenever necessary or requested. Only by exception is the guidance program transferred to primary care [10]. Information about the study was provided through the center's eHealth portal. Selection criteria were patients in their postoperative trajectory after bariatric surgery, who had at least 1 person living nearby, could speak the Dutch language, were above the age of 18 years, willing to participate and to have house visits by the research team, and who signed an informed consent form. Eligible

patients were informed by the research team, and in-depth information about the study was provided. A series of consecutive patients who had undergone bariatric surgery were informed about the study until 6 households were included. The number of inclusions was limited due to the explorative design of the study. Each household was followed for approximately 5 to 6 weeks.

Study Design

A data-enabled design approach was used, which means that the collected contextual data were used during the process to continuously enhance, update, and shape the design [11]. Such a study usually consists of 2 phases: the *contextual phase*, to get a good conception of the setting; and the *informed phase*, when design interventions are tested out in the participants' own context—in this study, their home. In the *contextual phase*, the focus was on collecting and determining which data was interesting and how to display this comprehensibly. This was mainly done by conversations with the participants, the research team, and health care professionals. No interventions were done in this phase. This was introduced in the *informed phase*, such as coaching and giving tips.

Semistructured interviews were used to gain insight on the lifestyle, daily routine, home environment, and social system of the patients. The interviews were planned beforehand and took about 2 hours; they were based on a predefined questionnaire that was compiled before the start of the study and was approved by the MEC-U. The interviews were important as they were used to correlate data points to behavior and put them into a contextual setting. During these interviews, several themes were discussed and clarified such as the general condition of the subjects, daily routine, mental health, commitment, satisfaction, possible changes to the previously mentioned elements due to the trackers, utilization of trackers, technical problems with the trackers, and unexpected outcomes. The interviews allowed for time to have practical discussions about the interactive system, the app, and to gain insights on the lifestyle, routines, and social system of the patients. This could further inform the research team of the trackers that could be used. Potential changes in the data tracking and system setups were part of this process. A translated transcription of the semistructured interviews is provided in [Multimedia Appendix 1](#). The interviews were transcribed and coded for analysis.

Furthermore, nonstructured interval interviews were held on demand during the follow-up period to gain contextual insights into the gathered data points.

For this study, the 3 pillars of the coresponsibility system ([Figure 1](#)) that were analyzed were the obesity team (as health care professionals), the patient, and their partner (as the social support system). It was recognized by the research team that a partner is only a part of a social support system. It can also include and is not limited to other individuals such as housemates, children, parents, a close friend, colleagues, etc. In this study, the role of the partner in the social support system was the subject of the investigation to simplify the methods and results. An interactive system was created that gathered data from different sources such as medical records, situated contextual data (eg, physical activity, mental health, and nutrition), and self-reported data (eg, which family member is cooking), and consisted of different communication platforms for each of the stakeholders to facilitate the presentation and sharing of personalized coaching content for the patients who had undergone bariatric surgery and their partners. The specific collected data types and the specific content of the communication functionalities were not preset and were subject to change during the study period. Therefore, there remained a possibility to experiment with different data types and features to explore multiple designs for benefitting coresponsibility based on care questions and priorities.

The intelligent system consisted of 4 elements: data trackers, a mobile phone app, an obesity team dashboard, and a research dashboard. Three types of data trackers were used ([Figure 2](#)), which are as follows: *personal data*, *contextual data*, and *open data*. *Personal data* (physical activity bracelet and weight scale) was used for measuring number of steps, heart rate, and weight. These devices were used to give patients more insights on their weight loss progress and physical activity; the activity bracelet could interact with the mobile phone app and the dashboards. *Contextual data* (smart sockets and accelerometer) was used for measuring the use of devices (eg, television, household equipment) and movement (eg, opening cabinets or picking up sports equipment); these were used to track activities in home environment. *Open data* (smart buttons and rotary knobs) was used for measuring events (eg, cooking) and experiences (eg, how bored I am).

Figure 2. Three examples of trackers used to collect contextual and behavioral data: activity bracelet (left), event button (middle), and smart socket (right).

Patients and their partners were able to use a phone with a study app conversational user interface (UI) to participate in preset conversations based on data triggers (eg, when the accelerometer registered motion in the kitchen cabinet) with preset times, or when they were initiated by the research team. An example is

shown in [Figure 3](#). Patient and partner each had their own phone and app and received individual conversations. They were instructed about the trackers and the apps and how to use them properly. The trackers were placed on places and objects in their house after agreement with the subjects.

Figure 3. Screenshot of the mobile app.

A large number of data points were expected to be collected. The activity bracelet gathered daily physical activity summary and sleep data. The weight scale generated data points upon weight measurement. The motion sensor produced data points when a movement was registered. App analytics were recorded when patients sent or received messages or when the app was opened, interacted on, and closed. The smart buttons and the rotary knobs recorded data points when patients interacted with the buttons and based on the value they entered. To process these data points, a few steps were taken. The data were preprocessed by filtering out test data, removing outlines, and removing data points that were sent over by the devices whether or not they were working (eg, battery status). Next, script-based data analysis was performed based on clinical guidelines (eg,

number of recommended steps, daily recommended meals). Lastly, dashboards were designed to visually interpret the data. An obesity team dashboard was produced to get insights on the data, and more importantly, to discuss within the research team which data were valuable. An example of the dashboard is shown in [Figure 4](#). This visualization shows time points when a subject registered a meal. Because the types of data were adaptable and decided in negotiation with the participants, the available data were different per household. Likewise, a dashboard was built for research purposes and used by the researchers to setup, modify, and analyze the study as well as trigger the personalized coaching content in the chatbot communication system.

Figure 4. Example of data on meals.

Results

In total, 12 participants were included in the study: 6 patients and their partners (Table 1).

The data trackers and app analytics generated around 483,000 data points, and the participants engaged in 1483 interactions with the system. The mean number of daily app interactions ranged from 7.2 to 16.9. This information was transferred into a data visualization timeline, where the interventions (eg, providing suggestions for an exercise or a recipe) were also taken into account. The data points are the sum of the collected

personal, contextual, and open data points described in the previous section. The most contextual data points were retrieved from the connected power sockets that were attached to the participants’ televisions and kitchen appliances. However, the large amount of data points was mainly due to power usages and not turn on or turn off events. The second most retrieved contextual data points were from the motion sensors. The participants themselves reported 641 events using the open data trackers (eg, smart buttons indicating an event or rotary buttons for emotion assessment). Lastly, the personal data points included the daily summaries of the activity tracker’s sleep and activity data.

Table 1. Study population characteristics.

Household ^a	Study phase	Postoperative time	Number of daily app interactions, mean (SD)
1 Anna and Alex	Contextual	10 months	16.9 (37.7)
2 Bella and Brian	Contextual	12 months	7.2 (6.7)
3 Chloe and Chris	Informed	Direct (first operative week)	10.6 (14.5)
4 Diana and David	Informed	4 months	11.1 (7.7)
5 Emily and Eric	Informed	5 months	9.8 (7.6)
6 Fiona and Felix	Informed	12 months	10.1 (4.4)

^aFictive names were used.

Findings that focused on coresponsibility between the patient and the obesity team were analyzed, and opportunities for interventions were consequently identified. Examples of these findings, which led to insights or changes in the intelligent system, will be explored below.

One example describes an interesting finding about household dynamics around food choices. In this household, the deep fryer was used more often than originally indicated in the meeting with the patient and the partner before the system was placed in their home. The household indicated that they eat fries once

a week. However, the smart socket showed usage of the deep fryer 6 out of 7 days. After this was brought up to the household, it became clear that this was due to a disagreement on what to eat between the patient, the partner, and their children. Instead, they chose to eat fries to accommodate everyone's eating desires.

The system permitted assessment of the effectiveness of an intervention, illustrated by an example on physical activity where feedback in the app led to changes in the intervention. In the same household of example 1, the frequency and duration of exercise was adequate, although weight loss was still unsatisfactory. In an effort to explain this, the physiotherapist had to look for other reasons for this insufficient weight loss. The patient noticed that by using the app after scoring the intensity of exercises for a week, she might need to increase the intensity rather than the duration or frequency to improve weight loss.

In another household, an example of coresponsibility between the obesity team and the patient was found. The participant's health record indicated low self-esteem. Her study data showed that she had a very good workout regime. She was advised to complement her workouts with the conversation app, which she found very difficult to do. Her realization supported the willingness for additional psychological help.

Two other examples were on the coresponsibilities between the patient and their partner. Involving the partner more in the care trajectory could be beneficial but difficult to organize. Therefore, the conversational UI system facilitated the discussion about the support structure by asking for awareness of the amount and type of support that the patients received from their partners. In one case, the partner was impressed that the patient was capable of reaching results on her own, whereas the patient still wanted to have support. Receiving questions on the app about the partner's support triggered a discussion between the patient and their partner about this subject. In another case, the patient realized that she had asked for support and received it but had found it difficult to appreciate it. In the face-to-face conference afterwards, the couple pointed out that the system had made them both feel as if they were part of the same lifestyle rather than having two separate lifestyles.

Upon asking, all the partners commented that they wanted to support the patients; however, they also felt that altering their own behavior was not part of that. One example of how the intelligent system could influence the behavior and coresponsibility of the partner was found in household 6. The partner received a coaching message on the app to surprise the patient with a healthy alternative. He agreed, got positive feedback, and asked for more recipes later on.

Discussion

Principal Results

The behaviors and experiences of patients who have undergone bariatric surgery in relation to their lifestyle change take place within a social context and interaction with others. Such a context is quite complex to investigate and, therefore, influence. On the other hand, it is important for a patient's long-term

outcome as well as for their households. One possible approach toward this is to get insights into behaviors in the home environment using a data tracking system. Data tracking and interviews might provide an understanding of coresponsibilities in these households. By using this approach, this explorative study revealed some examples of intermingling responsibilities of the household members (sometimes the children but mostly the partners), members of the obesity team, and the patients. A limitation of this study was that the results were case-specific and, therefore, not reproducible. They merely underlined the substantial variety in social dynamics in these households. A combination of different household members, each having different values and interests, was linked to a healthier way of living. In order to help the patients' household members, by design, to be supportive toward a healthy lifestyle change, they need to be approached in a way that fits these values and interests and the roles they take or could possibly take.

These data were regarded as a useful addition to the information normally gathered in short consultations and through some body measurements. For instance, the trackers showed that the intensity of the exercise, rather than frequency and duration, increased effectiveness. Another example showed that patients might, intentionally or unintentionally, underreport unhealthy intake, and an intelligent tracker system could reveal this. Having access to this information during a postoperative checkup might lead to choosing other intervention options. For instance, instead of a referral to a dietician, a family therapist might yield better results in some cases.

The relationship between the physicians' and patients' coresponsibilities is in some cases unilateral: a physician is restricted to advise on treatments and lifestyle changes based on what a patient communicates in a consultation and with a few measurements (eg, BMI, comorbidity status). It is up to the patient what to do with this advice. By using an intelligent data tracking solution, physicians could be able to control or evaluate a therapy. A recent study also showed that high compliance can be achieved by the use of supervised home monitoring [12].

The examples found in this study show opportunities for designing new intelligent systems. However, privacy concerns might limit the effectiveness of this approach. Therefore, for future research, we emphasize the importance of giving control of data sharing to the users themselves. Findings suggest that the effect of the partner is substantial. This would be an interesting field for future work, as the role of the partner in adjusting lifestyle remains unclear. Further research is also needed to discover to what extent the role of others (eg, children, friends, colleagues) is important in maintaining a healthy lifestyle postoperatively.

Another concern might be compliance. Prior studies have presented conflicting results in terms of compliance and reach of telehealth solutions to the use of telemonitoring intervention, ranging from 50% up to 94%. These studies, however, mostly consist of small pilot-design studies [13-16]. As home monitoring is a relatively new modality in health care, most research is explorative, and randomized controlled trials and systematic reviews are scarce. An early systematic review of the literature, however, added value to the bariatric pathway,

even though it is too early to draw final conclusions [17]. The willingness to participate in our study was high; this can be attributed to the small-scale design and, consequently, the close follow-up of the research team. Health technologies have the potential to provide additional support to a patient's social system. However, many questions are yet to be answered. Results from this study indicate opportunities for future research. As described before, compliance might be an important factor in whether telehealth solutions in home environments or social systems will be effective. Future larger studies must explore whether patients are also willing to use telemonitoring with less involvement from a research team. Furthermore, it is still unclear which type of telehealth intervention patients prefer to use. In this study, physical, dietary, and psychosocial support was delivered all together. It is not clear which of these support types is most effectively facilitated by telehealth technologies. Not only the type but also the means of delivery of the intervention might be important. This varies based on the individuals. For instance, some might prefer a more direct approach (eg, automated push notifications for recipes around dinnertime), while others benefit more from an "on-demand" approach (eg, actively asking the chatbot for recipes). Future studies are recommended to determine the optimal type of support and means of delivery, or an optimal combination of both.

Limitations

One of the drawbacks of this explorative approach was the number of participants, as well as the nonreproducibility of the results, as they were case-specific. Furthermore, an intelligent system was built with the full approval of the participants in this study, which could be limited by privacy concerns if applied on the general postbariatric population. Another limitation could be that the data found by trackers can be used by household members to check on each other instead of giving support. The substantial amount of data collected limited the analysis strategies. It remains challenging to process these data into a dashboard for each member of the coresponsibilities as well as distracting the focus of the obesity team.

Conclusions

The results of this pilot study indicate that using data trackers in the home environment of patients could help the obesity team members to be better informed in their medical decision-making and, thus, lead to personalized support. On the other hand, there remains much room for wrong interpretations of the data. Nevertheless, this study made the first steps in an explorative way, leading to a modest conclusion.

Abstract

Background: Mobile health technologies can be useful for providing disease self-management information and support to people with inflammatory bowel disease (IBD).

Objective: The aim of this study was to test a self-management SMS text messaging intervention for people with IBD. Our goal was to examine intervention feasibility, acceptability, and engagement and to preliminarily evaluate improvements in certain self-reported health outcomes among participants.

Methods: We developed an SMS text messaging program called *Text4IBD*. The program sent daily support messages and resources about disease self-management over the course of a 2-week, single-group, pretest-posttest intervention to participants (N=114) diagnosed with IBD. We examined intervention feasibility, acceptability, and engagement through *Text4IBD* message topic recall and use of resources (ie, visiting supplemental websites recommended by the *Text4IBD* program). We also assessed pretest-posttest measures of IBD-related distress, self-efficacy, perceived support, use of coping strategies, and medication adherence. Analyses examined participants' evaluations of the intervention and compared pretest-posttest changes in secondary outcomes using paired-samples statistics.

Results: Approximately all participants who completed the intervention (n=105) were receptive to *Text4IBD* and viewed the program as feasible and acceptable. In addition, most participants (103/105, 98.1%) recalled at least one of the message topics sent by the program, and 79% (83/105) of them self-reported engaging with at least one of the external self-management resources recommended by the *Text4IBD* program. Pretest-posttest results showed reduced IBD-related distress (mean 3.33, SD 0.68 vs mean 2.86, SD 0.73; $P<.001$) and improvements in most other secondary outcomes.

Conclusions: Findings from this study highlight the value of SMS text messaging as a useful digital medium for providing support to people with IBD, particularly to those who may struggle with disease-related distress. *Text4IBD* was highly feasible and acceptable and may help people self-manage their IBD. Future studies should aim to evaluate this program in a randomized controlled trial in clinical settings.

KEYWORDS

inflammatory bowel disease; mHealth; self-management; SMS text messaging; mobile phone

Introduction

Background

Inflammatory bowel disease (IBD) represents chronic gastrointestinal diseases—including Crohn disease (CD) and ulcerative colitis (UC)—that affect >3 million adults in the United States [1]. Examples of disease symptoms include chronic diarrhea, abdominal and joint pain, and fatigue. The relapsing-remitting nature of CD and UC can make self-management of disease symptoms difficult, which could increase the risk of experiencing disease-related distress. Recent evidence suggests that approximately 30% of people with IBD report symptoms of anxiety or depression [2,3], which is approximately triple that of US adults [4]. If unaddressed, such distress can lead to other harmful outcomes, such as a worse disease course and increased disease activity [5-11]. Thus, research should prioritize investigating methods to promote IBD self-management among individuals in distress.

SMS text messaging can be a useful medium to provide support. Research shows that SMS text messaging interventions have been successful in modifying health outcomes, particularly among people with chronic disease [12-14]. However, so far, few studies have investigated the effects of SMS text messaging among people with IBD. Recently, Riaz and Nielsen [15] developed a single-group pilot intervention that sent tailored SMS text messages about IBD medication and treatment to people with IBD. At the 12-week follow-up, participants increased their medication adherence and decreased their concerns about IBD treatment compared with baseline. Another study by Miloh et al [16] randomly assigned adolescents with IBD to either a medication reminder SMS text messaging intervention or a standard care control. Those in the SMS text messaging trial arm showed significant improvements in their medication adherence at the 6- and 12-month follow-ups than those in the control group.

However, not all IBD SMS text messaging studies have been effective. A randomized controlled trial tested educational SMS text messages about IBD self-management compared with standard care [17,18]. At the 1-year follow-up, there were no differences across trial arms in depressive symptoms, self-efficacy, or other outcomes such as quality of life. These null findings could be attributed to low intervention dose, as participants received messages only once or twice weekly. Another explanation is that the participants were assessed 6 months after beginning the trial, and message effects may have decreased before the assessment of the study outcomes.

These inconsistent findings indicate that more studies are needed to investigate effective applications of SMS text messaging as an intervention medium for facilitating disease self-management and support. Moreover, the current literature in this area is relatively homogenous, with many studies focusing on sending messages aimed at modifying medication adherence. Few interventions have sought to test whether such messaging efforts could impact other important outcomes, such as coping strategies or perceived support. Testing systematically designed messages that provide information about a multitude of disease self-management behaviors (beyond medication reminders)

could have important implications for future efforts aimed at improving health and well-being among people with IBD.

Objective

This formative study sought to develop and preliminarily evaluate the results of a single-group, pretest-posttest mobile health (mHealth) intervention called *Text4IBD*. This intervention provided information and support about disease self-management to people with IBD for 2 weeks via SMS text messaging. Our primary goal was to assess intervention feasibility and acceptability. On the basis of dissemination and implementation literature [19], we defined feasibility as relating to the trialability and practicability of the program as evaluated by participants in this intervention setting. We defined acceptability as participants' perceived advantage of using the intervention, such as whether they viewed the aspects of *Text4IBD* as satisfactory. We also examined engagement with *Text4IBD* through aided message topic recall and use of resource links that were featured in the program. The secondary goal of this study was to examine changes in pretest-posttest outcomes targeted by intervention messages, such as disease-related distress and perceived support.

Methods

Participant Recruitment

We built a semiautomated program using Python (version 3.8.1) to identify prospective participants on Reddit and Twitter, which are 2 popular social media platforms used for IBD discourse [20]. This program actively scanned public posts in real time to flag prospective participants. Criteria for study eligibility were that posts had to (1) discuss IBD and distress and (2) be published by individuals and not research organizations, medical providers, or patient advocate accounts. We controlled for these parameters using both Reddit and Twitter stream features and human validation. Recruitment began in December 2020 and occurred on a rolling basis for approximately 6 weeks. Users who met the eligibility criteria were contacted and sent information about the *Text4IBD* program. Those interested in the intervention were instructed to click a link directing them to a screener survey. Refer to [Multimedia Appendix 1](#) for participant identification and recruitment procedures.

Inclusion Criteria

Inclusion criteria (assessed during the screener survey) required that participants (1) be diagnosed with IBD, (2) live in the United States, (3) have a smartphone that can receive SMS text messages, and (4) self-report experiencing IBD-related distress. For the last criterion, participants completed a 6-item measure of IBD-related distress, adapted from an existing short-form diabetes distress scale [21,22]. We chose to use and adapt this scale because it captures broad constructs associated with perceived distress and disease self-management, which can be applied to IBD. We also tested this adapted scale in a pilot study of people with IBD and found it to have high internal reliability. The scale began with the prompt, "During the past two weeks, how much have you..." and example scale items were, "felt that you are often failing with your IBD routine" and "felt discouraged to keep up with managing your IBD." IBD-related

distress was assessed on a 5-point scale ranging from “not at all” (score=1) to “a great deal” (score=5). To qualify for the study, participants needed to score above a mean of 2 (“a little”) out of 5 on the composite distress scale. Reliability of the distress scale among those who completed the screener survey was high ($\alpha=.85$).

After passing the screening criteria, interested participants provided informed consent and continued to the pretest survey.

In total, 207 individuals were screened for eligibility. Of these 207 individuals, 114 (55.1%) individuals enrolled in the intervention. Of these 114 participants, 1 (0.9%) participant was removed because the intervention SMS text messaging system was unable to send messages to the phone number provided to the researchers and 8 (7%) participants were lost to posttest follow-up, resulting in 105 (92.1%) participants completing the study (Figure 1).

Figure 1. Flow diagram of participant recruitment, enrollment, and retention.

Intervention Design

We programmed *Text4IBD* to send daily support messages about IBD self-management to the participants' smartphones for 2 weeks. The topics of the support messages varied but centered around three self-management domains: (1) physical IBD symptoms, (2) IBD and mental health, and (3) IBD and nutrition. The first and second domains each contained 5 support messages, and the third domain contained 4 support messages (14 unique messages in total).

Support messages were constructed in 2 parts (ie, a message component pair). The first component acknowledged and validated a difficult aspect of IBD self-management. The second offered advice addressing the struggle in the first message component. For clarity, we refer to each message component pair as a singular *support message*. The advice offered by the support messages was informed by public content from IBD research organizations (eg, Crohn's and Colitis Foundation) to ensure that the messages were based on scientific and expert opinions. A larger set of messages was pilot-tested in a web-based study of 44 individuals with IBD. The 14 messages in this study were chosen and refined from that larger set.

Several support messages also contained links to web-based resources from the same research organizations. The purpose

of these resources was to provide additional information about self-management topics beyond what was discussed in the support messages. Resource links were in the form of a customized Bitly URL attached at the end of support messages (eg, “For more information, check out this link: [URL here]”). All support messages were reviewed for accuracy and credibility by one of the authors (EB), a gastroenterologist who specializes in IBD treatment.

Text4IBD sent support messages to the participants' phones at their preferred time of the day. The order in which the messages were sent was based on a partially static schedule (Figure 2). Participants first received all messages from the *physical IBD symptoms* domain, followed by all messages from the *IBD and mental health* and, then, from the *IBD and nutrition* domains; however, the order in which the support messages were sent within each domain block was randomized. *Text4IBD* also sent daily medication reminders to participants who reported currently taking daily oral medication in the pretest survey. These messages stated, “REMINDER: Be sure to take your IBD medication today.” Similar to the support messages, participants indicated a preferred time they wanted to receive their reminder message. Refer to Figure 3 for examples of *Text4IBD* messages and Multimedia Appendix 2 for all the support messages.

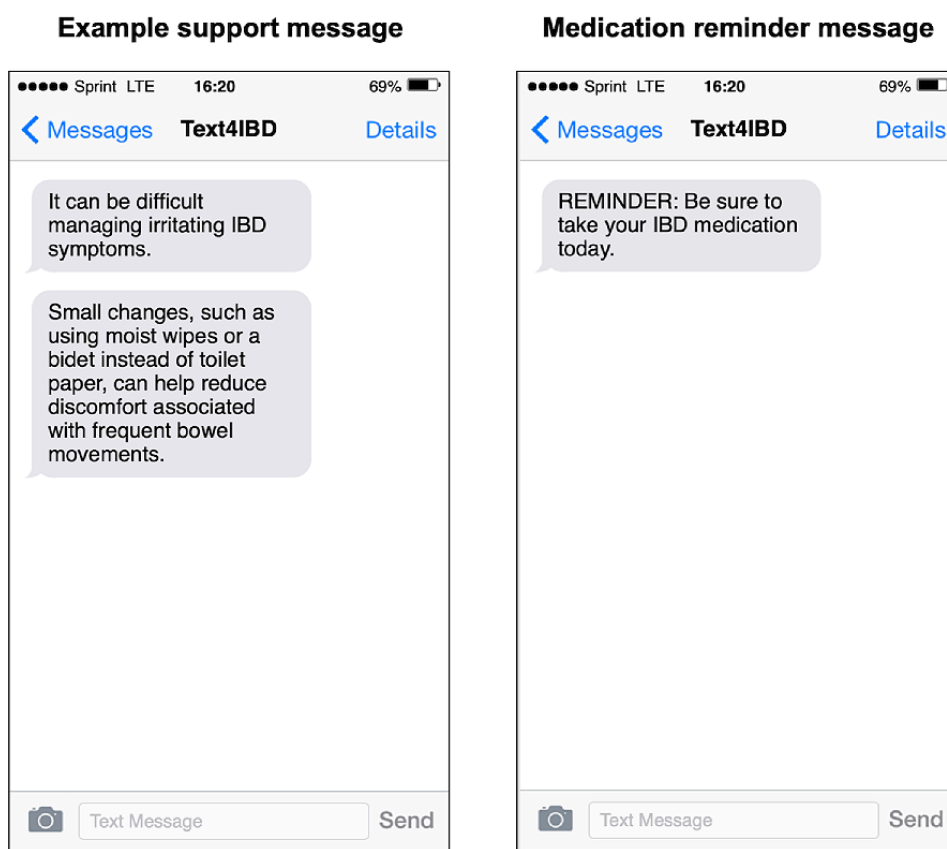

Figure 2. SMS text messaging schedule for the *Text4IBD* program. IBD: inflammatory bowel disease.

Day 1 Welcome message	Day 2 Support message 1	Day 3 Support message 2	Day 4 Support message 3	Day 5 Support message 4	Day 6 Support message 5	Day 7 Support message 6	Day 8 Support message 7
Day 9 Support message 8	Day 10 Support message 9	Day 11 Support message 10	Day 12 Support message 11	Day 13 Support message 12	Day 14 Support message 13	Day 15 Support message 14	Day 16 Conclusion message

Note. Message domains are color-coded; individual support messages within domains were sent in random order.

= Physical IBD symptoms domain
 = IBD and mental health domain
 = IBD and nutrition domain

Figure 3. Example SMS text messages sent by the *Text4IBD* program. IBD: inflammatory bowel disease.

Procedure

This study featured a 16-day intervention period. First, the participants completed the screener and pretest surveys (day 0) and, then, were enrolled in *Text4IBD*. After enrollment (day 1), participants received a message welcoming them to the study. Starting on day 2, participants received support messages each day for 14 days. Finally, participants received a last message (day 16) informing them that the *Text4IBD* program was complete and that they should receive an email containing a link to take a final survey within 24 hours. Participants were eligible to earn an Amazon gift card worth up to US \$40 for participating (US \$20 for completing each of the pretest and posttest surveys). Participants received their incentive by the end of the month in which they completed the study. Similarly,

those who completed only the pretest survey received their incentive by the end of the month.

Ethics Approval

The University of North Carolina at Chapel Hill Institutional Review Board approved all the study procedures (20-2201).

Measures

Participant Demographics and IBD Characteristics

For demographics, the pretest survey assessed participants’ age, gender, race, Hispanic ethnicity, education, household income, and sexual orientation. For IBD characteristics, the pretest survey assessed the type of IBD that the participants had (UC, CD, indeterminate colitis, or other), the age at which they were diagnosed with IBD, and whether they were currently taking

daily oral medication to treat their IBD or maintain IBD symptoms. The pretest survey also asked participants to rate their disease activity over the past 6 months using the single-item Manitoba IBD Index [23].

Intervention Feasibility

The posttest survey asked participants how difficult or easy they found participating in the study to be, whether they would enroll in the study again, and whether they would recommend the study to someone else with IBD (all on 5-point scales with neutral middle points). Feasibility items were dichotomized for analysis, such that responses above the middle point (ie, score of 4 or 5) were categorized as perceiving that component of the intervention as feasible. Participants were also asked what they thought about the frequency of messages they received during the study (with responses being “too little,” “about right,” or “too much”) and how many of those messages they read (5-point scale ranging from “none” to “all of them”). Feasibility items were informed by implementation and dissemination literature [19].

Intervention Acceptability

The posttest survey asked participants about their overall satisfaction with the content of the messages and resources sent by *Text4IBD* (5-point scales ranging from “not at all” to “extremely”). Those who were currently taking daily oral medication were asked how useful they thought the reminder messages were (5-point scale ranging from “not at all” to “extremely”). Participants also answered questions about their attitudes toward the study. Attitudes were assessed using a 4-item scale developed for this study. The scale began with the prompt, “Overall, would you say participating in this study was...” Responses to attitude items were on 10-point bipolar scales. Response anchors were (1) not helpful–helpful, (2) not informative–informative, (3) not supportive–supportive, and (4) not useful–useful. Reliability of the scale was high ($\alpha=.94$). Acceptability items were informed by implementation and dissemination literature [19].

Aided Topic Recall

The posttest survey asked participants to select message topics (all the applicable topics) that they remembered being sent by the *Text4IBD* program. Topics were the following: (1) IBD and mental health, (2) IBD nutrition, (3) IBD diets, (4) IBD management, (5) exercise and stress, (6) IBD symptom tracking, and (7) food journaling. In addition, participants could choose 3 topics in the same list that were not part of the *Text4IBD* program. These foil topics were the following: (1) irritable bowel syndrome versus IBD symptoms, (2) IBD procedures, and (3) IBD and ostomies. Participants could also choose that they did not recall seeing any of these topics.

Use of Linked Resources

The posttest survey asked participants to select the linked resources (all the applicable resources) that they clicked during

the intervention. This measure was to evaluate whether participants opened the messages on their phones, as it was not possible to collect those data. Resources in this list were the following: (1) MyGut, (2) IBD nutrition and what to eat, (3) coping strategies to improve mental health, (4) special IBD diets, (5) COVID-19 and mental health, (6) web-based IBD communities, and (7) IBD expert questions and answers.

Pretest-Posttest Outcomes

Both pretest and posttest surveys assessed measures of IBD-related distress [21,22], perceived IBD support (developed for this study), self-efficacy [24], use of 3 different coping strategies [25], and medication adherence [26] as secondary outcomes. Self-efficacy assessment included four subscales: (1) stress and emotions management, (2) medication management, (3) symptoms management, and (4) remission management. Medication adherence was reported as a binary outcome (complete adherence vs not complete adherence), and all other secondary outcomes were reported as approximations of continuous measures from Likert-style scales. Refer to [Multimedia Appendix 3](#) [21,22,24-26] for all the items associated with secondary outcomes.

Data Analysis

We used descriptive statistics to characterize intervention feasibility, acceptability, and engagement (ie, aided topic recall and use of linked resources). We used 2-tailed paired-samples *t* tests and McNemar tests to examine pretest-posttest changes in the secondary outcomes for continuous and categorical variables, respectively. Only the participants who completed both surveys were included in this analysis. We calculated effect size estimates for paired-sample comparisons of continuous variables using Cohen *d*. We interpreted effect sizes of Cohen $d=0.2$ as small, Cohen $d=0.5$ as medium, and Cohen $d \geq 0.8$ as large. Analyses were performed using R (version 3.6.2; R Foundation for Statistical Computing).

Results

Participant Demographics and IBD Characteristics Obtained From the Pretest Survey

Mean age of the participants was 29 years (range 19-53 years; [Table 1](#)); most participants were White (95/114, 83.3%), and approximately 8.8% (10/114) of the participants identified as Hispanic. More than half (68/114, 59.6%) of the participants were female, and more than one-third (44/114, 38.6%) identified as gay, lesbian, or bisexual. Slightly less than half (52/114, 45.6%) of the participants had a Bachelor's degree or higher. Household income varied, with 46.5% (53/114) of the participants earning <US \$50,000; 35.1% (40/114) earning between US \$50,000 and US \$99,999; and 16.7% (19/114) earning \geq US \$100,000.

Table 1. Demographic and IBD^a characteristics of the study sample obtained from the pretest survey (N=114).

Constantly active, n (%)	3 (2.6)
Complete medication adherence ^c (n=73), n (%)	41 (56)

^aIBD: inflammatory bowel disease.

^bIBD activity based on the Manitoba IBD Index, where high values indicate worse disease activity.

^cAssessed only among those who reported taking daily oral IBD medication in the pretest survey.

Most participants had CD (83/114, 72.8%) or UC (22/114, 19.3%); however, a small proportion (9/114, 7.9%) self-reported other IBD diagnoses such as lymphocytic or collagenous colitis. Mean age at diagnosis was 22.32 (SD 8.32) years, and approximately half (59/114, 51.8%) of the participants had been living with IBD for ≤ 5 years. In all, 31.6% (36/114) of the participants reported being in disease remission the past 6 months, whereas only 7.9% (9/114) reported active IBD symptoms (ie, experiencing symptoms “often” or “constantly”) over the same time. Most participants (73/114, 64%) reported currently taking daily oral IBD medication. Approximately half (41/73, 56%) of them reported complete medication adherence.

Feasibility and Acceptability

Approximately all participants (101/105, 96.2%; [Table 2](#)) said it was easy to participate in the study, that they would participate again if given the option (98/105, 93.3%), and that they would recommend the study to others with IBD (99/105, 94.3%). Most participants (90/105, 85.7%) thought that the message frequency during the intervention was approximately right, and 91.4% (96/105) of the participants reported reading “all” or “a lot” of the messages. The perceived usefulness of the medication reminder messages was modest (mean 3.37, SD 1.39). In addition, overall attitudes toward *Text4IBD* were positive (mean 8.03, SD 2.04), and participants tended to be satisfied with the content of the support messages (mean 3.81, SD 1).

Table 2. *Text4IBD* feasibility, acceptability, and engagement (n=105).

	Values
Easy to participate, n (%)	101 (96.2)
Would participate again, n (%)	98 (93.3)
Would recommend to others with IBD, ^a n (%)	99 (94.3)
Message frequency approximately right, n (%)	90 (85.7)
Number of messages read, n (%)	
All of them	76 (72.4)
A lot	20 (19)
Some	8 (7.6)
Very few	1 (0.9)
Overall attitude toward the intervention, mean (SD)	8.03 (2.04)
Helpful	7.88 (2.29)
Informative	7.99 (2.24)
Supportive	8.33 (2.05)
Useful	7.91 (2.34)
Medication reminder was useful, ^b mean (SD)	3.37 (1.39)
Satisfied with message content, mean (SD)	3.81 (1)
Satisfied with message resources, ^c mean (SD)	3.64 (0.98)
Used at least one message resource, n (%)	83 (79)
Message resources accessed,^d n (%)	
MyGut	45 (42.9)
IBD nutrition and what to eat	45 (42.9)
Coping strategies to improve mental health	41 (39)
Special IBD diets	39 (37.1)
COVID-19 and mental health	38 (36.2)
Web-based IBD community	32 (30.5)
IBD expert questions and answers	24 (22.9)

^aIBD: inflammatory bowel disease.

^bAssessed only among those who reported taking daily oral IBD medication in the posttest survey (n=65).

^cAssessed only among those who reported accessing at least one message resource (n=83).

^dVariables are not mutually exclusive.

Engagement With Message Topics and Use of Linked Resources

In the posttest survey, approximately all participants (103/105, 98.1%; [Figure 4](#)) reported recalling at least one *Text4IBD* message topic. The most recalled topic was IBD and mental health (84/105, 80%), followed by IBD and nutrition (81/105, 77.1%), IBD diets, (80/105, 76.2%), and IBD management

(75/105, 71.4%). The least recalled topics were IBD symptom tracking (58/105, 55.2%) and food journaling (55/105, 52.4%). A modest number of participants (19/105, 18.1%) falsely reported recalling one or more of the 3 foil topics, with the most selected foil topic (irritable bowel syndrome vs IBD symptoms) being inaccurately recalled by 12.4% (13/105) of the participants.

Figure 4. Aided topic recall of the *Text4IBD* messages. IBD: inflammatory bowel disease; IBS: irritable bowel syndrome.

In the posttest survey, 79% (83/105; [Table 2](#)) participants self-reported using at least one *Text4IBD* linked resource. Linked resource satisfaction was modest (mean 3.64, SD 0.98). The most used resources were MyGut (an IBD self-management mobile app; 45/105, 42.9%), IBD nutrition and what to eat (45/105, 42.9%), coping strategies to improve mental health (41/105, 39%), special IBD diets (39/105, 37.1%), and COVID-19 and mental health (38/105, 36.2%). The web-based IBD communities (32/105, 30.5%) and IBD expert questions and answers (24/105, 22.9%) resources were accessed by few participants.

Differences Between Pretest and Posttest Outcomes

In the posttest survey, participants reported lower IBD-related distress than during the pretest survey ($P<.001$; [Table 3](#)). This change constitutes a medium to large effect size (Cohen $d=0.77$). Participants reported a modest improvement in their perceived

IBD support from pretest to posttest period ($P<.001$; Cohen $d=0.47$). Participants also reported pretest-posttest improvements in stress and emotions management ($P<.001$), remission management ($P<.001$), and symptoms management ($P<.001$) self-efficacy. These changes exhibited medium to large effect sizes (Cohen d range 0.58-0.75). Changes in the use of coping strategies varied. Participants reported minor increases in their use of relaxation ($P=.009$) and positive thinking ($P=.03$) coping strategies from pretest to posttest period. In contrast, in the posttest survey, participants reported worse scores for the altering their diet to improve IBD symptoms coping strategy than in the pretest survey ($P=.02$). Changes among the 3 coping strategies exhibited small effect sizes (Cohen d range -0.22 to 0.26). Finally, participants currently taking daily oral medication for their IBD did not observe any pretest-posttest improvements in medication adherence ($P=.45$) or medication management self-efficacy ($P=.49$).

Table 3. Pretest-posttest differences among study outcomes (n=105).^a

	Pretest assessment	Posttest assessment	P value	Cohen d
IBD ^b -related distress, mean (SD)	3.33 (0.68)	2.86 (0.73)	<.001	0.77
Perceived IBD support, mean (SD)	2.89 (0.92)	3.26 (0.93)	<.001	0.47
Self-efficacy, mean (SD)				
Remission management	4.94 (1.94)	6.39 (1.97)	<.001	0.75
Stress and emotions management	5.19 (1.85)	6.45 (1.76)	<.001	0.69
Symptoms management	4.21 (1.96)	5.53 (2.09)	<.001	0.58
Medication management ^c	9.32 (2.23)	9.66 (1.64)	.49	0.09
Coping strategies, mean (SD)				
Use of relaxation techniques	2.63 (1.12)	2.93 (1.07)	.009	0.26
Think positively about IBD	2.47 (1.24)	2.69 (1.14)	.03	0.21
Alter diet to improve IBD	3.44 (1.26)	3.18 (1.09)	.02	-0.22
Complete medication adherence ^c (n=61), n (%)	36 (59)	40 (65.6)	.45	N/A ^d

^aMeasures were assessed on 5-point scales, except self-efficacy subscales (11-point scales) and complete medication adherence (dichotomous outcome); low values in the posttest survey for IBD-related distress indicate better outcome, whereas high values in the posttest survey for perceived IBD support, self-efficacy subscales, coping strategies, and complete medication adherence indicate a better outcome. We also ran the analyses controlling for age, gender, education level, type of IBD, time since IBD diagnosis, and disease activity and did not find any differences in the pattern of effects. Thus, we present the findings without adjustment.

^bIBD: inflammatory bowel disease.

^cAssessed only among those who reported taking daily oral IBD medication both in the pretest and posttest surveys.

^dN/A: not applicable.

Discussion

Principal Findings

This study sought to examine *Text4IBD* feasibility, acceptability, and engagement and to preliminarily evaluate pretest-posttest changes in health outcomes targeted by the intervention. Results demonstrate that delivering an IBD support intervention by SMS text message was feasible and that participants viewed the program as acceptable. Participants also recalled most of the support message topics, and many used the linked resources. Furthermore, results showed improvements in several self-reported outcomes, including IBD-related distress and perceived support. These findings provide much-needed empirical evidence to the ongoing discussion about the utility of eHealth in personal IBD health care [27-32] and suggest that digital technologies can play an important role in self-managing IBD symptoms.

The primary goal of this study was to assess whether people with IBD would be receptive to a support-based SMS text messaging intervention, and the results were promising. Approximately all participants evaluated *Text4IBD* as feasible and acceptable across multiple aspects of the program, including satisfaction with message content and frequency. Moreover, attitudes toward *Text4IBD* were typically scored ≥ 8 out of 10, and approximately all participants reported that they would participate in the study again if given the opportunity. This level of satisfaction with the program indicates the value of offering support to people with IBD.

Indicators of engagement with *Text4IBD* were also positive. For example, 79% (83/105) of the participants reported accessing at least one linked resource, aided topic recall was high overall, and few participants reported recalling a foil message topic. These findings support the literature showing that people with IBD tend to be receptive to the idea of eHealth interventions for disease self-management [33-37] and that digital technologies can be used for therapeutic purposes [38-40].

A secondary goal of this study was to test whether an SMS text messaging intervention would be useful in improving health outcomes. Although the lack of a control group precludes us from making strong causal conclusions, our pretest-posttest findings provide compelling evidence that the intervention may have reduced disease-related distress. This result has important clinical implications, given the high levels of distress that people with IBD typically experience [2,3] and the various health consequences associated with distress [5-11]. Results also suggest that participants increased their perceptions of IBD support, confidence to self-manage IBD (ie, self-efficacy outcomes), and use of some coping strategies. These findings support the implementation of similar mHealth frameworks in future self-management interventions for this population.

A surprising result of this study was its null findings regarding medication-related outcomes. In contrast to other research [15,16], participants did not show any pretest-posttest improvements in medication self-efficacy or adherence outcomes. Regarding the self-efficacy outcome, this finding is likely explained by the fact that mean pretest scores were high (mean 9.32 out of 11, SD 2.23), leaving little scope for

improvement. In contrast, medication adherence was modest during the pretest period (36/61, 59%) and only marginally improved by the posttest period (40/61, 66%). This nonsignificant change could be because medication reminder messages were only sent once per day, which may not help individuals taking multiple medications at different times throughout the day. Notably, participants in this study were individuals with IBD who likely had an established medication regimen. A similar type of intervention might prove more effective for those with new IBD diagnoses or those trying to implement a new regimen.

It should be stated that these null findings do not suggest that medication reminder messages have no role in IBD interventions. In fact, the opposite is true, as evidence generally shows positive effects of such interventions on disease outcomes in studies among people with chronic disease [12]. Instead, future studies should improve the reminder message component of this intervention, such as by better tailoring the messages to participants' needs (eg, allowing participants to set medication reminders at times and frequencies that fit their schedule).

Finally, participants reported a low likelihood of altering their diet to improve IBD symptoms from the pretest to posttest period, indicating a worse outcome. A possible explanation for this could be that altering one's diet is not a *regular* behavior. That is, people with IBD likely do not experiment with their diet, especially if they have adapted to a nutrition plan that works for them. However, diet is integral to IBD self-management, and thus, studies examining the viability of using mHealth to improve nutrition for those with IBD warrants further investigation.

Overall, findings from this formative study provide insight regarding the design, implementation, and dissemination of mHealth interventions in this area. As previously discussed, past IBD and SMS text messaging interventions have tended to last between 3 and 12 months [15-18], with follow-up results exhibiting inconsistent findings. In contrast, *Text4IBD* was intentionally designed to expose participants to a large number of diverse support messages in a short period. Our high sample

retention (105/114, 92.1%) and the effects exhibited between pretest-posttest secondary outcomes suggest that interventions of this design may be well suited for delivering support about IBD self-management and for lessening participants' burden and fatigue. Of course, it should be stated that the magnitude of our findings is attributable, in part, to the relatively short duration of this study and the assessment of outcomes immediately after intervention completion [41]. Therefore, researchers interested in examining longitudinal effects may wish to use other study designs. Nonetheless, future studies should consider iteratively testing *Text4IBD* across varying durations and populations to assess its efficacy over time.

Strengths of this study include high retention of participants at the 2-week posttest assessment, a diverse set of support messages about IBD self-management selected from pilot study findings, and implementation of a custom mHealth program that allowed participants to choose when to receive support messages. The main limitation of this study is that it used a single-group design, which limits our ability to fully attribute changes in study outcomes to the intervention. Future studies should test *Text4IBD* in a randomized controlled trial. Another limitation is that the participants were recruited via convenience sampling methods using public social media data. Factors such as digital literacy and nongeneralizable representation among social media users—as evidenced by characteristics of our study sample (ie, predominately White and female)—mean that additional studies are needed to examine whether our findings apply to all people with IBD.

Conclusions

We developed *Text4IBD* to provide information and support about disease self-management to people with IBD. Our SMS text messaging intervention was feasible and highly acceptable, and intervention retention was high. Given that people with IBD struggle with self-managing their disease, the results from this study are encouraging and support the future use and development of digital technologies to improve health outcomes in this population.

Acknowledgments

The authors would like to thank everyone who pilot-tested *Text4IBD* and offered feedback about how to improve the program.

Abstract

Background: Young African American women have higher rates of sexually transmitted infections, including HIV, than those of young women of other racial and ethnic groups. Gender-, culture-, and age-specific interventions are needed to end the HIV epidemic. The Women's CoOp (WC) is an HIV risk–reduction intervention that is proven to be efficacious in various face-to-face formats.

Objective: This study aims to adapt the delivery method of an evidence-based intervention, the WC, from an in-person format to a self-guided mobile health (mHealth) format while ensuring that core elements are maintained for intervention comparability and fidelity.

Methods: Several adaptation phases were conducted by using the Personal Health Informatics and Intervention Toolkit (PHIT) as a guiding point to create the mobile app version of the WC. Throughout 5 phases, we established the implementation groundwork for the app; conducted formative research activities to test the initial draft of the app and obtain feedback; applied the PHIT toolkit programming structure to produce the mHealth version of the WC intervention; conducted usability testing and pretesting with interested parties, followed by in-house testing by WC interventionists and PHIT developers; and deployed the app to tablets and distributed it to study participants. The app underwent regular maintenance updates during the study.

Results: The team converted the seven elements of the WC as accurately as possible for comparability to determine efficacy in a mobile app format while changing little about the basic delivery methods. For instance, *cue card* presentations of the materials delivered by the intervention staff were presented within the app but with voice-over narration and in a self-guided format rather than being led by a staff member. Other aspects of the intervention did not lend themselves to such straightforward adaptation, such as hands-on condom proficiency practice and one-on-one goal-setting activities. In these cases, the subject matter experts and app developers worked together to find comparable analogs to be used within the app. Once developed, tested, and finalized, the mHealth WC app was deployed into local health departments as part of a randomized trial.

Conclusions: This systematic adaptation process created an accurate mHealth equivalent of an existing, in-person behavioral health intervention. Although participants' reception of the app during the formative developmental phase was overall positive, maintaining fidelity to the in-person delivery compromised the natural capabilities of a mobile app, such as further gamification, different types of interactivity, and integrated notifications and messaging, which could be helpful for participants' adherence to the intervention schedule. Given the development and implementation of the app, the next step is to examine the impact of the app and its efficacy in HIV and substance use risk-reduction.

Introduction

Background

African American women have experienced an unparalleled burden of HIV since the start of the epidemic and currently account for 55% of new HIV cases among women in the United States, despite representing 13% of women in the US population [1]. The rate of new HIV diagnoses among African American women is 13 times higher than that of White women and nearly 4 times higher than that of Hispanic or Latina women [2]. The disparity is even greater among African American female adolescents and young adults, particularly in the US South. In 2019, adolescents and young adults aged 13 to 24 years represented 21% of 36,398 individuals newly diagnosed with HIV in the United States [3]. In addition, approximately 51% of the new cases occurred in the US South, with African Americans representing 52% of these cases in the region [3].

Sexually transmitted infections (STIs) further place women at an increased risk for HIV, with African American women experiencing similar disparities in STI rates. Adolescents and young adults aged 15 to 24 years represent approximately half of the estimated 19 million new STI cases that occur each year in the United States, with young African American women experiencing approximately 4.5 times the rate of chlamydia, 5.2 times the rate of syphilis, and 9.3 times the rate of gonorrhea compared with young White women in the same age group [4]. These disparities in STI rates are further reflected in the US South, including North Carolina. Previous research has shown that social determinants, such as poverty, food insecurity, housing instability, lack of childcare, lack of transportation, experienced stigma, substance use, violence from intimate partners, and other socioeconomic constraints and structural barriers are associated with STI risk and acquisition [5].

Despite these alarming rates, few cultural-, age-, and gender-specific strategies exist to reach young African American women, which promote positive health behavior change by addressing social determinants and providing HIV risk-reduction information and skill-building activities. Consequently, technologically innovative methods of reducing STI and HIV burden based on adapted evidence-based HIV prevention strategies need to be tested with young African American women.

An estimated 97% of the US population owns a mobile phone, with approximately 83% of African Americans reporting smartphone ownership and 99% reporting ownership of any type of mobile phone [6]. Notably, African Americans have the highest smartphone ownership and use compared with any other racial or ethnic group in the United States [7]. Among African Americans, an estimated 85% of individuals text an average of 70 texts per day, with higher rates among female adolescents and young adults [6]. In addition, current research indicates that individuals with lower levels of income and education text more

often than those at the higher end of the income and education scale [8-10].

The rapidly expanding accessibility of mobile technology, including smartphones and internet-based laptops or tablets, offers a unique opportunity for affordable linkage to health care and other valuable health information for hard-to-reach populations [11-13]. However, despite the large amount of time that young African American women engage with their smartphones, and given that racial and ethnic minority groups are using mobile phones to access health information more frequently than nonminority individuals, few targeted mobile health (mHealth) initiatives exist to reach young African American women, which are intended to increase their positive health outcomes, especially in HIV prevention [14].

Several behavioral health interventions have been developed and implemented for African American women that aim to reduce HIV, substance use, gender-based violence, and other related risks [15-20]. One such intervention developed specifically for African American women is the Women's CoOp (WC), a *best-evidence*, empowerment-based, in-person, HIV risk-reduction behavioral intervention [21,22]. The WC is one of a few best-evidence interventions for African American women in the US South who use substances—a key population at risk for HIV. Originally, a 4-session cue card intervention comprising 2 individual and 2 group sessions focused on achieving personal power and agency to reduce sexual risk for HIV and STIs through hands-on activities such as condom demonstrations, sexual negotiation, and partner communication role-play and by learning about their bodies and reproductive health. This intervention showed statistically significant reductions in sexual risk and substance use [22] and has been adapted to a variety of contexts and settings in the United States, South Africa, Russia, and the Republic of Georgia [23]. The WC has been delivered by both trained clinic staff and project staff interventionists.

Aim

As part of a crossover randomized trial, this study sought to test the efficacy of two delivery methods—face-to-face compared with mHealth—of an adapted version of the WC. This adaptation has reached female African American adolescents in the US South using the same information and methods as the original WC but adjusted to the context of a younger age group [24]. We aimed to develop a comparable mobile app version (mobile WC [mWC]) of the in-person WC program. The ability to tailor behavioral interventions to the culture, age, and gender of the intended population makes mHealth an innovative and valuable tool for reaching young African American women for HIV prevention.

This paper describes the adaptation process, activities, and rationalizations behind decisions made by behavioral health researchers and app programmers involved in the mHealth app development, the challenges encountered in the course of

implementation, and insights gained about the process of converting in-person programs to mobile formats [25].

Methods

Adaptation Process and Agile Development

Although the adaptation process was iterative rather than linear, the conducted activities encompassed multiple phases, from the initial selection of the mHealth platform to the app's maintenance.

Phase 1: Selection of the mHealth Platform

When deciding on a technological platform to adapt the intervention to an mHealth format, the behavioral health team, led by the developer of the WC, held 2 specific goals paramountly. First, it was important that the resultant app be accessible to and usable by all participants equally. Second, the participant information needed to be thoroughly secured. These 2 guiding intentions informed the ultimate decision to use the Personal Health Informatics and Intervention Toolkit (PHIT) platform to produce the app.

The PHIT platform is a software development framework that allows for rapid production of cross-platform, research-oriented custom mHealth apps [26]. This framework is most often used to build personalized health intervention apps using the subjective and objective measurement, assessment, and plan methodology [27]. The cross-platform aspect means that a single codebase can produce both a native Android app and a native iOS (Apple) app. Consequently, no participant would be turned away for having access to one type of device or another.

However, participant access to a reliable Wi-Fi internet connection, singular nonshared ownership of a private smartphone, and consistency of app appearance and performance across all devices were concerns shared by the team. Ultimately, these concerns led to the decision of providing participants with project-assigned devices preloaded with the app rather than installing the app on the participants' own devices, ensuring more consistency and participant confidentiality throughout the study. By providing a device for use during the study rather than having participants use their own devices, we were able to rely on using one type of device and operating system to ensure each participant's experience was the same from an equipment standpoint.

All research data collected and generated via the use of a PHIT app are stored locally within the app space in an encrypted SQLite database, allowing these apps to operate, gather, and save data without the need for an active cellular or internet connection. This was important when choosing a possible technology solution as some potential participants may not have had steady or predictable internet access. These data are stored with no participant information (only a unique participant ID) and can be uploaded whenever a Wi-Fi or cellular connection becomes available. Data transmission occurs using the secure https protocol and is stored in a secure SQL server database accessible only to authorized study personnel via user ID and password authentication. The app itself is protected from unauthorized access by a 4-digit personal identification number (PIN) chosen by the participant. The secure PIN must be entered

each time the app is accessed for use, which serves the dual purpose of keeping personal data hidden from others while allowing only the study participant to record data.

Phase 2: Planning

Once the technological platform was selected, the behavioral health team began a series of ongoing meetings with the software development team to plan the specifics of the mHealth adaptation. The subject matter experts explained the seven core elements of the in-person WC intervention and worked with the developers to devise the best adaptation methods to retain fidelity to the original delivery mechanisms [22]. The developers then created the first draft of the app intervention screens, which included the *cue card* user interface and embedded video vignettes of success stories from previous WC participants. These drafts were later shown to potential young female participants during the formative research phase to elicit their feedback.

Phase 3: Formative Research

Several activities were conducted as part of the formative research phase, including discussions with senior staff from the 3 proposed participating health departments in North Carolina, Community Collaborative Board members, and a series of focus group discussions (FGDs)—2 with young African American women at risk for HIV (N=8) and 6 with service providers who work with young African American women (N=40). Led by the same trained project staff member, all FGDs were audio recorded and had at least one notetaker present. All FGD participants provided written and signed informed consent. Notes and transcripts from each FGD were reviewed for main themes related to the intervention, which included delivery, content, length, and format.

The formative findings indicated that the adapted intervention delivered via mHealth would be well-received among the young women. Young, female focus group participants noted the following:

...certain things like that, that they can relate to that'll grab their attention.

It'll help. They'd probably like open up more, be honest...on the tablet versus...talking to somebody.

I feel like just bringing it on a device like that is making it a little bit more up to date. It's not a video you have to watch. It's not reading out of a textbook. It's a little bit more into, you know, today's time, interactive. I think if you're really trying to get them to be interested in that, it's just bringing the attention towards, you know, what they're interested in today.

Some service providers believed that the mHealth platform might be a way of engaging individuals who are not comfortable discussing certain sensitive topics face-to-face:

...if it's a meaningful interaction, I think it could play a big role...

They can do it at their own leisure.

...if it's on...as you mentioned, like a smartphone, then they can do it privately. They can watch it and they can cry if they want to and they don't have to feel, as

mentioned earlier, that they have to be super strong Black women and not express any emotions, even though they feel it.

I think with giving them something concrete to use—on their own schedule, their own time, in their own space will make it effective. It's not like the normal interventions; this is a little different.

However, service providers also indicated that potential barriers to young women participating and continuing in this study could include lack of motivation to participate or use the mobile app, the amount of information presented to them at once, the length of the sessions, and the potential to use the tablet for other activities being a distraction from completing the intervention. Service providers noted the following about the mHealth platform:

They going be doing everything else except for that app...

They might do one session and dip, but—but at least they did something.

I would prefer it, but I would also be motivated to do it on my own, whereas I don't know that everyone will do it.

Phase 4: App Development

Following the formative phase, the app developers began work on implementing the findings from the planning and formative research phases. Beginning with the aspects of the app that were more unambiguous with respect to adaptation methods, the developers used an iterative and responsive development process to construct the app. This involved rapid communication between the behavioral health and development teams via frequent in-person meetings coupled with more impromptu communication via instant messaging applications such as Microsoft Teams and Skype (Microsoft Inc) for progression and confirmation of app changes and additions to ensure that the content aligned with the source intervention. The team also addressed any early-on *bug fixes* in the app during this phase, such as the correction of programming glitches or content errors.

Phase 5: Usability and Pretesting

During this phase, the mHealth development team and various project staff conducted extensive usability testing to ensure the app was intuitive and self-guided. Specifically, members of the behavioral health team meticulously reviewed all the potential pathways of the app using a methodical iterative procedure to test for errors, clarity, and flow. This included going through all options within the app as a potential participant would and documenting any changes needed. Examples of changes requested by the behavioral health team included phrasing of statements, stylistic preferences, and usability enhancements. Continuing the agile development process required that changes and additional bug fixes be implemented by the development team, tested, and redeployed to project staff testing devices.

The pretesting of the mWC intervention was guided by the study staff. A total of 6 study participants who had attended formative FGDs and were eligible for the study were invited to the study team's main research campus to pretest the near-final mWC

intervention on a 7-inch Acer Iconia One 8 project tablet. Participants also completed a satisfaction and usability form for the app and were provided a gift card to thank them for their time.

Phase 6: In-house Testing

In the next to last stage of app development, the behavioral health team conducted in-depth testing to prepare for dissemination. Testing of the final intervention was conducted on the target study device: 7-inch Acer Iconia One 8 tablets purchased for the project. The study staff confirmed the basic functionality of all portions of the app, including app behaviors such as adherence to security measures (eg, whether the app required a PIN to access user information), the appropriate progressive disclosure of intervention materials, and acceptable media performance on the tablet.

Throughout testing, the behavioral health team stayed in close contact with the app development team to ask questions, make requests, and identify bugs.

Phase 7: Finalization and Maintenance

Once in-house testing was completed, the app development team made a canonical *version 1* build of the mWC app. An initial set of study tablets was provisioned and loaded with the app and then provided to the previously identified study sites in 3 North Carolina health departments.

Over the course of the study, updates to the app were made 5 times. One of the revisions was to implement a method of PIN recovery for participants who had forgotten the required 4-digit PIN they created to access the app. Other revisions were to update and expand the *referral guides* section of the app (refer to the following sections). Whenever the app was updated, the newest version was installed on each new batch of tablets as they were provisioned for the study. In the case of the PIN recovery app modification, the user's app could be updated on the tablet from a connected computer without the loss of previously collected study data.

Ethics Approval

This study was approved by the RTI International Office of Research Protection Institutional Review Board (ID Number 13836), in addition to the research committees of Wake County Human Services and the Durham County Department of Public Health. The Guilford County Department of Public Health Director granted approval in lieu of a formal review by a research committee.

Results

Overview

When setting out to design the app-based version of the WC, it was important to the researchers that the mobile adaptation closely matched the original version of the WC to enable a faithful comparison between the effectiveness of the two modalities. As previously stated, the in-person intervention sessions comprise health information content delivered via cue cards followed by a behavioral goal-setting process, both guided by a trained project staff member. We decided to keep the

content and delivery modes of the sessions the same where possible and to modify only as necessary for presentation on a mobile device. Although the decision to provide participants with study-issued devices was made early on, tablets were chosen over smaller devices, such as smartphones, to provide a better user experience for the rich media of the intervention.

The primary difference between the two delivery methods is the self-directed aspect. The in-person intervention is guided by a trained interventionist, whereas the mobile version is almost

entirely self-paced and self-guided. In the app, participants choose options from menus and can move forward and backward as they please, with the opportunity to replay any portion of the app at any time. Although repeating the consumption of content and time spent in sessions is largely up to the participant while using the mobile app, the linear nature of the intervention sessions is preserved by providing access to subsequent sessions and related activities only as the previous ones are completed. **Table 1** presents a comparison of the two delivery methods regarding components and characteristics.

Table 1. Comparison between the two delivery methods of the WC^a.

Components	Face-to-face WC	mWC ^b
Timing	This includes 2 sessions, typically scheduled a week apart.	Session 2 is immediately available to the participant upon completion of session 1.
Interventionist or navigation of intervention	Sessions are one-on-one between a trained project staff member and a study participant.	Sessions are self-guided by using forward and backward navigation to move between slides, videos, and activities. Each card is accompanied by an audio narration reading the content.
Order of content	Cue cards and video vignettes are reviewed in a specified order by the interventionist.	Cue cards and videos are presented in a specified order via programming.
Activities and participant engagement	Key ideas are discussed as they are presented, with back-and-forth communication to aid in knowledge retention.	Key ideas have been developed into accompanying <i>activities</i> that intersperse the cue cards. These are interactive <i>minigames</i> the participant completes to aid in knowledge retention.
Role-play and rehearsal	Scenarios such as condom negotiation and application are practiced during role-play to allow the participant to develop skills.	Cue cards prompt participants to consider how they might react in certain situations. There are also <i>follow along at home</i> videos presented, during which participants are encouraged to practice along.
Personalized action plan	At the end of each session, the participant develops their action plan with guidance from the interventionist.	At the end of the session, the participant constructs their action plan by reviewing a series of screens with common goals and steps from prior studies.
Revisiting action plan or check-in	In session 2, the participant and interventionist discuss progress on the participant's action plan from session 1.	Once an action plan is confirmed by the participant, a new menu item becomes available on the home screen. Participants are encouraged to visit this <i>monitor goals</i> screen often to reflect on and update their action plan.
Check-in	After session 2, the interventionist follows up with the participant to check on the progress of their action plan.	After session 2, the participant unlocks an additional set of potential goals to add to their action plan. The <i>monitor goals</i> screen tracks all action plan goals in one place and can be visited at any time.

^bmWC: mobile Women's CoOp.

Cue Cards and Video Media

The bulk of the health information content was adapted to a self-directed slideshow by converting the Microsoft PowerPoint slide decks, or cue cards, originally presented in person by an interventionist. The participant enters a session by choosing it from the home screen menu and is placed into an engaging full-screen presentation (**Figure 1**).

Cue card design, content, and order are the same in the face-to-face WC and the mWC interventions. However, in the mWC app, the participant moves through the cards at their own pace by tapping forward and backward buttons. The participant could also choose to pause or exit the app at any time and pick up later where they left off. Each card's content is narrated by

embedded audio narration and can be replayed if desired. The entire session itself is available for play or replay from the home screen menu at any time after the participant has unlocked it by completing the previous session or goal-setting activity (action plan).

Video vignettes of mostly African American young women sharing brief personal stories relating to the session topics are interspersed throughout the text and image-based cue card content (**Figure 2**).

Owing to concerns about future scale up and dissemination, the amount and file size of videos were reduced. At the time of development, the Apple App Store limited the size of apps to 100 MB if they were to be downloadable over a cellular connection.

Figure 1. Sample cue card.

Figure 2. Sample frame from a video vignette.

Referral Guides

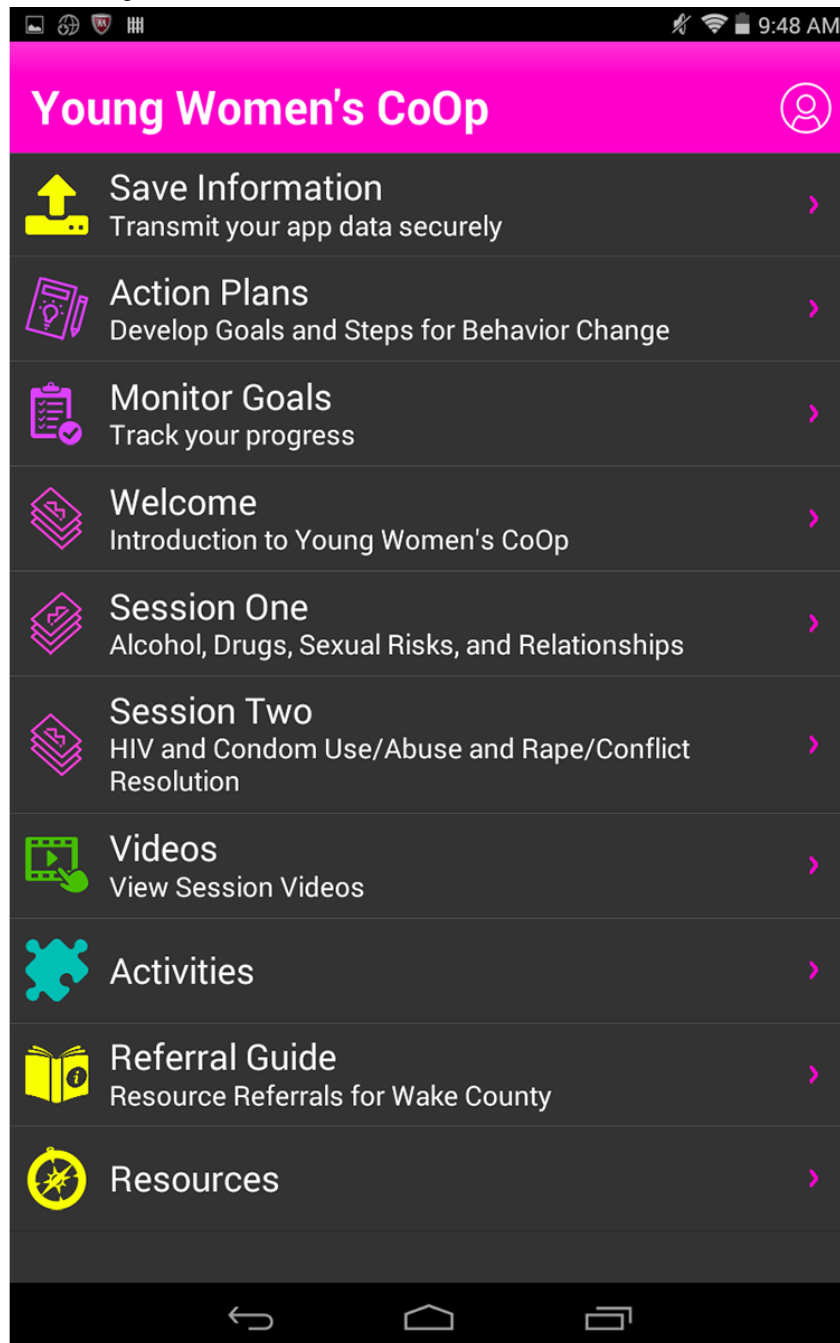

Participants in the in-person intervention received referrals, as needed, to local organizations or resources providing services in the domains of food aid; employment, education, housing, legal, parenting, and substance use; sexual, mental, and general health; and domestic violence and sexual assault support.

The same resources are provided in the app but with a self-directed aspect. A *referral guide* option is always available

from the home screen menu (Figure 3) and participants choose which geographical location (out of the ones provided based on the location of the study health clinics) is most convenient to them.

As referral resources are updated by health staff, the app is also updated with new information. Participants joining the study would receive the most up to date version of the app during their scheduled mHealth appointments.

Figure 3. Home screen with the referral guide available.

Adaptation to the mHealth Format: Interactivity

Interactive Activities

Although adapting a more passive activity such as consuming information by following along with cue cards or watching videos is relatively straightforward, replacing the back-and-forth communication during knowledge retention activities in the in-person intervention provided a greater challenge. The goal of this aspect of the behavioral intervention is to recap previously presented key topics in a reciprocal manner with the aim of assessing understanding while reinforcing recall and absorption of crucial information. Therefore, 3 *minigames* and 2 *follow-along* video activities were developed to take the place of the person-to-person interaction present in the original WC

and adapted WC interventions. Similar to the video vignettes, these activities are interspersed throughout the cue card presentations.

The minigames present the participant with an exercise to complete and provide real-time feedback about how well they are doing. The *Upper or Downer* activity (Figure 4) reviews topics about alcohol or other drugs and tasks the participant with sorting a list of previously discussed illicit drugs into their respective category of *upper* or *downer*. Each correct answer is rewarded with a checkmark and a notice of *Correct! Nice Job!*; incorrect answers elicit a message for the participant to try again. Once all drugs have been sorted, the participant sees their final score.

Figure 4. Two screens of the Upper or Downer activity.

Similarly, the *Levels of Risk* minigame recaps sexual risk information and asks participants to sort a mixed-up list of sex acts into order from *least risky* to *most risky*. The third minigame, *Myths and Truths*, assesses participants' recall of the veracity of some commonly held but erroneous beliefs about violence against women by posing the question "Myth or Truth?" In addition to the minigames, there are 2 follow-along videos that demonstrate male and female condom mastery. The videos show the process of removing a male or female condom from its wrapper, its application (on a banana or hand stand-in, respectively), and its proper removal and disposal. Participants are encouraged to practice along with the video using condoms provided by the study when they receive the tablet [24].

Action Plans

Another important component for the mWC adaptation was translating the personalized risk-reduction action plan for the mHealth app. At the end of each session, participants in the in-person WC work with the guidance of the interventionist to

set goals related to the intervention material and create specific and concrete steps to reach these goals. In the absence of the advice and direction of trained health staff, the app provides the participant with a list of session-related objectives curated from a review of a random sample of common goals and steps recorded on hard-copy action plans from a previous North Carolina WC intervention study with adolescents (Figure 5) [28].

Participants are instructed to review the goals presented to them and choose 3 goals to work toward from each topic domain (eg, in session 1, goals are divided into two categories: alcohol and drug use and life improvement). Once they have selected their goals, they review them on a confirmation screen and tap a button to confirm their goals. Once their goals are confirmed for the session's categories, a new menu option appears on the home screen—*Monitor Goals*. Participants are encouraged to come back frequently to review or revise their goals or choose new goals when the previous goals have been met.

Figure 5. Two screens from the Action Plans activity.

Reminder Notifications

As part of the face-to-face WC, participants are called in advance of their next session to remind them to attend. Similarly, for the mobile app, periodic reminders were programmed to pop up in the form of notifications on the tablet; the participant is able to set the frequency of these notifications during their mHealth introduction appointment. As these notices could potentially be seen by anyone looking at the tablet without the need to log into the app, they were developed to be generic to protect the privacy and confidentiality of the participant. An example notification was, “Don’t forget to visit the app!”

Discussion

Principal Findings

The disparity in HIV and other STI rates among young African American women in the US South, when compared with other groups, continues to be a public health concern. Targeted behavioral health interventions such as the WC have been shown to be helpful but are costly to conduct in person, and the time and resources required to participate can sometimes be prohibitive for those in the intended populations.

Owing to the COVID-19 pandemic, health resources are even more strained, which makes a new application more feasible and acceptable. The increased adoption of mobile devices has opened a potential avenue for reaching a greater number of

young women at risk for HIV and other STIs. Public health practitioners have the opportunity to adapt evidence-based interventions to an mHealth format and possibly reach more individuals than ever at a lower cost. However, it is still largely unknown how these adaptations are received by the intended populations. Will the decreased in-person interaction be detrimental? Or perhaps the innovative and efficient media format of an mHealth app will be of more interest to younger age groups.

Limitations

For future studies, it may not always be possible to provide participants with an electronic device (eg, tablet) to complete the intervention. However, in this study, it was not a confounding factor, as participants were not excluded because of a lack of access to a tablet.

Conclusions

In the case of the WC to mWC adaptation process, the development team wanted to mirror the in-person intervention as closely as possible for fidelity and provide a true comparison of the two formats. Future research could adapt this approach further, such as by potentially using more interactive gamification components, including rewards and points for completing intervention activities, to encourage engagement and retention in intervention content. This first adaptation of the mWC app showed promise for participant engagement with a mobile app modality and may pave the way for future

participant recruitment and retention strategies, more accessible knowledge dissemination, and practicable participant behavior change via mobile gamified behavioral intervention activities.

Acknowledgments

RLW and FAB drafted the manuscript and worked with the other authors to finalize it. PNK conceptualized the manuscript focus. RE provided feedback and comments. BNH and LBT helped complete the draft and revisions to finalize and confirm references. WMW is the contact principal investigator. WMW conceptualized the R01 trial and provided ongoing feedback regarding the paper structure and draft. Abstract

Background: Evidence-based digital health tools allow clinicians to keep up with the expanding medical literature and provide safer and more accurate care. Understanding users' online behavior in low-resource settings can inform programs that encourage the use of such tools. Our program collaborates with digital tool providers, including UpToDate, to facilitate free subscriptions for clinicians serving in low-resource settings globally.

Objective: We aimed to define segments of clinicians based on their usage patterns of UpToDate, describe the demographics of those segments, and relate the segments to self-reported professional climate measures.

Methods: We collected 12 months of clickstream data (a record of users' clicks within the tool) as well as repeated surveys. We calculated the total number of sessions, time spent online, type of activity (navigating, reading, or account management), calendar period of use, percentage of days active online, and minutes of use per active day. We defined behavioral segments based on the distributions of these statistics and related them to survey data.

Results: We enrolled 1681 clinicians from 75 countries over a 9-week period. We based the following five behavioral segments on the length and intensity of use: short-term, light users (420/1681, 25%); short-term, heavy users (252/1681, 15%); long-term, heavy users (403/1681, 24%); long-term, light users (370/1681, 22%); and never-users (252/1681, 15%). Users spent a median of 5 hours using the tool over the year. On days when users logged on, they spent a median of 4.4 minutes online and an average of 71% of their time reading medical content as opposed to navigating or managing their account. Over half (773/1432, 54%) of the users actively used the tool for 48 weeks or more during the 52-week study period. The distribution of segments varied by age, with lighter and less use among those aged 35 years or older compared to that among younger users. The speciality of medicine had the heaviest use, and emergency medicine had the lightest use. Segments varied strongly by geographic region. As for professional climate, most respondents (1429/1681, 85%) reported that clinicians in their area would view the use of an online tool positively, and compared to those who reported other views, these respondents were less likely to be never-users (286/1681, 17% vs 387/1681, 23%) and more likely to be long-term users (655/1681, 39% vs 370/1681, 22%).

Conclusions: We believe that these behavioral segments can help inform the implementation of digital health tools, identify users who may need assistance, tailor training and messaging for users, and support research on digital health efforts. Methods for combining clickstream data with demographic and survey data have the potential to inform global health implementation. Our forthcoming analysis will use these methods to better elucidate what drives digital health tool use.

Introduction

Digital health tools, including evidence-based clinical resources (EBCRs), can enhance health workers' knowledge base and skill set and can provide decision-making support. They improve diagnostic accuracy and promote quality, efficient care by allowing clinicians to integrate evidence-based information directly into clinical decision-making [1,2]. Recent research from the United States demonstrates that the use of UpToDate, a leading commercial EBCR, increased clinicians' performance on standardized exams and reduced patients' average length of stay and risk-adjusted mortality rates at nonteaching hospitals [3,4]. Observational research from several low-income countries shows that the use of an EBCR is associated with either improved outcomes or process measures [5-7].

However, in many resource-limited health care settings, the subscription cost of commercial EBCRs is prohibitive. Over the past decade, the Better Evidence program at Ariadne Labs has collaborated with UpToDate to distribute free subscriptions to clinicians serving vulnerable populations. The program now reaches a diverse group of over 30,000 medical professionals in more than 120 countries annually. Although most donation recipients do integrate this tool into their practices [8], usage still varies among clinicians. To maximize the impact of digital health tools, we seek to understand the barriers and facilitators that shape the way clinicians use (or do not use) EBCRs, so that we can tailor our outreach and interventions to encourage engagement with and the sustained use of these tools [9,10].

Social scientists and program implementers are aware of the effects of behavioral heterogeneity and have used psychographic-behavioral segmentation to group study subjects based on their preferences, beliefs, and self-reported behaviors [11]. We believe that online behavior, which has fueled extensive behavioral modeling in computer science [12,13], provides another useful dimension for behavioral segmentation in global health. Segmenting users based on online behavior may allow us to better understand, predict, and support the uptake of EBCRs among different populations.

Websites and apps generate clickstream data, which include each click from every user, identifying which pages users visit and when users visit them. Although the field of e-commerce extensively mines these data to understand online consumer behavior, analyses of clickstream data from digital health tools have been scarce [14-16]. To our knowledge, no studies have defined user segments based on clickstream data from EBCR users across the globe, possibly due to the difficulty of generating the data structure and analytics for these large, detailed data sets.

The goal of this research was to define behavioral user segments among EBCR users around the globe, with the larger aim of understanding that behavior and tailoring the implementation of digital health tools to encourage uptake, including identifying clinicians who may need assistance and designing training and

messaging for them. We hope that this research will also provide a useful method and approach for studying other digital health efforts. To this end, we conducted a study of clinicians, who were awarded with donated UpToDate subscriptions, and collected data from the following two data sources: (1) clickstream data from the back end of UpToDate and (2) a baseline user survey on demographics, access to internet-enabled devices, and the professional climate around using EBCRs in practice. Herein, we report on our process for defining behavioral segments from the raw clickstream data and how these segments relate to demographics and baseline survey responses.

Methods

Data Use Agreement and Ethical Approvals

We worked with UpToDate to design a fair data use agreement. We received ethical approval from the Partners Human Research Committee and Harvard TH Chan School of Public Health institutional review boards and designed informed consent language that covered the collection of both the survey and clickstream data for research purposes (institutional review board approval: June 19, 2017, under protocol 2017P001045).

Study Participants

Clinicians were eligible for the research study if they applied for a new UpToDate donation on the Better Evidence website [17] during the 9-week study enrollment period (March 1 to May 4, 2018), met the eligibility criteria for the donation program, and provided informed consent. The donation program eligibility criteria included being a physician, surgeon, or physician's assistant; having at least intermittent internet access; and being able to complete the application in English. In addition, clinicians had to demonstrate a need for a donation by working or volunteering at a public or nonprofit entity, attesting that neither they nor their organization could afford UpToDate otherwise, and submitting personal statements describing the mission of their organization and the communities they serve. Using the standard application review process, staff at Better Evidence and UpToDate then vetted each application to confirm the declaration of need. Clinicians could be based in any country outside the United States as long as they worked in low-resource settings. We did not actively recruit clinicians; they typically visited the Better Evidence website after learning about the donation program from a colleague.

Clickstream Data

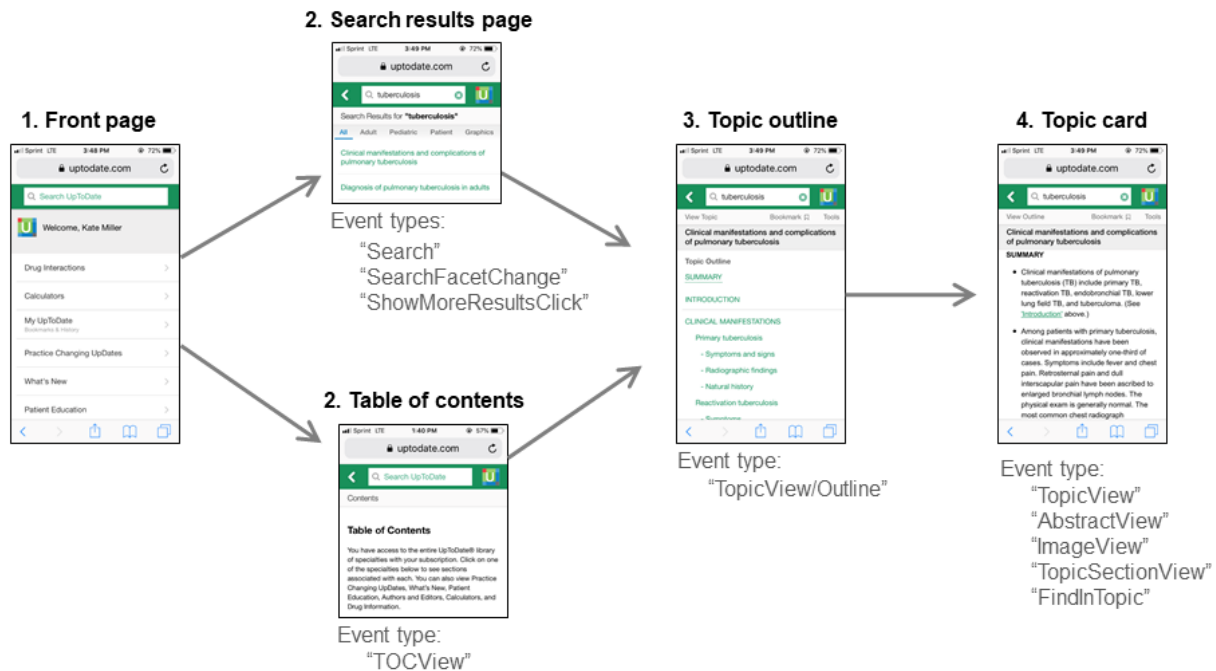

After approval for an UpToDate donation, clinicians received a subscription activation link by email. We tracked their clicks on UpToDate for 12 months, following the date that their subscription activation link was sent to them. Clicks were recorded across all mobile and desktop applications as well as during offline use.

Each row in the data set represented an individual click by an individual clinician. We used the following three variables per

row in this analysis: an anonymized unique identifier for each clinician; the time stamp of the click (recorded to the millisecond); and the click's "event type," which was assigned by UpToDate. An event type defines the action taken or material presented by each click (Figure 1). For instance, if a clinician typed a term in the search window and clicked "Search," the click was labeled with the event type "Search." If the clinician

navigated to the central table of contents, the click was labeled with the event type "TOCView." If the clinician selected a particular topic, the click was labeled with the event type "TopicView/Outline." If the clinician clicked on a topic card (which contained medical content), the click was labeled with the event type "TopicView."

Figure 1. UpToDate user interface, typical navigational path, and selected click events.

Other event types included making changes to search settings ("SearchFacetChange") or viewing a specific section within a topic ("TopicSectionView"). Offline use and text-mode use also generated specific event types.

We removed all double clicks (clicks within 500 milliseconds of each other) and any cases in which a clinician had exactly 1 click in the data set.

Defining Activities

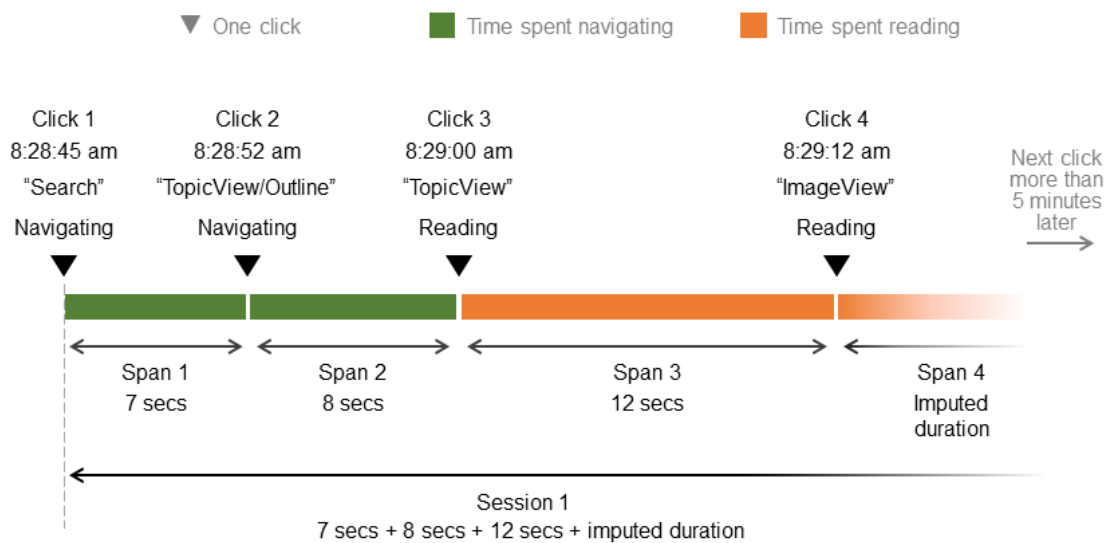

We categorized all event types into the following three main activities: navigating, reading, and account management. Navigating events included searches and any movement toward the medical content, such as clicking through the table of contents. Reading events included any exposure to medical content in the form of topic cards, abstracts, images, or drug interactions. Additionally, we viewed events that involved printing or sharing medical content as a continuation of reading events and classified them as reading events. Account management events included changes to account information, the creation of bookmarks, and the setting of preferences. Finally, some event types, such as "ExternalLinkClick," signaled the end of activities within UpToDate and did not need to be

classified as an activity. We present the full set of 42 event types and their classifications in [Multimedia Appendix 1](#).

Defining User Sessions

Next, we identified clinician "sessions"—discrete groupings of clicks that represented a single, continuous interaction with UpToDate. The clickstream data did include a system-generated session variable, but these sessions often overlapped in time and were difficult to interpret, as we did not have access to the algorithm that generated them. Moreover, in the literature on session identification from clickstream data, no consensus yet exists on standard methods [18,19]. For these reasons, we defined our own simple method of grouping clicks into sessions of measurable activity.

We first grouped together clicks with less than 5 minutes between them (Figure 2). If clicks occurred more than 5 minutes apart, we assumed that the first session had ended and that the second click was the start of a new session. Using such a time-out value is a common way to define sessions, and although longer times of up to 20 minutes are often used, we chose a shorter period because UpToDate is designed for use at the point of care when time and attention are limited [20].

Figure 2. From clicks to sessions.

In the time span between 2 clicks, we assumed that the clinician was actively engaged in the activity signaled by the first click in the pair, that is, navigating, reading, or account management. However, we could not assume that the activity ended with the final click, as that would assume that the clinician spent no time on performing the final activity, nor could we assume that the entirety of the time (sometimes days or weeks) between clicks represented the time spent on the final activity, given that the app may remain open. Thus, in the example shown in [Figure 2](#), click 4 was the final click in the session but did not necessarily signal the end time of the session because the clinician likely spent some time actively engaged with the final reading activity.

We modeled the duration of these final activity periods as follows:

$$\text{Duration} = \beta_0 + \beta_1 \text{Activity} +$$

where “Activity” was a nominal variable with 3 values (navigating, reading, or account management), and we included individual clinicians as a random effect. The duration of activity periods with a known length followed a log distribution, so we used a Box Cox power transformation for the dependent variable, as follows:

$$\text{Duration}_{\text{Transformed}} = (\text{Duration}^{\lambda} - 1) / \lambda$$

where λ was estimated at -0.25 . We back-transformed all predicted activity period durations to a natural scale. Finally, we aggregated activity periods into sessions with known start and end times and identified the time spent on navigating, reading, or account management within each span.

Defining Segments

We assessed sessions at the level of the individual clinician, resulting in several statistics describing each clinician’s online behavior over the subscription year, as follows:

- Number of sessions: total number of sessions over the full year
- Time online: total duration of all sessions summed over the full year

- Time spent per activity: percentage of total time online spent on each activity (navigating, reading, or account management)
- Lag: number of days between clinician’s receipt of activation email and clinician’s first click
- Period of use: number of days between a clinician’s first and last clicks
- Active days: percentage of days in the period of use with at least 1 session
- Rate of use: average minutes spent online per active day during the period of use
- Lapse: number of days between a clinician’s last click and the end of one year, defined as 365 days after the activation email was sent to the clinician

By design, the sum of the lag, period of use, and lapse days equaled 365 for every clinician. We defined “dropouts” as those who stopped using UpToDate for a period of 6 weeks or more before the end of the year.

We used these statistics describing individual use to define behavioral segments. We did not follow formal statistical rules to build these segments but aimed for definitions that reflected the observed distributions and would be programmatically meaningful, be simple to explain, and be easily calculated in future data sets.

Surveys

We created the baseline survey in REDCap (Research Electronic Data Capture; an online software platform created by Vanderbilt University). The survey explored expected barriers to and facilitators of the use of the EBCR (see [Multimedia Appendix 2](#) for survey questions). We pilot-tested the survey with approximately 1 dozen clinicians from 4 countries for clarity, wording, response options, ability to answer, and acceptability, and integrated it into the application for a donated UpToDate subscription. We linked the survey responses and clickstream data through a unique identifier.

We presented the distribution of the segments by the following demographic traits: gender, age group, specialty, patient load per week, and geographic region of the world (see [Multimedia Appendix 3](#) for a list of countries). We also presented the segment distributions by the baseline survey responses to questions about access to a device and professional context. For the survey responses, we adjusted the segment distributions by demographic traits by using multinomial logistic regression. We performed no statistical tests of the differences in segment distribution, both to avoid multiple testing and to recognize that our convenience sample may not be representative of all EBCR users in resource-limited settings. We performed all analyses by using SAS version 9.4 (SAS Institute).

Results

Measures of Individual Use

Of the 1681 clinicians enrolled in the study, 249 (14.8%) never used UpToDate, and the other 1432 (85.2%) did appear in the

clickstream data, which included 3,059,985 clicks; these aggregated to 398,089 sessions ([Figure 3](#)). Among those who ever used UpToDate, 38% (544/1432) had 100 or fewer sessions over the year, and 18% (258/1432) had between 100 and 200 sessions (panel A). The median number of sessions was 187, and 3% (43/1432) of clinicians had more than 1200 sessions, with a maximum of 3326 sessions for 1 particular clinician. Half of the clinicians (716/1432, 50%) spent up to 5 hours total on UpToDate over the year (panel B), while the other half (716/1432, 50%) spent more time on UpToDate—up to a maximum of 141.3 hours. Clinicians spent an average of 71% of their time reading, with the rest of the time spent navigating or managing their accounts (panel C). Only 7% (100/1432) of clinicians spent less than half their time online reading.

Figure 3. Measures of online behavior.

The first and last clicks of most clinicians (773/1432, 54%) were ≥ 48 weeks apart (panel D). In other words, more than half of the sample used UpToDate for, essentially, the full year. Only 5% (72/1432) of clinicians used UpToDate for 4 weeks or less over the year. Overall, lags were brief; 73% (1045/1432) of clinicians logged on to UpToDate within 1 week of receiving the activation email, and 88% (1260/1432) logged on within 4 weeks of receiving the email. Another 31% (444/1432) of clinicians dropped out; their use lapsed for 6 or more weeks before the close of the study period (data not shown).

On average, clinicians were active on UpToDate for 30% of the days in the period between their first and last sessions in the

year. For example, clinicians whose first and last sessions were 90 days apart logged on to UpToDate on 30 of those days on average. Overall, 3% (43/1432) of clinicians were active nearly every day during their period of use (panel E). On the days that clinicians logged in to UpToDate, 80% (1146/1432) spent 3 or more minutes online on average, 9% (129/1432) spent more than 10 minutes online, and the highest user spent 26.6 minutes online. The median number of minutes per active day of use was 4.4 (panel F).

Defining Segments

First, we attempted to capture the intensity of use of UpToDate among enrolled clinicians. We compared the total number of

sessions with the total time spent online and found them to be very highly correlated (correlation coefficient: 0.97), suggesting that either measure could stand in for the other in the definition of behavioral segments. We decided to focus on time spent online because we believe that it is more intuitively representative of clinician activity than the number of sessions. To capture the intensity of this time online, we focused further on time spent online per active day (panel F). To simplify this distribution, we wanted to create a binary classification of clinicians based on “light” and “heavy” rates of use. The median rate of use per active day was 4.4 minutes, which was close to

5 minutes—a round and intuitive number that would split the sample more or less evenly.

Second, we wanted behavioral segments to reflect the period of use of UpToDate according to the calendar. Approximately half of all clinicians 54% (773/1432) used UpToDate for 48 weeks or more—roughly the full year (panel D). From this information, we constructed another binary variable designating “long-term” users, whose period of use was 48 weeks or more, and all other “short-term” users. This classification is easily interpretable as clinicians who used UpToDate for roughly the full subscription year versus those who used it for less than the full subscription year (Figure 4).

Figure 4. Segment definitions.

We defined 4 segments based on these two binary variables (light or heavy use and short-term or long-term use) and a final segment containing the never-users who had no online behaviors, as follows:

- Segment A (lower left quadrant): short-term, light users (25%, 420/1681)
- Segment B (upper left quadrant): short-term, heavy users (15%, 252/1861)
- Segment C (upper right quadrant): long-term, heavy users (24%, 403/1681)
- Segment D (lower right quadrant): long-term, light users (22%, 370/1681)
- Segment E: never-users (15%, 352/1681)

Descriptive Statistics of Segments

Among the full sample, 25% (420/1681) of applicants were short-term, light users; 15% (252/1681) of applicants were short-term, heavy users; 24% (403/1681) of applicants were long-term, heavy users; 22% (370/1681) of applicants were

long-term, light users; and the remaining 15% (252/1681) of applicants never logged on to the tool at all. Segment distribution was very similar among men and women; however, the distribution varied somewhat by age group, specialty, and patient load per week (Figure 5). For instance, applicants aged 35 years or older were more likely to be never-users, while those under 25 years of age were more likely to be short-term, light users. Those specializing in medicine (including internal medicine, general practice, and family medicine) were the most likely to be long-term, heavy users, whereas those specializing in emergency medicine were the most likely to be short-term, light users. Applicants with high patient loads (200 or more per week) were more likely to be long-term, heavy users and less likely to be never-users compared to those with lower patient loads.

Segment distribution varied much more strongly by region (Figure 5). Applicants from the Americas and Europe were more likely to be long-term, heavy users compared to, for example, those in other regions.

Figure 5. Distribution of segments by demographic and practice characteristics. OB/GYN: obstetrician-gynecologist; SE: southeast; SS; Sub-Saharan; W: west.

¹ Includes internal medicine, general practice, and family medicine

N = 1,681 for all demographic characteristics, except as noted.

Baseline Survey Data

At baseline, 94% (1580/1681) of applicants reported that they always, almost always, or often had access to a device on which they could use the EBCR. The remaining 6% (101/1681) had

less frequent access to a device, and these applicants were more likely than others to be never-users (454/1681, 27% vs 303/1681, 18%) or short-term users (857/1681, 51% vs 723/1681, 43%; Figure 6).

Figure 6. Relationship between baseline facilitators and online activity over the full year. UTD: UpToDate.

All segment distributions are adjusted for age category, specialty, and cohort of UTD donees in country.
¹ Pools the responses "neutrally," "negatively," and "it's highly variable."

As for professional climate, 57% (958/1681) of clinicians reported that half or more of their clinical colleagues used an online clinical resource at baseline, but user segment distribution did not differ greatly for those reporting less use of an online clinical resource among colleagues. Most respondents (1429/1681, 85%) reported that clinicians in their area would view the use of an online tool positively, and compared to those who reported other views, these respondents were less likely to be never-users (286/1681, 17% vs 387/1681, 23%) and more likely to be long-term users (655/1681, 39% vs 370/1681, 22%). Nearly half of the users (773/1681, 46%) reported that they thought that patients would positively view the use of an online tool during clinical care. The segment distribution of this group was similar to the complementary group of clinicians who thought that patients would view the use of a tool neutrally, negatively, or variably (Figure 6).

Discussion

Principal Findings

Overview of Segments

In this study, we developed a method for behaviorally segmenting users of an established digital health tool based on their clickstream data. From a sample of 1681 clinicians in 75 countries, we defined 5 segments of users based on their online behavior. This involved performing extensive technical work to preprocess the raw clickstream data and identify patterns of use, resulting in the synthesis of 3 million clicks into a handful of segments. The value of the segments, in turn, is to support implementation efforts to increase the utility of EBCRs in

low-resource settings. Understanding more about the meaning and behavior of each segment can help drive uptake.

User segments are often based solely on demographic characteristics, such as age, gender, or geography, and while we did find some variation in segments based on these traits, they are not precise correlates of online behavior. Clinicians aged over 35 years, for example, are more likely than younger clinicians to never log on, yet 88% (1479/1681) of them did log on at some point, and 21% (353/1681) were long-term, heavy users. In this way, these behavioral segments add distinct information about clinician users beyond demographics.

These segments also reveal the impact of barriers to access that clinicians may face even before they receive the donated subscription. We find, for example, that clinicians who have less frequent access to a device are more likely to never log on and less likely to be long-term users, suggesting that if we work toward improving access to devices, we may remove a powerful barrier to use. We also asked about barriers regarding professional climate in 3 ways. With regard to these three aspects, the perceived attitudes of fellow clinicians in the area were most strongly related to the following segment: those who believed that other clinicians viewed the use of EBCRs positively were more likely to log on at all and be long-term users compared to those who believed otherwise. This relationship was weaker based on perceptions of patient attitudes, suggesting that interventions for increasing use should focus on trying to change clinician attitudes rather than patient attitudes.

In this way, these segments can richly inform efforts to implement EBCRs in low-resource settings. Each segment itself suggests different needs.

Segment A: Short-Term, Light Users

Segment A clinicians logged in but did not use UpToDate for the full year and used it for less than 5 minutes per day when they did. They may have had challenges with slow internet, managing the search and navigation tools, implementing results in English, or paying for data. They may benefit from having a local collaborator demonstrate the value of the tool, receiving targeted communication materials from the Better Evidence program, or other early interventions to enable them to overcome these barriers. Discovering more about the barriers that this segment faced will allow us to design interventions for bypassing such hurdles.

Segment B: Short-Term, Heavy Users

Segment B clinicians did not use the tool for the full year, but on days when they logged on, they used it for 5 minutes or more. They may have been involved in a research project, may have found the tool useful, or may have been excited to improve their practice. The short-term nature of their use may be related to a loss of access to a device, the loss of a password or login, the cost of data related to use, or a change in position or job. Studying both the barriers and facilitators of use in this segment will provide additional insights into generating excitement for the tool's use and into bypassing contextual hurdles.

Segment C: Long-Term, Heavy Users

Segment C clinicians used the tool for the full year and for longer than 5 minutes on the days that they logged on. Heavy use may be related to patient load, disease burden, or other job responsibilities. Segment C clinicians could be strong advocates for EBCRs; they could explain the value of the tool to colleagues or mentor segment A clinicians. Studying segment C clinicians will reveal the facilitators to EBCR usage in various contexts.

Segment D: Long-Term, Light Users

Segment D clinicians used the tool over the full year, with fewer than 5 minutes online per active day. They may be specialists who do not see a wide array of conditions and therefore have fewer topics to review, or they may be skilled navigators who find the answers to their questions quickly. They also may only be using certain features of the tool. Segment D clinicians might benefit from learning about additional features that they have not yet explored.

Segment E: Never-Users

Segment E clinicians never logged in to their subscription at all. They may change email addresses between the time of

application and the time of award, they may not recognize or see the subscription email, or they may lose interest between the time of application and the time of receipt. The option to update one's email address while pending application review, clearer explanations of how the subscription award notice will arrive, or follow-up emails with nonusers may increase participation, reduce dropout, and improve the value of the program. Survey responses may also further inform how we can better serve segment E clinicians and their patients.

Using these behavioral segments to implement program changes will require further research. In forthcoming analyses, we will join these clinicians' clickstream data with additional longitudinal survey data on barriers and facilitators. In the future, in-depth qualitative interviews with clinicians from each segment may yield useful information for ensuring uptake.

Limitations

This study faces some limitations. First, these clickstream data arose from a convenience sample of Better Evidence donation recipients who enrolled over a 9-week period. This sample may not be representative of all Better Evidence recipients or all digital health tool users working in resource-limited settings or with vulnerable populations. Second, we followed these users for a 12-month period, but multiple years of data may reveal more about user behavior. Third, many sessions did not have an "ending event," requiring an imputation approach. In the aggregate, the distribution of imputed values reasonably approximated the length of the sessions, but as with any imputation method, they may not have been exact at the individual level.

Conclusions

Digital health tools promise to improve health care delivery across the globe, including in traditionally underserved areas, in isolated settings, and for clinicians serving vulnerable populations. However, without appropriate and active implementation, it is likely that resource gaps with regard to digital health will widen rather than narrow. Ensuring that we implement digital health tools successfully and measure their impact accurately requires new methods for analyzing the big data generated by such tools. Other fields, such as e-commerce, have developed methods for using these kinds of data; global health must do the same to ensure that digital health tools equip clinicians with essential evidence for providing the best possible care to patients and populations. We believe that the user segments we have defined can be used broadly to better implement digital health tools (eg, improve the onboarding process and increase retention), thereby expanding their impact and reach.

Acknowledgments

Thank you to Atul Gawande and Stephen Kahn for serving as ongoing mentors in this work. Thank you to all of our colleagues at UpToDate who make this work possible, including Denise Basow, Peter Bonis, Denise Gilpin, Becky Letendre, Ellie Baron, Cara Rapoport, Laura Blockhus, Bin Cao, and others. Thank you to Claire Donovan; Iman Ahmad; Robbie Singal; Shreyas Srinath; Bridget Neville; and all our colleagues at Ariadne Labs, as well as those in the Division of Global Health Equity who have provided advice and guidance. Thank you to the Abundance Foundation for nearly 1 decade of financial support that has

allowed us to grow the program. Thank you to the Horace W. Goldsmith Foundation and the Paul G. Allen Foundation for their critical support of Better Evidence.

Thank you to all the participants who agreed to take part in this research and share their experiences with us.

Abstract

Background: The integration of teleconsultation into health care systems as a complement to existing approaches to care is growing rapidly. There is, however, limited information on the extent of its implementation across low- and middle-income countries.

Objective: The aim of this study was to determine the availability and the extent of teleconsultation in Malaysian primary care clinics.

Methods: A cross-sectional study of public primary care clinics in Malaysia was conducted between November 2020 and December 2020. All clinics in Malaysia that see more than 300 daily patients were recruited. A web-based, self-administered questionnaire including questions on availability of the service, whether it uses video or telephone, and the types of services it provides was distributed to the medical officer in charge of each clinic.

Results: In total, 97.6% (249/255) of the clinics responded. Out of these clinics, 45.8% (114/249) provided teleconsultation. A majority of the clinics providing consultation (69/114, 60.5%) provided only telephone consultation, while 24.6% (28/114) of the clinics offered video and telephone consultation, and 14.9% (17/114) offered only video consultation. Eighty percent (92/114) of the clinics were located in urban areas. A breakdown by state showed that 17.5% (20/114) and 16.7% (19/114) of the clinics were from two larger states; other states comprised less than 10% each (range 7-9/114). For the clinics providing video consultation, funding for the service came mostly (42/45, 93%) from the Ministry of Health. Conversely, nearly 1 out of 4 (23/97) clinics that provided telephone consultation funded the service either from donations or through self-funding. Most of the clinics provided teleconsultation for diabetes and hypertension. Less than 50% of the clinics with teleconsultation used it for follow up with allied health care providers or pharmacists (video consultation, 20/45; telephone consultation, 36/97).

Conclusions: Our findings show that telephone consultation is more widely used than video consultation, despite a quarter of its funding being self-subsidized or obtained through donations. Also, teleconsultation was less utilized by allied health care providers and pharmacists. Plans for the expansion of teleconsultation in Malaysian primary health care should take into consideration these findings to ensure a better and more cost-effective implementation of the service.

Introduction

Telemedicine focuses on the use of information and communication technologies, such as computers, cell phones, and the internet, to provide clinical services remotely, to achieve long distance clinical health care [1], and subsequently to improve the overall efficiency of the health care system [2]. In an umbrella review of countries in the Organization for Economic Co-operation and Development, 83% of reviews found that telemedicine was as effective as face-to-face care, while 39% found that the use of telemedicine was cost-effective [3]. The use of telemedicine has also been reported to lead to high patient satisfaction. Nevertheless, in many low- and middle-income countries, comprehensive evaluations of the clinical and cost-effectiveness of telemedicine, as compared to conventional health care, have yet to be conducted. This is likely as a result of the poorer implementation of such services.

Despite the evidence, telemedicine has only been adopted on a large, global scale recently. A report from the World Health Organization showed that the proportion of countries with established telemedicine services ranged from 13% to 33% [1]. It also showed that telemedicine was provided more in high-income countries than in countries of other income statuses [1]. High-income countries that have implemented telemedicine programs include the United States [4], the United Kingdom [5], and various countries in Europe [6]. While high-income countries often face problems surrounding patient privacy and confidentiality, competing health system priorities, reimbursement, and infrastructure [1,3,7], the implementation of these services in low- and middle-income countries has been limited mainly by financial and technology infrastructure constraints [8]. For instance, the uptake of telemedicine in Pakistan, India, and Sri Lanka has been low, with the estimation that about 99.9% of the need for telemedicine remains unmet across these countries [9]. In particular, the integration of telemedicine services into primary health care settings as a complement to existing modes of care has also been slow [10].

Malaysia is one of the fastest-growing countries within Southeast Asia and is an upper-middle income country, with a per-capita income of RM 46,524 (US \$11,512) [11]. In Malaysia, the first telemedicine blueprint was launched in 1997 [12] and was incorporated by the government into 1 of 7 flagship applications under the Multimedia Super Corridor project [13]. The government eventually established 4 main pilot projects, of which 1 involved teleconsultation between doctors of different disciplines and different health care facilities to overcome the lack of specialist care in rural areas [13]. In September 2019, the Ministry of Health (MOH) of Malaysia piloted teleconsultation based on video consultation technologies at 5 public primary care clinics in an effort to improve accessibility to health services and to reduce congestion at these clinics [14]. Bookdoc (Health4U Solutions Sdn Bhd), the current main platform contracted by MOH Malaysia for teleconsultation services, uses the fully Health Insurance Portability and

Accountability Act (HIPAA)-compliant tool Twilio (Twilio Inc). Due to the COVID-19 pandemic, the teleconsultation service was expanded to an additional 35 public primary care clinics by the end of 2020. At the same time, many other clinics that were not part of the government initiative also proactively initiated teleconsultation in response to the pandemic. Despite such a recent rapid expansion of teleconsultation services, there is, at present, limited information on the extent and the availability of teleconsultation in primary health care settings in Malaysia.

Therefore, the objective of our study was to determine the availability and extent of teleconsultation in public primary care clinics in Malaysia. The focus of our study was only on synchronous teleconsultation in the form of video or telephone consultation between health care providers and patients, as part of either government projects or self-initiated projects. The information collected will be crucial to map out teleconsultation availability in Malaysia and help the MOH plan further expansion of the teleconsultation project in Malaysian primary care clinics.

Methods

Setting and Study Population

Primary health care in Malaysia is provided by both public and private health care providers. The MOH is the largest health care provider in Malaysia. The public sector is tax-funded, while the private sector is funded through fees for services, private health insurance, and employers, as part of employee health benefits [15,16]. Private primary care clinics are mainly located in urban and suburban areas, while public primary care clinics cover a wider area, including rural and remote areas [15]. Public primary care clinics under the MOH are classified into Types I, II, III, IV, V, and VI according to the total patient attendance per day [17]. Type I clinics have the greatest number of patients at more than 800 per day, while type VI has the lowest number of patients at less than 100 per day. In 2019, there were 1016 public primary care clinics led by medical officers or family medicine specialists [18]. In this study, we included all MOH public clinics categorized as Types I, II, and III.

Questionnaire and Data Management

Consistent with our objectives, we developed a questionnaire to capture 3 aspects of teleconsultation: availability and whether it was based on video or telephone. In total, 15 questions were adapted from literature reviews and the local teleconsultation guidelines [19]. The questionnaire was pretested on 3 medical officers serving in public primary care clinics; each respondent was debriefed immediately after completion of the survey. A quick interview with the respondents was conducted to assess the comprehensibility of the questionnaire and whether the number of questions placed a burden on the taker. Modifications to the questionnaire were subsequently made in accordance with the pretest findings.

Study data were collected and managed using Research Electronic Data Capture (REDCap) hosted at the Clinical Research Centre, Penang General Hospital, Malaysia. REDCap is a secure, web-based software platform designed to support data capture for research studies. It provides (1) an intuitive interface for validated data capture; (2) audit trails for tracking data manipulation and export procedures; (3) automated export procedures for seamless data downloads to common statistical packages; and (4) procedures for data integration and interoperability with external sources [20,21].

Data Collection

Data collection was conducted from November 6, 2020, to December 10, 2020. The study information sheet and survey link were sent to all state health departments along with an endorsement letter by the Family Health Development Division of the MOH before being distributed to the respective district health offices and selected clinics. Consent for participation was indicated by completion of the survey.

To improve the response rate for this survey, as the participation for this self-administered survey was voluntary and without compensation, we sent reminders to the participants who did not complete the survey 3 weeks after receiving the study invitation.

Statistical Analysis

Descriptive analyses were conducted with continuous variables presented as the mean, median, SD, or IQR, while categorical variables were presented as frequencies and percentages. Analysis was performed using RStudio (version 1.3.1093; R Foundation).

Ethics Approval

This study was approved by the Medical Research and Ethics Committee, Ministry of Health Malaysia

(NMRR-20-1819-56089) with a waiver for informed consent, as the data collected were aggregated from each clinic without collection of any personal identifiers.

Results

Principal Outcomes

In total, 249 Type I to Type III clinics completed the questionnaire (for a response rate of 249/255, 97.6%). Of 13 states and 3 federal territories, 11 had a 100% response rate (Perlis, 4/4; Kedah, 18/18; Perak, 20/20; Melaka, 13/13; Negeri Sembilan, 16/16; Pahang, 11/11; Kelantan, 16/16; Terengganu, 12/12; Sabah, 12/12; Sarawak, 14/14; and Labuan, 1/1), while the remaining 4 states had response rates of 88% to 96.6%. Teleconsultation was provided in 114 (45.8%) of the public primary care clinics. The majority of these clinics (60.5%) provided only telephone consultation, followed by 24.6% (28/114) that offered video and telephone consultation, while 14.9% (17/114) had only video consultation. Of the remaining clinics that did not provide teleconsultation, 39.3% (53/135) planned to initiate the service.

Table 1 shows the characteristics of the clinics providing teleconsultation in Malaysia. In terms of distribution of the clinics across states in Malaysia, Selangor and Johor had the highest proportion, contributing to 17.5% (20/114) and 16.7% (19/114) of the total clinics providing the service, respectively. Other states accounted for less than 10% each; none were from Labuan. The majority of the clinics that offered teleconsultation were in urban areas (92/114, 80.7%). In addition, 69% (31/45) of the clinics that offered video consultation were Type I clinics. Interestingly, more than half of the clinics (38/69) that offered only telephone consultation were Type III clinics.

Table 1. Characteristics of the clinics.

Characteristics	Total (N=114)	Video consultation only (n=17)	Telephone consultation only (n=69)	Both video and telephone consultation (n=28)
State, n (%)

Type III	41 (36.0)	2 (12)	38 (55)	1 (4)

^aWPKL and Putrajaya: Wilayah Persekutuan Kuala Lumpur and Putrajaya.

^bThe type of clinic was classified according to attendance numbers of patients per day: Type I, at least 800 patients per day; Type II, 500-800 patients per day; Type III, 300-500 patients per day.

Characteristics of Teleconsultation Service

As shown in Table 2, telephone consultation had been offered for a longer time, with a median duration of 237 days, compared to video consultation, with a median of 107 days. Funding for video consultation in the clinics providing the service was mostly from the MOH (42/45, 93%). In comparison, nearly 1 out of 4 (23/97) clinics that provided telephone consultation

service funded the service either by donation or through self-funding. Among the most frequent platforms used for video consultation were BookDoc (35/45, 75%), an online health care platform that supports video calls, followed by WhatsApp (9/45, 20%). For telephone consultation, about half the clinics (46/97, 47%) reported that they were using the health care provider's own mobile phone.

Table 2. Characteristics of the services.

Characteristics of the service	Video consultation (n=45)	Telephone consultation (n=97)
Duration the service had been offered in days, median (IQR)	107.0 (91.0-121.0)	237.0 (182.5-288.0)
Source of funding, n (%)

^aMOH: Ministry of Health Malaysia.

^bSome clinics used more than one platform for video consultation, so the percentage sums to more than 100%.

^cN/A: not applicable.

^dOther platforms included Facebook video calls, Google Meet, GoToWebinar, Zoom, and Skype.

Types of Health Care Services Provided Via Teleconsultation

Figure 1 and Figure 2 show the types of health care services provided by video and telephone consultation, respectively, at the clinics. The majority of clinics implemented video and telephone services for diabetes (37/45, 82% and 74/97, 76%, respectively) hypertension (32/45, 71% and 67/97, 69%, respectively), quitting smoking (16/45, 36% and 22/97, 23%, respectively), and maternal and child health (15/45, 33% and 34/97, 35%, respectively). Other services were also provided via teleconsultation, but in smaller proportions.

As demonstrated in Table 3, care plan consultation and health education were the most frequently provided services through teleconsultation, both via video and telephone. Less than half of the clinics utilized video or telephone consultation for follow up with allied health care professionals (20/45, 44% for video and 36/97, 37% for telephone). Furthermore, only 11% (5/45) of the clinics provided follow up with pharmacists via video consultation, while 5% (5/97) did so via telephone consultation. Virtual directly observed therapy for tuberculosis patients was provided via video consultation at 16% (7/45) of the clinics.

Figure 1. Type of services provided through video consultation. Some clinics provided more than one type of service using video consultation, so the percentages sum to more than 100%. a: Others included pre-pregnancy care clinic, obesity clinic, general outpatient consultation, and unspecified allied health service.

Figure 2. Types of services provided through telephone consultation. Some clinics provided more than one type of service using telephone consultation, so the percentages sum to more than 100%. a: Others included sexually transmitted infections, pre-pregnancy care, methadone, COVID-19 surveillance, one-stop addiction service, general outpatient consultation, unspecified allied health service, and unspecified pharmacist service.

Table 3. Types of health care activities provided through teleconsultation.

Type of health care activity, n (%)	Video consultation (n=45), n (%)	Telephone consultation (n=97), n (%)
Care plan consultation	40 (89)	72 (74)
Health education	40 (89)	69 (71)
Disclosure of lab results	39 (87)	58 (60)
Follow up with allied health care	20 (44)	36 (37)
Follow up with pharmacist	5 (11)	5 (5)
Virtual directly observed therapy	7 (16)	N/A ^a

^aN/A: not applicable.

Discussion

Principal Results

This is the first study attempting to map out the availability and extent of teleconsultation in Malaysian public primary care clinics. Our study found that 45.8% (114/249) of the clinics provided teleconsultation, with telephone being the most frequently used type (97/114). The majority of the clinics providing teleconsultation were in urban areas across Malaysia. Funding from the MOH was mostly used for the provision of video consultation in selected clinics, despite telephone consultation being more widely used. Less than half of the clinics with teleconsultation utilized the service for follow up with either allied health care professionals or pharmacists.

Comparison With Prior Work

We found that less than half of public primary care clinics in Malaysia provided teleconsultation. In comparison, high-income countries have reported much higher proportions of the availability of this service. A cross-sectional study conducted in Norway showed that 80.8% of general practitioners in the country offered video consultation in 2020 [22]. Similarly, in Australia in 2020, teleconsultation was used by 96% of general practitioners [23]. Literature on the availability of teleconsultation in low- and middle-income countries is limited and has mainly been reported in the form of pilot projects or as interventions for research purposes [9,24]. A majority of this literature highlights financial and technological constraints as the main implementation barriers in low- and middle-income countries in initiating and providing teleconsultation [9,25].

Our study demonstrated that most of the clinics providing teleconsultation were in urban areas. The majority of clinics were located in Selangor and Johor, which are the two central, major state economies in Malaysia, with 91.4% urbanization in the former and 71.9% in the latter [26]. Absolute poverty is low, with an incidence estimated at 1.7% in Selangor and 5.9% in Johor; both states show a lower incidence than the national average, which was 8.4% in 2020 [27]. These findings are parallel to findings from a cross-sectional study in the United States that showed that more than half of hospitals that provided outpatient teleconsultation were from urban areas [28]. Additionally, Martin et al [29] reported similar findings in their study; they showed that only 3.3% of rural primary care providers and 8.3% of rural hospitals were implementing teleconsultation. The discrepancy in the availability of

teleconsultation between rural and urban areas could be attributed to the digital divide, which has been defined as “the growing gap between the underprivileged members of society, especially the poor, rural, elderly, and handicapped portion of the population who do not have access to computers or the internet; and the wealthy, middle-class, and young living in urban and suburban areas who have access” [30]. In essence, there is a gap in availability of teleconsultation between urban and rural dwellers.

Generally, Malaysia has been portrayed as a highly digitized nation, with 88.7% of Malaysian households having access to the internet in 2020 [31]. Based on the International Telecommunications Union Report, which measures different aspects of internet penetration, an average of 81.2% of the Malaysian population are internet users, compared to the global average of 73.6% across 82 reporting countries in 2018 [32]. The proportion of internet users who are above the age of 50 years was reported to have increased sharply, from 4.2% in 2012 to 16.0% in 2018, accounting for a 2.1% increase in this age group in the general population [32]. Over the same time span, the average age of internet users in Malaysia also increased, from 29.7 years to 36.2 years, suggesting a narrowing digital divide in terms of age [32]. However, the same report demonstrated that higher median household income corresponded to a higher broadband subscription rate (with a correlation coefficient ranging from 0.59 to 0.72, $P < .001$) [32]. Urban households report a higher median household income of RM 6561 (US \$1624) compared to a rural median household income of RM 3828 (US \$947) [33]. This further supports our finding that digital divide is widening between urban and rural populations in Malaysia. Furthermore, this observation corresponds to the results of the Malaysian Internet Users Survey 2020, which showed that 75.6% of internet users were from urban areas [34]. The same survey also reported that one-third of Malaysian internet users resided in Selangor or Johor [34]. Even though the prevalence of noncommunicable diseases in rural and urban areas is almost the same [35], the utilization of public health care facilities is higher among rural dwellers [36]. Therefore, this urban-rural divide works against the initial aim of developing teleconsultation, which was to allow health care providers to overcome health service accessibility issues, especially for rural patients [25].

It is also worth noting that compared to video consultation, telephone consultation was more widely used by the clinics, even though a quarter of the telephone consultations were

self-subsidized or funded by donations. This finding is in line with Brant et al [37], who found that the majority of practices in 5 areas of the United Kingdom conducted telephone consultation, while none provided video consultation. In addition, Heba and colleagues [38] reported that during COVID-19, 96.6% of general practitioners in southwestern Ontario used teleconsultation, but 99.5% of this was conducted via telephone consultation. A study looking at telehealth implementation in Australia showed that even with a change in reimbursement policy in the country, Australian health care providers, especially primary care providers, still preferred telephone consultation over video consultation [39]. While there is a lack of literature looking at synchronous teleconsultation between patients and health care providers over either video or telephone in low- and middle-income countries, we speculate that the availability of video consultation would be similar in Malaysia. This could be due to barriers in the adoption of video consultation, such as infrastructure requirements, digital proficiency, cost, and technical support availability [40], which can be extremely challenging to overcome, especially in low- and middle-income countries. By contrast, telephone consultation has a low start-up cost [41] and is easier to implement [42]. In our present study, the majority of the clinics that used video consultation were public primary care clinics, which have been identified for inclusion in the virtual clinic initiative funded by the MOH. Cost is likely one of the main reasons for the preference for telephone consultation over video among primary care providers from clinics that were not included in the initiative. As observed in our results, some clinics provided both telephone and video consultation services. However, we were not able to identify the proportion of exclusively video consultations to video consultations that were eventually converted to telephone, nor the reasons for why these unsuccessful video consultations were converted to telephone.

Our study also reports that the majority of clinics provided teleconsultation services for patients with chronic diseases, such as diabetes mellitus and hypertension. Similar findings were made by Kim et al [43], who reported that diabetes mellitus and hypertension accounted for 39.4% of teleconsultations conducted in their clinics. With the high prevalence of noncommunicable diseases in Malaysia, such as diabetes (with a prevalence of 18.3% in 2019) and hypertension (prevalence of 30.0% in 2019) [35], the bulk of the workload in public primary care clinics has always been the management of these patients. Active use of teleconsultation as an alternative method of consultation for these groups of patients would reduce crowding in clinics without compromising continuity of care for patients. Moreover, there are potential opportunities to expand the services to accommodate telemonitoring of these patients. Both services have been shown to be useful to improve disease control while at the same time reducing the use of resources [44].

Another interesting finding from our study is that very few clinics used teleconsultation for follow up with allied health care professionals or pharmacists. This is in keeping with results from a previous study in Brazil that showed only 5.8% of total teleconsultation was conducted by allied health care professionals or pharmacists [45]. Other than infrastructure and technology constraints, the limited use by allied health care

professionals could have been due to their perceptions and attitudes, as well as a lack of information and training [46,47]. Similarly to patients, allied health care professionals, particularly physiotherapists, perceive teleconsultation negatively due to concerns about subpar health service due to the lack of hands-on examination and the lack of equipment at home, an attitude that could affect the uptake of teleconsultation [46]. The same concern about hands-on care has also been expressed by occupational therapists [48]. Allied health care professionals and pharmacists play an important role in providing complete, comprehensive care in managing primary care patients. They usually provide services like counseling on medication adherence and dietary intake, physiotherapy, and occupational therapy sessions during follow up. These forms of health care service have been shown to be as effective when delivered via teleconsultation as face-to-face [49,50]. Thus, the use of teleconsultation should be encouraged among these groups of health care providers.

Implications for Policy and Research

The primary care setting is the best place for the adoption of teleconsultation, because it is where management of chronic conditions largely takes place [16]. The COVID-19 pandemic has demonstrated the relevance of teleconsultation, as the need for routine clinic visits by patients with chronic diseases tended to decrease during the pandemic. Hence, teleconsultation appears poised to stay a robust option for primary care in the near future.

Our findings showed that as of the end of 2020, approximately 50% of public primary care clinics in Malaysia provided teleconsultation. Our findings also indicate that the rate of adoption of teleconsultation differs between urban and rural areas. Nevertheless, several factors can be addressed to increase the effective and successful spread of such services, as well as their scaling up.

First, policymakers have to identify the obstacles that hinder the efficient delivery of teleconsultation services in primary care. It is imperative to understand potential barriers in order to offer solutions that can enhance the rate of adoption of teleconsultation. For example, technology that is unreliable or a lack of access to technology and broadband internet may pose barriers to video visits. This in turn may prevent end users from participating in teleconsultation. Thus, to increase teleconsultation utilization, the focus should be on providing end users with instant, always-on access that can be used anywhere and at any time. Alternatively, telephone consultation or asynchronous teleconsultation might be a better option for areas that are not equipped to participate in synchronous video consultation.

Second, proactive efforts should be made to reduce disparities in access to health services for vulnerable populations with limited digital literacy or access to technology, such as rural residents, if teleconsultation is to be implemented nationwide. Access to technology or digital inclusion has been increasingly considered as a leading social determinant of population health. As such, strategies to narrow the digital divide are especially important for increasing the use of digital applications in health care, not only to help the uptake of teleconsultation in the country, but also, crucially, to promote health equity in the

population [51,52]. This is also an important consideration in primary care, especially because clear communication between health care providers and patients is essential for successful management of chronic diseases.

Third, it is important to change health care providers' behavior, especially that of allied health care professionals and pharmacists, regarding their willingness to use this technology for patient care. The successful adoption of teleconsultation could potentially overcome the issue of personnel shortages among allied health care professionals and pharmacists. For instance, there were only a total of 64 dietitians in Malaysia in 2019 serving patients in 1016 public primary care clinics in the country [18]. The use of teleconsultation would allow group dietary counseling to be provided simultaneously to multiple patients and to remote areas.

Fourth, additional research on the teleconsultation experiences of patients and health care providers is imperative to enable us to obtain sufficient information on some of our findings, for example, to explain why telephone consultation was more widely used, or why certain clinics decided to utilize both telephone and video consultation. It is also crucial to account for the views of patients on the perceived usefulness and feasibility of teleconsultation services. Targeted strategies for successful implementations can only be planned after understanding the factors influencing the use of teleconsultation services among health care providers in Malaysia.

Limitations

To the best of our knowledge, our study is one of the first in low- and middle-income countries to provide vital information on the availability and the extent of synchronous teleconsultation services in a primary health care setting. This study has several limitations. First, this is a descriptive cross-sectional study, and it is not possible to determine the causality of the findings. Second, our study only involved public primary care clinics. Nevertheless, we are confident that our findings, to a certain extent, reflect a near-actual representation of teleconsultation services in Malaysian primary health care. This is mainly because we had a relatively high response rate; the public primary care clinics in this study cover 64.6% of all primary care attendance in Malaysia [36]. Third, we only examined synchronous teleconsultation between health care providers and patients; thus, our findings are only relevant to this target population.

Conclusion

In summary, we found that the availability of teleconsultation in public primary care clinics in Malaysia remains inadequate, with telephone consultation being more widely used than video consultation. Furthermore, there was a low utilization of these services among allied health care professionals and pharmacists. Plans for the expansion of teleconsultation in Malaysian primary health care should take into consideration these findings to ensure a better and more cost-effective uptake of teleconsultation in this country.

Acknowledgments

The authors would like to express their gratitude to the director general of Health Malaysia for his permission to publish this article.

Authors' Contributions

SWN, WYH, MH, NAR, and SS contributed to the design of the study. SWN, WYH, MH, NAR, NHN, KJ, and SS were involved in the coordination of the data collection process. SWN, WYH, MH, and NAR performed the data analysis. SWN and WYH drafted the manuscript. All authors critically revised and approved the final version of the manuscript.

Abstract

Background: Patients with cancer experience multiple symptoms related to cancer, cancer treatment, and the procedures involved in cancer care; however, many patients with pain, depression, and fatigue, especially those outside the hospital, receive inadequate treatment for their symptoms. Using an electronic patient-reported outcome (ePRO) platform to conduct symptom management follow-up in outpatients with advanced cancer could be a novel and potentially effective approach. However, empirical evidence describing in detail the preparation and implementation courses in a real setting is needed.

Objective: The purpose of this paper was to describe the implementation process and evaluation of an ePRO platform that facilitates symptom management for patients with cancer, share our experiences and the problems we encountered during the process of implementation, and share the solutions we identified for those problems. Moreover, we tested the feasibility, safety, and efficacy of the ePRO platform.

Methods: This was a real-world, ongoing, longitudinal, single-center, prospective study with a total of 7 follow-ups conducted within 4 weeks after the first visit to the symptom management clinic (on days 1, 3, 7, 10, 14, 21, and 28). Participants were encouraged to complete scales for physical symptoms (pain, fatigue, and shortness of breath), cognitive symptoms (memory problems and impaired concentration), and affective symptoms (especially depression and anxiety) during follow-up. The design and function of the ePRO-doctor client and ePRO-patient client, the patient-reported outcome (PRO) scales used in the study, and the strategies to promote symptom tracking have been described. Moreover, the training and evaluation for research assistants have been presented. The efficacy of the ePRO platform was assessed with a comparison of the baseline and 4-week outcomes on the MD Anderson Symptom Inventory.

Results: Using the ePRO platform for symptom management follow-ups in advanced cancer patients was associated with a high completion rate (72.7%-86.4%) and a low drop-off rate (23.6%). The ePRO platform sent 293 alert notifications to both

patients and doctors, which promoted patient security. The short and sharp PRO tool selection, user-friendly interface, automatic reminder notifications and alerts, and multiple dimensional training were essential components for the preparation and implementation of the ePRO system. The results showed significant improvements in the mean scores of pain, fatigue, and numbness from baseline to day 28 ($P=.02$, $P=.02$, and $P<.001$, respectively).

Conclusions: The use of an ePRO platform for symptom management follow-ups in advanced cancer patients is time-saving, energy-saving, and effective. PRO tool selection, platform design, and training of research assistants are important aspects for implementation. Future research should validate the ePRO platform in a larger randomized controlled study.

KEYWORDS

electronic patient-reported outcome; symptom management; advanced cancer; outpatient; follow-up

Introduction

Patients with advanced or metastatic cancer usually have severe symptom burden, which is significantly higher than that in patients with no evidence of cancer metastasis [1]. Symptom burden has also been found to be correlated with treatment-related factors. About one-third of advanced cancer patients were found to have persistent severe symptom burden during chemotherapy [2], and high symptom burden was found to be negatively associated with patients' psychological status, function, and quality of life [3,4].

However, research on symptom management has mainly focused on inpatients. Relevant research for outpatient symptom management has been limited. Traditional outpatient follow-up is usually via email or telephone, but a low response rate is a common problem in these 2 modes.

In China, since the average length of hospitalization has shortened dramatically, especially in some top cancer centers, much works on symptom management has been carried out in the outpatient department [5]. Symptom management in outpatients has some difficulties. First, outpatients only come to the clinic at a certain time point. Most of the time, they are outside of the hospital, and there is a lack of monitoring of their situations. Second, the means of communication between outpatients and doctors are limited. Many patients only come back to see their doctors when their symptoms become very serious. In some cases, patients cannot get timely and effective symptom management due to various factors, even though their symptoms are very serious. The poor situation of symptom management creates a burden for not only patients but also their families and caregivers, and it even introduces huge burdens of medical resources and costs. Unmet care needs may also decrease patient adherence to treatments [6]. A recent study [7] showed that a web-based app can improve symptom management and adherence for aromatase inhibitors in breast cancer patients.

Patient-reported outcomes (PROs) assess the problems a patient can report about his or her own experiences. These include symptoms, functioning, and mental health. However, a key barrier of using PRO data in clinical settings is the limitation of paper-based questionnaires, which cannot be transformed into instantly accessible information. Compared with traditional paper and pen testing, the electronic patient-reported outcome (ePRO) platform has the advantages of data collection

standardization and quality management [8]. An effective ePRO platform can monitor the symptoms of patients outside the hospital better, give a timely alarm, and facilitate timely symptom management; therefore, the ePRO system can improve symptom management in outpatients. In recent years, many techniques of ePRO system design have been greatly developed, such as data transmission, storage, confidentiality, applicability, and convenience. Traditional electronic platforms are mainly based on an email system, while the new generation of ePRO platforms is mainly based on smartphones [9,10].

Most ePRO systems are treatment-centered and have been designed to serve a special kind of treatment [8,11,12]. In the selection of PRO tools, most involve treatment-related symptoms, and follow-up frequency and interval are set for the treatment. So far, an ePRO-based symptom management follow-up system for patients with advanced cancer generally is lacking. Nowadays, in China, the access rates of the internet and smartphones are very high. In 2018, an ePRO symptom management research project was launched in Peking University Cancer Hospital, which included a single-institute longitudinal study and a multi-center cross-sectional study. In the longitudinal study, we aimed to monitor the symptoms of outpatients with advanced cancer using an ePRO symptom management follow-up system based on a smartphone. The purpose of this paper was to describe the implementation process and results, present the advantages of the ePRO system, and share our experiences and the problems we encountered during the process of implementation, as well as the solutions we identified to solve the problems.

Methods

ePROhub, ePRO-Doctor Client, and ePRO-Patient Client

ePROhub

ePROhub provides the primary function of collecting data through PRO tools, as well as adapting and managing the data. Because of the connection with the hospital information system, the ePRO data are more convenient to be managed and analyzed together with other medical data. Intelligent operations include generating and managing the accounts of doctors and patients, collecting and checking patients' information, sending follow-up reminders, and alerting automatically about serious symptom. This platform also has an electronic signature system that could be used for both subjects (sign informed consent) and research

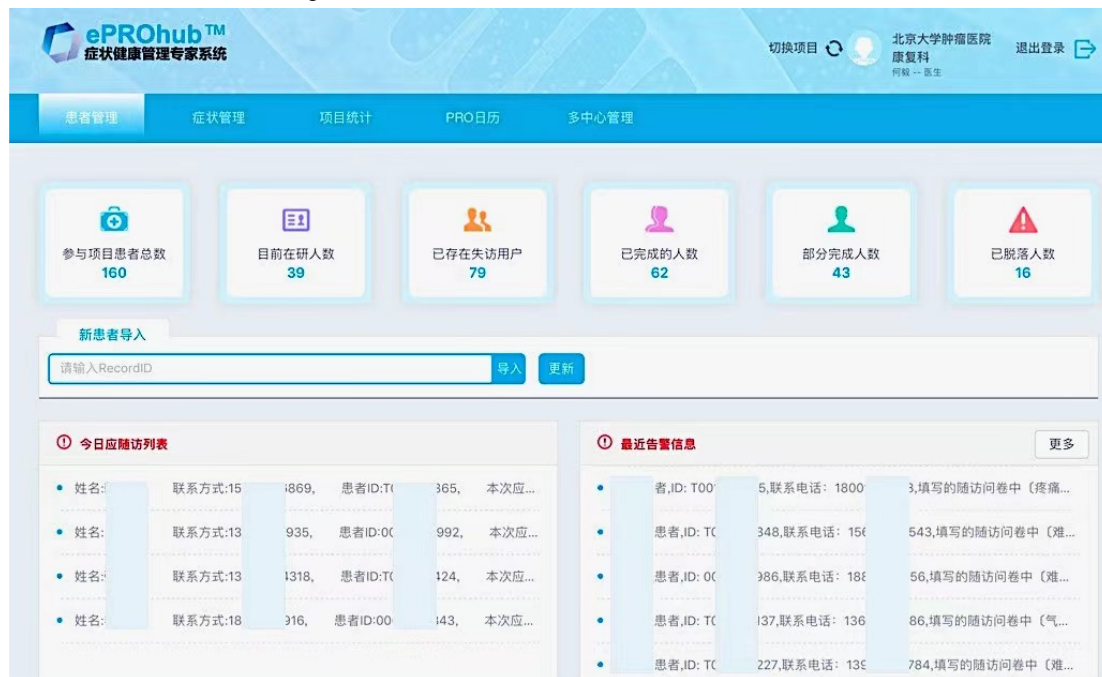

assistants (sign after each subject's enrollment and follow-up to improve research quality management).

ePRO-Doctor Client

The doctor-client interface shows the important information of the program, such as the number of participants, the number of participants completed, the number of participants partly completed, and the number of drop-offs. The interface is updated in real-time to present the latest progress of the program for

doctors and researchers. There is a list of people who need to be reminded to do the follow-up survey and another list of people who have symptoms over the alert level. In this study, according to the cut-off point of the MD Anderson Symptom Inventory (MDASI; ≥ 7), the platform sent an alarm to the ePRO-doctor client. Each doctor or researcher could view his/her own participants, and the management staff could view the entire enrollment situation (Figure 1).

Figure 1. Doctor's interface for research management.

ePRO-Patient Client

The interface has been designed as a touch screen, which conforms to patients' usage habits. Due to the limitation of the screen size of a mobile phone, the PRO scale has been designed to display in the horizontal direction, which is in line with the users' experience to the maximum extent. There are only 1 or 2 questions on a page, making it easier to read, and the page could be enlarged, making it easier for patients to touch the

screen to choose their answers (Figure 2). PRO data could be reported by patients anywhere through an applet based on the WeChat app, which is the most popular social app, without restrictions on the type of smartphone operating system. The ePRO system could identify how many times patients had fulfilled and matched the right scales. All the data were uploaded to a database established in Peking University Cancer Hospital. A strict encryption system was used to ensure data security.

症状问卷

随访2 (3天)

第一部分：您的症状有多严重？
癌症患者常有疾病本身或治疗相关引起的各种症状。我们想知道您在过去的 24 小时中，下列症状的严重程度。请将下列每一项从 0 (无症状) 至 10 (能想象的最严重程度) 之间圈一数字以表示症状的严重程度。

1.您疼痛最严重的程度为？

无症状 能想象的最严重程度

0 1 2 3 4 5 6 7 8 9 10

2.您疲劳（乏力）最严重的程度为？

无症状 能想象的最严重程度

0 1 2 3 4 5 6 7 8 9 10

3.您恶心最严重的程度为？

无症状 能想象的最严重程度

PRO Scales

We used several validated instruments in the multi-dimensional ePRO system, which are presented below.

MDASI

The MDASI [13,14] is a widely used symptom inventory with 19 items (13 items for symptom severity and 6 items for life interference; 0=nothing to 10=most severe). A psychometric study has revealed that the Chinese version of the MDASI has good reliability and validity. Moreover, we added 5 more items for specific cancer sites in our study to capture the special characteristics (constipation was added for all cancers, hot flash and upper limb lymphedema were specific for breast cancer, cough was specific for lung cancer, and swallowing difficulty was specific for esophagus cancer). Compared to the European Organization for Research and Treatment of Cancer Quality of Life Questionnaire (EORTC-QLQ) [15], which needs at least 1 week between 2 follow-ups, we used the MDASI as our screening tool, which could be used every day, because we needed to monitor symptoms at a high frequency.

Insomnia Severity Index

There are a total of 7 items in the Insomnia Severity Index (ISI; 0-4 score for each item, with a sum score of 28). The ISI is a validated scale for measuring insomnia severity in the last 2 weeks. Scores of 0-7 indicate no insomnia, 8-14 indicate subclinical insomnia, 15-21 indicate moderate insomnia, and 22-28 indicate severe insomnia. The simplified Chinese version of the ISI has been validated by Lin et al [16].

Hospital Anxiety and Depression Scale

The Hospital Anxiety and Depression Scale (HADS) has 14 items with a score spectrum of 0-4 for each item, which is used to measure the anxiety and depression of patients in the past week. It is more commonly used for patients with somatic symptoms in general hospitals, with good reliability and validity,

and is recommended for use in patients with advanced cancer or those receiving palliative care [17].

Patient Health Questionnaire-9 Items

The Patient Health Questionnaire-9 Items (PHQ-9) is used to evaluate depression in patients in the past 2 weeks. The score spectrum of symptom severity is from 0 (none at all) to 3 (almost every day), and the total score is from 0 to 27. Depression can be considered when the sum score is ≥ 10 . The simplified Chinese version of the PHQ-9 has good validation [18].

EuroQol 5 Dimensions Questionnaire-5L Version

The EuroQol 5 Dimensions Questionnaire-5L Version (EQ-5D-5L) is a multidimensional measurement for health-related quality of life, which contains the following 5 domains to describe patients' health: (1) mobility, (2) self-care, (3) usual activities, (4) pain/discomfort, and (5) anxiety/depression, with a scale from 0 (no difficulty) to 4 (extreme difficulty) [19,20]. The Functional Assessment of Cancer Therapy: General (FACT-G) [21] contains too many items, and some of them are easily avoided by patients. We used EQ-5D-5L to measure the quality of life because it has fewer items and has convenient access to get reliable results.

Distress Thermometer

Distress Thermometer is recommended by the National Comprehensive Cancer Network in the distress management guideline. It has only 1 item with a scale from 0 (no distress) to 10 (extreme distress). The problem list includes the following 5 domains: practical problem, communication problem, emotion problem, physical problem, and spirit and religion problem. It is recognized as the briefest tool for distress screening, especially in busy oncology clinical practice [22].

Symptom Tracking Promotion Strategies

Enrolled patients completed the baseline assessments and accepted ePRO standard operating procedure training when they first visited the symptom management clinic. Baseline

assessments included demographic and medical information, symptom situation, and medication situation. The ePRO system application training included instructions on how to log into the ePRO system, and how to report their symptoms and other medication situations. In order to improve follow-up compliance, the system sent a message automatically to remind patients at 8 AM on each follow-up day (1st, 3rd, 7th, 10th, 14th, 21st, and 28th day after the first clinic visit). If the follow-up self-report was not completed at 4 PM, the system automatically sent a message again. If there was still no response, research assistants would call them again the next day and record the reasons for noncompletion. If the patient was not connected after 2 calls, the data of this follow-up session were regarded as “lost.”

A time window of 24 hours before and after each follow-up was set, and the system recorded all the completion time points of the patients. Additionally, the system set the alert function. If the score of symptoms reported by the patients exceeded the cutoff value, the system reminded the patients to see a doctor in time.

Training and Evaluation for Research Assistants

Making a standardized operation process manual and an operation video for research assistants is convenient for them to study. The group training was organized for one time, while individual (one-to-one) training was carried out one-to-one. After the training, all research assistants were required to pass a test of practical operation to get started on their official work.

There was a question and answer session to solve operation problems after enrollment of around 10 cases. In addition, the

practical problems faced by research assistants were shared in the WeChat working group at any time.

Before application in clinical practice, some evaluations were carried out, including running the trial test for the ePRO system and its supporting system, testing the function of SMS text message notifications for patients, confirming the process of patients’ online follow-up, updating the layout of the doctor version of the ePRO system, and switching the testing system database to the formal project database.

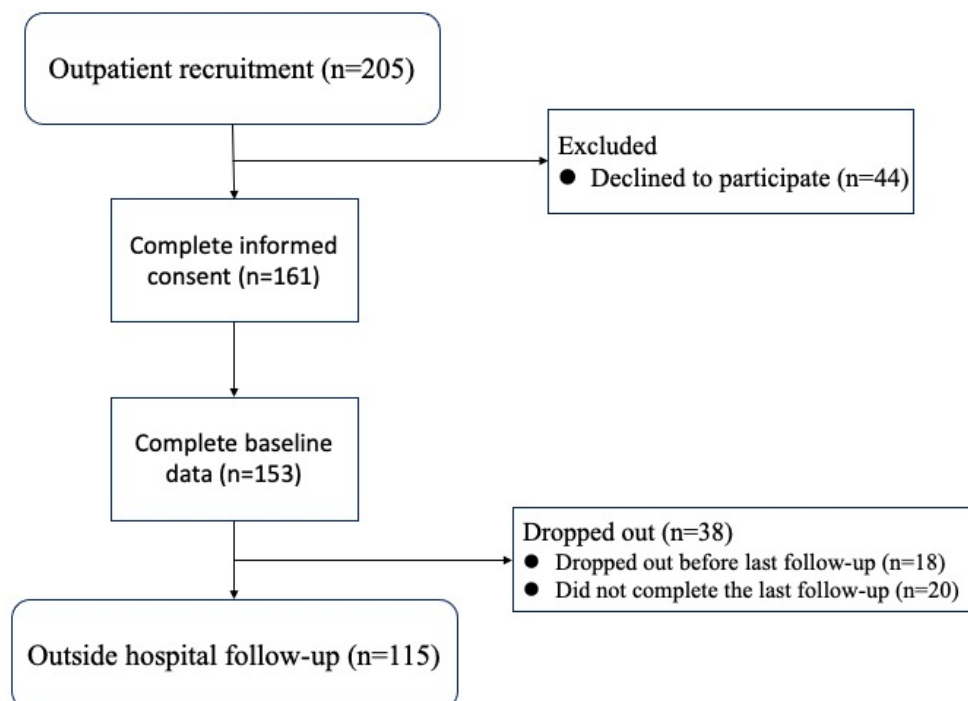

Study Population, Eligibility Criteria, and Recruitment

All eligible patients who visited the symptom management clinic for the first time were invited to participate in the study by the doctors in the clinic. The inclusion criteria were as follows: (1) age over 18 years; (2) fluency in Chinese; and (3) confirmed diagnosis of advanced lung cancer, liver cancer, gastric cancer, esophageal cancer, colorectal cancer, or breast cancer. The exclusion criteria were as follows: (1) a history of major severe mental disorders (unable to cooperate with the investigator); (2) being in poor physical condition, as judged by the attending physician (not able to complete the whole study); and (3) being unable to use the ePRO platform.

Data Collection and Process

Completed data with both PROs and other information were collected at baseline (day 0, patient’s initial visit) and follow-ups conducted within 4 weeks after the first visit to the symptom management clinic (days 1, 3, 7, 10, 14, 21, and 28), using an ePRO platform system supported by the research team and ePRO Vision. The flow chart of the study is shown in [Figure 3](#).

Figure 3. Study flowchart.

PRO data were collected using an ePRO platform. The system could recognize the individual scores of MDASI items due to the cutoff points that we set up. For those scales that needed

results to be calculated, such as PHQ-9, data were first captured by WeChat, saved in REDCap, and then calculated. The output data could be transferred to professional statistics programs,

like SAS or SPSS, with a standard data format for the final data analysis. All data were deidentified and stored on the REDCap platform.

Evaluation

The completion rate was defined as the proportion of patients who completed the self-report using the ePRO system within the stipulated time. The drop-off rate was defined as the proportion of patients who refused to complete the self-report using the ePRO system or failed to complete the last follow-up at day 28.

Ethics and Consent

The original study was approved by the Institutional Review Board of Peking University Cancer Hospital on February 13, 2019 (study #2019YJZ07). All participants provided written informed consent.

Statistical Analysis

Baseline characteristics were summarized using mean and SD for continuous variables or number and percentage for categorical variables. Assessments for symptom (MDASI)

characteristics were conducted for all patients, and a paired t test was used to determine whether there was a statistically significant change between the baseline and day 28 scores. SPSS software v26 (IBM Corp) was used to analyze the data. All P values were 2-sided, and $P < .05$ was considered statistically significant.

Results

Recruitment

Among 205 eligible patients with advanced cancer who were approached, 161 agreed to participate in the study and 153 completed the baseline assessment. Eligible patients refused to participate for various reasons, and the main reason was “I don’t want to be disturbed and it’s useless to improve my symptoms.” Patient characteristics are detailed in [Table 1](#).

The completion rates were from 72.7% to 86.4% at each follow-up, and the highest completion rate was at follow-up 1 (day 1), while the lowest rate was at follow-up 6 (day 21) ([Table 2](#)).

Table 1. Disease and demographic characteristics of the participants (N=153).

Variable	Value
Age (years), mean (SD)	56.3 (11.0)
Age range (years)	27-86
Gender, n (%)

Yes	90 (58.8)

Table 2. Completion rate and missing rate at each follow-up (N=153).

Time point	Completion, n (%)	Missing, n (%)
Baseline (day 0)	153 (100%)	0 (0%)
Follow-up 1 (day 1)	132 (86.3%)	21 (13.7%)
Follow-up 2 (day 3)	128 (83.7%)	25 (16.3%)
Follow-up 3 (day 7)	125 (81.7%)	28 (18.3%)
Follow-up 4 (day 10)	122 (79.7%)	31 (20.3%)
Follow-up 5 (day 14)	123 (80.4%)	30 (19.6%)
Follow-up 6 (day 21)	111 (72.5%)	42 (27.5%)
Follow-up 7 (day 28)	120 (78.4%)	33 (21.6%)

Feasibility

Overall, 43.5% (263/604) person-time follow-up assessments were completed by patients automatically before the notification was sent by the ePRO system, 42.6% (257/604) were completed within 8 hours after the first reminder message was sent, and 13.9% (84/604) were completed after the reminder phone call of a research assistant.

The drop-off rate was 23.6% (38/161) in the longitudinal study. Eighteen patients dropped off before the last follow-up (day 28), while 20 patients did not complete the last follow-up assessment. Among them, 14 patients rejected participation in the follow-ups continually, 19 patients could not be contacted,

3 patients died, 1 patient was considered not capable of participating in this study continually by a doctor, and 1 patient dropped off for an unknown reason.

The ePRO system sent a total of 293 alert notifications to both doctors and patients when the patient-reported symptom severity reached the altered score.

In the cohort, 153 patients underwent symptom assessments with the MDASI, HADS, ISI, and PHQ-9 scales at baseline. Of these 153 patients, 119 (77.8%) underwent reassessment at day 28, and we observed significant decreases in the mean scores of pain, fatigue, and numbness from baseline to day 28 ($P=.02$, $P=.02$, and $P<.001$, respectively) (Table 3).

Table 3. Symptom assessment scores between baseline and day 28.

Assessment	Baseline score, mean (SD)	Day 28 score, mean (SD)	P value
Pain	4.91 (3.3)	3.52 (2.7)	.02
Fatigue	5.12 (2.8)	4.29 (2.8)	.02
Nausea	2.52 (2.7)	2.29 (2.5)	.32
Disturbed sleep	5.32 (2.9)	3.94 (2.7)	.50
Distress	4.42 (3.0)	3.28 (2.8)	.31
Shortness of breath	3.14 (2.7)	2.70 (2.7)	.79
Difficulty remembering	3.30 (2.6)	2.65 (2.4)	.10
Lack of appetite	4.32 (2.9)	3.31 (2.9)	.89
Drowsiness	3.69 (2.8)	3.08 (2.7)	.38
Dry mouth	3.78 (2.8)	2.92 (2.6)	.19
Sadness	3.58 (3.1)	3.03 (2.9)	.24
Vomiting	2.03 (2.7)	1.64 (2.4)	.06
Numbness	3.74 (3.2)	3.14 (2.6)	<.001

Discussion

Advantages of Using an ePRO System

Using an ePRO system for symptom management follow-up had a lot of advantages. First, compared with the paper-pencil test, the ePRO reporting interface is much more friendly to seniors with poor sight, and the size of the font could be enlarged to make reading easier. Second, the system could remind patients that there are items missing answers automatically and could

improve data integrity. Third, the system's automatic reminder for each follow-up was very effective, and over 40% of patients completed the follow-up assessments within 8 hours after the first automatic reminder was sent, which improved the completion rate greatly and saved the time of the research assistants when compared with traditional follow-up by telephone, mail, or email [23].

Studies showed that the real-time symptom severity alarm function has an important role in symptom management [24,25].

During the study period, nearly 300 alert notifications were sent, so this function was very necessary for symptom management.

The ePRO system made research management easier. The researchers could see the real-time research progress of their clients. Researchers at different levels saw different kinds of reports, which not only made their research management easier but also protected the confidentiality of the research.

Experiences of Implementation

Consideration for ePRO Platform Design

Follow-up Times

Follow-up times should be determined according to the study purpose. Our platform was designed to complete high-frequency self-reports in a short period of time, with 7 follow-ups over 4 weeks. Several platforms have already been set up with their own follow-up time according to different aims such as a platform for posttreatment surveillance in head and neck cancer [26].

Flexibility

The electronic symptom management system applet was based on the most popular social app in China, WeChat, which can be used in any place with wireless internet or mobile network coverage, without the issue of different smartphone operating systems. This saves the cost of developing a new app and saves users the hassle of downloading one more app, and the app is convenient and totally free [27].

Alerts

For patients and medical researchers, alert information about symptoms can be sent in real-time, and the system can display reminders directly on the screen when the doctor logs into the platform. By contrast, other foreign ePRO platforms [28] send the medical staff an email notification as a reminder, which may delay the information.

Applicability for Interfacing With Other Systems

There is good interoperability with the REDCap system. For instance, the software company ESD (Evaluation Software Development) has been developing the CHES Platform (Computer-Based Health Evaluation System) [29], which is a specialized software dedicated to the assessment, storage, and processing of ePRO data.

Education

Education for patients is beneficial for better symptom management, like cancer-related pain [30], so we have added educational material and doctor's advice into the applet, as well as referral tips. This could help patients and caregivers to learn the skills of symptom management.

Integration Capacity

Most previous platforms can be divided into the following 2 categories: (1) treatment center, which is a platform designed according to a certain treatment, such as a PRO platform in chemotherapy [31], and (2) patient center, which is a PRO

platform designed for a certain patient population. This system is integrated with treatment-related (such as symptom management) and population-related (such as outpatients) aspects.

Experiences of Training Research Assistants

Multiple training methods were combined before the study implementation, including self-training, one-to-one training, and together with training, which makes the whole training process more time-saving and more effective. The training was not stopped after the evaluation, and the question and answer session at the beginning of the study was very helpful for research assistants to solve the problems they faced in practice.

Patient Adherence and Benefit

Several studies on patients who were followed up outside the hospital found that the traditional follow-up compliance was less than 50% [32,33]. In our study, the overall response rate of patients reached at least 70% in each follow-up, and there was an average response rate of 80.3% for all 8 out-of-hospital follow-ups in 2 months. Even in app-based studies, there has been a problem of a high dropout rate, and in intervention research, the dropout rate usually reached 60% [34,35]. It was suggested that we should pay attention to this problem in future intervention research.

Several studies found that integration of ePROs into routine cancer care was associated with increased survival compared with usual care [36,37]. This was an observational cohort study (no intervention), and it was found that patients had benefits for several symptoms. Symptom monitoring via ePROs following treatment for cancer was associated with increased benefits among patients.

Limitations

This study introduced the use of an ePRO platform. In the initial process, only patients who were referred to the symptom management clinic were enrolled in the study (not all patients treated in the oncology clinic). At the same time, only patients with advanced cancers at 6 sites were included. Our next goal is to integrate the platform with patient records, and future research should extend to all cancer patients.

Although the current ePRO platform had relatively high compliance, future studies should continue to explore ways to address dropout in populations at a high risk of dropout, especially in an intervention study.

In addition, the prospective nature of the study presented a limitation, and there was only 1 group of patients and no control group.

Conclusion

The use of an ePRO platform for symptom management follow-ups in advanced cancer patients is time-saving, energy-saving, and effective, which can improve the completion rate and decrease the drop-off rate. PRO tool selection, platform design, and training of research assistants are important aspects that require attention.

Authors' Contributions

LT, YH, and YP contributed to the study design. LT, YH, YP, ZS, JL, Y Zhang, XW, XH, YW, ZL, SH, LS, Y Zhou, BW, and XL performed the study. YH, YP, ZS, JL, Y Zhang, and XH drafted the initial manuscript. LT revised the draft. All authors have reviewed and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Effective self-care is an important factor in the successful management of patients with heart failure (HF). Despite the importance of self-care, most patients with HF are not adequately taught the wide range of skills required to become proficient in self-care. Digital health technology (DHT) may provide a novel solution to support patients at home in effective self-care, with the view to enhancing the quality of life and ultimately improving patient outcomes. However, many of the solutions developed to date have failed to consider users' perspectives at the point of design, resulting in poor effectiveness. Leveraging a human-centered design (HCD) approach to the development of DHTs may lead to the successful promotion of self-care behaviors in patients with HF.

Objective: This study aimed to outline the HCD, development, and evaluation process of a DHT designed to promote effective self-care in patients with HF.

Methods: A design thinking approach within the HCD framework was undertaken, as described in the International Organization for Standardization 9241-210:2019 regulations, using a 5-step process: empathize, ideate, design, develop, and test. Patients with HF were involved throughout the design and evaluation of the system. The designed system was grounded in behavior change theory using the Theoretical Domains Framework and included behavior change techniques. Mixed methods were used to evaluate the DHT during the testing phase.

Results: Steps 1 to 3 of the process resulted in a set of evidence- and user-informed design requirements that were carried forward into the iterative development of a version 1 system. A cross-platform (iOS and Android) mobile app integrated with Fitbit activity trackers and smart scales was developed. A 2-week user testing phase highlighted the ease of use of the system, with patients demonstrating excellent adherence. Qualitative analysis of semistructured interviews identified the early potential for the system to positively influence self-care. Specifically, users perceived that the system increased their confidence and motivation to engage in key self-care behaviors, provided them with skills and knowledge that made them more aware of the importance of self-care behaviors, and might facilitate timely help seeking.

Conclusions: The use of an HCD methodology in this research has resulted in the development of a DHT that may engage patients with HF and potentially affect their self-care behaviors. This comprehensive work lays the groundwork for further

development and evaluation of this solution before its implementation in health care systems. A detailed description of the HCD process used in this research will help guide the development and evaluation of future DHTs across a range of disease use cases.

Introduction

Heart failure (HF) is a significant global public health problem, with a prevalence of >100 per 1000 people aged ≥ 65 years [1]. As HF progresses, it is associated with significant morbidity and mortality, resulting in an increased number of hospitalizations. In addition to the impact that deteriorating health has on the patient's quality of life, these hospitalizations place a significant burden on health services, representing 80% of the costs associated with HF care [2].

Self-care centers have autonomy, independence, and a person's responsibility for healthy behaviors and the development of activities required to manage and monitor health conditions [3]. It is well-accepted that promoting effective self-care and disease management in patients with HF is central to reducing the burden on patients and the health system [3-5]. Despite this, patients often struggle to develop the wide range of skills required to become proficient in HF self-care [6]. For example, it is suggested that patients should be able to manage fluid retention through intake and weight monitoring; adhere to diet, medication, and exercise regimens; monitor symptoms; recognize deterioration; and ultimately, identify when they need to engage in help-seeking behaviors [3,6]. However, research has shown that most patients with HF do not understand the nature of their HF, cannot link changes in symptoms to their condition, and do not engage in these key self-care behaviors on a regular basis, suggesting that current educational practices around self-care are not effective or sufficient to elicit lasting change [6].

Over the past 20 years, consumer-wearable and mobile technologies have become ubiquitous. These technologies provide an opportunity to develop new approaches to empower patients to engage with and manage their chronic conditions at

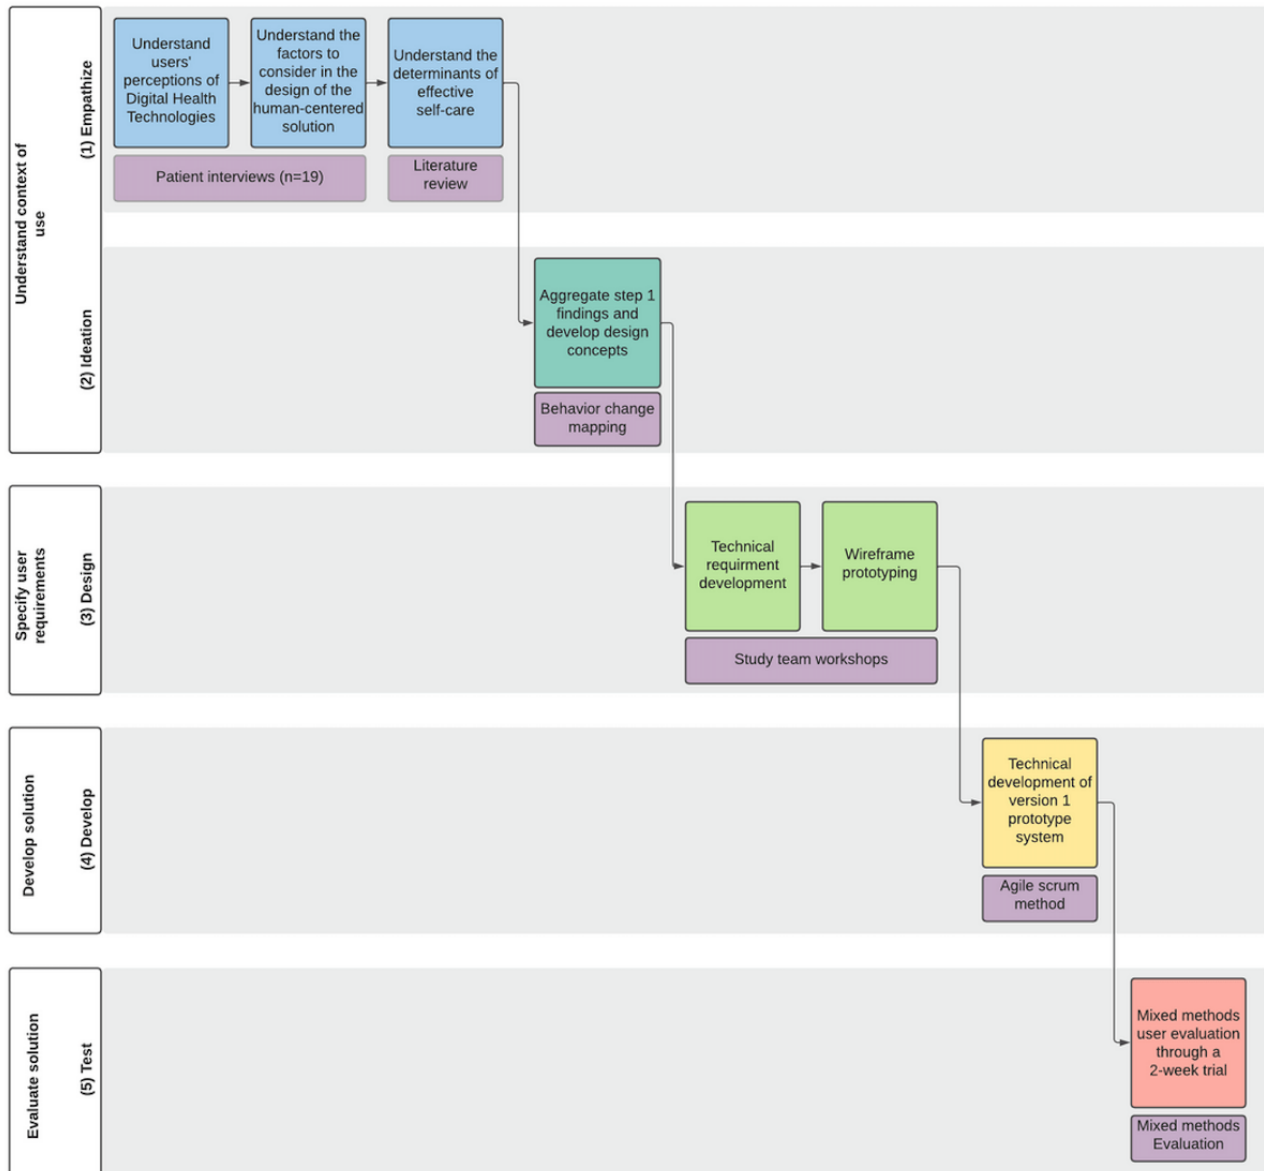

home and connect them to their care team in a timely manner when most required [7,8]. However, although existing solutions have demonstrated some success, their effectiveness has been relatively inconsistent [9-11]. One of the key reasons put forward for this lack of success is the failure of these solutions to integrate the users' perspective at the point of design, thus neglecting to take into account the patients' actual needs and failing to truly understand the problems to be solved [12-14]. Recently, the use of human-centered design (HCD) approaches has led to the successful development of digital health technologies (DHTs) designed to support chronic disease management [15]. As such, leveraging an HCD approach to the development of DHTs designed to promote self-care behaviors in patients with HF may positively influence the impact their condition has on their quality of life.

Therefore, the aim of this study was to use an HCD approach to design and develop a DHT to promote effective self-care behaviors in patients with HF. This paper provides a detailed step-by-step description of the HCD process followed in this research, detailing the process from initial requirement gathering and conceptual design to user testing.

Methods

Design Approach

This study leveraged a design thinking approach within the HCD framework, as described in the International Organization for Standardization 9241-210:2019 regulations [16]. This methodology follows a five-step iterative process: (1) empathize, (2) ideate, (3) design, (4) development, and (5) test (Figure 1). The entire design and development process was conducted between 2019 and 2021. The methods used in each phase are detailed sequentially in the *Methods* and *Results* sections.

Figure 1. The multistep human-centered design process.

Step 1: Empathize

Overview

The aim of step 1 was three-fold: (1) to understand the perceptions of patients with HF on the use of DHTs for the management of their condition, (2) to understand the factors to be considered in the design and implementation of DHTs, and (3) to understand the key determinants of effective self-care in patients with HF. To address the first 2 aspects, a cohort of patients with HF was recruited to participate in semistructured interview sessions (study 1) [17]. To further understand the key determinants of effective self-care in patients with HF, the previously published systematic review of patient and caregiver perceptions conducted by Clark et al [6] was consulted, alongside international best practice statements on HF self-care promotion by the American Heart Association [4] and the European Society of Cardiology [3].

Semistructured Interviews (Study 1)

Participants

A total of 19 participants (n=6 [32%] women and n=13 [68%] men; median age 71, range 36-84 years) were recruited from a private hospital and cardiac physiotherapy clinic in Dublin, Ireland, to take part in individual semistructured interviews. To be included in this study, participants had to have a confirmed diagnosis of HF, be aged >18 years, be willing to participate, and have the capacity to provide informed consent. Exclusion criteria included not having a confirmed diagnosis of HF, being a child or adolescent, lack of English understanding, a cognitive impairment that would preclude the capacity to provide informed consent, and having rheumatic heart disease or severe aortic or mitral valvular heart disease. This was to ensure that within the criteria, a representative sample would be included so that the impact of HF could be explored.

Study Methods

Patient data were collected during single face-to-face interviews (17/19, 89%) and over the phone (2/19, 11%) when patients

could not attend the interview in person. Demographic data such as age, sex, occupational status, marital status, class of HF, and presence of other medical conditions were collected. Open-ended questions were used to explore their perceptions on the use of DHT for the management of their condition and understand the factors to be considered in the design and implementation of DHT. The interviews were audio recorded, and a topic guide was developed based on the aims of the study to ensure consistency across the interviews ([Multimedia Appendix 1](#)).

Data Analysis

The interviews were transcribed verbatim and anonymized. An inductive, thematic analysis of the transcribed data was undertaken using a realist approach, whereby the researcher assumes that the opinions of the patients reflect their real perceptions and can be considered real [5]. A total of 2 researchers (RC and AK) analyzed the transcribed data following the protocol of Braun and Clarke [5]. This protocol comprises the researchers familiarizing themselves with the data, generating a list of initial codes relevant to the aims of the study, and refining these codes by grouping them into potential themes. The list of codes and themes was iteratively revised until an agreement was reached using NVivo (version 12; QSR International) and Microsoft Excel.

Literature Review

Clark et al [6] conducted a systematic review of qualitative studies that investigated the determinants of effective self-care in patients with HF. This review analyzed data from 49 qualitative studies that examined patients with HF and caregivers' views and needs about the nature and determinants of effective self-care. This comprehensive work formulated a series of key skills that are crucial to the development of effective self-care in this population. The key skills highlighted by Clark et al were then combined with the findings of the semistructured interviews and the best practice statements on HF self-care promotion by the American Heart Association [4] and the European Society of Cardiology [3] and were carried forward into the ideation process.

Step 2: Ideation

The aim of step 2 was to aggregate the findings from step 1 to formulate ideas and design concepts for a prototype solution to promote self-care behavior change. The barriers to and facilitators of the use of DHT and key design considerations identified in the qualitative interviews were first mapped to the determinants of effective self-care highlighted by Clark et al [6] and then subsequently to the relevant domain and intervention functions as listed in the Theoretical Domains Framework (TDF) [18]. The TDF is a theory-based framework that helps researchers understand their target behavior; identify its determinants; select intervention functions that best influence these determinants; and finally, select relevant behavior change techniques (BCTs) that are most effective toward these functions and determinants [18]. BCTs are the smallest, reproducible component of an intervention designed to change behavior either alone or in combination with other BCTs. Thus, once the desired intervention outcomes and intervention functions were mapped from the TDF, potential BCTs, as listed within the BCT

Taxonomy version 1 [19], were identified using the web-based Theory and Techniques tool [20]. BCTs to be included in the DHT were selected based on their evidence or hypothesized links to TDF domains and intervention functions, along with their potential to be operationalized in a DHT, to ensure that the determinants of behavior were targeted within the contents of the system.

Step 3: Design

The identified BCTs from step 2 were taken by the study team (a consultant cardiologist, a mobile developer, and 2 digital health clinical research physiotherapists), and a series of high-level requirements for the system were iteratively developed, taking into account the patient requirements identified in step 1, as well as clinical and technical feasibility. These requirements were then used to develop wireframe prototypes and technical requirements to guide mobile development.

Step 4: Develop

The finalized wireframe design and requirements were developed into a version 1 prototype solution, which was then evaluated with a group of patients with HF in step 5. As detailed further in the Results section, the developed system comprised a mobile phone app, a Fitbit Charge 4 activity tracker (Fitbit Inc), and Aria Air smart scales (Google).

Step 5: Test (Study 2)

Overview

The developed prototype solution was examined in a 2-week pilot evaluation phase. A mixed methods approach was used to evaluate the feasibility of the system, focusing on the acceptability, usability, demand, and practicality of the DHT system according to the participants [21]. In addition, this phase was used to identify any technical issues that needed to be addressed in a version 2 system and highlight any additional feature requirements identified by the patients that would be required in any further evaluation of the system. A 2-week period was deemed acceptable for this initial feasibility phase as it allowed sufficient time for users to familiarize themselves with the system, identify usability issues, and explore the practicality of using it within their daily life. This initial, short follow-up is commonly used in HCD studies [22,23].

Participants

A convenience sample of 9 participants (n=4 [44%] women and n=5 [56%] men; mean age 74, range 54-91 years) volunteered to participate in the study. Participants were recruited from a private hospital in Dublin, Ireland, and had previously been diagnosed with HF. This purposive sample allowed for the aggregation of usability and acceptability data pertaining to the initial system, facilitating the iterative development of a system for deployment in the full feasibility study. Previous research has shown that a sample size of approximately 9 participants is sufficient to reach data saturation in similar contexts [24]. Participants were deemed eligible if they could provide written informed consent; were previously diagnosed with HF; were under the care of Beacon Hospital Cardiology (aged ≥ 18 years); were under New York Heart Association classification 1 to 3;

were open to the use of technology in the promotion of HF self-care; had access to an internet connection or mobile data; and were intellectually, visually, and auditorily capable of communicating with the investigator and understanding and complying with the requirements of the study. Participants were deemed ineligible if they were medically unstable or undergoing medical treatment judged not to be medically compatible by the investigator or if they had any skin condition that may affect the integrity of their skin when wearing the activity tracker.

Study Methods

The recruited participants were invited to an initial setup session at the hospital. Demographic data such as age, sex, and the highest level of education were collected at the beginning of the session. The participants then completed the European HF Self-care Behavior Scale (EHFScBS) [25,26] and the Minnesota Living with HF Questionnaire (MLWHFQ) [27,28]. These questionnaires were designed to evaluate self-care behaviors in patients with HF and the effect of HF treatments on the quality of life.

Following a setup and familiarization session with the first author (approximately 40 minutes), participants were asked to use the system as part of their usual daily routine for the following 2 weeks. During this period, the patients were asked to wear the Fitbit Charge 4 activity tracker on their wrist, take their weight every morning using the Fitbit Aria Air scales, and interact with the developed mobile app. A *check-in* symptom questionnaire was also completed 7 days into the trial period [29].

At the end of the 2-week period, individual semistructured interviews were completed over the phone and recorded with each participant. Open-ended questions were used to explore their perceptions of the acceptability, usability, and practicality of the system; understand their experiences pertaining to the impact of the system on their self-care behaviors; identify usability and user experience issues; and identify aspects that could improve the system (Multimedia Appendix 1). Before completing the interviews, participants also completed 3 questionnaires: System Usability Scale (SUS), a questionnaire designed to measure system usability [7]; Wearable Technology Motivation Scale (WTMS), a questionnaire based on the intrinsic needs listed within self-determination theory [30]; autonomy, competence, and relatedness and the Comfort Rating Scale (CRS), a questionnaire designed to assess the comfort of wearable devices across the dimensions of emotion, attachment, harm, perceived change, movement, and anxiety [31].

Data Analysis

The recorded interviews were transcribed verbatim and anonymized. The same thematic analysis approach was used as detailed in the *Step 1: Empathize* section.

The questionnaire data were scored using the appropriate standardized procedure for each questionnaire, and the scores were presented as medians and ranges. The MLWHFQ is broken down into 2 components, the physical and emotional dimensions, which are combined to form the total score. It is scored by summing each of the components, resulting in a score ranging from 0 to 105 (high impairment) [27]. The EHFScBS is scored by summing the components of the questionnaire, z score normalizing, and calculating the percentiles. This results in a score ranging from 0 to 100 (good self-care), with <30 deemed as inadequate [25]. The SUS is scored out of 40 but converted to a 0 to 100 scale as per the standard procedure, with >68 deemed acceptable and >80 considered excellent [32]. The CRS is scored by summing the components, resulting in a score from 0 to 120 (poor comfort) [31]. Finally, the WTMS is scored by calculating the average score across the different components for each participant, resulting in a score ranging from 0 to 7 (extremely motivated) [30]. In addition, adherence was determined by identifying the number of days a user wore the Fitbit device throughout the day and recording their weight.

Ethics Approval

The study received ethical approval from the Beacon Hospital Research Ethics Committee (BEA0114 and BEA0151), and written informed consent was obtained from all participants before commencing the study.

Results

Step 1: Empathize

Study 1: Semistructured Interviews

The full and detailed results of these interviews are listed elsewhere [17]. In summary, the results highlight that although patients are generally interested in engaging with technology, aspects such as technology literacy, previous exposure to technology, age, and lack of perceived usefulness are all important factors in driving whether it is adopted or not. Furthermore, several key factors to be considered in the design of a DHT were identified (Textbox 1).

Textbox 1. Key factors identified by patients with heart failure.

Key factors and details (required elements of the factor)
<p>Ease of use</p> <ul style="list-style-type: none"> • Easy to use, with appropriately sized font and easily understandable language and health data
<p>Vital sign monitoring</p> <ul style="list-style-type: none"> • Support vital sign (eg, resting heart rate, blood pressure, and oxygen saturation) monitoring and actuation
<p>Physical activity promotion</p> <ul style="list-style-type: none"> • Support physical activity monitoring and guide patients in pacing strategies and exercise targets
<p>Weight and fluid control</p> <ul style="list-style-type: none"> • Facilitate weight and fluid management through daily weight tracking
<p>Feedback loops</p> <ul style="list-style-type: none"> • Feedback from the vitals and other health data should be patient specific and not generic comparisons with healthy nonclinical populations
<p>Health data analytics</p> <ul style="list-style-type: none"> • Background analysis of the collected health data to help proactively inform about potential deterioration and facilitate help seeking
<p>Reminders</p> <ul style="list-style-type: none"> • Include a reminder feature for medications and appointments
<p>Medical information</p> <ul style="list-style-type: none"> • Educational information should be included from a reliable source and should not be intimidating for the user • Provide patients with the requisites to participate in their own condition management
<p>Included devices</p> <ul style="list-style-type: none"> • Any devices associated with the digital health technology should not be medically oriented to reduce negative associations of having a chronic illness
<p>Diet tracking</p> <ul style="list-style-type: none"> • Ability to record calorie intake, similar to solutions such as MyFitnessPal
<p>Emergency information</p> <ul style="list-style-type: none"> • Medical information about their condition and medications for emergency situations
<p>Social support</p> <ul style="list-style-type: none"> • A social networking aspect to facilitate social support

Literature Review

In the Clark et al [6] systematic review investigating the determinants of effective self-care, the authors highlighted that patients demonstrate or report a low knowledge of HF or lack of understanding of self-care behaviors through the following:

- Lack of recall about the basic elements of the nature of HF
- Apparent misattribution of HF symptoms to other conditions, age, or medication
- Low understanding of the links between signs or symptoms of HF
- Absence of references to the importance of weight management or monitoring

- Avoidance or low awareness of the severity of HF

In addition, they identified that HF self-care was shared between the patients and informal caregivers.

The skills for effective self-care, as identified in this review, are presented in [Textbox 2](#) [6]. In addition to these, the international best practice statements on HF self-care by the American Heart Association [4] and the European Society of Cardiology [3] highlight that the desired goal of supporting self-care in HF is to improve quality of life, reduce the need for unnecessary hospitalizations, and reduce the risk of early mortality.

Textbox 2. Key skills for effective self-care.**Skill and description****Integrating self-care within normal life patterns**

- It is helpful to incorporate self-care into daily life as it facilitates adherence.

Early detection of signs and symptoms

- Patients have an overreliance on subjective symptoms.
- Patients are often only able to identify relevant changes associated with worsening conditions formatively with experience.

Caregivers, their knowledge, and the range of heart failure

- Caregivers typically provide substantial support with medication and diet adherence.
- Caregivers rarely help with daily weighing, fluid restriction, physical activity, and timely help seeking.

Caregivers foster patient independence

- Poor caregiver support can lead to difficulties with managing self-care, although a lack of support is not limited to those who live alone.

Step 2: Ideate

On the basis of the key determinants of effective self-care, combined with the best practice recommendations and patient interviews, a number of behavioral outcomes were identified as a focus for the development of DHT: (1) engagement in regular physical activity; (2) management of fluid status daily through weight monitoring; (3) adherence to medication; (4) understanding the signs and symptoms of HF, including the consequences of an exacerbation; and (5) seeking medical help appropriately when required.

The barriers to and facilitators of self-care behavior were mapped to the determinants of behavior and appropriate TDF domains ([Multimedia Appendix 2](#)). A pragmatic decision was taken to focus initially on the key needs and requirements of version 1 of the system. If this simple version is successful in supporting self-care in HF, features designed to address additional behaviors can be iteratively added to the solution. This incremental approach is in line with recommendations for the development of complex interventions [33,34] and has previously been applied in the development of DHT for chronic disease management [15]. Subsequently, the determinants of behavior were mapped to the TDF domains, appropriate intervention functions, and evidence-based BCTs as listed within BCT Taxonomy version 1 to ensure that the determinants of behavior were targeted throughout the contents of the system ([Multimedia Appendix 3](#)).

Step 3: Design**Overview**

The system was required to comprise a cross-platform (iOS or Android) mobile app capable of linking to a consumer activity tracker and smart scales. Owing to the common use of Fitbit activity trackers and smartwatches, the Fitbit Charge 4 and Aria Air Smart scales were chosen for use in this system. Fitbit activity trackers have previously been shown to demonstrate sufficient consistency in their measurement for relative comparisons of within-subject use in community-dwelling older adults and patients with HF [35-37]. The designed prototype

was broadly divided into five sections—(1) advice, (2) symptom reporting, (3) activity tracker and scale data (exercise, weight, heart rate, and sleep), and (4) medication reminders and other vital sign tracking—all targeted through the inclusion of specific BCTs (detailed in [Multimedia Appendix 3](#)). The wireframe design for the prototype system is presented in [Multimedia Appendix 4](#).

Advice

This section was designed to provide targeted educational content through a series of animated explainer videos and to-camera information videos by a consultant cardiologist. In addition, *how to* instructional videos were included throughout the system to guide patients in the use of the DHT. Additional information on educational content and BCT mapping is provided in [Multimedia Appendix 5](#).

Symptom Report

This section allowed patients to complete a short symptom check-in questionnaire if they felt that their symptoms had changed in the preceding days. Once completed, the questionnaire was sent to the Beacon Hospital Cardiology Team, which would follow up within 24 to 48 hours to facilitate timely help seeking.

Fitbit/Scales Data

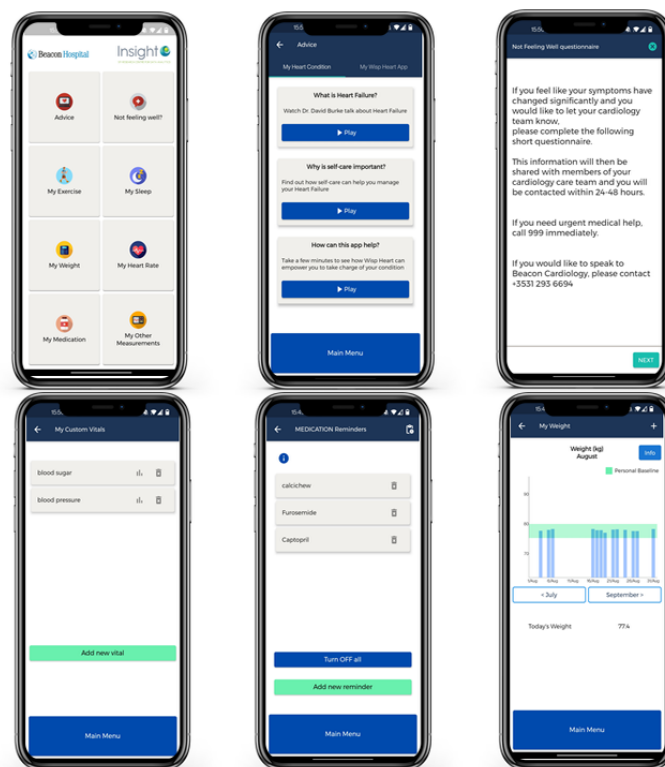

To facilitate the promotion of paced exercise, sleep hygiene, heart rate monitoring, and weight and fluid retention tracking, the mobile app was integrated with the Fitbit activity tracker and smart weighing scales to help the integration of self-care into daily life and detection of early signs and symptoms and prompt early help-seeking. The system was designed to automatically track patients' exercise (step count), sleep time, resting heart rate, and weight. In addition, to support patients in understanding how these measurements fluctuate over time and how a change from their *normal* is presented, these end points were visually displayed within the mobile app. The individual's baseline for any of the 4 end points was displayed as a green band, termed their *personal baseline*. This was also designed to automatically monitor for alterations in these end

points from the individuals' *personal baseline*. When a patient's weight, resting heart rate, sleep time, or step count changed by >2 SDs of their *personal baseline* for 3 consecutive days within the past 5 days, participants could be prompted with a symptom questionnaire, which would be shared with the cardiology care team for evaluation [38]. However, because of the short 2-week trial duration, only the visual feedback of the *personal baseline* was used. Future evaluations of the long-term use of this system will incorporate fully automated monitoring and symptom questionnaire triggering. Additional information on the computation of the *personal baseline* and trigger logic can be found in [Multimedia Appendix 6](#) [38].

Medication Reminders

As patients with HF are typically required to take a large number of medications, the ability to add medications and set time-based reminders was incorporated into the mobile app.

Figure 2. Screenshots from the mobile app detailing the main menu, advice section, symptom report, other vital sign tracker, medication tracker, and weight tracker screens.

Step 5: Test

Overview

All 9 participants completed the 2-week trial period, semistructured interviews, and evaluation questionnaires. [Table 1](#) presents the demographic characteristics of the participants recruited during this phase of the research.

During the 14-day trial, 78% (7/9) of participants wore the watch for the entire 14 days, whereas 22% (2/9) of participants wore it for 13 of the 14 days. Similarly, 56% (5/9) of participants

Other Vital Sign Tracking and Reminders

The capacity to add additional vital sign end points (eg, blood glucose, blood pressure, and spirometry) was incorporated into the design to facilitate patients with HF with relevant comorbidities in an attempt to centralize most of their monitoring requirements. Users could also set time-based reminders to facilitate adherence to the monitoring.

Step 4: Develop

The finalized wireframe design and requirements were then developed into a version 1 prototype mobile app ([Figure 2](#)). A video demonstrating the mobile app can be viewed in the Johnston study [39].

recorded their weight on all 14 days, whereas the minimum number of days on which weight was recorded was 10. The median scores for the MLwHFQ and EHfScBS were 24 (0-78) and 32 (10-93), respectively. For the EHfScBS, 44% (4/9) of participants were deemed to have inadequate self-care. [Table 2](#) details the responses for the SUS, CRS, and WTMS, which were collated at the end of the 2-week trial period, all of which demonstrate the acceptability of the system to participants and the impact on motivation to exercise.

The analysis of the semistructured interview data identified 3 key themes and their associated subthemes ([Figure 3](#)).

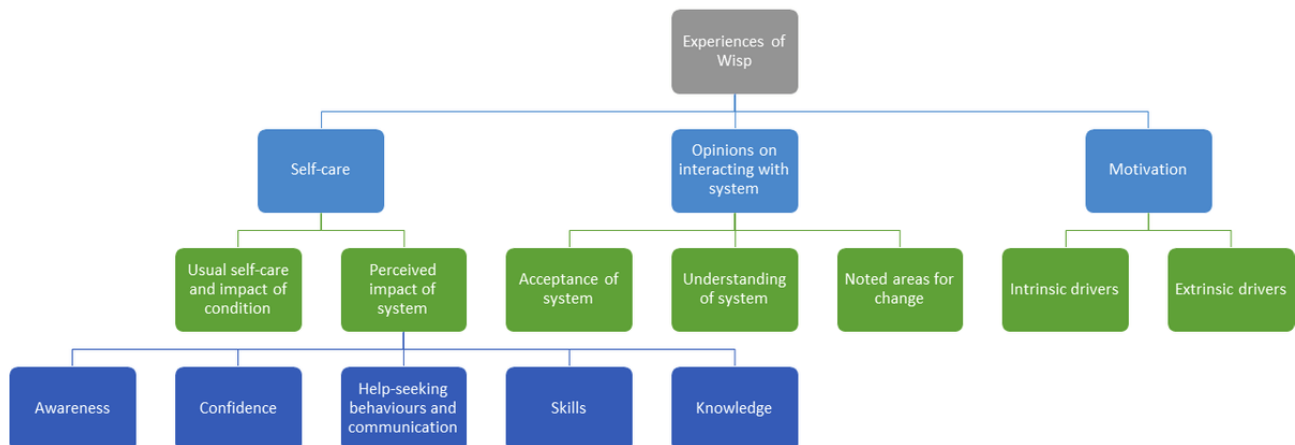

Table 1. Demographic data for the recruited patients with heart failure (N=9).

Demographic details	Participants, n (%)
Lives with	
Spouse	6 (67)
Family	1 (11)
Alone	2 (22)
Marital status	
Married	6 (67)

System Usability Scale (0-100)	92.5 (72.5-100)
Comfort Rating Scale (0-120)	6 (0-38)
Wearable Technology Motivation Scale (0-7)	5.9 (5.1-7)

Figure 3. Themes and subthemes from the semistructured interview analysis.

Self-care

Overview

Within self-care, 2 key subthemes were evident: usual self-care and the impact of the condition and perceived impact of

system/changes resulting from it. Within the *Perceived impact of the system*, 4 additional subthemes (awareness, confidence, help-seeking behaviors and communication, and skills and knowledge) were identified. These themes are closely related to the focus of self-care—autonomy, independence, and a

person's responsibility for healthy behaviors—and the development of activities required to manage and monitor health conditions [3].

Usual Self-care and Impact of Condition

Patients highlighted that HF significantly and negatively affected their confidence and perceived ability to engage in self-care promoting activities such as physical activity, thus affecting their quality of life:

before I got the blockage cleared in my heart, my breathing got to the point that I felt that every step I took I was pushing a boulder in front of me, or dragging one behind me, one or the other, I just didn't have the energy to do anything and it knocked me [sic] confidence an awful lot because I've never had to build myself back up from doing two, three years of doing nothing, whereas before you could get a period with six months where you're doing nothing and you have to go back and start being physical again,... it's not that I'm afraid to get out and do anything it's just that I felt that I've been so long doing nothing I didn't have it in me, and my breathing's still not 100%, so it sort of scared me [Male, 54 years, inadequate self-care]

Regarding usual self-care behaviors, participants highlighted that they were aware of helpful self-care behaviors; however, they found it difficult to build and continue a structured routine. For example, when discussing setting a sleep routine, one of the participants detailed how she struggled to build good sleep hygiene practices despite knowing what was required:

You know, the first night I did it, it worked great. But then the next night I wanted to watch a programme that was on a bit late, a documentary that was on a bit late, and I thought I'm not going to get to bed till after midnight. And I didn't. And I haven't done it since, properly. But I am going to try and do it now again. I'm going to try and start doing it. [Female, 81 years, inadequate self-care]

Similarly, the difficulty in maintaining consistency in routines was highlighted when discussing physical activity:

Well I would have been very inconsistent. I would spend a week doing great, I'd go out walking every day and then the following week I wouldn't go out at all, maybe only one or two days or even less. So, it [FitBit] made a huge difference to the consistency side of things. [Male, 64 years, inadequate self-care]

Perceived Impact of System/Changes Resulting From it

Overall, all patients reported a positive experience using the version 1 prototype system and expressed an interest in its continued use beyond the evaluation. When focusing on the perceived impact of the system and the changes resulting from its use, the topics of awareness, confidence, help-seeking behaviors and communication, and skills and knowledge emerged.

- Awareness: The participants stated that the use of the system had a positive impact on their awareness of their condition,
- Confidence: Participants also stated that using the system provided them with increased confidence in their condition,

self-care behaviors, and lifestyle. In particular, participants noted that while using the system, they developed an increased awareness and consciousness of their physical activity levels and weight:

Apart from, now, keeping a closer eye I suppose on the weight. And now I'll be keeping a closer eye on my exercise as well, with it. So over all, it has, made me...I wouldn't say made me, but convinced me to focus a little bit more on what your doing, rather than just doing it. Focusing a little bit more on trying to get a little bit more information about yourself as you are doing stuff. [Male, 68 years, adequate self-care]

Although the participants noted that they could see value and comfort in sleep and resting heart rate tracking, their understanding of the intended specific purpose of these measures was less clear:

my pattern of sleep or going to bed or anything like that never changed, but it just gives me the picture that I am sleeping for eight-and-a-half-hours every night most nights and you know it's a great comfort to know that you're doing that. [Female, 91 years, inadequate self-care]

That is very comforting to know what your resting heartrate is and mine has been literally the same the whole way through the test, I think it's gone from about 64 and the highest it's gone resting is about 68, and it has stayed that way every single day, for the whole of the test. Which, it is comforting to know. [Female, 81 years, inadequate self-care]

Importantly, several participants noted that over the course of the trial, they developed a greater awareness of the impact that positive self-care behaviors, such as increasing physical activity and proactively monitoring weight and fluid consumption, had on their symptoms and quality of life:

No, I think I get pains in my joints from the fluid, in my knees mostly and in my hips, but the exercise helps with that. Whereas before I was doing nothing and when I was sitting down I'd get pains in my hip joints and when I go to move then my knees felt like they were dislocating, but I, it doesn't, the exercise, a walk helps with that. [Male, 54 years, inadequate self-care]

One day it frightened me, because I went up to, eh, I went up to 0.9...[pause]...Up to 67.9 or something. And I got an awful fright because I'm going upwards or downwards. Or not static. But I realised I hadn't been to the bathroom, I hadn't been to the toilet sort of, for two days. Now I wasn't constipated, but I just hadn't been. There was a big difference the next day, from that reading to the next day. There was nearly a kilo. I wasn't eating anything different as such, you know I still have my three meals a day. I'm trying to stick to my three meals a day. Now I do graze at night time. You know what I'm talking about? [Female, 81 years, inadequate self-care]

providing them with an increased sense of control over themselves and their conditions. Furthermore, using the system made them aware of how capable they were of engaging in self-care behaviors such as increasing their physical activity, thus further increasing their confidence:

It just made me more secure, if you like in a sense, that I knew nothing was happening, that I was still the same, that I wasn't putting on weight, or losing too much weight, excuse me, but other than that, no, just nice to look at it. [Female, 91 years, adequate self-care]

It [the system] has, it's given me a lot more confidence around it [physical activity], where I was a bit, not that I was scared or anything but I was apprehensive about doing anything anymore, and the kids were sort of treating me like I was made out of glass, you know that sort of way, so, and I know my heart failure isn't as serious as it could be, but it was just that I got a blockage in my foot and I got a blockage in my heart and just everything seemed to collapse in on me at the same time and it sort of knocked my confidence about everything really, so yeah I, listen I don't feel that way now, I know I'm not in any real danger where I wasn't really in any real danger once I'd been sorted out anyway but I just felt a lot, I just felt I wasn't doing well, you know that sort of way, I was afraid to do stuff, my wife was afraid to do anything with me, if I came home tired from work she would say go to bed, which is totally the wrong thing to do, but yeah it has certainly helped me in that respect, it has taught me an awful lot about what I can and can't do, what I should and shouldn't do, you know? So yeah listen I'm a huge advocate for it, I think it's great, I really think it's great and so does my wife. [Male, 54 years, inadequate self-care]

- **Help-seeking behaviors and communication:** The participants were universally positive about the prospect of the system monitoring various end points. They discussed that being monitored would provide them with increased comfort and that it would create an additional safety net to facilitate help seeking in the event that their condition changed. Interestingly, participants did not appear to mind whether their data was being monitored by a human or a computer-based system, although it is unclear how much they understood the difference between the two. This was particularly clear when the topic of data security arose. No participants had any privacy concerns and trusted that as the system was managed by health care and research institutions, there were sufficient data protection procedures in place:

I think [the monitoring is] absolutely brilliant. I think it is a super idea that that sort of apparatus can be used for people to see what is happening to you. Whereas I might not pick up on something that it would be going else where and experts would be able to look at it and say something is happening here and we can see what the situation is. I think it is a super idea. [Male, 74 years, inadequate self-care]

It wouldn't make any difference once it had monitored if I had something wrong with me. I think it's great to have it monitored on all the time, and the fact, the way I look at it is, if it's being monitored then a human is looking then at the monitoring and then sees the way things are going, it's a two-part thing, really. [Female, 81 years, inadequate self-care]

Participants appeared to feel that simply having access to the data collected by the system would facilitate communication about their condition with health care professionals. Importantly, one of the participants (male, 84 years, adequate self-care) used the system to share an acute change in symptoms with the hospital's cardiology care team and reported a recent increase in dizziness. This process initiated consultation with the cardiology care team:

As I said, when I go back to talk to the consultant, I feel like I can have a better conversation with him about my condition and if I have any questions, I feel like I am in a better position to ask. And when he is speaking to me, I am able to give him better information than I was before. So other than that, I think it was great and well worth doing. [Male, 68 years, adequate self-care]

- **Knowledge:** Linked closely to increased confidence and awareness, the participants also perceived that the data provided within the app increased their knowledge about themselves and their conditions and helped them make more informed self-care decisions. However, despite this, many of the participants also felt that the educational content throughout the app was relatively basic and did not provide them with much new information from what they would have obtained at diagnosis:

Well it did because it made me aware that I had a heart condition and it's making me think more of my health, but I've always been reasonable about getting out and doing things, I don't sit around and that sort of thing but the heart, it's making me feel safer, like having that set there and knowing, it's like as if I have help on my doorstep. [Female, 81 years, inadequate self-care]

I was going out for one long walk, and I over did it one day when I was out for an hour and a half and I felt a bit...I didn't feel great after it, so I decided I'd change. And I saw something in the advice about being active every hour or something like that. I don't know how it said it. But this is very beneficial to my arthritis as well as I was having back trouble. I think it is improving, so touch wood, I think it is improving since I have gone onto this new regime and it was thanks to the app I wouldn't have found anything. [Male, 64 years, inadequate self-care]

I did, I watched the videos. They're very simple and very quick so they're easy to follow you know? Again a lot of the information I'd know anyway just from my time in it but yeah they're helpful, they are definitely helpful. [Male, 54 years, inadequate self-care]

Although participants generally reported a positive impact of the system on their knowledge of their condition, some participants demonstrated a perception that they lacked control over the system end points other than physical activity. This suggests that the potential impact of the other end points was not clear or that participants were not aware that no change should be seen as a good thing in some cases:

I said it made me probably do a bit more exercise sort of thing. Other than that, at the exercise side of it, I probably wouldn't have seen anything other than that as being beneficial you know. Not because...That's probably the only thing on it that you can judge yourself into what you're doing physically and the exercise end of it tells you whether you're doing it or not doing it. It gives you the incentive to do a little bit more. Other than that, the other things I don't think I can do an awful lot about the sleep. At the moment I can't do an awful lot about the sleep...As hard as I'm trying. And eh, the heart rate is pretty good and explains itself. [Male, 74 years, inadequate self-care]

- **Skills:** Participants perceived that using the system over the 2-week period helped them develop self-care skills that they felt they lacked before the trial. Specifically, they highlighted that being able to track physical activity allowed them to set measurable goals for activity and promoted structured weight and fluid monitoring routines. Furthermore, many noted that they used the heart rate function on the Fitbit watch to help guide pacing and recovery during bouts of physical activity:

oh big time, everything is based on it now at the moment. First thing in the morning I do the weight and I'm very aware that every hour or so that I get up and get off sitting on my arse looking at the television and I do a thousand steps or so and I accumulate over 10,000 before the day is over, and also the climbing of the stairs is good and all that. Oh yes it has impacted big time on my life. [Male, 64 years, inadequate self-care]

It changed, where before, I was sort of, where I said if I was cutting the grass, doing anything physical like that I would sort of feel, I'm getting a little warm here, are you doing a bit too much or that carry on. Now over the last fortnight, what I was doing is if I felt like that I would just look at the heart rate on the fitbit and see it had gone up, and if that's a bit high just take a break for a few minutes, and that type of thing. And that has worked very well for me, because I felt by doing that, I am able to do a lot more during the day. [Male, 68 years, adequate self-care]

When asked about medication and other vital sign tracking, participants' responses toward these functions were mixed. Most participants did not use these functions as they reported their own strategies for medication adherence. However, 22% (2/9) of participants reported that they used it to keep on top of medications that followed a different dose timing requirement for most of their medications:

no I didn't use either of those. The reason for that is I wanted to sort of put myself in a position where I was looking at stuff myself. Now if I were to use this thing long term, I probably would. [Male, 68 years, adequate self-care]

Opinions on Interacting With System

When considering participants' interactions with the system, 3 key subthemes emerged: acceptance of the system, understanding of the system, and areas for change.

Acceptance of the System

When talking about their experience over the 2-week trial, most participants communicated that they were initially intimidated by the thought of learning to use new technology and were scared of using the system incorrectly. However, they universally expressed that they quickly became comfortable with the system and found it easy to use:

Yeah, well starting off I was nervous, and the reason I was nervous is I wanted to get it right, but when I got it set up and going, I felt pretty confident, but it took a couple of days for me to be confident. [Female, 81 years, adequate self-care]

very easy to use...very easy to use. I was a bit apprehensive at the start. Because as I said I am not a techie person, I'm not into gadgets or anything like that. A bit apprehensive, but it only took me a day or two to fall into line with it and find then my way around with it. I found it very useful. One thing led onto another and I find it very useful now. [Male, 68 years, inadequate self-care]

Understanding of the System

Participants generally had a good understanding of the system and found it easy to use and beneficial to their self-care. However, despite feeling that the system was generally easy to use, some participants discussed particular incidents where they were not completely sure of the functioning of the system. Furthermore, although there was no universal struggle with regard to broadly understanding how the system worked, individuals reported difficulties with certain aspects of its functionality. For instance, participants were often unable to clearly distinguish between the proprietary Fitbit app and the version 1 DHT system. Others struggled with reading the digital weighing scales. In addition, one of the participants expressed a lack of understanding of the purpose and functionality of the heart rate monitoring aspect. Despite the Fitbit activity tracker simply measuring the heart rate, they discussed how they were concerned about *an irregular heart*, suggesting that they were under the impression that the device was similar to an electrocardiogram:

My experience with it has been very positive. It's very like taking, or somebody injecting you with something without you knowing about it, because it just sort of, I don't know, I've wore FitBits before I think, but they didn't do this to me sort of, you know what I mean? It didn't get me thinking about it. [Male, 57 years, inadequate self-care]

I started using the other app a bit, I got into using the other app and adding in the different things. Now for example, for the resting heart rate it just gives the resting heart rate for the day. The wisp [Version 1 DHT] app doesn't give you, as far as I know, doesn't give you a graph showing the highs and the lows. [Male, 74 years, inadequate self-care]

Well it would because when things start to happen to you you're worried about an irregular heart or

something, that's what I suffered from originally, and there's none of that and I don't pick anything up and it's kind of a safeguard. [Male, 84 years, adequate self-care]

Areas for Change

Despite their generally positive experience using the system, participants noted some technological glitches that occurred during the trial and aspects that they would like to see improved (Table 3).

Table 3. Identified areas for refinement of the digital health technology.

Component	Details	Solution
Font size changes	Although adaptive scaling was implemented within the version 1 system, it was not optimized for the largest font sizes on small screens.	Updated when identified within the trial
Smart scales not compatible with implanted medical devices	Participants who had a fitted medical device requested that an alternative smart scale could be used to reduce the need for manual input.	An alternative scale has been identified for version 2
Difficulty in setting up smart scales	Of 9 participants, 8 (89%) required technical support when setting up the Fitbit Smart scales because of the need for a Wi-Fi connection. Therefore, an alternative, easier to set up scale was requested.	An alternative scale has been identified for version 2
Decimal point issue on iOS	iOS users initially identified the inability to input a decimal point when manually recording weight and other vital signs.	Updated when identified within the trial
Screen time-out in videos	One of the participants noted that their screen would time out during educational videos.	Updated when identified within-trial
Information button not obvious	Participants were not initially aware of the location of the information button throughout the version 1 system.	Will be incorporated into version 2
Intermittent issue with displaying activity and sleep data	Approximately 33% (3/9) of participants experienced a technical glitch lasting 3 days whereby "Today's Sleep" and "Today's Weight" did not display.	Updated when identified within-trial
Within-day heart rate data alongside resting heart rate	Approximately 33% (3/9) of participants expressed an interest in being able to visualize within-day heart rate data within the version 1 system to help inform pacing.	Will be incorporated into version 2

Motivation

Across the board, participants expressed that using the DHT system over the 2-week trial motivated them to engage in effective self-care behaviors, with both intrinsic and extrinsic motivators at play.

Intrinsic Drivers

Participants commonly identified that they were keen to be involved with research activities that may help them or others with HF and were motivated by the nature of being on a program. However, it would appear that the key motivational driver for them interacting with the system was increased perception of both autonomy and competence. Specifically, seeing changes in their data based on their own behaviors was an important element of this:

well I honestly feel that if you go and support other people, no matter what it is. Whether it is this or something else you're doing, you get something back. No matter what you do you get something back. You go and you volunteer to do something, it doesn't matter what it is. You do something in the community and you always get paid back. You always get something back from it. So, you don't do it for getting something back, but it always seems to come your way. [Male, 68 years, inadequate self-care]

I feel more confident in what I can do. And that...it feels like I am in control of what I can do. And watch what I can do and know how far I can push myself and that sort of thing. I found it very good from that point of view. [Male, 68 years, adequate self-care]

but as I say when I look at the scales, I know, like the 800 grams I put on yesterday which is nearly 2 pounds, you don't put that on overnight when you haven't eaten anything extra, and you haven't drank anything extra, so I knew that yesterday I had to stop drinking water and have less tea and all of that stuff to try and, and I'm raging a bit at myself because it would have told me whether I was successful or not today but it is handy knowing day to day what you weigh. [Male, 54 years, inadequate self-care]

Extrinsic Drivers

Participants also discussed how many of the motivating factors for engaging in self-care activities were driven by extrinsic factors. Specifically, participants reported feeling safe as they perceived they were being watched by someone. Their social support structures encouraged the use of the system, and it also acted as a mechanism to encourage conversation with friends and family about health-promoting activities:

But I certainly will talk, like I do discuss it with her, I discuss it with her quite regularly, is this normal

and is that normal, you know, and just her, like she set the target for me at 8000, and that's going back quite some time ago. [Female, 71 years, adequate self-care]

I found I was doing it and the lads were doing it. I said I look, I have this fitbit—"is that expensive that." They start doing it as well. That type of thing. So I just pace off and the lads would pace off as well. That sort of thing was good. It was sort of like, four people playing together and rather than one person pacing off, everyone was. It was sort of a fun thing to do, I'll put it that way. everyone was sort of happy to do it and we all fell in line with one another. [Male, 68 years, adequate self-care]

Discussion

Principal Findings

This study provides a detailed description of the design, development, and initial evaluation of an evidence-based, human-centered DHT designed to promote effective self-care in patients with HF. The mixed methods evaluation demonstrated that it was generally easy to use, positively affected their motivation to engage in key self-care behaviors, provided them with skills and perceived knowledge that made them more aware of the importance of self-care behaviors, positively influenced their confidence, and facilitated help seeking. This process also identified aspects of the system that required further attention before progressing to the next stage of development and evaluation.

Although this research is not the first to use technology in the quest to promote self-care in HF, the effectiveness of previous solutions has been relatively inconsistent. A systematic review by Cajita et al [40] investigating mobile health-based HF interventions demonstrated that the impact of the developed systems on end points such as all-cause mortality, cardiovascular mortality, HF-related hospitalizations, length of stay, New York Heart Association functional class, left ventricular ejection fraction, quality of life, and self-care were inconsistent at best. One of the key reasons put forward for the lack of success of these solutions is their failure to thoroughly integrate users' perspectives at the point of design. This results in the development of solutions that are not user-centric and will likely not drive continued engagement, failing to affect behavior in the long term [12-14]. To address this limitation, our research followed a best practice HCD approach, as outlined in the International Organization for Standardization 9241-210:2019 regulations, to ensure the development of a system that places the user at the center, maximizing the potential positive impact on self-care behaviors and quality of life [16]. This process involved initial patient interviews and HF literature consultations, followed by behavior change mapping to develop evidence-informed design concepts. These were then used to guide the development of the technical requirements and initial wireframe prototyping. A version 1 system was then developed and subsequently evaluated using a mixed methods approach with a cohort of patients with HF. This theory-driven approach ensured that the evidence backed the development of a system

that was not only usable but was best placed to drive self-care behavior change. This approach of combining HCD with behavior change theory has led to the successful development of other DHTs, such as that developed by Korpershoek et al [15] for chronic obstructive pulmonary disease (COPD). Korpershoek et al [15] used an HCD process to design and develop a system to enhance self-management in patients with COPD. Following an approach similar to that followed in our research, they demonstrated that the developed DHT met the needs and preferences of patients with COPD and therefore had a high potential to be effective in reducing exacerbation impact. Although within a different chronic disease context, the overarching principles remain the same, demonstrating the value of engaging in an HCD approach. One of the key aspects of the developed system is the use of a consumer-wearable activity tracker. This approach was leveraged because of the outcome of the initial qualitative interviews conducted in study 1, where patients highlighted the need for devices that did not draw attention to their condition. Although this is one of the first studies to outline the comprehensive development of DHT-leveraging consumer technology for this population, similar approaches have been used within the context of cardiac rehabilitation. The iCardia system was developed using user-centered design approaches and was designed to support remote monitoring and health coaching in cardiac rehabilitation. Interestingly, the iCardia system predominantly centered on remote monitoring by specialists, whereas the DHT described in this paper was designed to empower patients to take control of their condition and engage in effective self-care behaviors. This is an important distinction, as it is acknowledged that engaging in effective HF self-care and disease management is central to reducing the burden on patients and the health system [3-5].

The use of a science-driven approach to design within this work has led to the development of a solution that may be more likely to be used by patients with HF and successfully promote self-care behaviors, positively influencing the impact of their condition on their quality of life. However, further research is required to investigate this in full. High engagement with the technology was highlighted by excellent compliance with wearing the activity tracker and completing daily weighing during the 14-day trial. Furthermore, although the 2-week trial did not lend itself to robustly evaluate the longitudinal impact on self-care behaviors, the results of the EHFScBS questionnaire completed at enrollment highlight the impact of the system on behaviors in the short term. For example, only 33% (3/9) of participants initially reported completing daily weighing at the commencement of the study. Despite this, during the 2-week trial, 56% (5/9) of participants weighed themselves every day, whereas the remaining 44% (4/9) of participants weighed themselves on days 13, 12, 11, and 10. Furthermore, the qualitative analysis highlighted that using the system resulted in increased awareness and consciousness of their weight, noting the impact of lifestyle factors on fluid retention and associated increases in weight. This indicates that the solution may address the key behavior outcome of facilitating the daily management of fluid status through weight monitoring (key target 2). Similarly, perceived increases in awareness and self-care skills were identified by patients in relation to physical activity

behaviors (key target 1), with many participants identifying that the system increased their motivation to engage in exercise, aided goal setting/achievement, and helped them with pacing strategies. Importantly, many participants also identified a positive relationship between the perceived increase in physical activity and improvement in their symptoms. The impact on motivation to engage in physical activity was also highlighted by the high WTMS score (median 5.9, range 5.1-7). In addition, the effect on key aspects of self-care behavior is of note, as an inability to link relevant changes with an evolving condition has been identified as a key trait in patients with HF [6]. The short 2-week trial suggests a positive impact on self-care behaviors, along with excellent engagement with technology. However, it is possible that engagement may decrease over extended periods, reducing the positive impact on self-care behaviors [41]. As such, it is planned that future research will investigate the impact of this technology over a longer period.

The key targets of the solution were to support patients in understanding the signs and symptoms of HF and facilitate timely help-seeking behaviors. Although it was beyond the scope of this initial evaluation to thoroughly investigate this, participants reported an increase in their awareness of their condition and how self-care behaviors can positively affect their condition. Furthermore, one of the participants (male aged 84 years) used the *not feeling well* functionality to report a recent increase in dizziness to the cardiology team during the 2-week trial. This resulted in prompt consultation and review with the cardiology team to determine if the intervention was further required. In this instance, the participant showed the ability to link changes in symptoms with a potential alteration in their condition, with the system facilitating timely help seeking. The final key target of the solution was to promote medication adherence. Despite participants in the initial study requesting such a feature in a digital solution, only 22% (2/9) of participants used the medication reminders. The qualitative interviews highlighted that the main reason for this was that most participants reported having a relatively simple medication regime that required most medications to be taken in the morning or evening. Indeed, the participants reported having their own reminder systems or triggers in place. Why these appear to be more easily integrated into their routines than other self-care behaviors needs to be explored in greater depth. Furthermore, it must be considered that self-reported adherence to medication regimens may not reflect true adherence [42]. The 2 participants who used the medication reminder component did so for individual medications that did not follow their typical regimen. As such, although most participants did not engage with this feature during the 2-week trial, it may still be useful for the selection of patients who have more complex dosing regimens.

The solution developed in this process focused on key skills, as informed by the *empathize* stage. Although a broader intervention that endeavored to incorporate all aspects of HF self-care could have been attempted, it was decided that a pragmatic approach to the development of a simple targeted system would be most appropriate, focusing on key behaviors

identified by Clark et al [6] and addressing the key needs highlighted during requirement gathering (study 1). It is envisaged that if the version 1 system is successful in driving targeted behavior change, features designed to address additional behaviors could be iteratively added to the solution. This stepwise approach aligns with the guidelines for the development of complex interventions [33,34] and has been applied in the development of chronic disease management DHTs [15].

A key limitation of the evaluation component of this study was that participants were required to be smartphone users and have access to the internet to ensure an adequate level of technology literacy. Although this results in a nonrepresentative sample of the HF population, the key aim of the study was to investigate the perceived impact of the system on self-care behaviors without the requirement to provide extensive training in smartphone use before being able to interact with the newly developed system. This factor reduces the generalizability of these findings to wider HF cohorts, and future HCD efforts should focus on identifying the additional features and/or training required to ensure suitability for a wider, more representative sample of patients with HF. It should also be considered that over time, it is likely that a high proportion of patients with HF will be technologically literate smartphone users.

Despite the promise of these findings, the design, development, and initial 2-week evaluation form the first key steps in the process; however, it is clear that further research is required before this system is incorporated into clinical practice. To do so, we are engaged in a 6-month observational trial to investigate the feasibility and utility of this system; establish whether engagement remains high; and observationally evaluate whether the solution affects end points such as quality of life, self-care behaviors, hospitalizations, and mortality. Furthermore, we seek to understand how best to incorporate the developed technology within a health care system to ensure that it fits into the daily practices of health care professionals. If this work is successful, a full-scale evaluation within a randomized control trial may be warranted to investigate whether the solution is efficacious when compared with standard care.

Conclusions

This study describes in detail the HCD approach used in the development of a DHT to promote self-care in patients with HF. This science-informed methodology has resulted in the development of a system that patients indicate is easy to use, positively affected their confidence and motivation to engage in key self-care behaviors, provided them with skills and knowledge that made them more aware of the importance of self-care behaviors, and might facilitate timely help seeking. This science-driven design process will lay the groundwork for further development and evaluation of this solution before its implementation in health care systems. Furthermore, a detailed description of the HCD process used in this research will help guide the development and evaluation of future digital health solutions across a range of disease use cases.

Abstract

Background: An accurate evaluation of the nutritional status of malnourished hospitalized patients at a higher risk of complications, such as frailty or disability, is crucial. Visual methods of estimating food intake are popular for evaluating the nutritional status in clinical environments. However, from the perspective of accurate measurement, such methods are unreliable.

Objective: The accuracy of estimating leftover liquid food in hospitals using an artificial intelligence (AI)–based model was compared to that of visual estimation.

Methods: The accuracy of the AI-based model (AI estimation) was compared to that of the visual estimation method for thin rice gruel as staple food and fermented milk and peach juice as side dishes. A total of 576 images of liquid food (432 images of thin rice gruel, 72 of fermented milk, and 72 of peach juice) were used. The mean absolute error, root mean squared error, and coefficient of determination (R^2) were used as metrics for determining the accuracy of the evaluation process. Welch t test and the confusion matrix were used to examine the difference of mean absolute error between AI and visual estimation.

Results: The mean absolute errors obtained through the AI estimation approach were 0.63 for fermented milk, 0.25 for peach juice, and 0.85 for the total. These were significantly smaller than those obtained using the visual estimation approach, which were 1.40 ($P<.001$) for fermented milk, 0.90 ($P<.001$) for peach juice, and 1.03 ($P=.009$) for the total. By contrast, the mean absolute error for thin rice gruel obtained using the AI estimation method (0.99) did not differ significantly from that obtained using visual estimation (0.99). The confusion matrix for thin rice gruel showed variation in the distribution of errors, indicating that the errors in the AI estimation were biased toward the case of many leftovers. The mean squared error for all liquid foods tended to be smaller for the AI estimation than for the visual estimation. Additionally, the coefficient of determination (R^2) for fermented milk and peach juice tended to be larger for the AI estimation than for the visual estimation, and the R^2 value for the total was equal in terms of accuracy between the AI and visual estimations.

Conclusions: The AI estimation approach achieved a smaller mean absolute error and root mean squared error and a larger coefficient of determination (R^2) than the visual estimation approach for the side dishes. Additionally, the AI estimation approach

achieved a smaller mean absolute error and root mean squared error compared to the visual estimation method, and the coefficient of determination (R^2) was similar to that of the visual estimation method for the total. AI estimation measures liquid food intake in hospitals more precisely than visual estimation, but its accuracy in estimating staple food leftovers requires improvement.

Introduction

Background

The prevalence of malnutrition among hospitalized patients is reportedly between 20% and 50% [1], and this rate is significantly high among patients who are older or who have cancer [2]. Malnourished hospitalized patients are at a higher risk of complications, such as pressure ulcers, infections [3], and frailty [4]. These are the risk factors of disability associated with daily living activities, and they can result in death [5,6]. In current superaged societies, malnutrition poses an increased risk. Therefore, an accurate evaluation of the nutritional status of hospitalized patients is crucial for the prevention of malnutrition among such patients [7].

Nutritional status is determined by anthropometric parameters (eg, body mass index) and laboratory parameters (eg, ion or protein concentration). Patients' food intake can also be used as an assessment metric because it affects their nutritional status [8]. Based on weight, the median plate waste in hospitals is 30% higher than that in other food service sectors [9]. Therefore, measurement and assessment of the actual amount of food consumed by patients are necessary.

The most accurate method for measuring food intake among hospitalized patients involves weighing foods before and after consumption [10]. Although this method optimizes accuracy, it is labor-intensive and requires space for holding soiled trays to measure waste [11]. In clinical environments, a popular method for evaluating food intake involves direct observation by medical staff. This approach is commonly referred to as the visual estimation method. However, it has been reported that the accuracy of the visual estimation method is lower than that of the weighing method [12,13], and the results obtained through these methods tend to vary depending on the training of the medical professionals and their job categories [14,15]. Additionally, although the measurement approach is simple, various problems exist, such as the fact that patients are often asked to measure their own food intake. This request is made because it is difficult for medical professionals to check all the food.

Recently, there have been significant advancements in the field of artificial intelligence (AI), and technological approaches for image analysis—such as organ segmentation [16] and lesion detection support [17]—have been utilized in various medical fields. Therefore, AI-based technological approaches can be

applied to ensure improved accuracy in the measurement and evaluation of food intake among hospitalized patients. Additionally, such methods are more convenient than visual estimation methods because they estimate the remaining amount of food using digital images of food obtained through photography.

Currently, there exists an AI-based system that can estimate the classifications and names of foods through photographic images [18,19]. Additionally, Ege et al [20] proposed an AI-based system for estimating calories through the selection of recipes that match each food detected from photographic images. However, their proposed AI-based system estimates the caloric intake by identifying the predetermined menu based on photographic images of the meal before consumption. Therefore, there is no system that can be used to accurately measure and evaluate the actual amount of food consumed by considering the leftover amount.

Objective

In this study, an AI-based model was developed that can be used to estimate the amount of leftover liquid food by learning the pattern of leftover liquid food obtained from images of liquid food in hospitals. There were three tasks associated with the estimation of leftovers from images of different foods. An object-detection approach was developed in this study for detecting multiple types of food on a tray and a classifier for determining the names of foods matching those in the detected object. Furthermore, the accuracy of the remaining task was evaluated because it pertains to the measurement and estimation of leftover liquid food.

Methods

Measurement of Leftover Liquid Food in Hospitals

Liquid foods were photographed to evaluate their leftovers (Figure 1). The liquid foods used in this study were similar to those provided to hospitalized patients, with multiple food items served on a tray.

The menu comprised a combination of staple food, side dishes, packaged beverages, and seasonings. The types of liquid foods are listed in Table 1. The leftover plates were evaluated through a measurement of the actual amount of each liquid food item on a digital scale, so that the leftovers of each liquid food item were on an 11-point scale ranging from 0 to 10 (Table 2).

Figure 1. Example of liquid food served on a tray in hospitals.**Table 1.** Types of dishes and number of images used for artificial intelligence (AI) training and evaluation.

Type of food and liquid food name	Training images, n	Evaluation images, n	Accuracy evaluation
Staple food			
Thin rice gruel	504	432	✓ ^a
Side dishes 1			
Japanese clear soup	144	72

Salt	504	432	

^aThe checkmark indicates the liquid foods used for accuracy evaluation.

Table 2. Actual measurement of the converted values of the leftover liquid food.

Converted value	Leftover liquid food
0	Ingesting 5% or less of the entire amount.
1	Ingesting between 5% and 15% of the entire amount.
2	Ingesting between 15% and 25% of the entire amount.
3	Ingesting between 25% and 35% of the entire amount.
4	Ingesting between 35% and 45% of the entire amount.
5	Ingesting between 45% and 55% of the entire amount.
6	Ingesting between 55% and 65% of the entire amount.
7	Ingesting between 65% and 75% of the entire amount.
8	Ingesting between 75% and 85% of the entire amount.
9	Ingesting between 85% and 95% of the entire amount.
10	Ingesting 95% or more of the entire amount.

AI estimation was conducted by analyzing the liquid food images using an AI-based model for estimating leftover liquid food. All images of the lunch menu containing thin rice gruel, fermented milk, and peach juice were evaluated. Visual estimation was conducted by a person looking at similar liquid food images. Images were randomly selected from the images of the lunch menu containing rice gruel, fermented milk, and peach juice so that all the dishes with 0 to 10 leftovers of each dish were evaluated, and dietitians and students evaluated the same images. Each method used an 11-point scale to estimate the leftover liquid food. Visual estimation was performed by 10 dietitians from Tokushima University Hospital and 6 students from the Department of Medical Nutrition, Tokushima University. A total of 576 images of liquid food (432 images of thin rice gruel, 72 of fermented milk, and 72 of peach juice) were analyzed through AI estimation and visual estimation.

Ethics Approval

This study was conducted as part of a study approved by the clinical research ethics committee at Tokushima University Hospital (#3758).

Data Set

For a single menu, 12 types of liquid food images were created, each comprising the following portions: the state before eating (no. 1 in Table 3), in which the amount of leftover liquid food was 100%; 10 combinations of the states with some leftovers (nos. 2-11 in Table 3), in which the amounts of leftovers for each liquid food were at 0%, 10%, 20%, 30%, 40%, 50%, 60%, 70%, 80%, and 90%; and the state with no leftovers (no. 12 in Table 3), in which the amount of leftover liquid food was 0%.

Table 3. List of leftover liquid food combinations prepared for each grouping of dishes.

Number	Category	Staple food ^a	Side dishes 1 ^a	Side dishes 2 ^a
1	Before eating	10	10	10
2	Some leftovers	1	9	8
3	Some leftovers	3	8	6
4	Some leftovers	5	7	3
5	Some leftovers	7	6	1
6	Some leftovers	9	5	5
7	Some leftovers	0	4	2
8	Some leftovers	8	3	0
9	Some leftovers	6	2	7
10	Some leftovers	4	1	4
11	Some leftovers	2	0	9
12	No leftovers	0	0	0

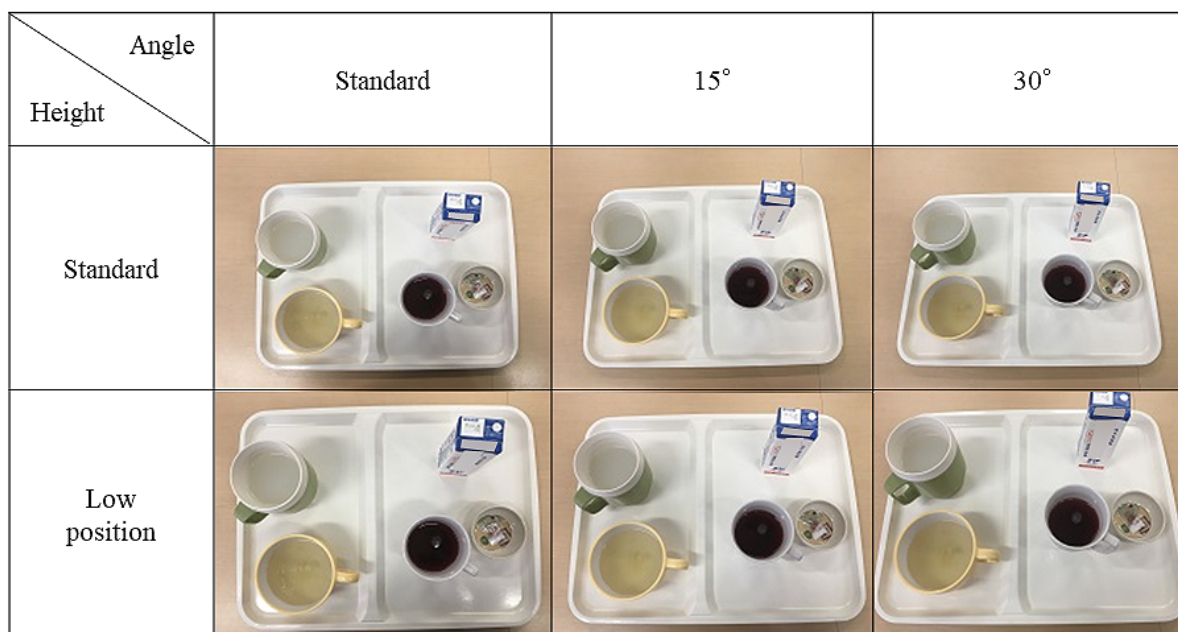

^aConverted values of the leftover liquid food.

For the camera position, the standard angle was the angle taken from directly above the liquid food tray at the height where the entire tray was contained, and the margin maintained (Figure

2). Angles of 15° and 30° were added to the standard angle. Additionally, the camera was repositioned to a lower position that included the entire tray and eliminated any blank space.

Similarly, angles of 15° and 30° were added to the standard angles. A total of 6 different liquid food images were created for a single portion of a single menu.

Figure 2. Photographs of a single portion of a single menu taken from six different camera positions.

In this study, liquid food images were taken separately for breakfast, lunch, and dinner on multiple dates and times, each under different conditions, such as light coming in from outdoors, for application in clinical environments. Images of the breakfast and dinner foods were used as the training images, and images of the lunch foods were used as the evaluation images. Therefore, the photographic environments for the training and evaluation images differed. The liquid foods used for accuracy evaluation are listed in Table 1.

AI-Based Model for Estimating Leftover Liquid Food

A convolutional neural network (CNN), which is commonly applied in AI-based image analysis approaches, was used to analyze the liquid food images employed in this study. The AI-based model comprises two parts: (1) an object-detection part that identifies the positions of multiple dishes on a tray and extracts their regions from a single liquid food image and (2) a leftover-estimation part that classifies the names of liquid foods associated with the detected objects and estimates the amount of leftover liquid food. YOLOv3 [21] was used for object detection, following training using the FoodLog data set [22]. This is a one-class detection model with the liquid food region as the foreground and the others as the background. A multitask CNN was used to classify the names of liquid foods and estimate the leftover liquid food. Liquid food name classification is a task that consists of classifying 17 different liquid food names, and leftover estimation is a task that consists of classifying leftover liquid food on an 11-point scale. The architecture of the multitask CNN involved a calorie-volume estimation model based on the method proposed by Ege et al [23]. Both tasks were shared up to the last fully connected layer of ResNet50v2 [24], thereby resulting in 512-dimensional fully connected output layers for each task. The training process was fine-tuned

using data prepared for this study through the ImageNet training model published by GluonCV [25] as the initial parameter. The loss function L for training was calculated as follows:

$$L = L1 + L2$$

where L1 represents the cross-entropy loss for liquid food name classification, and L2 represents the cross-entropy loss for estimating the amount of leftover liquid food. The AI-based model development was performed using Python (version 3.6.5) as the programming language and PhpStorm and PyCharm as the integrated development environment.

Accuracy Evaluation

The accuracies of the AI estimation and visual estimation methods were compared using actual measurements obtained through the weighing method employed for each staple food (thin rice gruel) and the side dishes (fermented milk and peach juice) as well as the total of these three liquid foods combined. The images of the side dishes created in different conditions for the training and evaluation processes were those of fermented milk, peach juice, grape juice, and orange juice. Fermented milk images, which had the lowest AI estimation accuracy, and peach juice images, which had the highest accuracy, were selected. Then, visual estimation was used to evaluate these images and those of the staple food (thin rice gruel).

In the hospital setting, liquid foods primarily contain milk, milk-based products including oatmeal, and clear liquid food [26]. In this study, menus that corresponded to these categories were selected. Thin rice gruel was selected because rice is often used in place of oatmeal in Japanese hospitals. Packaged beverages, salt, and seasonings were excluded from this study

because it is difficult to evaluate such leftover foods through visual estimation.

Bland-Altman plots were used to examine the differences between the estimated and measured values and the limits of agreement were calculated as the mean difference ± 1.96 SD. The mean values of the measurements were calculated, and a paired *t* test was used to examine the differences.

There are two types of AI models: classification models, which are used to classify the category to which the objective variable belongs, and regression models, which are used to calculate the estimated value of the actual measured value. In this study, the estimated value of the continuous scale was used to estimate the amount of leftover liquid food, which is the average of the classification results achieved through multiple classification models. Because the AI-based model for estimating leftover liquid food predicts the estimated value of the actual measured value, mean absolute error, root mean squared error, and coefficient of determination (R^2) were used as metrics for determining the accuracy of the evaluation process. The mean absolute error was calculated as follows:

$$\frac{1}{n} \sum_{i=1}^n |x_i - y_i|$$

where *x* represents the estimated value, and *y* represents the measured value.

Welch *t* test was used to examine the differences between the AI estimation and visual estimation approaches in terms of the absolute error.

The root mean squared error squares the errors and then averages them, so that large errors are weighted more heavily. It is a useful metric when large errors are not particularly desirable. The root mean squared error was calculated as follows:

$$\sqrt{\frac{1}{n} \sum_{i=1}^n (x_i - y_i)^2}$$

The coefficient of determination (R^2) indicates the insignificance of the error compared to that of a model that always returns the average of the measured values. The closer the value is to 1, the higher its accuracy. It was used as a relative evaluation metric of which estimate was closer to the actual measurement—the AI estimation or the visual estimation. R^2 was calculated as follows:

$$1 - \frac{SS_{res}}{SS_{tot}}$$

In addition, a confusion matrix of the estimated and measured values was created to evaluate the distribution of the absolute errors. The confusion matrix compares the measured values with the estimated values to evaluate which values have been incorrectly estimated. Statistical analyses were performed using SPSS Statistics version 24 (IBM Corp).

Results

Differences Between Estimated and Measured Values

The limits of agreement from the Bland-Altman plot estimated and measured values for AI estimation and visual estimation were -3.4 to 2.1 and -3.4 to 2.7 (thin rice gruel), -0.8 to 1.9 and -4.4 to 2.5 (fermented milk), -1.0 to 0.9 and -3.0 to 1.9 (peach juice), -3.0 to 2.2 and -3.5 to 2.6 (total) (Figure 3). The differences between the estimated and measured values by AI estimation for fermented milk and peach juice were particularly small. The value of the measurements by AI estimation for peach juice was not significantly different from the estimated value (4.53) and the measured value (4.58) (Table 4). The estimated value by AI for fermented milk (5.15) was significantly larger than the measured value (4.58). For the rest, the estimated value was significantly smaller than the measured value.

Figure 3. Bland-Altman analysis of the differences between estimated and measured values of leftover liquid food. AI: artificial intelligence.

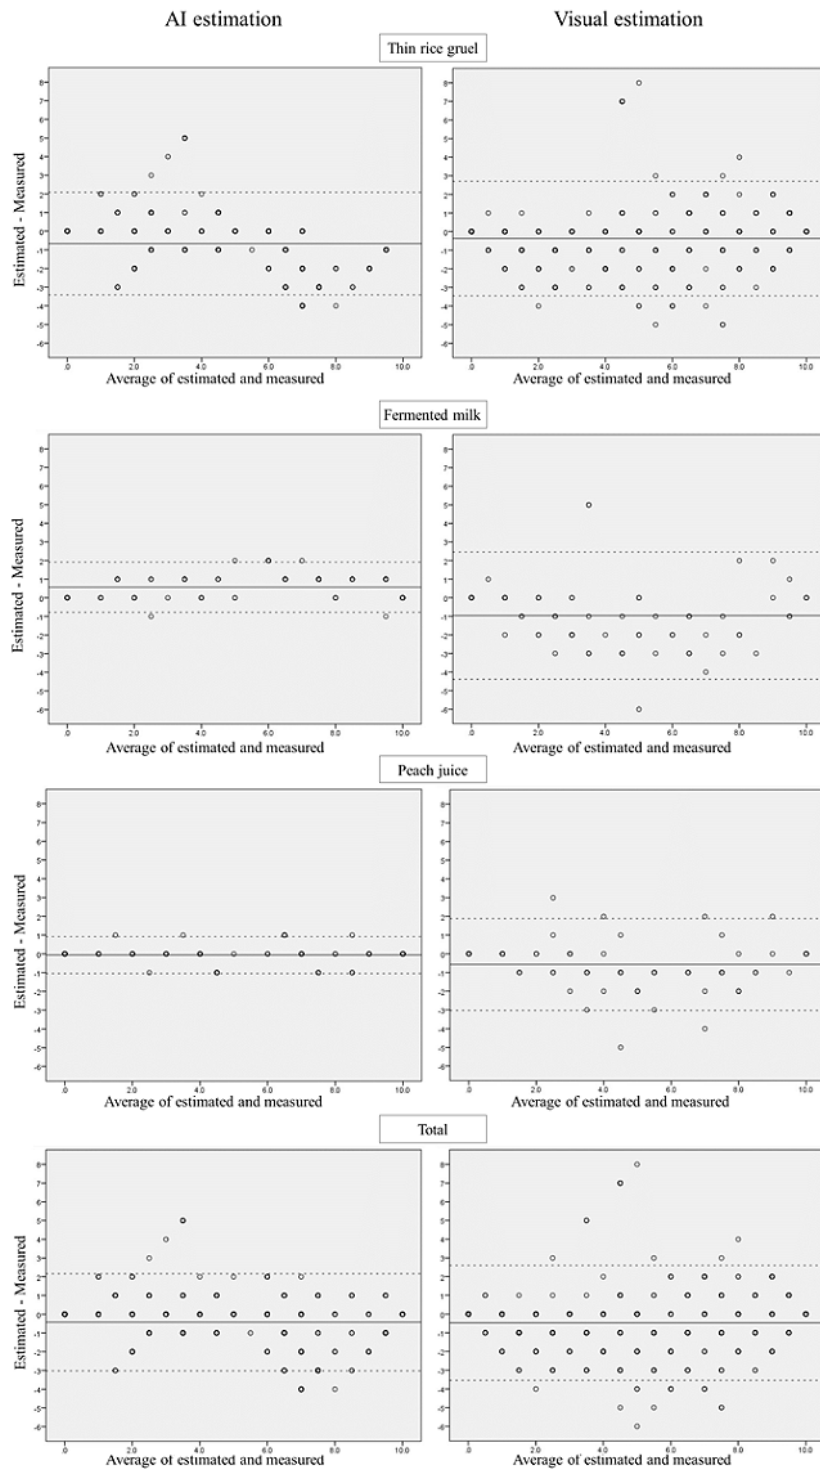

Table 4. Comparison of estimated and measured values of leftover liquid food.

	Leftover food, n	Measured value	AI ^a estimation		Visual estimation	
			Estimated value	P value	Estimated value	P value
Thin rice gruel	432	4.58	3.93	<.001	4.21	<.001
Fermented milk	72	4.58	5.15	<.001	3.62	<.001
Peach juice	72	4.58	4.53	.35	4.01	<.001
Total	576	4.58	4.15	<.001	4.11	<.001

^aAI: artificial intelligence.

Mean Absolute Error

The mean absolute error of staple food leftovers obtained using the AI estimation approach (0.99) was not significantly different from that obtained via visual estimation (0.99) (Table 5). Moreover, the mean absolute errors obtained through the AI estimation approach for side dishes were 0.63 for fermented

milk and 0.25 for peach juice. These were significantly smaller than those obtained using the visual estimation approach for fermented milk (1.40) and peach juice (0.90). The total mean absolute error obtained through AI estimation (0.85) was also significantly smaller than that obtained through visual estimation (1.03).

Table 5. Mean absolute errors obtained using the AI^a estimation and visual estimation methods.

	Images, n	AI estimation	Visual estimation	P value
Thin rice gruel	432	0.99	0.99	.96
Fermented milk	72	0.63	1.40	<.001
Peach juice	72	0.25	0.90	<.001
Total	576	0.85	1.03	.009

^aAI: artificial intelligence.

Root Mean Squared Error

The root mean squared error tended to be smaller for the AI estimation of thin rice gruel (1.55), fermented milk (0.89), peach

juice (0.50), and total (1.39) than that for the visual estimation of thin rice gruel (1.61), fermented milk (1.98), peach juice (1.37), and total (1.64) (Table 6).

Table 6. Root mean squared error obtained using the AI^a estimation and visual estimation methods.

	Images, n	AI estimation	Visual estimation
Thin rice gruel	432	1.55	1.61
Fermented milk	72	0.89	1.98
Peach juice	72	0.50	1.37
Total	576	1.39	1.64

^aAI: artificial intelligence.

Coefficient of Determination

The coefficient of determination (R^2) for staple foods tended to be smaller for the AI estimation method (0.69) than for the visual estimation (0.78) method. However, the coefficient of determination (R^2) for side dishes tended to be larger for the AI

estimation of fermented milk (0.94) and peach juice (0.98) than that for the visual estimation of fermented milk (0.62) and peach juice (0.82) (Table 7). The R^2 value for the total was equal in terms of accuracy between the AI estimation (0.78) and visual estimation (0.77) methods.

Table 7. Coefficient of determination (R^2) for the AI^a estimation and visual estimation methods.

	Images, n	AI estimation	Visual estimation
Thin rice gruel	432	0.69	0.78
Fermented milk	72	0.94	0.62
Peach juice	72	0.98	0.82
Total	576	0.78	0.77

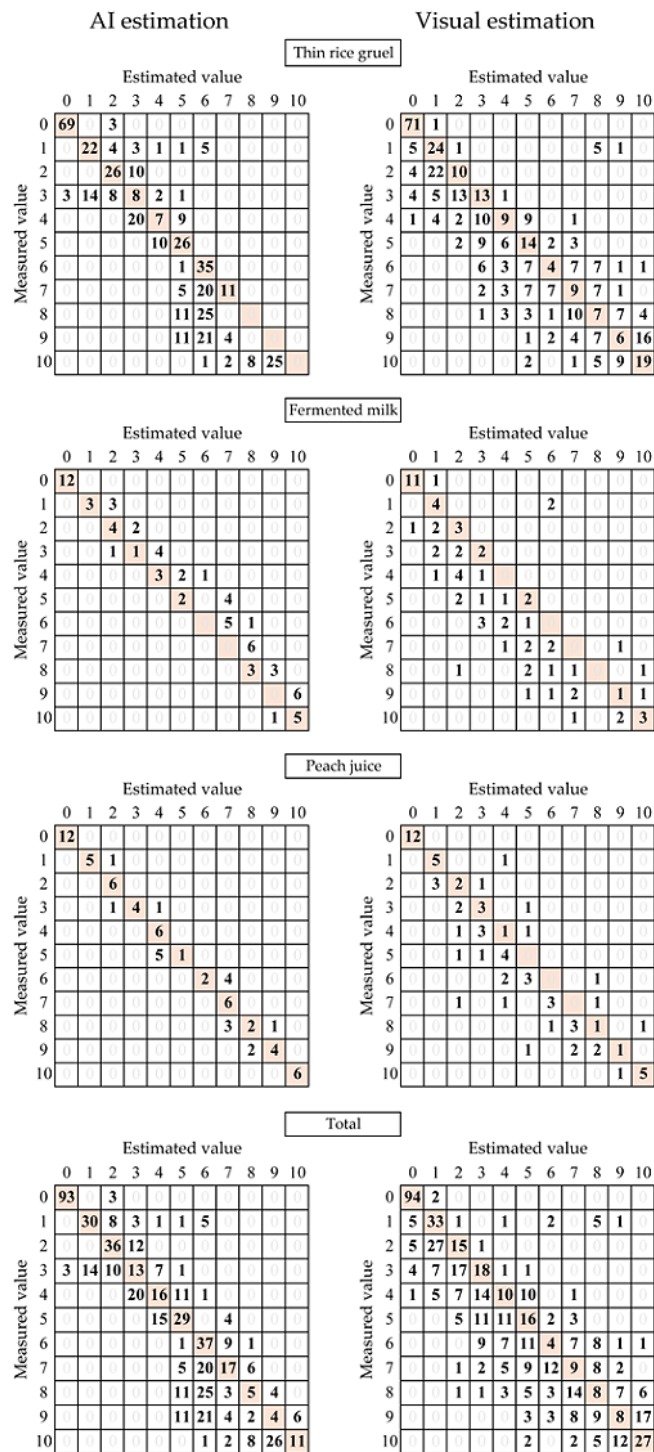

^aAI: artificial intelligence.

Distribution of Errors

The confusion matrix for staple foods (Figure 4) shows variation in the distribution of errors, indicating that the errors in the AI estimation were biased toward the case of many leftovers. The values converged to a specific estimated value, as the estimated values were biased toward 6 for images with measured values of 6 to 9. In addition, many evaluations estimated that the

estimated value was less than the measured value for both the AI estimation and visual estimation methods. However, for the confusion matrix of side dishes, the AI estimation had a small error, and the estimated and measured values were in close agreement, whereas the visual estimation demonstrated a large variability. The confusion matrix for the total also showed the same trend as for the staple food, with more evaluations estimating that the leftover was less than the measured value.

Figure 4. Confusion matrices of the estimated and measured values. AI: artificial intelligence.

Discussion

Principal Findings

The AI estimation approach achieved a smaller mean absolute error and root mean squared error and a larger coefficient of determination (R^2) than the visual estimation approach for the side dishes. Additionally, the AI estimation approach achieved a smaller mean absolute error and root mean squared error

compared to the visual estimation method, while the coefficient of determination (R^2) was similar to that of the visual estimation method for the total. These results indicate that the accuracy of the AI estimation method was high, except for staple foods. In particular, peach juice was highly reliable because there was no difference between the AI estimation and the weighing method. Underestimating liquid food consumption can lead to incorrect nutritional guidance, whereas a correct assessment of

food intake can lead to improvement through nutritional intervention.

The accuracy of estimation through the AI-based model was evaluated by comparing the estimated value to that of the actual measured value using the weighing method. For the accuracy indicator of the continuous scale, it is recommended to use the mean absolute error and the root mean squared error when evaluating the prediction performance of the same scale and applying measures, such as the coefficient of determination (R^2), when outliers are included [27]. Therefore, three indicators—the mean absolute error, the root mean squared error, and the coefficient of determination (R^2)—were used in this study. On the other hand, previous studies of human visual estimation of photographed food images have used mean differences as the accuracy indicator [28]. The analysis has been reported to be highly reliable for visual estimation using food images because it is highly correlated with the actual value obtained via the weighing method.

The visual estimation approach used in this study was as accurate as the visual estimation method used in previous studies. The AI estimation approach achieved higher accuracy than the visual estimation approach, suggesting that the AI estimation approach is more reliable for the precise measurement of liquid food intake. Moreover, the mean absolute error achieved through the AI estimation method was 8.5% in this study, indicating that the goal of this measurement method in clinical contexts was also achieved because the measurement method used in clinical contexts should have an error of less than 10% using the weighing method [29].

Regarding the side dishes, the AI estimation approach had a small error and was in close agreement with the measured values (Figure 4). The value of the coefficient of determination (R^2) was also large, but it was smaller for staple foods. However, there was no difference in the mean absolute error. These results suggest that a large percentage of AI estimators made evaluations that had large errors. The confusion matrix shows that estimates for images with actual values ranging between 6 and 9 were biased toward 6, and the image features for distinguishing between 6 and 9 were not well discovered during the training process. For staple foods, the fact that the error grew larger when there was a large amount of leftover liquid foods remains an issue. In this study, liquid foods were prepared such that the number of cases per leftover would be equal, to make it easier to discern the accuracy of each leftover. However, in a previous study conducted in a clinical environment, the mean value of food intake was 82.5% [15]. Therefore, it is conceivable that the accuracy of the AI estimation could be even higher in actual clinical environments because there is less leftover food.

Liquid foods are recognized via the information obtained from the image, such as its color, whether it is well-lit, and its density [19]. In this study, the color and density of the liquid food were ascertained from this information. The fact that the accuracy levels achieved through AI estimation varied significantly

among different liquid food types suggests that the estimation was affected by differences in color between the liquid food and the dish and the density of the liquid food. In this study, dishes that were actually served to patients in hospital wards were used, assuming a demonstration in clinical contexts. The thin rice gruel was pale white, and the dishes were white, thus similar in color. Furthermore, it was difficult to distinguish the border between liquid food and dishes because thin rice gruel is translucent and thick. This attribute may be the reason for the lower accuracy obtained compared to that of fermented milk, which is similar in color. Therefore, the accuracy of AI estimation for thin rice gruel could be improved by changing the color of the dish to a non-white color.

Limitations

There are four limitations of this study. First, images of hospital liquid food taken using a camera were used for the visual estimation process to compare it with the AI estimation process. In clinical contexts and environments, medical staff estimate and record dietary intake by looking at the actual food. Therefore, it is also necessary to compare the results of the visual estimation approach by ensuring that medical staff look at the actual foods provided to patients and compare the results with those achieved through the AI estimation of food images taken in wards. Second, packaged beverages were excluded from this study because it is difficult to evaluate leftover liquid foods through visual estimation. For such foods, it is necessary to consider methods such as measuring by transferring the leftover liquid food to another dish. Third, this study is limited to the evaluation of liquid food images in a single institution. Because the menus and plates of liquid foods served to patients vary from institution to institution, it is necessary to evaluate whether the training images used in this study can be used to estimate the amount of leftover liquid food in multiple institutions while determining the additional training images required for each. Finally, the usability of the proposed AI-based measurement method is unclear. In daily use, systems that use image analysis to support food recording have been evaluated for their usability [22]. In clinical contexts and environments, further research is required to evaluate whether the use of AI-based measurement methods can be easily executed by medical staff.

Conclusions

The proposed AI-based model demonstrated improved accuracy in the measurement and evaluation of leftover side dishes and similar accuracy levels for the total leftovers compared to the visual estimation method for leftover liquid foods. Additionally, errors incurred in the AI estimation approach were within the acceptable range of the weighing method, thereby indicating that the proposed AI-based model for estimating the amount of leftover liquid food can be applied in clinical contexts and environments. However, further evaluations and improvements of the AI-based model presented in this study are necessary for the development of an AI estimation method that can be used to accurately measure the intake of liquid food in hospitals.

Abstract

Background: Type 2 diabetes (T2D) is increasingly prevalent in society, in part because of behavioral issues, with sedentary behavior, reduced exercise, and the consumption of foods with a high glycemic index being major contributors. There is evidence for the efficacy of mobile apps in promoting behavior change and lifestyle improvements in people with T2D. Many mobile phone apps help to monitor the condition of people with T2D and inform them about their health. Some of these digital interventions involve patients using apps on their own or in conjunction with health care professionals.

Objective: This study aimed to test the acceptability of receiving app-based, daily physician feedback for patients with T2D that is informed by the continuous monitoring of their activity, food choices, and glucose profiles, with the aim of encouraging healthier behavior. The *GLOOK!* app was designed and developed by an academic research team and pilot-tested at an Australian public hospital.

Methods: A total of 15 patients diagnosed with T2D wore a glucose monitor and an Apple Watch for 12 days. The uploaded data were integrated into the *GLOOK!* app on the patients' smartphones, which also enabled the recording of activity and consumed food. A physician provided daily feedback to each individual through the app based on their data from each of the 12 days. At the beginning and end of the study, data were collected on vital signs, anthropometry, hemoglobin A_{1c} level, fructosamine level, and fasting lipids level. Participants were also interviewed at the beginning and end of the study to assess the acceptability of the intervention and its potential impact on promoting positive behavior change.

Results: Over the 12 days of the study, there was a significant reduction of 0.22% ($P=.004$) in hemoglobin A_{1c} level. There were favorable changes in fructosamine and lipid fractions; however, none reached significance. There was also a fall of 0.65 kg in body weight and falls in blood pressure and pulse rate that did not reach significance. Patient feedback on the *GLOOK!* system was positive. Of the 15 participants, 13 (87%) were enthusiastic about continuing to use the app system if some usability and reliability aspects were improved. All participants regarded the personalized physician feedback as supportive and helpful in understanding their own health behavior. Of the 15 participants, 4 (27%) felt that using the system encouraged long-term behavior changes.

Conclusions: A mobile app system that provides people with T2D daily, physician-generated, personalized feedback can produce favorable changes in glycemic and cardiovascular risk parameters—even in the short term—and encourage better self-management of their condition. Study participants found the experience of using the mobile app system acceptable and were motivated to establish longer-term lifestyle improvements through behavior changes.

Introduction

Background

Type 2 diabetes (T2D) is a widespread chronic health condition that is increasingly prevalent in society, in part because of people's behavior. A lack of physical exercise and the consumption of foods with a high glycemic index are at the core of the current epidemic of obesity and increased risk of diabetes and consequent cardiovascular disease [1,2]. As T2D is the fastest growing chronic disease in Australia [3], there is a significant burden on the health system and on individuals themselves to manage their disease. Australian estimates put the prevalence of prediabetes at 10% (approximately 2 million people), with a conversion rate to diabetes of 2% to 3% per year. Known T2D affects 1.2 million Australians, with a further 500,000 undiagnosed cases, and health care costs are estimated at Aus \$14.6 billion (US \$10.9 billion) [4]. In addition, the high incidence of prediabetes amplifies this concern as these participants are destined to develop diabetes in the future and also intrinsically carry an increased cardiovascular risk. Current models of health care involve periodic reviews by health care professionals and delivery of education at a long interval of several months. This model often fails to provide sustained change, as multifaceted behavioral adjustments and commitment to self-care are required to achieve treatment goals [5]. We believe that more frequent and personalized feedback is likely to promote the motivation of patients with T2D to sustain positive behavior change by addressing their unmet need for self-care support [5,6].

The core activities in chronic disease self-management are medical management (medication and dietary advice adherence), management of necessary behavior changes, and managing emotions and feelings around coping with chronic diseases. This aspect of T2D treatment is relatively underdeveloped worldwide [7]. Improving systems for and providing active support with patient self-management can motivate sustained behavior change, reduce health complications, and reduce associated costs [6,7].

Several mobile health apps have been developed to help people with T2D self-monitor their condition and provide them with diabetes education and information. The increased use of health-related apps is partly because of their convenience, portability, and reach [3] and partly because of the high smartphone ownership; in 2021, almost 80% of Australians were estimated to be using smartphones [8]. Approximately 1800 of the >50,000 health care apps available on both the web-based app store and Google Play Store [9,10] were specifically for diabetes management [11], with diabetes being the primary chronic disease targeted by the mobile health industry, followed by asthma and depression [12]. Mobile app developers and publishers consider diabetes care in digital health as having the best market potential in any health field, with

artificial intelligence (AI) being a major transformative force in the sector. In diabetes self-management apps, AI can be used to perform the tasks of advanced analytics, machine learning, and symbolic reasoning to support patient decision-making [13]. Currently, diabetes management apps offer a range of features such as blood glucose meter interconnectivity, real-time feedback, fitness tracking, diabetes education, psychosocial support, tracking of sugar and glucose levels and meal content, and recommendations on meal changes [11].

Prior Work

Mobile phone interventions for diabetes self-management have been found to be a useful support in promoting health-related behavior changes. People tend to keep their phones with them constantly—even at night—thus providing an inexpensive, real-time delivery mechanism for health and behavioral support messaging [6]. Self-management apps for diabetes can help patients monitor their condition and provide input to self-education, complementing information about a more suitable diet [14]. Studies on the use of mobile apps for diabetes self-management suggest that useful features of apps include hemoglobin A_{1c} (HbA_{1c}) tracking and monitoring of medication, meals and nutrition, physical activity, physical health, and mental well-being. Apps can deliver up-to-date diabetes education and patient reminders about taking medication and engaging in physical activity [15-18]. Some apps include *coaching* in the form of telemanagement and 2-way consultations with health care providers, who can remotely follow up and provide recommendations based on patient-generated health data collected by the diabetes management app and system [12].

More than 10 systematic literature reviews of studies on the use of mobile apps for self-management of diabetes have been published in the past 5 years [3,11,12,14-22]. Overall, 57 primary studies were included in this review. These studies found that using diabetes self-management apps can significantly improve the health outcomes of patients with T2D. In 18 of the 25 reviews, Greenwood et al [18] found that HbA_{1c} (average blood glucose) levels were significantly reduced through the use of technology-based self-management solutions. Randomized controlled trials on apps used specifically in T2D management have shown positive outcomes for app users, particularly in lowering HbA_{1c} levels and hypoglycemia [12]. In addition, when people with T2D are able to connect data on their monitored glucose levels with self-generated data from other health-related behaviors such as exercise, they are better informed and motivated to improve their self-care [11].

Core features in diabetes self-management apps vary widely among different apps [14,15], particularly in the extent to which these features are included. Studies have found that low-risk diabetes apps (those that offer education and health tracking rather than handling insulin dosing) are not regulated [14,20,21]

and that mobile health apps lack evidence-based support when compared with clinical guidelines for disease management [12,16]. Regulation may improve app accuracy, information quality, and clinical validity, as well as enable patients to select the most suitable mobile app for their needs.

Previous studies on diabetes mobile app interventions have explored different types of feedback messaging based on several behavior change theories. These include targeting messages based on the patient's disease stage within the transtheoretical model of behavior change [5] or using social cognitive theory and protection motivation theory [23]. Other mobile app message types are triggered by biometric and activity inputs, such as continuous glucose monitoring metrics, blood pressure levels, and data on activity levels and diet [24]. Baptista et al [11] suggested that advice conveyed by diabetes

self-management apps that allow for reflection and interpretation, leading to specific and actionable recommendations, is the most useful for patients with diabetes. For example, receiving specific advice on how a meal could be healthier (Table 1) is more helpful than receiving generic nutritional advice. Nudge theory was first developed by Thaler and Sunstein [25]. Briefly, decisions about certain behaviors are made in a choice architecture that can be manipulated to favor a particular choice as the most likely outcome while maintaining freedom of choice. This *nudging* approach to messaging used in our study stands in contrast to a more restrictive system such as the banning of certain foods or the prohibition of alcohol or smoking. Daily personalized messages conveyed through the *GLOOK!* mobile app were intended to be advisory and, as much as possible, suggest positive choices rather than stimulating guilt over poor choices.

Table 1. Examples of feedback provided by physicians after reviewing the previous day's data.

Participant number	Date	Physician feedback
2001	February 22, 2019	"Main issue is the high sugars after lunch and dinner, White flour-based bread and pizza base are causing problems, consider multigrain bread and a healthier choice for dinner. Good steps but no recorded activity. Try for 20 minutes extra exercise of moderate level per day."
2001	February 23, 2019	"Good morning activity and low carbohydrate breakfast kept things nicely controlled thorough the morning. Low activity after lunch and multiple carbohydrate snacks in early afternoon kept blood sugar high in the afternoon. Try some low-GI snacks e.g. cheese on Vita Wheats or fruit (banana, berries etc.)."
2001	February 24, 2019	"Excellent morning after low carb breakfast. The coatings of schnitzels are a trap as they contain rapidly absorbed carbohydrate. Steamed chicken breast may have been a better choice. Well done for the extra exercise on the bike. Although exercise can acutely put the blood sugar up, the overall effect will be positive."

The reviewed studies suggested that the design and development of diabetes self-management apps must be informed by an understanding of the needs and desires of the people who will use them and must incorporate the features and support mechanisms that patients value [11,12,15,17,26]. Many of the almost 2000 diabetes self-management apps available on the market do not discriminate between type 1 diabetes (T1D) and T2D, although studies have shown that people with T2D favor different app features than those with T1D. For example, in Australia, patients with T2D primarily use mobile apps for glucose monitoring, whereas patients with T1D use apps for carbohydrate counting [3]. This emphasizes the need for an individualized, customized app design.

Goal of This Study

This clinical study at the Eastern Health Clinical School (Box Hill Hospital, Melbourne, Australia) aims to evaluate the satisfaction of patients with T2D with wearable technology alongside using a diabetes management app and examine the potential effectiveness of physicians' real-time feedback in promoting behavior change around participants' diet, activity, and health choices. The 12-day *GLOOK!* diabetes management system trial was designed as a pilot study for feasibility and proof of concept, with the primary goal of diabetes prevention.

Over a 5-month period in 2019, we aimed to test the hypothesis that wearable devices with real-time feedback from a physician might motivate behavior change in participants with T2D. The study used wearable sensor technology to track glucose profiles, medication, insulin dose, food and drink intake (through self-reported photographs of every meal), and activity levels of

participants with T2D. Participants were provided with daily personalized SMS text message advice from a physician who had access to all the study participants' collected data. A physician rather than a dietician reviewed the data and offered recommendations via the app as we monitored medication use and exercise, as well as diet.

Methods

System Design

We analyzed and identified the preferred features of a mobile app diabetes management system, as discussed in prior study. The analysis informed the design of the mobile app *GLOOK!*, which was designed and developed by an academic research team and tested at the Box Hill Hospital. The research team comprised endocrinologists, information technology and knowledge management experts, developers, interaction designers, and health specialists. The team was supported by diabetes nurse educators at the Eastern Health Clinical School.

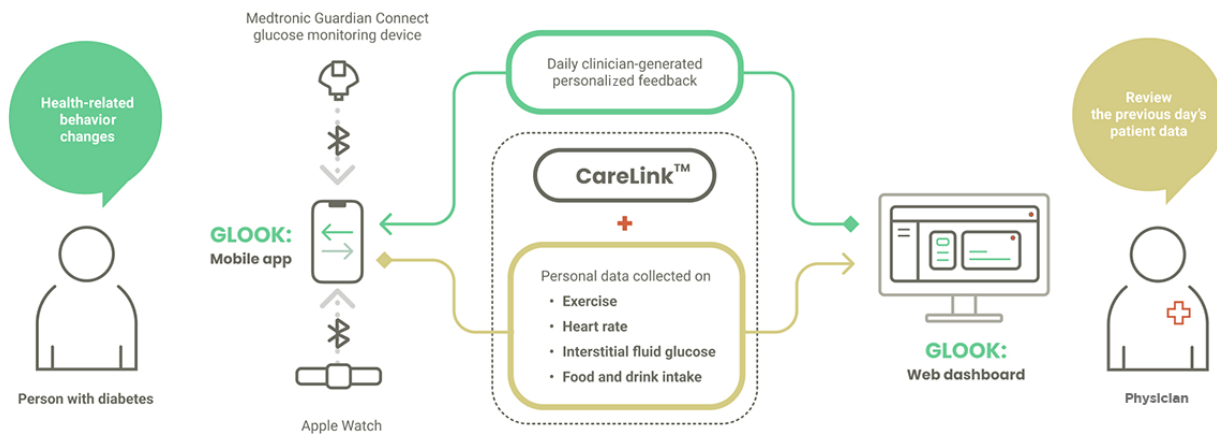

GLOOK! was designed as a diary-style tracking and feedback-delivery system. The system integrates 3 components: a smartphone-based app for data collection and analysis, a smartwatch linked to the Apple Health App for activity recognition, and a wearable device—the Medtronic Guardian Connect (Medtronic Pty Ltd) continuous glucose monitor—for continuous interstitial fluid glucose monitoring. Although 2 of the 3 components were off the shelf, the third—the *GLOOK!* app that integrated all the data—was specifically designed and

developed at an Australian university. In this paper, the app is referring to the *GLOOK!* app (Figure 1).

The system combines user input and sensor data to track patients' behavior and food intake data and medication and insulin use and record patients' daily activities. Other personal data were tracked using the mobile device's built-in sensors;

these included insulin use, number of steps, heart rate, and glucose levels. The uploaded data were integrated into the smartphone app, which also enabled participants to record their activities and food intake. The study physician received a report on these integrated data, which allowed the creation of personalized feedback for each study participant.

Figure 1. Schematic of the *GLOOK!* system connecting a patient to a physician.

User Interface Design

The *GLOOK!* mobile app's graphical user interface uses a communication-driven design process to simulate intuitive communication between patients with T2D and physicians. User experience expert Everett McKay [27] regards the user interface as a mode of conversation between users and technology. The

user interface enacts tasks so that users can achieve their goals through the language of the user interface instead of natural language. The communication-driven design process (Figure 2) underpins a clear understanding of users' needs, tasks, and goals. The top-prioritized needs, tasks, and goals for both patient and physician user groups in the design of the *GLOOK!* app were determined using a user story mapping method.

Figure 2. Communication-driven design process applied in the *GLOOK!* app’s graphical user interface design.

Empirical User Study

A technology package was prototyped for the study, assembling 3 applications to gather data and provide 1-way communication between the physician and participants (Figure 3).

The iOS app (*GLOOK!* app developed by Monash University) was installed on an Apple iPhone provided to the study participants. Participants also wore an Apple Watch linked to phone-recorded data on heart rate and steps. The Medtronic

Guardian Connect continuous glucose monitor was applied to the skin according to the manufacturer’s instructions, and it provided 24-hour continuous glucose monitoring for 6 days. At the end of 6 days, another continuous glucose monitor was applied, thus providing a total of 12 days of data. The glucose data were scrubbed from the CareLink website. All sensor data were combined for display in the *GLOOK!* app (Figure 4). The app enabled participants to self-record activities and planned exercise episodes, as well as record all meals and snacks by inputting text descriptions and photographs.

Figure 3. Technology used in the *GLOOK!* system.

Figure 4. Examples of *GLOOK!* app screens for uploading and editing food and drink images.

1. Editing option
is available on the day of entry

2. Change the description
detailing food content and
nutrition value

3. Adjust consumption
note down the portion of
food consumed

All data in the app were mirrored on a webpage that was accessed by the physician, who reviewed the previous day's data each morning and provided text-based feedback, which would appear both in the app and as a notification. There were no opportunities for 2-way communication with the physician. Feedback was limited to 2 to 3 sentences and concentrated on a few aspects of health-related behavior, with the aim of providing positive recommendations for improvements. Examples of daily feedback responses are listed in [Table 1](#).

Recruitment

A total of 15 patients with T2D were recruited for the pilot study from a larger cohort of registered outpatients attending a large public hospital in Melbourne, Australia.

Participants were preselected from the public hospital database and associated clinics based on their T2D diagnosis (none were recently diagnosed), basic computer skills, and access to digital media. In addition, the recruited participants had no disabilities or health conditions that could interfere with their activity levels. Of the 15 participants, there were 4 (27%) women and 11 (73%) men. Patient ages ranged from 42 to 65 years. Participants aged >65 years were excluded because of presumed unfamiliarity with the use of smartwatches, smartphones, and SMS text message communications. It was important that participants had a reasonable familiarity with using smart technology (smartphones) and the ability to adapt to any smart gadgets and devices provided in this study ([Figure 5](#)).

Figure 5. Study participant being taken through the *GLOOK!* app functions.

Qualitative Design Research Methodology

Overview

Two Monash University design researchers conducted and audio recorded 30 in-depth, semistructured, and descriptive interviews with the 15 study participants. The interviews were conducted twice over the period of the 12-day study: once at the beginning—while participants were being fitted with the sensor and trained on *GLOOK!* app use—to provide a baseline and then again at the end of the study.

Interview questions were based on the study's primary outcome measures and covered the participants' background, how they managed their diabetes before and after the study, their digital literacy, their attitudes toward managing their health and diet, and their levels of satisfaction with using digital eHealth technology represented by the *GLOOK!* app. The questions acted as open-ended prompts for discussions. Design research methods used a conversational interview technique that encouraged participants to offer personal narratives and describe their lived experiences [28].

Power Dynamics

Although sourced from public clinics, only 1 patient was known to the lead physician of the study before the study. The feedback was anonymous, and the physician was not identified.

Data Analysis

Patient characteristics were compared from baseline to the final visit using the Student *t* test (2-sided with equal variance). In addition, activity levels (steps), average blood sugar, glucose variability, glucose time in range, and resting pulse rate were compared for the first 4 days of the study with those for the final 4 days of the study using the mean of 4 days' data for each participant compared by Student *t* tests. Statistical analysis of the collected biometric data was performed using SPSS software (IBM Corporation).

All audio recordings from participant interviews were reviewed by 2 design researchers using a deductive framework approach for data analysis [29,30]. A Microsoft Excel spreadsheet was developed for the thematic synthesis of interview data, where themes were drawn from the study's hypotheses and aims. Interview data were abstracted, synthesized, and then charted according to the parts of the framework they were related to. The tabular form allowed a snapshot of insights and keyword searches. Novel themes that did not correspond directly to the study aims or objectives but were identified during the framework analysis were added during the process.

Ethics Approval

Ethical approval for this pilot project was applied for and was granted (project ID LR63/2017) by the Eastern Health Research Ethics committee on October 9, 2017.

Results

Clinical Outcomes

Our study's participants were on a wide range of antidiabetes

medications (Tables 2 and 3), and these were not changed during the 2 weeks of the study apart from variations in insulin doses at the patient's discretion. Specific advice regarding medication changes was not provided in the feedback.

Table 2. Glucose lowering therapies at baseline (n=15).

Therapy	Participants, n (%)
Diet alone	0 (0)
Insulin	2 (13)
Metformin	14 (93)
SU ^a	2 (13)
TZD ^b	0 (0)
DPP-4 ^c	1 (7)
GLP-1 ^d	6 (40)
SGLT-2 ^e	3 (20)

^aSU: sulfonylurea.

^bTZD: thiazolidinedione.

^cDPP-4: dipeptidyl peptidase-4 inhibitor.

^dGLP-1: glucagon-like peptide-1 agonist.

^eSGLT-2: sodium-glucose cotransporter-2 inhibitor.

Table 3. Baseline characteristics of the patients in the study (n=15)^a.

Characteristic	Values, mean (SD; range)
Age (years)	54.07 (7.16; 41-65)
Height (cm)	135.67 (12.44; 110-158)
Weight (kg)	98.09 (10.50; 80.8-115.6)
Systolic BP ^b (mm Hg)	135.67 (12.44; 110-158)
Diastolic BP (mm Hg)	85.07 (9.11; 71-103)
BMI (kg/m ²)	31.95 (3.64; 26.0-40.1)
Waist to hip ratio (n=13)	0.98 (0.04; 0.91-1.06)
HbA _{1c} ^c (%)	7.94 (2.14; 5.8-13.6)
HbA _{1c} (mmol/mol)	63.3 (23.4; 40-125)
Fructosamine (mmol/L)	295.80 (80.78; 221-545)
Total cholesterol (mmol/L)	4.78 (0.89; 3.7-6.70)
HDL ^d cholesterol (mmol/L)	2.39 (1.06; 0.90-4.70)
Triglycerides (mmol/L)	1.19 (0.22; 0.90-1.87)
Creatinine (μmol/L)	82.27 (34.30; 39-163)

^aFemale to male ratio was 4:11.

^bBP: blood pressure.

^cHbA_{1c}: hemoglobin A_{1c}.

^dHDL: high-density lipoprotein.

Electronic data collected by wearable arrays were incomplete for a variety of technical reasons. The original data set contained 30,000 data points for each patient. It was estimated that approximately 79.86% (2300/2880) of the glucose trace and

76.19% (4320/5670) of the activity and pulse rate data were available for analysis. There were sufficient data for a feedback response on 83% (10/12) of the days of the study. As a pilot or feasibility study, this study was underpowered to detect changes

in HbA_{1c}, nor did it have a control group that did not receive feedback.

The effects of the intervention on anthropometry and parameters derived from bioelectrical impedance are shown in Table 4. Body weight fell 0.65 kg on average (from 98.1 kg to 97.45 kg). This failed to reach significance, with $P=.06$. There were also falls in systolic blood pressure, diastolic blood pressure

(4.47 mm Hg and 2.93 mm Hg, respectively), and heart rate by 1.67 beats per minute; however, these did not reach significance. There were no significant changes in waist circumference and waist to hip ratio. Bioelectrical impedance analysis revealed falls in both lean mass and fat mass, with the fat mass decline exceeding the lean mass decline (3.47 kg vs 0.57 kg). None of these changes or changes in other bioelectrical impedance parameters reached significance in this small study.

Table 4. Changes in measured parameters from day 1 to day 12 of the study.

Parameter	Mean change from day 1 to day 12	P value
Systolic BP ^a (mm Hg)	-4.47	.21
Diastolic BP (mm Hg)	-2.93	.09
Heart rate (beats/min)	-1.67	.41
Weight (kg)	-0.64	.06
BMI (kg/m ²)	-0.91	.12
Waist hip ratio	0.01	.27
HbA _{1c} ^b (%)	-0.22	.004
Fructosamine (mmol/L)	-10.36	.16
Creatinine (μmol/L)	3.27	.10
Total cholesterol (mmol/L)	-0.25	.15
LDL ^c cholesterol (mmol/L)	-0.15	.30
Triglycerides (mmol/L)	-0.24	.43
HDL ^d cholesterol (mmol/L)	0.01	.66

^aBP: blood pressure.

^bHbA_{1c}: hemoglobin A_{1c}.

^cLDL: low-density lipoprotein.

^dHDL: high-density lipoprotein.

The changes in blood parameters and vital signs between the baseline and final visits are shown in Table 4. HbA_{1c} fell by 0.22% ($P=.004$). Fructosamine fell by 10.36 mmol/L; however, this did not reach statistical significance. There were favorable movements down in total cholesterol, triglycerides, and low-density lipoprotein cholesterol and favorable movements up in high-density lipoprotein cholesterol, but none of these changes reached statistical significance.

Activity was assessed by the number of steps per hour, as measured by the Apple Watch. The average number of steps per hour declined from 442 in the first 4 days to 399 in the last 4 days of the study, and this did not reach significance. Heart rate, as measured by the Apple Watch, was analyzed for changes in maximum heart rate, SD of heart rate, and resting heart rate (defined as heart rate at 5 AM), comparing values for the first

4 days of the intervention with those for the last 4 days of the intervention; no significant changes were found.

Changes in the continuous blood glucose trace were examined from the first 4 days of the study (days 1-4) and compared with those for the last 4 days of the study (days 9-12; Figure 6). There was no change in average blood glucose (9.18 vs 9.15 mmol/L; P value not significant). There was no change in glucose variability, as measured by SD (1.90 vs 1.76; P value not significant). There was no change in time in the range defined as the number of glucose data points ≥ 4.0 mmol/L and < 10 mmol/L (636 data points vs 736 data points; $P=.16$). Of the 15 participants, 1 (7%) participant had no data points in the range, and 2 (13%) participants had all data points in the range. If very poorly controlled or very well-controlled patients are removed from the analysis, then there is a significant improvement in the time in range.

Figure 6. Mean interstitial glucose recorded over the first 4 days of the study compared with last 4 days of the study.

Interview Outcomes

Overview

Analysis of the interviews showed that participants were curious about their personal health information and were keen to learn how to use real-time tracked information to manage their health. Although they tended to have a long-standing relationship with their family physician, they felt that the depth of information about their diabetes from scheduled general practitioner (GP) checkups was limited. Most participants planned their meals as per family and convenience rather than nutrition, influencing meal choices and quantities. Activity levels varied; fewer than half engaged in planned exercise, and only 13% (2/15) were *high-level* exercisers. Almost all participants expressed general satisfaction with the study. They felt that they had learned something about how their dietary habits, in particular, had affected their glucose levels. They appreciated having to be accountable to the physician providing them with daily feedback but would only want to continue using the *GLOOK!* system if the usability and reliability of the app were improved.

Results From Specific Domains in the Study

Experience With Digital Health Technology

Of the 15 participants, 6 (40%) had previously used health-tracking devices. Of these 15 participants, 10 (66%) had used smartphone apps before for monitoring their health, and 11 (73%) had sought additional information from the internet during the study period.

Engagement With Traditional Health Care

All patients reported having a relationship with their existing family GP for a long duration (between 2 and 30 years), with an average of 12 years. Adherence to regular health practitioner

visits varied; almost half (7/15, 47%) made 3-monthly GP visits for prescription renewal or checkups. Many had been referred to dietitians and other allied health professionals but did not attend regularly after the initial education following a diabetes diagnosis. Only 20% (3/15) of patients visited their diabetes nurse educator at either the 3- or 6-month intervals. Patients who saw their GP more regularly visited their diabetes nurse educator more frequently. Patients felt that the usefulness and amount of advice and follow-up on diabetes from health professionals varied. One of the study's patients who initially saw a diabetes nurse educator felt that "there was nothing that she could tell me that I didn't already know" (P2014). Another reported that their physician did not give advice on aspects of diabetes management: "He's a doctor, not a physical educator" (P2002).

A patient who visited their GP strictly for prescription renewal suggested a strong desire to be given relevant information about T2D self-management: "...don't tell me that I'm a naughty boy and that I'm sick but tell me how to manage it" (P2009).

Patients we talked with showed curiosity and willingness to learn even in the perceived absence of professional health advice: "I'm trying to figure this stuff out on my own" (P2010).

One of the patients expressed exasperation at having to deal with a chronic disease with so many individualized variables:

I've been diabetic for a bloody long time. Twenty-odd years. And I still don't get it...I just found the whole process damn confusing. [P2007]

Diet

Of the 15 patients, 11 (73%) cooked for themselves at least part of the time. For many, family requirements restricted their free choice of meals. Some noted a lack of time, not wanting to plan,

or simply finding it *easier* to eat out. Convenience outweighed nutrition in meal choice, and most felt that their diet could be improved, that it was “not the best, but not the worst” (P2001).

Exercise

Only 27% (4/15) of the participants actively engaged in moderate planned exercise and only 13% (2/15) in high-level exercise. One of the participants felt that *GLOOK!* study had encouraged them to engage in more planned exercise; they stated that the study physician’s feedback around exercise was personalized and empathetic in its delivery:

So he’s like, “can you see if you can just increase a little bit?” and suggested a five-minute walk. And I’m thinking, well, he understood that I do have issues. And he’s like, “We’re not asking you to go for a 10-kilometer run” [P2007]

Satisfaction With the GLOOK! App

Of the 15 participants, 13 (87%) said they would have been happy to continue using the *GLOOK!* app and felt that using it for longer would have enabled them to gain a better understanding of patterns in their personal data. Of the 15 participants, 2 (13%) said they would not continue using the *GLOOK!* app as they felt the wearable Guardian Connect device was too invasive. Specific comments regarding the usability of the app included the need for faster uploads, a visible icon indicating that the app was processing data, and the ability to zoom in on the data displays. Other suggested features were comparative visuals of what was *normal* for people without T2D and how the user’s levels compared, weekly summaries, and highlights and *next steps* to increase motivation.

Some participants felt that photographing food was difficult to do in public, especially when dining out. From feeling self-conscious to feeling as if it was a nuisance, participants noted that this aspect of the study was the biggest burden. However, at the same time, participants commented that photographing their food made them feel more accountable (to themselves) and aware of what they were eating and drinking. Participants would have liked 2-way communication with the physician, especially to clarify aspects of the meal they had photographed or to ask a question about the SMS text message feedback:

It would have been nice if there was an option to be able to respond to the feedback and ask questions, because...he [the physician responding] gives you a direct, “if you do this, this and this...” But that was based on assumptions. Like, for example, yesterday my lunch was a quiche where it’s not a real egg and bacon pie. He’s like, “Your sugar spiked because of the crust on that.” But it doesn’t have a crust on it because I made it myself. It’s just basically egg and bacon in a pie dish. So just to give back and say, “Well, you actually haven’t quite got the advice right”...at the moment it’s sort of a one-way street. [P2001]

Satisfaction With the Feedback

All participants were satisfied with the tone and helpfulness of the feedback, even when the physician’s comments on food choices were not always positive: “It’s nice having someone in your corner” (P2015).

They looked forward to receiving the feedback and appreciated the personalized aspects. Some perceived that the information was already known to them; it validated their own knowledge about their diet and habits as a patient suggested:

...it didn’t provide me anything I didn’t know...I might not have known it at the front of my mind, but I DO know it [P2004]

Others gained useful new insights and felt more in control of their choices.

Patient 2015 felt more in control and could see how continued app use might improve knowledge of their specific health behavior: “If I’d known what I know now, then things would be so much better” (P2015).

Behavior Change

Of the 15 participants, 3 (20%) noted an increase in their feelings of positivity and well-being following the study, and some felt that participation increased discussions and changed family routines around healthy food choices. Others determined that they would measure glucose levels daily rather than every few days as a result of being in the study. An awareness of the need to change behavior by acting upon the advice was suggested: “It’s like anything, if you’re getting the information, it’s worth nothing if you don’t work off it” (P2001).

Of the 15 participants, 2 (13%) participants mentioned feeling supported and motivated to change their behavior as a result of having the physician’s feedback on a daily basis, as patient 2007 commented the following:

All this, I consider learning; it’s a learning thing. And it’s understanding. For diabetes is massive. And I mean, even this—being held accountable. And I think, as I said, my diabetes people are fantastic. But they can’t phone me daily. [P2007]

Discussion

Principal Findings

This pilot study used wearable technology to gather data on activity, exercise, pulse rate, interstitial fluid glucose, and food intake and give patients with T2D daily text-based feedback that would provide short advisory comments (nudges) on food intake and activity based on the previous day’s data.

Advice on behavior change is often based on the average responses of groups to particular foods rather than on individual responses. It has recently become clear that there are large differences between individual glycemic responses to food and that approaches based on average responses, such as a glycemic index, may be inherently flawed [31]. Therefore, a system that uses individual glycemic responses as the basis of dietary recommendations is appealing.

It is crucial that new technologies are brought to bear to facilitate behavior change both through providing real-time visibility of blood glucose profiles and by providing nudging messages to reinforce positive messages on a frequent (daily) basis. We believe that regular, frequent, positive, and suggestive feedback using the strategy of nudging will, over time, significantly modify behavior and prevent the development of diabetes and reduce other cardiovascular risk factors such as hypertension and hypercholesterolemia, thus leading to weight loss or a positive change in body fatness.

Comparison With Prior Work

A survey of Australian patients with T2D about a *perfect* diabetes self-management app [11] identified personalization and the ability to monitor information about sugar levels and medications over the long term as the most desired features. Baptista et al [11] also suggested that people want the app to address the psychological, cognitive, and emotional aspects of living with diabetes, as well as assist with the practical elements of diabetes management. We also acknowledge several other empirical studies that have investigated the perceptions of patients with diabetes and the potential for using mobile health apps for behavior change and improved health outcomes. Several studies [6,32-34] found a high degree of patient satisfaction with receiving SMS text messages (whether motivational or educational) and that patients found this useful and beneficial. In their study, Dobson et al [33] noted that there was a significant difference in perceptions of being supported between patients in the mobile app intervention group that received generic SMS text messages and the nonintervention control group that did not receive SMS text messages.

The main difference between our research and others is in testing the usefulness of the *GLOOK!* app as a complementary tool for continuous communication between physicians and patients with T2D. This demonstrates that there is a certain gain in reinforcing positive behavioral changes through timely and personalized mobile phone messages sent on a daily basis.

Although the optimum frequency of messages is not yet known, our study and others [5,6,24,32,33] suggest that regular text-based feedback can increase patient motivation and understanding of how their diet and activity can affect T2D. Previous research on the use of diabetes self-management applications has shown increased efficacy in interventions that allow more patient customization and choice over the frequency of text-based message delivery [6]. The timing of received messages can also influence patient acceptance of and adherence to the program; enabling patient choice over what time of day they receive messages reduces the effect of them feeling *nagged* and may allow more reflection and interpretation [5]. An ideal protocol may comprise a personalized text-based message per day at a time chosen by the patient, with the option of receiving additional generic messages related to diabetes education and health.

The diabetes self-management app studies we reviewed deployed both generic (not based on individual data inputs) and personalized tailored messages. The degree of personalization varied. On one end, Dobson et al [33] used SMS text messages conveying daily reminders (eg, to check glucose levels),

reassurance and praise, tips for diabetes care, and diet to determine whether these might affect a change in HbA_{1c} levels or any positive behavior change in patients with poorly controlled diabetes. These messages were not triggered by continuous glucose monitoring or other (eg, activity) inputs, and the only personalization was the recipient's name. On the other end, Park et al [24] used similar data inputs as used in the *GLOOK!* study to trigger messages customized in response to data inputs.

In our *GLOOK!* pilot study, we found that the coaching aspect of having the physician assess an individual's data and share their feedback through SMS text messages was a key driver of motivation and emotional support. One of the study's participants shared the following:

I like having someone to report to. I find it keeps me on track. It keeps me honest; it keeps me motivated [P2007]

Although it is possible that participants might become *addicted* to this level and type of feedback, similar to any other coaching-type interaction, the frequency and extent of feedback could be scaled back as the patient develops self-efficacy and "...an understanding of what is going on and even where you can improve in things as a real-life daily action" (P2007). In the *GLOOK!* pilot study, patients' average steps declined over the study period, suggesting that the effect of the intervention was wearing off over the 2-week study. Furthermore, patients reported in the interviews that their motivation to exercise fluctuated according to their mood, mental health, and social situation. For sustained behavior change, methods for enhancing motivation and increasing activity levels over the long term would need to be tested.

Limitations

The study had some limitations because of limited resources, including time and specific technical components (eg, Medtronic continuous glucose monitor, Apple Watch, and Android smartphone) used for the *GLOOK!* app implementation. This explains the relatively short period (12 days) that the patients used the system for the physician to communicate with them. A small group of 15 patients was recruited, as the pilot study objective was to collect initial feedback on the new treatment process and demonstrate the feasibility of the technology to communicate personalized feedback rather than a full clinical trial. This also explains the lack of a control group in the study design, which is another limitation. One patient had very poor control, with very high blood glucose levels; they needed a treatment change, which was not performed in the context of this study. In retrospect, we would have selected patients with intermediate levels of control.

The study was intended to address the consumption of foods with a high glycemic index rather than a poor diet in general (eg, one high in saturated fat and sodium); this is a limitation of the study. The tool had a basic functionality to support glucose levels, activity data monitoring, and physician feedback. Feedback from the participants regarding their experience using the *GLOOK!* app corresponds to some of the limitations and will be addressed in the planned new phase of the study.

Future Research

Despite the small sample sizes in our pilot study, our findings support the potential of mobile app-based, daily personalized physician feedback as an intervention for positive changes in behavior and health outcomes in people with T2D. A follow-up study is needed to ascertain both the long-term engagement with the app and the extent to which long-term behavior change is feasible. Specific areas to be explored in follow-up studies include the following:

- How feedback that is analyzed and delivered via AI rather than by a physician might reproduce the personal and motivational effect of coaching-style feedback
- Whether 2-way communication enhances motivation for sustained behavior change
- How behavior change models could be deployed to personalize feedback messaging [5,34]

Interviews with patients with T2D in this study provided important insights into how the experience could be made more engaging and presumably more effective. Future wide-scale applications of daily personalized feedback delivered through an app would be limited by the availability of physicians or even specially trained dietitians to provide this feedback. This

factor, and the learning points from our pilot study, could be incorporated in the design of new integrated wearable technology that will enable scaling up of this kind of intervention through the use of newer and less invasive sensor technology, possibly by deploying an AI approach in the generation of feedback. This approach aligns with predicted advances in customized diabetes treatment by incorporating machine-based algorithms [13,20,24]. The increasing capability of big data analytics could even generate personalized interventions for behavior change tailored to different patients' needs for specific motivational techniques [5]. New technology will allow sufficient upscaling of this approach to have an impact on the incidence and community costs of diabetes.

Conclusions

Our study suggests that providing daily physician-generated personalized feedback based on wearable sensor information and recorded food intake and activity data can produce favorable changes in glycemic and cardiovascular risk parameters even in the short term. The participants found the experience acceptable, and it provided them opportunities for positive long-term behavior changes. We plan to address the feedback collected through the interviews to redevelop the system and conduct a longer study with more participants.

Acknowledgments

This work was supported by a seeding grant from the Monash Institute of Medical Engineering granted to CG. Contributions were also provided by the Monash Faculty of Information Technology and the Special Purpose Fund of the Endocrine Department of Eastern Health. The authors would like to thank Flavia Xie-Ku of Monash University Art, Design, and Architecture and Yuxin Zhang and Farid Raisi of Monash University Faculty of Information Technology for their contributions to the *GLOOK!* app user interface design and development. The authors would also like to Vanessa Viola, Gabrielle Garner, and Kerrie Peacock from the Eastern Clinical Research Unit for providing *GLOOK!* app pilot study participants with app training, the initial setup of the glucose monitoring sensor, and technical support.

Authors' Contributions

CG led and conducted the clinical study design and implementation and contributed to manuscript writing and reviewing. MME assisted CG and helped conduct the clinical study. FB led the system development, contributed to the study design and technical evaluation, and drafted the first manuscript. DF led the *GLOOK!* app study design and implementation, collected interview data from patients, and contributed to the review. EP helped design the qualitative study, collected data from patients through interviews, analyzed and reported on that data, and led the manuscript writing and reviewing. TD helped design the qualitative study, collected data from patients through interviews, and analyzed the data. IDH developed the system interface and implementation and contributed to manuscript writing and reviewing. TYG led the technical development of the *GLOOK!* app and manuscript review until final version approval.

Conflicts of Interest

None declared.

Abstract

Background: Chinese immigrants bear a high diabetes burden and face significant barriers to accessing diabetes self-management education (DSME) and counseling programs.

Objective: The goal of this study was to examine the feasibility and acceptability and to pilot test the potential efficacy of a social media–based DSME intervention among low-income Chinese immigrants with type 2 diabetes (T2D) in New York City.

Methods: This was a single group pretest and posttest study in 30 Chinese immigrants with T2D. The intervention included 24 culturally and linguistically tailored DSME videos, focusing on diabetes education and behavioral counseling techniques. Over 12 weeks, participants received 2 brief videos each week via WeChat, a free social media app popular among Chinese immigrants. Primary outcomes included the feasibility and acceptability of the intervention. Feasibility was evaluated by recruitment processes, retention rates, and the video watch rate. Acceptability was assessed via a satisfaction survey at 3 months. Secondary outcomes, that is, hemoglobin A_{1c} (HbA_{1c}), self-efficacy, dietary intake, and physical activity, were measured at baseline, 3 months, and 6 months. Descriptive statistics and paired 2-sided *t* tests were used to summarize the baseline characteristics and changes before and after the intervention.

Results: The sample population (N=30) consisted of mostly females (21/30, 70%) who were married (19/30, 63%), with limited English proficiency (30/30, 100%), and the mean age was 61 (SD 7) years. Most reported an annual household income of <US \$25,000 (24/30, 80%) and a high school education or less (19/30, 63%). Thirty participants were recruited within 2 months (January and February 2020), and 97% (29/30) of the participants were retained at 6 months. A video watch rate of 92% (28/30) was achieved. The mean baseline HbA_{1c} level was 7.3% (SD 1.3%), and this level declined by 0.5% (95% CI –0.8% to –0.2%; *P*=.003) at 6 months. The mean satisfaction score was 9.9 (SD 0.6) out of 10, indicating a high level of satisfaction with the program. All strongly agreed or agreed that they preferred this video-based DSME over face-to-face visits. Compared to baseline, there were significant improvements in self-efficacy, dietary, and physical activity behaviors at 6 months.

Conclusions: This pilot study demonstrated that a social media–based DSME intervention is feasible, acceptable, and potentially efficacious in a low-income Chinese immigrant population with T2D. Future studies need to examine the efficacy in an adequately powered clinical trial.

Introduction

In the United States, the Chinese immigrant population is a fast-growing minority group and bears a disproportionately high type 2 diabetes (T2D) burden compared to the general adult population [1,2]. In New York City, data from an epidemiological survey of 2071 participants revealed that almost 1 out of every 2 adult Chinese immigrants has T2D or impaired fasting glucose [2]. This is a concerning rate, given the high proportion and the continuing rapid influx of Chinese immigrants over the last few decades. Indeed, between 2000 and 2015, the New York City Chinese population grew by 49% (increased from 260,928 in 2000 to 388,783 in 2015) compared to 12% in the overall New York City immigrant population (increased from 2.87 million in 2000 to 3.21 million in 2015) [3]. Although the poverty rate of Chinese Americans in New York City is comparable to that of the overall New York City population, the older Chinese adults (28.6%) who are more likely to be impacted by diabetes have a much higher poverty rate relative to the overall older adults (18.8%) in New York City [4].

Despite the high T2D burden, research in this patient population is quite limited, with only few diabetes intervention studies identified [5-8]. In each study, the interventions relied on busy health care providers or dedicated study staff to deliver them, thereby limiting their sustainability and scalability. Each intervention required frequent travel to a central location to receive the intervention (6-12 face-to-face sessions lasting 1-2 hours), which is unlikely to be feasible in a real-world setting, especially among low-income Chinese immigrants, given their long work hours [9,10].

Diabetes self-management education (DSME) and counseling programs are evidence-based interventions that provide important knowledge, skills, and counseling to patients with T2D [11]. Chinese immigrants face numerous barriers to accessing these in-person programs [8,10,12-15], and these programs have proven to be effective in mostly English-speaking populations [16-18]. The lack of linguistically and culturally sensitive health care providers and tailored diabetes programs have been cited as the major reasons for poor diabetes outcomes in Chinese Americans [13,19-21]. While over 60% of Chinese immigrants report limited English proficiency in New York City [3], language-concordant providers are also limited in number [13,19-21]. Differing cultural norms also complicate the delivery of effective diabetes care and counseling [10,13-15,22]. These cultural and linguistic discordances between providers and patients often contribute to poor

patient-provider communication, inefficient diabetes education and counseling, and diminished understanding and confidence in managing T2D at home [21]. Moreover, these DSME programs are often labor-intensive for providers and time-consuming for patients [9,23]. Chinese immigrants are often engaged in low-wage jobs with long working hours, limited sick leave, and lack of health care insurance [4], which prevent them from participating in these in-person multiple-session programs [9,10,22].

Leveraging widely used social media platforms may be a promising approach to deliver DSME to underserved Chinese immigrants in a time and place that is convenient to them [24,25]. In a prior study, we demonstrated ownership of smart devices by a majority of Chinese immigrants with T2D, widespread use of the free social media app, “WeChat,” and a strong interest in a WeChat-based DSME [26]. Indeed, over 90% of Chinese immigrants with T2D reported owning a smart device and more than 70% currently use WeChat [26]. Given the ubiquitous nature of mobile phones, a social media–based asynchronous intervention holds strong promise to be integrated into the daily lives of Chinese immigrants. The goal of this pilot study was to examine the feasibility, acceptability, and potential efficacy of an asynchronous WeChat-based DSME program in Chinese immigrants with T2D.

Methods

Study Design

The CARE (Chinese American Research and Education) study was a pretest and posttest single-group study on 30 Chinese immigrants with T2D. During the 12 weeks of the intervention, each participant received links to 2 diabetes videos via WeChat each week. Participants completed in-person surveys at enrollment (prior to the intervention) and 3- and 6-month follow-up surveys over the telephone. All participants provided written informed consent.

Ethics Approval

This study was approved by the New York University Grossman School of Medicine Institutional Review Board (s18-00609).

Participants

Participants were eligible if they (1) self-identified as a Chinese immigrant, (2) were between 18 and 70 years old, (3) self-reported a diagnosis of T2D, (4) were able to understand Mandarin Chinese, (5) were currently using WeChat, (6) had a smartphone/tablet or were willing to use a study smartphone, and (7) reported interest in receiving diabetes videos via

WeChat. Exclusion criteria included pregnancy, breastfeeding, or living in nursing homes or facilities in which participants had limited opportunity to engagement in independent decision-making regarding management of their T2D. We chose to focus on Mandarin in this study because this is among the most popular spoken languages among New York City Chinese immigrants [27].

Recruitment, Screening, and Baseline Assessment

Participants were recruited from a diabetes research registry that has been established from one of our prior studies [26], which aimed to examine diabetes self-management behaviors in Chinese immigrants with T2D in New York City. Study staff contacted potential participants, explained the study, and screened them for eligibility. Once eligibility was confirmed, study staff scheduled a date and time to meet in person for written consent and baseline assessment.

Intervention Overview and Theoretical Frameworks

We culturally and linguistically adapted a DSME intervention shown to be efficacious for decreasing hemoglobin A_{1c} (HbA_{1c}) levels in a highly educated non-Hispanic White population in the ENHANCE trial [28]. Adaptation of the ENHANCE intervention was guided by the Cultural Adaptation Model [29] and the Ecological Validity Model [30]. These models were chosen because they have been widely used in the literature to guide the cultural adaptation processes of evidence-based interventions. The study team first reviewed the ENHANCE intervention content to make sure it is consistent with the latest diabetes and DSME guidelines [11] and covers all of the Association of Diabetes Care & Education Specialists self-care behavior topics [31]. Then, informed by the adaptation models

and our prior formative work, we tailored the content based on Chinese culture and norms. For instance, when talking about diet, we used commonly consumed Chinese dishes, food items, seasoning, and cooking methods. We also discussed tips to maintain healthy eating during Chinese holidays (eg, Lunar New Year). When discussing medication taking, we shared commonly reported barriers to medication taking in Chinese immigrants and provided tailored strategies to improve medication adherence. Once the initial adaptations were completed, the intervention content was shared with a Chinese diabetes educator and a nurse for feedback on cultural relevance and content accuracy.

CARE included a 12-week intervention program involving DSME videos that participants could access in a time and place convenient to them. We developed 24 brief (~5 minutes) diabetes videos in Mandarin Chinese. Each week, 2 video links were sent to the participants via WeChat, with one video focusing on diabetes education (eg, basics of diabetes care, diet, physical activity) and the second one focusing on social cognitive theory–based behavioral change techniques (eg, goal setting, self-reward, problem solving) (see Table 1 for the outline of the intervention videos) [30,31]. At the end of the baseline visit, participants were sent the first video and shown how to open the video by clicking the play button. Since all participants knew how to use WeChat, we did not provide any guidance around using WeChat. In addition to sending brief videos, study staff called the study participants every 2 weeks to ask if they had questions regarding the video content and gave them an opportunity to discuss any challenges encountered in their diabetes self-management efforts. The phone calls typically lasted about 15 minutes.

Table 1. Outline of the intervention content.

Week	Education materials (A)	Social cognitive theory–based behavioral materials (B)
1	Overview of diabetes	Goals for life
2	Healthy diet part 1	Setting goals
3	Healthy diet part 2	Self-reward, turning goals into habits
4	Medication management	Social support, developing and making your social support network
5	Glucose self-monitoring	Problem solving: barriers and setbacks Problem solving model
6	Exercise and diabetes	Problem solving: behavioral triggers and stimulus control
7	Building muscles with strength training	Problem solving: emotional eating
8	Grocery shopping at a Chinese grocery store	Problem solving: cravings for white rice, noodle, bun, dumplings etc
9	Stress and diabetes	Problem solving: eliminating negative self-talk
10	Chinese holidays and eating out	Problem solving: anticipating high-risk situations
11	Attending doctor appointments	Problem solving: lapse and relapse
12	Navigating the US health care system	Problem solving: coping with lapses and setting new goals

Measures

Unless specified otherwise below, measurements were obtained at baseline, 3 months, and 6 months.

Sociodemographic Data

At baseline only, we collected data on age, gender, income, education, marital status, employment status, and English proficiency. English proficiency was measured by 1 question “how well do you speak English,” and limited English proficiency was defined as speaking English less than very well.

Primary Outcomes

Feasibility was measured as the percentage of those screened and eligible who enrolled in the study, retention rates at 3- and 6-month follow-up, and the video watch rate. At the end of each video, participants were asked 2 brief questions via WeChat: (1) how much of the video did you watch? (part of the video vs the entire video) and (2) how helpful was the video? (not at all helpful, somewhat helpful, or extremely helpful). If participants responded to these 2 questions, we considered that they watched the video. The number of responses was used as a proxy measure to estimate the video watch rate. Acceptability was measured by a 10-item patient satisfaction scale used in a prior study [32]. Participants were provided with 9 statements regarding their experience and satisfaction to which they provided their level of agreement, using a 5-point Likert scale (1=strongly agree to 5=strongly disagree). Participants also responded to a single 11-point Likert-scaled item reflecting their overall satisfaction with the intervention (0=not at all satisfied to 10=totally satisfied).

Secondary Outcomes

HbA_{1c} Levels

Baseline HbA_{1c} was abstracted from the medical record if a result was available within 3 months prior to enrollment. If a baseline HbA_{1c} result was not available, point-of-care A1C NOW testing was performed. Follow-up HbA_{1c} was obtained from the electronic record. Because of COVID-19 interruptions in the delivery of ambulatory care, many participants did not seek routine care during the study midpoint (3 months follow-up) and HbA_{1c} data were not available for them. However, ambulatory care delivery returned to normal as the study concluded, and HbA_{1c} data were available for most participants at the 6-month follow-up.

Self-efficacy

Self-efficacy was measured with the Stanford 8-item Self-Efficacy for Diabetes scale [33,34] on which participants report confidence in their ability to manage various diabetes

self-care behaviors. Each item was rated using a 10-point Likert scale (from 1=not at all confident to 10=totally confident). The final score was the mean across the 8 items, with higher scores reflecting higher self-efficacy.

Dietary Intake

Dietary intake was measured with the 8-item Starting The Conversation scale [35], which asks participants to report the frequency with which they consumed various foods and drinks over the past few months (eg, fruits, vegetables, sodas, desserts). The final score was the sum of 8 items, with a possible range of 0-16. Lower scores reflect more healthy eating behaviors.

Physical Activity

Physical activity was measured with the International Physical Activity Questionnaire (short version) [36]. Participants were asked whether they engaged in any vigorous, moderate, or mild level of physical activity over the past 7 days and the duration for each exercise intensity. Results were calculated in total MET-minutes/week [37], with higher scores reflecting a higher level of physical activity.

Statistical Analyses

For primary outcomes, we used descriptive statistics to summarize demographics, retention rates at 3 and 6 months, the video watch rate, and intervention satisfaction scores. For secondary outcomes, we used paired 2-sided *t* tests to identify changes over time. Changes in means and their 95% CIs were presented. We performed all data analyses using SPSS (version 25.0, IBM Corp).

Results

Characteristics of the Sample Population

As shown in Table 2, the sample consisted of 30 middle-aged adults or older Chinese immigrants who were primarily married women with a high school education or less, an annual household income of less than US \$25,000, and who reported limited English proficiency.

Table 2. Sample characteristics (N=30).

Characteristic	Value
Age (years), mean (SD)	61 (7)
Gender, n (%)	
Female	21 (70)
Male	9 (30)
Marital status, n (%)	
Currently married or living as married	19 (63)
Divorced or separated	7 (24)
Widowed	3 (10)
Single or never married	1 (3)
Educational attainment, n (%)	
High school education or less	19 (63)
Some college or technical school	9 (30)
College graduate or more	2 (7)
Annual household income, n (%)	
<US \$25,000	24 (80)
US \$25,000-US \$55,000	3 (10)
≥US \$55,000	2 (7)

Retired	1 (3)
English proficiency, n (%)	
Very well	0 (0)
Well	4 (13)
Not well	18 (60)
Not at all	8 (27)
Number of years living in the United States, mean (SD)	13 (7)
Duration of self-report of having type 2 diabetes, mean (SD)	9 (7)

Feasibility and Acceptability Outcomes

We report feasibility in the following 3 ways.

Recruitment

A total of 30 participants were recruited from January 16 to February 27, 2020, prior to the onset of the COVID-19 pandemic in New York City. We called 70 potential patients and were able to reach 45 participants (64%). Of these 45 patients, 38 were eligible and 30 enrolled (79%) in this study. Thus, we needed to screen 1.5 patients to enroll 1 participant in the study (45 screened/30 enrolled).

Retention Rates

The retention rate was 100% (30/30) at 3-month follow-up and 97% (29/30) at 6-month follow-up. One participant moved back to mainland China and was lost to follow-up at the 6-month follow-up.

Video Watch Rate

The mean video watch rate was 92% (SD 4%), indicating that on average, each video was watched by 92% (28/30) of the sample. The video watch rate over the 12-week intervention ranged from 83% to 100%. Almost all (99.6%) reported

watching the entire video when they watched a video and 86% (26/30) agreed that the videos were very helpful.

Acceptability

Out of a possible score of 10 with higher scores reflecting greater satisfaction, the mean overall satisfaction with the intervention was 9.9 (SD 0.6). Table 3 summarizes participants' responses to each satisfaction item. All participants agreed or

strongly agreed that it was very easy to receive and view diabetes videos and that the videos provided very helpful information on diet and physical activity. All participants strongly agreed or agreed that the diabetes videos enhanced their confidence to manage their T2D. Of note, all strongly agreed or agreed that they preferred video-based diabetes education over in-person face-to-face education in their doctor's office.

Table 3. Satisfaction survey results (N=30).

To what extent do you agree with the following statements?	Strongly agree, n (%)	Agree, n (%)	Neutral, n (%)	Disagree or strongly disagree, n (%)	Not applicable, n (%)
It was easy to receive and view the WeChat diabetes videos from the research team.	22 (73)	8 (27)	0 (0)	0 (0)	0 (0)
I found this program to be helpful for providing me more information about healthy diet.	27 (90)	3 (10)	0 (0)	0 (0)	0 (0)
I found this program to be helpful for providing me more information about physical activity.	28 (93)	2 (7)	0 (0)	0 (0)	0 (0)
I found this program to be helpful at motivating me to take my diabetes medication as prescribed.	24 (80)	5 (17)	0 (0)	0 (0)	1 (3)
I found this program to be helpful at motivating me to check my blood sugar as recommended.	21 (70)	6 (20)	1 (3)	0 (0)	2 (7)
I found this program to be helpful at increasing my confidence to manage my diabetes.	27 (90)	3 (10)	0 (0)	0 (0)	0 (0)
I would be willing to join similar programs in the future to help me manage my diabetes.	27 (90)	3 (10)	0 (0)	0 (0)	0 (0)
I would recommend this program to my friends/family that have diabetes.	23 (77)	7 (23)	0 (0)	0 (0)	0 (0)
I prefer to receive diabetes education via WeChat than scheduling appointment and going to doctor's office.	24 (80)	6 (20)	0 (0)	0 (0)	0 (0)

Secondary Outcomes

Table 4 shows the changes in the secondary outcomes over time. Compared to baseline, there were significant improvements at

3 months in self-efficacy, while no changes were observed in dietary and physical activity behaviors. Between baseline and 6 months, significant improvements were observed in HbA_{1c}, self-efficacy, dietary behavior, and physical activity.

Table 4. Changes in secondary outcomes over time.

	0 month (baseline), mean (SD)	3 months, mean (SD)	6 months, mean (SD)	0-3 months change (95% CI)	P value	3-6 months change (95% CI)	P value	0-6 months change (95% CI)	P value

Discussion

Principal Findings

To the best of our knowledge, this is the first study examining the feasibility and acceptability of leveraging a free social media platform to deliver culturally and linguistically tailored,

asynchronous DSME to underserved Chinese immigrants with T2D. The results of this study demonstrated high feasibility and acceptability of this intervention. The retention rate was comparable to or better than that previously reported in in-person diabetes interventions in Chinese immigrants [8,9,38]. The video watch rate was high over the 12-week intervention, with an

adherence rate higher than most in-person DSME interventions in Chinese immigrants [6,8,9,38]. For example, in a study of 145 Chinese immigrants with T2D, Chesla and colleagues [8] examined the effect of a 6-session intervention program and found that the cumulative percentages of participants who attended 4, 5, or 6 sessions were 92%, 79%, and 58%, respectively. Similarly, in another in-person diabetes prevention program in Chinese immigrants, the average session attendance was 77% [38]. Several factors may explain the higher engagement observed in this study, including culturally and linguistically tailored intervention content, bilingual study staff, and remote delivery of the intervention via a commonly used social media app to Chinese immigrants, which allows participants to access the intervention videos at a time and place convenient to them. In addition, the study staff called participants every 2 weeks to check whether they had any questions with regard to the video content, which may help build a trusting relationship with participants and thus enhance retention and engagement.

The intervention in this study shows promise for improving glycemic control and key diabetes psychosocial and behavioral outcomes. The reduction in HbA_{1c} levels was both statistically and clinically significant, with an effect size similar to in-person but more labor-intensive DSME programs [39]. We also found that participants reported higher self-efficacy for managing T2D and better adherence to diet and physical activity, which have been considered as critical factors in improving glycemic control and diabetes outcomes [11,40]. It is possible that the effect of our intervention was mediated by improvements in self-efficacy and adherence to self-management behaviors. The small sample size of this study precluded the possibility of mediation analyses. Future large randomized controlled trials may consider exploring the mechanism of this social media-based DSME intervention.

The literature regarding mobile health-based interventions has been rapidly growing over the past few decades. However, most published studies have focused on developing and designing sophisticated applications or technologies to serve well-educated

English-speaking populations [41]. Use of mobile technologies to deliver health education to underserved populations, particularly marginalized low-income immigrants with limited English proficiency, is largely untested [41-43]. Our data suggest that leveraging a communication app widely used by an underserved immigrant community is feasible for delivering asynchronous DSME among Chinese immigrants. The intervention is acceptable and promising to improve diabetes outcomes and related health behaviors among low-income Chinese immigrants.

The data in this study need to be interpreted cautiously, and additional research will be required to confirm the results, given the small sample and pretest-posttest study design. In addition, the video watch rate and program satisfaction were measured by self-reported questions that could reflect response bias. Nonetheless, this study is the first to examine the use of a free social media platform to increase access to culturally tailored DSME among underserved Chinese immigrants. Future large-scale randomized controlled trials are needed to explore whether this approach can be used for other chronic disease management interventions or in other high-risk immigrant populations in the United States. Use of a free widely used communication platform enhances future scalability and minimizes potential digital literacy concerns.

Conclusion

Underserved racial and ethnic minority and immigrant populations bear disproportionately high burden of T2D and face numerous barriers to accessing culturally appropriate DSME. In this study, we demonstrate the feasibility, acceptability, and potential efficacy of an asynchronous intervention that employs a free social media platform to deliver culturally and linguistically tailored DSME videos to underserved low-income Chinese immigrants. These findings add to the scarce literature on the use of mobile health interventions in underserved populations. Future studies are required to confirm the efficacy of the intervention in a randomized controlled trial.

Acknowledgments

Parts of this study were presented at the 81st Annual Scientific Conference of the American Diabetes Association (virtual) on June 25-29, 2021 and the 42nd Annual Meeting and Scientific Sessions of the Society of Behavioral Medicine (virtual) on April 12-16, 2021. We would like to acknowledge Ms Tsz Kit Li and Virginia Lee for reviewing and providing feedback on the intervention content and the participants for joining this study. This research is supported in part by the National Institutes of Health (NIH, grants U54MD000538-15, K99MD012811, R00MD012811, and P30DK111022). Funding for the Socio-Spatial Determinants of Health (SSDH) Laboratory is provided through the Intramural Research Program of the National Institute on Minority Health and Health Disparities (NIMHD) of the NIH and the NIH Distinguished Scholars Program. The views of this study are those of the authors and do not necessarily represent the views of the NIMHD, NIH, and the US Department of Health and Human Services.

Abstract

Background: The COVID-19 pandemic has accelerated the adoption of digital tools to support individuals struggling with their mental health. The use of a digital intervention plus human coaching (“dual” intervention) is gaining momentum in increasing overall engagement in digital cognitive behavioral interventions (dCBIs). However, there is limited insight into the methodologies and coaching models used by those deploying dual interventions. To achieve a deeper understanding, we need to identify and promote effective engagement that leads to clinical outcomes versus simply monitoring engagement metrics. Motivational interviewing (MI) is a collaborative, goal-oriented communication approach that pays particular attention to the language of change and is an effective engagement approach to help people manage mental health issues. However, this approach has been traditionally used for in-person or telephonic interventions, and less is known about the application of MI to digital interventions.

Objective: We sought to provide a dual intervention approach and address multiple factors across two levels of engagement to operationalize a dCBI that combined cognitive behavioral therapy–based techniques and MI-based interactions between the digital health coach (DHC) and user.

Methods: We reviewed hundreds of digital exchanges between DHCs and users to identify and improve training and quality assurance activities for digital interventions.

Results: We tested five hypotheses and found that: (1) users of a dual digital behavioral health intervention had greater engagement levels than users of a noncoached intervention ($P<.001$); (2) DHCs with a demonstrated competency in applying MI to digital messages had more engaged users, as measured by the DHC-to-user message exchange ratio ($P<.001$); (3) the DHC-to-user message exchange ratio was correlated with more engagement in app activities ($r=0.28$, 95% CI 0.23-0.33); (4) DHCs with demonstrated MI proficiency elicited a greater amount of “change talk” from users than did DHCs without MI proficiency ($H=25.12$, $P<.001$); and (5) users who were engaged by DHCs with MI proficiency had better clinical outcomes compared to users engaged by DHCs without MI proficiency ($P=.02$).

Conclusions: To our knowledge, this pilot was the first of its kind to test the application of MI to digital coaching protocols, and it demonstrated the value of MI proficiency in digital health coaching for enhanced engagement and health improvement. Further research is needed to establish coaching models in dCBIs that incorporate MI to promote effective engagement and optimize positive behavioral outcomes.

Introduction

Background

Over the last several decades, digital technologies have drastically transformed health care delivery and clinical care. From electronic medical records to wearable devices and mobile apps, digital tools have enhanced disease diagnoses and treatment, access to care, and population health management [1,2]. The COVID-19 pandemic has further accelerated digital health adoption, as consumers have increasingly turned to digital health solutions such as telemedicine and digital trackers for medical emergencies or to treat/manage a chronic or mental health condition [3]. While the United States has a long history of mental health concerns, access to treatment has become critical, as the increased psychological strain due to the pandemic has exacerbated this crisis and driven behavioral health referrals to record levels [4,5]. Given the limited availability of mental health providers and the widespread population needs, the possibility of deploying digital behavioral health solutions to wider audiences demands rigorous consideration [6].

Digital cognitive behavioral interventions (dCBIs) have the potential to address unmet behavioral health needs by offering scalable, cost-effective solutions, increasing reach and availability, and allowing consumers to engage and progress at their own pace [7-9]. However, the clinical success of dCBIs is dependent on ample user engagement, and these programs have often faced low levels of adherence and high levels of attrition [10,11]. Researchers in the digital engagement literature have presented nuanced and comprehensive discussions regarding the complexity of different types of engagement, as well as how to view, define, and measure them [10,12-14]. For example, Cole-Lewis et al [13] proposed that engaging with the digital intervention features such as the number of logins, clicks, and time spent (“Little e”), are a critical precursor to engagement in health behaviors such as physical activity or smoking (“Big E”). Yardley et al [12] recognized engagement as multifaceted, presenting two different levels: (1) micro-level engagement—the moment-to-moment engagement with the intervention, including intervention use (eg, number of activities completed) and the user experience (eg, level of user interest and attention when completing activities); and (2) macro-level engagement—the depth of involvement with the behavior change process (eg, extent of motivation for changing behavior) and the link of this engagement to the behavioral goals of the intervention. These definitions help bring clarity to how users interact with a digital solution; however, the engagement metrics presented in the literature fail to include the effects of a key component of many dCBIs: a digital health coach (DHC).

The use of a digital intervention plus human coaching (ie, a “dual” intervention) is gaining momentum in increasing the overall engagement in and clinical effectiveness of dCBIs. In dual programs, the DHC provides support and guidance using asynchronous, chat-based communication. There is substantial

evidence in the literature that the addition of health coaching support successfully reinforces adherence to the intervention and improves clinical outcomes for those experiencing mental health issues [7-9,15,16]. However, among those interventions that have specifically measured engagement with a DHC (as opposed to measuring engagement with app features), evaluations are often focused solely on volume, such as the number of messages sent to and from the coach [7,17]. As a result, there is limited insight into methodologies and coaching models used by those deploying dual interventions. To achieve a deeper understanding, we need to establish and promote “effective engagement” versus simply more engagement, with “effective engagement” defined empirically as sufficient engagement with the intervention to achieve the intended outcomes [12].

Motivational interviewing (MI) has been studied for multiple decades and is an effective engagement approach to help people manage mental health issues such as anxiety and depression [18-21]. MI is a collaborative, goal-oriented communication approach that pays particular attention to the language of change [22]. It is the most evidence-based health coaching approach to date with over 1400 clinical trials, standardized and validated tools that measure proficiency and fidelity to the approach, and congruency with the prevailing science of self-determination, self-efficacy, stages of change, and self-perception theories [22-24]. The most compelling research in MI demonstrates that an MI-proficient practitioner can minimize client “sustain talk” (ie, barriers and challenges to change) while evoking “change talk” (ie, desire, ability, reasons, and need for change) [25]. This results in the strengthening of the client’s commitment to change and, in turn, an increase in targeted behaviors and clinical outcomes, such as adopting the practice of CBT exercises and gaining improved mood as a result [25]. However, as this approach has been predominantly used for in-person or telephonic interventions to date, less is known about the application of MI to digital interventions.

Objective

To date, there is a dearth of literature regarding how or if an MI-based health coaching approach can be successfully integrated into digital coaching and whether it is effective in increasing engagement, eliciting change talk, and improving outcomes in digital settings. Given the evidence supporting MI as an effective approach for engaging people in behavior change, we hypothesized that if a DHC were to incorporate MI into digital messages, they would better engage and activate the user. Therefore, the purpose of this pilot study was to define and articulate an MI-based digital coaching protocol for dCBIs targeting anxiety and depression to better understand the extent to which a dual intervention approach can increase user engagement. A secondary objective was to assess the impact of full proficiency in MI on behavioral health outcomes.

Methods

Dual Intervention Model

First, we sought to develop and provide the equivalent of a “dual intervention.” The dual intervention model delivered two concurrent interventions within a mobile app-based dCBI: (1) cognitive behavioral therapy (CBT)–based techniques (eg, relaxation, cognitive reframing, mindfulness); and (2) MI-based interactions between the DHC and the user, including identifying strategies and goals outside the app activities. The mobile app was developed from evidence-based approaches to behavioral health (CBT and mindfulness) by a large health plan in northeast United States that is part of an integrated health care delivery system. The app delivers anxiety or depression programming to users. Individuals choose which program to enroll in, and access to a DHC is dependent upon the client’s health care benefits package or relationship with the health care organization. The coach-enhanced dCBI has been evaluated in diverse care settings including primary care, adolescent care, women’s health, and patient-centered specialty medical homes [26,27].

DHCs received approximately 90 hours of training through an in-house health coach academy. The curriculum was based on national coaching standards and the proprietary health plan Health Coaching Model, which includes a foundation of MI along with other evidence-based health coaching strategies. The model is designed to support coaches in partnering with and empowering their clients to self-manage health behaviors, reach their health and wellness goals, be more productive and resilient,

achieve better clinical outcomes, and enhance their overall well-being. After foundational training, the DHCs received an additional training curriculum specific to incorporating MI into the digital coaching platform. A mixed methods training was used with a combination of asynchronous and synchronous training, feedback, mentoring, and assessment using the standardized and validated Motivational Interviewing Competency Assessment (MICA) tool, which was adapted for digital coaching [28]. As DHCs began their interactions with members, they received ongoing skill-building training and quality assurance review assessments, paired with strength-based mentoring and monthly feedback on their digital user interactions.

Ethics Approval

This quality improvement project was approved by the UPMC Quality Improvement Review Committee (QRC Project ID 2809).

Testing the Dual Intervention: Five Hypotheses

Building on the model of engagement by Yardley et al [12], we reviewed hundreds of digital exchanges between DHCs and users on an ongoing basis to improve training and quality assurance activities for our mobile app-based dCBI. During this process, we sought to address multiple factors across two levels of engagement to operationalize engagement metrics that incorporated both CBT-based app activities and DHC interactions. Thus, we organized our five hypotheses around micro (ie, engagement within the app) and macro (ie, engagement around behavior change) engagement levels (Table 1) [12].

Table 1. Five dual intervention hypotheses.

Engagement	Hypotheses
Microengagement	
Hypothesis 1 (H1)	Users of a dual dCBI ^a (coaching plus techniques) will have greater engagement than users of a self-guided (techniques only) intervention.
Hypothesis 2 (H2)	DHCs ^b with a demonstrated competency in applying MI ^c to digital messages will have more engaged users compared to DHCs without MI proficiency, as measured by DHC-to-user message exchange ratio.
Hypothesis 3 (H3)	DHC-to-user message exchange ratio (engagement metric) will be correlated with engagement in app activities (number of techniques, days in app in 30 days).
Macroengagement	
Hypothesis 4 (H4)	DHCs with demonstrated MI proficiency will elicit a greater amount of “change talk” from users than DHCs without MI proficiency.
Hypothesis 5 (H5)	Users who were engaged by DHCs with MI proficiency will have better clinical outcomes, indicated by validated mood assessments, as compared to users engaged by DHCs without MI proficiency.

^adCBI: digital cognitive behavioral intervention.

^bDHC: digital health coach.

^cMI: motivational interviewing.

Hypothesis 1

There is evidence to show that coaching support in a digital intervention can positively impact engagement [16,29-31]. We sought to validate this research by analyzing whether there were

substantial differences in engagement in app activities between users who participated in a coach-enhanced program and users who participated in the same intervention but self-guided (without a DHC). Self-guided users were selected from a client who opted to not include DHCs as part of their benefits package.

To evaluate baseline differences between groups and programs, a chi-square statistic was used to test the difference in the proportion of coached users in groups and programs.

Hypothesis 2

To test this hypothesis, we randomly selected 50 transcripts with a 30-day exchange period between DHCs and users, intentionally using a cross-section of DHCs across a continuum of experience and training. We then assessed the MI skillset of the DHC using the MICA [25], a standardized, validated tool to assess the competency of clinicians in using the MI approach [25]. For this study, we adapted the MICA scoring methodology by classifying the composite (total) MICA score into quartiles

to accommodate the somewhat low DHC-to-user exchanges that occurred in some transcripts (Table 2). Higher MICA scores (and quartiles) indicate a more skilled coach: quartile 4 equates MI proficiency; quartile 3 equals a client-centered level; and quartiles 1 and 2 are considered below client-centered. Two experienced MICA coders double coded 25% of the transcripts to ensure interrater reliability using the quartile method. We also examined the corresponding message ratio between the user and DHC by measuring the ratio of the number of messages from the coach to the number of messages from the user. A lower ratio signifies more interaction from the user (which is preferable).

Table 2. Motivational interviewing competency assessment quartiles.

MICA ^a Score	Quartile	Description
2.0-3.9 (very low)	1	Below client-centered
4.0-5.9 (low)	2	Below client-centered
6.0-7.9 (medium)	3	Client-centered
8.0-10.0 (high)	4	MI ^b proficient

^aMICA: Motivational Interviewing Competency Assessment.

^bMI: motivational interviewing.

Hypothesis 3

We examined 1128 transcripts during the users' initial 30-day period of using the app. Inclusion criteria were "coach-engaged users," defined as users who sent at least one message to their assigned coach. High coach engagement was defined as users who responded with at least one message to every two messages from the DHC (ie, a DHC user ratio of 2.0 or less, N=413). App engagement metrics included the number of techniques and days in app in a 30-day period and were evaluated as dependent measures against coach engagement metrics.

Hypothesis 4

As previously discussed, change talk is a client utterance during a coaching session that is associated with clinical outcomes in traditional MI-based health coaching interventions [25,32]. A standardized and validated scoring system using the validated Motivational Interviewing Skill Code (MISC) was used to determine a change talk score based on the type of change talk (preparatory or mobilizing) and the strength of the change talk [33].

Hypothesis 5

This analysis examined differences between clinical outcomes for users who engaged with DHCs with MI proficiency and those who engaged with DHCs without MI proficiency. Anxiety and depression scores were measured within the app via the Generalized Anxiety Disorder 7-item scale (GAD-7) [34] and the Patient Health Questionnaire 8-item scale (PHQ-8) [35].

Clinical success was defined as a reduction of four points [36,37]. Because of this indicator, any user with a baseline score of four or less was not used for this analysis. The groups for DHC proficiency were based on the MICA quartiles, and the first two quartiles were grouped together because the n for quartile 1 was very small, and quartiles 1 and 2 were also similar in terms of ability (ie, less than client-centered). Fisher exact test was used to assess an association between DHC capability and rate of success.

Results

Hypothesis 1

During this pilot window, there was a total of 4628 users (Table 3). Out of 3218 users that were enrolled in the anxiety dCBI, 62% (1995/3218) were in the coach-enhanced program. Out of 1410 depression dCBI users, 60% (846/1410) were in the coach-enhanced program ($\chi^2=2.4$; $P=.12$). Users were between 16 and 87 years of age (mean 40, SD 14) and 70% were female. dCBI app engagement was measured via two metrics: the number of app activities ("techniques") completed by the user and the total number of days that the user was active in the app. A Kolmogorov-Smirnov statistic was run on coached and self-guided user samples with app engagement metrics as the dependent variable. We found significant group differences between self-guided and coached users in terms of app engagement metrics ($P<.001$). Coached members in both anxiety and depression programs spent more days in the app ($P<.001$) and completed more app activities ($P<.001$).

Table 3. Coached versus noncoached engagement.

	Noncoached	Coached	Statistic	P value
Anxiety				
Users, n	1223	1995	N/A ^a	N/A
Age (years), mean (SD)	42 (10)	38 (15)	9.068	<.001
Gender, n (% female)	773 (64)	1556 (78)	N/A	N/A
Techniques, mean (SD)	0.96 (2.77)	5.82 (10.7)	0.43	<.001
Days in app, mean (SD)	3.67 (6.37)	11.1(10.7)	0.42	<.001
Depression				
Users, n	570	840	N/A	N/A
Age (years), mean (SD)	43 (10)	39 (15)	6.007	<.001
Gender, n (% female)	342 (60)	605 (72)	N/A	N/A
Techniques, mean (SD)	1.23 (2.64)	5.3 (9.1)	0.31	<.001
Days in app, mean (SD)	4.07 (6.9)	10.2 (10.6)	0.34	<.001
Total				
Users, n	1793	2835	N/A	N/A
Age (years), mean (SD)	42 (10)	39 (15)	8.161	<.001
Gender, n (% female)	1115 (62)	2161 (76)	N/A	N/A
Techniques, mean (SD)	1.05 (2.7)	5.67(10.3)	0.39	<.001
Days in app, mean (SD)	3.8 (6.5)	10.8 (10.7)	0.40	<.001

^aN/A: not applicable.

Hypothesis 2

A Pearson product-moment correlation examined the relationship between the MICA quartile and message ratio and found that higher MICA quartiles had a lower message ratio with their users ($r=-0.79$, 95% CI -0.87 to -0.66). A Kruskal-Wallis nonparametric statistic was also calculated to

detect differences in message ratios based on the MICA quartile group (Table 4). The P value for the Kruskal-Wallis test was significant ($P<.001$); the mean message ratio improved with increasing MI proficiency, indicating that coaches who were more skilled experienced more interaction/engagement with their users.

Table 4. Coach quartile and average message ratio.

	Message transcripts (N=50)	Average message ratio ^a	Standard deviation	Median	Correlation ratio	P value (Kruskal-Wallis test group differences)
MICA^b score quartile					0.79	$P<.001$
1	10	3.83	0.99	3.58		
2	14	2.55	0.70	2.68		
3	12	1.95	0.31	1.94		
4	14	1.44	0.36	1.33		

^aAverage message ratio is better when exchange number is lower.

^bMICA: Motivational Interviewing Competency Assessment.

Hypothesis 3

A Pearson product-moment correlation was used to examine differences in app engagement between users who had high engagement with their assigned DHC and those who had low engagement with their DHC (Table 5). Users who were more engaged with their coach completed a greater number of techniques ($r=0.28$, 95% CI 0.23 - 0.33) and spent more days in

the app ($r=0.37$, 95% CI 0.32 - 0.42). A Kruskal-Wallis nonparametric test evaluated group differences in app engagement metrics within high and low coach engagement and found that both techniques and days in app were significant ($P<.001$). Overall, app engagement increased with greater coach engagement, indicating greater rates of response to coach messages.

Table 5. Coach engagement and app engagement.

Coach engagement	Participants (N=1128)	Average number of techniques	Standard deviation	Median	Correlation ratio	Kruskal-Wallis test (group differences)	P value
Number of techniques					0.28	92.4	<.001
Low ^a	715	7.46	9.4	5			
High ^b	413	15.56	18.3	9			
Days in the app					0.37	174.9	<.001
Low ^a	715	15.43	9.73	15			
High ^b	413	23.15	8.71	28			

^aLow engagement=digital health coach (DHC):user message ratio>2.0

^bHigh engagement=DHC:user message ratio<2.0

Hypothesis 4

The average change talk score increased as the MI proficiency increased for the DHCs. A Kruskal-Wallis nonparametric statistic was calculated to determine whether there were

substantial differences in change talk in user responses between users who interacted with an MI-proficient DHC and those who interacted with DHCs below MI proficiency (Table 6). The test indicated that there was a difference in change talk scores with higher MI proficiency ($H=25.12$, $df=2$; $P<.001$).

Table 6. Change talk score by the Motivational Interviewing Competency Assessment (MICA) score^a.

MICA score	Transcripts (N=30)	Min	25th percentile	Median	75th percentile	Max	Mean	Standard deviation
Low	10	3	5	7.5	8	12	7.2	2.86
Medium	10	11	14	17	18	20	15.8	3.16
High	10	25	27	35.5	45	51	36.6	9.57

^aKruskal-Wallis (group differences): $P<.001$.

Hypothesis 5

Users who were engaged by DHCs with MI proficiency had a higher success rate (Table 7; $P=.02$). This result was also significant for users in the anxiety program ($P=.03$), while the results for users in the depression program trended toward significance ($P=.06$); this cohort had a much lower volume, particularly those users interacting with a highly skilled DHC.

A Cochran-Mantel-Haenszel (CMH) trend test was also used to determine whether there was a linear trend between DHC proficiency and success. The CMH trend test showed similar results for the overall and anxiety discussion groups ($P=.02$ and $P=.007$, respectively). These findings indicate that there was an increased rate of clinical success among users who engaged with more skilled DHCs.

Table 7. Program success based on MICA quartile.

Reduction	Yes, n (%)	No, n (%)	Overall independence <i>P</i> value (CMH ^a test)	Trend <i>P</i> value (CMH test)
Depression and anxiety			.02	.02
MICA ^b quartiles 1 and 2	36 (46)	43 (54)

Discussion

Principal Findings

The emergence of digital health interventions has afforded the opportunity to address behavioral health crises in the United States by improving access to care and reaching more people who are struggling with mental health issues. Evidence continues to demonstrate that dCBIs can effectively help people manage anxiety and depression, and these effects increase with greater intervention engagement [9,15,30,38]. While DHCs are emerging as important mediators to this, it remains critical to better understand how to strengthen the impact of DHCs by focusing on the quality of engagement rather than simply on quantity (ie, volume of messages sent). This pilot study tested the hypothesis that systematically applying an evidence-based coaching approach (MI) to digital coaching protocols would enhance dCBI engagement and outcomes.

First, our results underscored the importance of a dual intervention approach, as our findings were consistent with literature demonstrating that combining technology with coaching elicits greater app engagement compared to self-guided interventions [30,31]. Moreover, we validated that a standardized MI coaching protocol can be effectively integrated into a digital intervention. MI is considered a best practice communication approach with extensive evidence supporting its ability to positively impact behavioral outcomes [18-20]. Given the historical use of MI for in-person or telephonic interventions, it is encouraging to see that not only can it be applied to an asynchronous chat but also that increased user engagement with a DHC was correlated with spending more days in the app and completing more app techniques. This is critical, as evidence suggests a dose-effect relationship between intervention engagement and health improvement [13]. Therefore, the more a user practices app techniques and interacts with their DHC, the more CBT they receive, and the better they

ultimately feel. We found these effects were even greater when a user interacted with a DHC who was fully proficient in MI.

An additional question we aimed to answer was what level of MI proficiency a digital coach needs to be effective. An MI-proficient DHC empowers and activates the user while a client-centered DHC engages and responds to user needs in a supportive way. DHCs in this pilot who empowered and activated users had more interactions and elicited a greater amount of “change talk,” which allowed the DHC to strengthen motivation and the desire to change by evoking, reflecting, affirming, summarizing, or elaborating on the change talk. This in turn allowed for more dialogue in the direction of change and empowered the user by increasing language that indicates a sense of self-efficacy and personal agency. As a result, users with more highly skilled coaches completed more app activities, spent more days in the app, and had better clinical outcomes. While these benefits were demonstrated among client-centered DHCs, we found that MI-proficient DHCs produced the greatest outcomes.

Implications for Practice

The success of dCBIs is dependent on robust user engagement. Unfortunately, these programs often demonstrate low levels of engagement and high dropout rates [31,39]. Results from this pilot suggest that developing an MI-proficient DHC skill set is critical to enhancing dCBI engagement, health behavior change, and behavioral health outcomes. Reaching MI proficiency depends not only on initial comprehensive training but also on ongoing competency assessment, feedback, mentoring, and skill building [40]. Unfortunately, while organizations are investing in bringing digital tools into their clinical workflows, they are not investing the time or resources to reach this level of proficiency among those delivering the intervention. While employing DHCs who are client-centered may help to move the needle, MI proficiency may be necessary to optimize the return on the digital health investment.

Conclusion

DHCs have emerged as a new care role that can extend our reach and ability to support individuals struggling with their mental health. To our knowledge, this pilot was the first of its kind to test the application of MI to digital coaching protocols, demonstrating the value of MI proficiency in digital health

coaching for enhanced engagement and health improvement. To have a significant impact on the field of dCBIs, organizations investing in digital health have key decisions to make regarding DHC training and support, as clinical behavioral health outcomes may depend on making a stronger commitment to strengthen the exchange between users and DHCs.

Acknowledgments

We would like to acknowledge Allison Siegel, Daniel Watson, and Nicole Beswick for their support in conducting this pilot. In addition, we acknowledge the University of Pittsburgh Medical Center (UPMC), the UPMC Health Plan digital health coaches, and the leadership support from Laetitia Rohan and Laura Francis.

Conflicts of Interest

Abstract

Background: Increasing youth mental health problems over time correlate with increasing rates of social media use (SMU); however, a proposed contributory relationship remains unproven. To better understand how SMU impacts mental health requires a more nuanced understanding of the relationship between different patterns of SMU and specific individual factors. Studies suggest that more *active* forms of SMU may offer mental health benefits when compared with more *passive* forms. Furthermore, the literature suggests important differences in patterns of SMU and affective states among those identifying as racial and ethnic minorities.

Objective: Using ecological momentary assessment (EMA), this study aims to investigate potential differences in affective states during *active* and *passive* forms of SMU and whether such differences vary by race and ethnicity.

Methods: We recruited patients seeking care at a large urban adolescent medicine clinic who exhibited at least mild depressive symptoms based on Patient Health Questionnaire-9 (PHQ-9) scores. Participants completed an enrollment survey and a 7-day EMA protocol, receiving 5 EMA questionnaires per day, which assessed real time SMU behaviors and affective states using the Positive and Negative Affect Schedule-Expanded form subscales. To correct for nonindependent data with EMA responses clustered within individuals, data were analyzed using mixed-effects modeling, allowing for a random intercept at the individual level to examine associations between EMA-reported SMU and affective states while adjusting results for age, gender, race and ethnicity, PHQ-9 score, and EMA response rate.

Results: A racially and ethnically diverse group of 55 adolescents aged 14 to 19 years provided a total of 976 EMA responses, averaging 17.76 (SD 8.76) responses per participant, with a response rate of 51.15%. Participants reported higher mean levels of negative affect during *active* SMU ($F_{1,215}=3.86$; SE 0.05; $t_{1,215}=1.96$; $P=.05$) and lower mean levels of positive affect during *passive* SMU ($F_{1,369}=3.90$; SE 0.09; $t_{1,369}=-1.98$; $P=.049$). However, within different racial and ethnic groups, higher levels of negative affect during moments of *active* SMU were seen only among Black non-Hispanic participants: $F_{1,81}=6.31$; SE 0.05; $t_{81}=2.51$; $P=.01$). Similarly, lower levels of positive affect during *passive* SMU were seen only among White non-Hispanic participants ($F_{1,295}=10.52$; SE 0.13; $t_{295}=-3.24$; $P=.001$).

Conclusions: Although in aggregate, adolescents with depressive symptoms experienced more negative affect during *active* SMU and less positive affect during *passive* SMU, these mean outcomes were driven solely by greater negative affect during *active* SMU by Black non-Hispanic participants and lower positive affect during *passive* SMU by White non-Hispanic participants. Differences in intentionality, content, context, and expectations of SMU among youths across racial and ethnic groups may result

in different affective outcomes. Exploration of the interactions among cultural differences in SMU strategies and characteristics will be critical to furthering our understanding of the impact of SMU on youth mental health.

Introduction

Background

Social media use (SMU), the use of “internet-based networks that enable users to interact with others, verbally and visually,” [1] is exceedingly popular among youths as it combines their desire to connect with peers with their interest in engaging technologies. Increasing rates of SMU over time [2-4] have been correlated with rising rates of youth mental health problems [5-7]; however, a proposed contributory relationship remains unproven. Much attention has been paid to the potential link between SMU and rates of major depression [8], with the latter having increased dramatically in the United States and abroad over the past one to two decades, particularly among adolescents and young women [9,10].

Although some evidence suggests that children and adolescents with high-frequency SMU experience increased rates of mental health problems and greater depressive symptoms, the overall data are inconclusive, with some studies demonstrating no difference or even suggesting minor psychological benefits [11,12]. A recent study examined 6 systematic reviews from the past decade, 3 large-scale national cohort studies, and 5 diary and ecological momentary assessment (EMA) studies examining associations between SMU and adolescent mental health [13]. Although some studies demonstrated negative associations with small effect sizes, the larger picture revealed a combination of mixed, null, and positive associations between SMU and mental health. One of the reviews demonstrated that SMU accounted for only 0.4% of the variation in well-being, palling in comparison with factors such as family socioeconomic status, family history of depression or anxiety, and exposure to adverse childhood experiences, which account for 5% to 20% of the differences in mental health symptoms [14,15]. Another large-scale review examined >80 key studies, systematic reviews, and meta-analyses, concluding that there exists a small, negative association between SMU and psychological well-being but emphasizing the ongoing need for higher-quality data with a more nuanced view of different types of SMU and the role of potential confounders [12].

Variations in the relationships between SMU and mental health outcomes may have resulted from how SMU was defined and measured, what mental health symptoms were considered, and the potential influence of confounders. When SMU is considered as a binary or duration-of-use variable, without discriminating among user characteristics or their specific SMU behaviors, a more granular and useful understanding of how SMU can affect mental health may be lost.

Most SMU studies thus far have relied on retrospective self-reports, which may experience recall bias. Studies that

incorporate EMA, which allows for *in-the-moment* data collection by asking participants to report on recent lived experiences, can produce more reliable and complete data, capturing specific patterns of SMU [16].

Patterns of SMU Characteristics

Some recent studies have taken a more nuanced look at different patterns of SMU and their relationship with specific mental health outcomes [17,18]. Evidence suggests that certain SMU characteristics may help determine whether one experiences any SMU-related negative mental health consequences. For instance, individuals who report using greater numbers of social media platforms or longer durations of SMU are more likely to experience depression or other mental health problems [19-21]. Similarly, individuals whose SMU comprises more negative interactions or who perceive themselves to be less popular or successful than their peers on social media experience decreased levels of happiness [22-25].

Regarding individual patterns of use, SMU that is *active* rather than *passive* has been associated with improved mental health outcomes [26-29]. *Active* SMU, which is characterized by the act of engaging in direct interactions with other users, sharing life experiences, or creating new content, is associated with decreased depressive symptoms in adults. As a potential explanation, *active* SMU is theorized to lead to an improved sense of well-being by increasing one’s social capital among acquaintances and eliciting more emotional support and positive feedback from friends [30]. An alternative explanation is that individuals who are less depressed may be more likely to engage in *active* SMU.

On the other hand, *passive* SMU, characterized by the act of *lurking* or observing while maintaining low engagement with other users, is associated with higher levels of depressive symptoms [28,29,31,32]. *Passive* SMU may result in more instances of upward social comparison, in which one negatively evaluates oneself in comparison with the perceived realities of others [33]. Alternatively, individuals who are more depressed may be more likely to engage in *passive* SMU. Therefore, when studying the relationship between SMU and mental health outcomes, distinguishing between *active* versus *passive* SMU is likely an important consideration.

Individual Characteristics

Overview

At present, it remains unclear how the characteristics of individuals using social media may affect their frequency or type of SMU or lead to different mental health outcomes. Although there are reasons to hypothesize a contributory link between certain types of SMU and declining mental health (eg, SMU that displaces face-to-face social interactions and leads

to increased social isolation and loneliness), underlying mental or behavioral health issues may actually drive high-frequency SMU. In fact, young people with certain behavioral health conditions—especially attention-deficit/hyperactivity disorder, social anxiety disorder, autism spectrum disorder, and depression—use screen media more and are predisposed to *problematic interactive media use*, characterized by a clinically relevant decline in one's functional status [34-42]. Underlying mental health conditions may also amplify or otherwise alter the effects of SMU. Therefore, youths with depression may be at an increased risk of experiencing mental health problems related to SMU, and research focusing on this group could reveal important susceptibilities.

Differences in SMU by Race and Ethnicity

Multiple studies have suggested that race/ethnicity may be an important moderator of the impact of SMU on mental health. Different experiences using social media networks may confer different levels of risk by race/ethnicity for mental health outcomes. Although adolescents of different racial/ethnic groups do not differ in their total number of *social media ties* (ie, friends on social media platforms), Black youths report a higher number of *weak ties* (ie, low perceived level of closeness) and White youths report a higher number of *strong ties* (ie, high perceived level of closeness). Furthermore, when considering past patterns of SMU among college students, Black and Latinx students reported more web-based social media content creation than White students, despite having historically less access to the internet [43,44]. Increased content creation, as an *active* form of SMU, may contribute to some mental health benefits. Therefore, social media platforms may provide different levels of social support and mental health protection for these groups [45].

Conversely, minority groups face potential exposure to racist and/or discriminatory content during SMU. Among Black young adults, SMU on certain platforms is associated with increased anticipatory race-related stress, bodily alarm responses, and anger expression, in part mediated by individual experiences of perceived racism and everyday discrimination [46]. Higher levels of discrimination during SMU are associated with increased symptoms of depression and anxiety among young Latino adults, although not among young Latina adults [47]. SMU may expose Black individuals and other racial/ethnic minority groups to discriminatory content not experienced by their White peers, resulting in poorer mental health outcomes [48,49].

Goals of This Study

This study has 3 aims. The first is to investigate, within a sample of youths with depression, momentary associations between SMU and three types of affective states: positive affect, negative affect, and sadness. The second aim is to investigate whether adolescents' *active* and *passive* SMU are related to these affective states. The third aim is to determine whether there are racial/ethnic differences in momentary affective states during SMU and in the associations between SMU and affect.

Methods

Participants, Design, and Study Procedures

Overview

This study used EMA survey data from a clinical sample of patients aged 14 to 19 years recruited from a large urban adolescent medicine clinic during the period from August 2016 to March 2018. Patients seeking well care were asked to complete the Patient Health Questionnaire-9 (PHQ-9), and those with a score of ≥ 5 , indicating at least *mild depression* as per PHQ-9 scoring guidelines [50], were eligible for inclusion. The data for this study were collected to answer a series of questions investigating youth media use behaviors and individual user characteristics, with this study answering specific questions about the role of racial/ethnic differences in use behaviors and affective experiences during SMU.

Ethics Approval

The institutional review board of Boston Children's Hospital approved this study (Institutional Review Board protocol number IRB-P00019244), and participants were assured of their confidentiality. All participants or parents of minor participants provided written informed consent. Once enrolled, participants completed surveys at the time of enrollment and EMA questionnaires multiple times a day for the next 7 days.

Enrollment Survey

After completing the PHQ-9 as a screener for inclusion, qualifying participants completed an enrollment survey that assessed key demographic information. Consistent with the most recent US national census questionnaire, race/ethnicity/ancestry (hereafter referred to as *race/ethnicity*) was assessed with a single item that asked, "Which of the following best describes you?" with the ability to select all answers that apply from the following options: (1) *White/Caucasian*; (2) *Hispanic, Latino/a, or Spanish*; (3) *Black*; (4) *African American*; (5) *Asian or Asian American*; (6) *Middle-Eastern or North African*; (7) *Native American/American Indian/Alaskan Native*; (8) *Native Hawaiian/Other Pacific Islander*; or (9) *other, please specify*. For the purpose of our analyses, participants were grouped by self-identified race/ancestry (eg, White, Black or African American, biracial) and ethnic background (ie, Hispanic or non-Hispanic origin). The 3 primary groups identified were Black non-Hispanic, White non-Hispanic, and Hispanic.

EMA Assessment

Overview

For the week following enrollment and based on standard EMA protocol, participants received 5 daily EMA assessments administered at random intervals sent to their personal smartphones (or 1 provided to them) using MetricWire [51] software package. Notifications for surveys were sent from 8 AM to 10 PM on weekends, from 6 AM to 8 AM, and then again from 3 PM to 10 PM on weekdays. Each EMA survey assessed whether participants engaged in a series of social behaviors, including SMU, texting/asynchronous messaging,

making voice/video calls, or having face-to-face conversations and concurrent affective states.

Capturing Real Time SMU

SMU behaviors reported in EMA surveys were characterized with respect to frequency and type of use. For the purpose of this study, SMU was defined as any behavior for which the participant indicated using a web-based platform that allows for interaction and communication. This included behaviors such as *checking a social network, checking a web-based bulletin board or asynchronous messaging* (eg, text, email, Snapchat, or WhatsApp), and *real time messaging* (eg, web-based chats, Skype, FaceTime, telephone calls, and messaging or chatting while playing a video game). Whenever a participant reported an instance of SMU, they were asked to answer follow-up questions about whether they were interacting or messaging with anyone to further characterize their behaviors. *Active* SMU was defined as any moment of reported SMU that included direct engagement with another person or persons via posting, responding to a post, messaging, or chatting. Conversely, *passive* SMU was defined as use that did not include direct engagement with another person (eg, reading posts or scrolling without commenting). A final term, *any* SMU, was used to describe any moment that comprised either *active* or *passive* SMU.

Capturing Real Time Affective States With the Positive and Negative Affect Schedule–Expanded Form Subscales

Each EMA survey assessed emotional affect using subscales of the Positive and Negative Affect Schedule–Expanded form, which measured participants' positive affect, negative affect, and sadness [52,53]. As a tool, the Positive and Negative Affect Schedule–Expanded form is widely used and well-validated for measuring an individual's emotional states that fluctuate over time. The subscales for positive affect (eg, attentive, alert, excited, and enthusiastic) and negative affect (eg, hostile, irritable, ashamed, and distressed) each comprise 10 items with potential responses ranging from 0 to 4 (0=very slightly or not at all and 4=extremely). The sadness subscale comprises 5 items, with potential responses ranging from 0 to 4. These subscales vary independently, meaning that negative affect does not necessarily increase when positive affect decreases and vice versa.

Statistical Modeling and Analysis

Real Time Affective States During SMU

We used the EMA responses to compare reported levels of positive affect, negative affect, and sadness during SMU moments and non-SMU moments. To correct for nonindependence of the data with EMA responses clustered within an individual, we used mixed-effects modeling, allowing for a random intercept at the individual level to examine associations between SMU and EMA-reported affective scores while adjusting the results for age, gender, race/ethnicity, PHQ-9 score, and EMA response rate. We used similar procedures to examine differences in affect during *active* and *passive* SMU.

Real Time Affective States During SMU by Race/Ethnicity

To investigate the differences in the associations between SMU and affect by race/ethnicity, the abovementioned mixed-effects models *active*, *passive*, or *any* SMU were analyzed separately with the inclusion of an interaction term, *race/ethnicity*×*SMU behavior*. As this was an interaction between a 2-category (race/ethnicity) and 3-category variable (*active* or *passive* SMU vs any other behavior), it was represented in the model by 2 interaction terms. When either of these 2 variables was significant at $P<.10$, pairwise contrasts based on estimated means adjusted for the covariates were compared to determine the direction of the interaction.

Results

Sample Characteristics

The sample was mostly female and comprised similar percentages of Black non-Hispanic, White non-Hispanic, and Hispanic participants (Table 1). Approximately 5% (3/55) of participants were excluded from the analysis because of a lack of EMA data. Overall, participants responded to more than half of the EMA prompts. The average PHQ-9 score from enrollment revealed moderate amounts of depressive symptoms with a normal distribution. On the basis of the EMA survey data, participants reported SMU during 14.2% (139/976) of EMA responses, texting/asynchronous messaging during 13.8% (135/975) of EMA responses, making a voice/video call during 2.4% (23/975) of EMA responses, and having a face-to-face conversation during 19% (185/975) of EMA responses.

EMA Outcomes

Affect During SMU

When comparing moments with *active*, *passive*, or *any* type of SMU with non-SMU moments using generalized linear modeling, there were some observed differences in overall real time affective states (Table 2). During moments of *any* SMU, participants reported higher overall levels of both negative affect ($F_{1,131}=5.30$; SE 0.04; $t_{131}=2.30$ [2-tailed]; $P=.02$) and sadness

($F_{1,39}=4.59$; SE 0.08; $t_{39}=2.14$; $P=.04$). During moments of *active* SMU, participants reported higher overall levels of negative affect ($F_{1,215}=3.86$; SE 0.05; $t_{215}=1.96$; $P=.05$) and trended toward higher levels of sadness. However, during moments of *passive* SMU, participants instead reported lower levels of positive affect ($F_{1,369}=3.90$; SE 0.09; $t_{369}=-1.98$; $P=.049$) without apparent differences in negative affect or sadness.

Table 2. Effects of SMU^a type on mean affect scores^b.

SMU type and affect type	Coefficient	SE	<i>t</i> test (<i>df</i>) ^c	Significance, <i>P</i> value	95% CI
Any					
Negative affect	0.08	0.04	2.30 (131)	.02	0.01 to 0.16
Positive affect	-0.10	0.10	-0.94 (55)	.35	-0.30 to 0.11
Sadness	0.16	0.08	2.14 (39)	.04	0.01 to 0.32
Active					
Negative affect	0.09	0.05	1.96 (215)	.05	0.00 to 0.18
Positive affect	-0.04	0.13	-0.30 (40)	.77	-0.31 to 0.23
Sadness	0.17	0.10	1.74 (154)	.08	-0.02 to 0.04
Passive					
Negative affect	0.03	0.06	0.46 (256)	.64	-0.09 to 0.14
Positive affect	-0.18	0.09	-1.98 (369)	.049	-0.35 to 0.001
Sadness	0.04	0.11	0.39 (17)	.70	-0.20 to 0.28

^aSMU: social media use.

^bThe above results are from mixed-effects modeling with adjustments for age, sex, race/ethnicity, Patient Health Questionnaire-9 score, and ecological momentary assessment response rate.

^c2-tailed.

Affect During SMU by Race/Ethnicity

Using generalized linear modeling with the addition of a race×SMU type interaction term, there were some observed differences in reported affective states by race/ethnicity during moments of *active* and *passive* SMU compared with all other moments. During the moments of *active* SMU, the race×*active* SMU interaction term approached significance (Table 3). Among different racial/ethnic groups, Black non-Hispanic participants reported higher levels of negative affect during moments of *active* SMU ($F_{1,81}=6.31$; SE 0.05; $t_{81}=2.51$; $P=.01$), which was not observed for participants from other racial/ethnic

groups. Notably, a similar trend in the direction of change that did not rise to the level of significance was seen for Hispanic participants, whereas no such trend was observed for White non-Hispanic participants.

During the moments of *passive* SMU, the race×*passive* SMU interaction term was also found to be significant (Table 3). Within different racial/ethnic groups, White non-Hispanic participants reported lower levels of positive affect during moments of *passive* SMU ($F_{1,295}=10.52$; SE 0.13 $t_{295}=-3.24$; $P=.001$), a finding not seen in Black non-Hispanic or Hispanic participants.

Table 3. Group differences in mean affect during SMU^a versus all other moments^b.

Affect and race/ethnicity ^a	Coefficient	Mean difference	SE	<i>t</i> test (<i>df</i>)	Significance, <i>P</i> value	95% CI
Negative affect (during active SMU)						
Race and ethnicity×active SMU (1)	0.125	N/A ^c	0.07	1.89 (132)	.06	−0.01 to 0.26
Race/ethnicity×active SMU (2)	0.012	N/A	0.11	0.12 (132)	.91	−0.20 to 0.22
Black non-Hispanic	N/A	0.13	0.05	2.51 (81)	.01	0.03 to 0.24
White non-Hispanic	N/A	0.01	0.04	0.18 (118)	.86	−0.08 to 0.09
Hispanic	N/A	0.12	0.09	1.33 (144)	.19	−0.06 to 0.30
Positive affect (during passive SMU)						
Race/ethnicity×passive SMU (1)	0.405	N/A	0.18	2.24 (677)	.03	0.05 to 0.76
Race/ethnicity×passive SMU (2)	0.047	N/A	0.24	0.20 (677)	.84	−0.42 to 0.52
Black non-Hispanic	N/A	−0.03	0.12	−0.22 (586)	.82	−0.26 to 0.21
White non-Hispanic	N/A	−0.43	0.13	−3.24 (295)	.001	−0.69 to −0.17
Hispanic	N/A	−0.07	0.20	−0.36 (868)	.72	−0.48 to 0.33

^aSMU: social media use.

^bThe abovementioned results, including the mean differences, are adjusted for age, gender, race/ethnicity, Patient Health Questionnaire-9 score, and ecological momentary assessment response rate. Mean differences represent average affect during SMU type (*active* or *passive*) minus average affect during any other activity.

^cN/A: not applicable.

Discussion

Principal Findings

In summary, during moments of *active* SMU, participants reported higher overall levels of negative affect and sadness. However, this relationship was observed only among Black non-Hispanic participants and was not observed in White non-Hispanic participants. Similarly, during moments of *passive* SMU, participants reported lower overall levels of positive affect, and this finding was observed only among White non-Hispanic participants and not among Black non-Hispanic or Hispanic participants.

Considering Different SMU Experiences by Race/Ethnicity

This study attempts to enrich our understanding of the complex interrelations between SMU and affective states. Previous research has revealed that the association between SMU and indicators of mental health varies considerably among individual youths [54]; however, our understanding of what drives these differences is extremely limited. Our findings indicate that race may be an individual characteristic that determines the associations between SMU and mental health. Using our full sample, we found that certain types of SMU were linked to more sadness and negative affect and less positive affect.

Through follow-up interaction analyses, we discovered that these results hold true only for specific racial/ethnic groups in our sample.

Differences in media and SMU by ethnicities were well-documented during the emergence of mobile and social media, as minority youths (ie, Black, Hispanic, and Asian) were shown to consume 4.5 hours a day more media than their White peers and were more likely to be early users of social networking sites [55]. The size, closeness, and racial homogeneity of web-based social networks may differ across racial and ethnic groups. Although Black and White youths were shown to have similar numbers of friends on Facebook (when it was the dominant social media platform for youths), Black youths had weaker ties among those relationships, indicating an effort to diversify their social network and potentially increase their social capital [45]. Social media offers ethnic minorities a dualistic environment: the opportunity to develop a supportive community of similar peers tempered by increased levels of cyberaggression driven by racism [56]. These opposing forces shape the web-based communication of Black youths into experiences that likely vary greatly from those of White youths. Although our findings provide evidence that racial/ethnic differences are apparent in SMU and possible mental health effects, this area remains understudied. Additional research may help reveal how web-based experiences translate into different

affectual and mental health experiences across racial/ethnic groups.

Our findings regarding differences in affect during *active* and *passive* SMU may be most informative in enhancing our understanding of different ethnic/racial groups' experiences in web-based interactions. For White youths in our sample, *passive* SMU was linked to lower levels of concurrent positive affect. This result is consistent with other research showing that lurking, scrolling, and other passive uses of social media are linked to more symptoms of depression [29]. It is notable that lower levels of positive affect more aptly describe *classic* symptoms of depression (eg, fatigue, difficulty in concentrating, and loss of interest) than increases in negative affect, which include feelings of hostility and irritability. Therefore, the findings for our White non-Hispanic participants are in line with prior studies in this area that used mostly White samples, which are likely not generalizable to more diverse populations [57]. Overall, our study supports the idea that for this subsample of users, *passive* SMU is linked to indicators of depression.

However, considering that our participants were determined to be at least mildly depressed before the study, this result may be better understood as indicating that young people who are depressed are more likely to engage in *passive* SMU when experiencing lower levels of positive affect. Entertainment has been identified as the highest-rated motivation for SMU [58,59]. It seems that White youths with depression are likely to turn toward social media for entertainment and distraction when experiencing low levels of positive affect. Being actively engaged with others may not be congruent with such an affective state. Although this interpretation is consistent with our findings, our methods did not test the contributory relationship of this association. Additional research is necessary to fully reveal the complex interplay between SMU and momentary affect.

For Black non-Hispanic participants in our study, interacting directly with other people while using social media (*active* SMU) was associated with higher levels of negative affect. This finding is somewhat counter to other research showing that the active use of media is protective against symptoms of depression [26]. Although feelings of hostility and irritability are not necessarily indicators of depression, youths with depression have been shown to have higher levels of hostility both on the web and offline [60]. In our study, *active* SMU may have elicited an increase in negative affect among Black non-Hispanic youths who are depressed rather than providing a type of social support that could reduce negative symptoms.

Such a response by Black non-Hispanic adolescents may be explained by the dual nature of SMU for minority youths. The risk of experiencing racism-based cyberaggression, blatant acts of racism, microaggressions, and other forms of systemic oppression on social media, which can be further amplified by platform-based algorithms, may lead to different SMU experiences for minority-identifying individuals than for their White peers [61,62]. Lower levels of minority representation and fewer minority voices on social media, in general, may contribute to a less welcoming social media environment, leading to more negative affective experiences.

Even in web-based community building and activism, the positive side of the dual nature of SMU for minorities may hold experiences that could be more upsetting for Black non-Hispanic youths as they can include being exposed to, sharing experiences about, and building solidarity and organizing against racism and inequality. Previous research has demonstrated that Black and Hispanic participants report higher rates of *active* SMU in the form of political activism and that Black participants are more likely to engage actively with news stories posted on social media [63,64]. Considering the potential for exposure to race-related or underrepresentative news and political content on social media, it is reasonable to expect that activism and responses related to this material might contribute to greater negative affect. Although this interpretation may explain our findings, our study did not test it directly. Additional research is necessary to determine what aspects of *active* SMU might differ by race/ethnicity and translate into more negative affect for Black non-Hispanic youths.

Again, it is important to remember that our study did not test the direction of effect. Black non-Hispanic youths may turn to *active* SMU when they are experiencing higher levels of negative affect or *active* SMU may increase their negative affect or both. Given that Black non-Hispanic youths may have web-based social networks with a wider variety of relationship types (strong and weak) [45] than their White non-Hispanic peers, they may be more likely to have web-based social resources to cope with high levels of negative affect. Future research should examine how youths of different ethnicities differ in their motivations for and expectations of SMU to help understand whether and why minority youths are at a higher risk for poorer mental health outcomes.

Research, Clinical, and Industry Implications

On the basis of these findings, researchers should investigate the possibility that SMU is not experienced uniformly. One's racial/ethnic identity may be an important mediator of affective experiences during SMU. Although depression and anxiety have often been a major focus of research on the effects of SMU, there may be value in studying affect in greater detail, given the relationship between lower positive affect and depression and between higher negative affect driven by irritability/hostility and activist solidarity.

From a clinical standpoint, as associations between SMU and behavioral health conditions become more clear, clinicians will need to become comfortable with assessing and providing counseling on *problematic interactive media use* behaviors as they do with other well-established health risk behaviors. It may be clinically useful to consider how affective states may drive school or homework avoidance and/or excessive interactive media use. Conversely, we need to better understand individuals' intentions and the context of SMU, as this may be a modifiable factor that can influence affective outcomes. Our society has grown increasingly dependent on the use of digital communication for critical life activities, from education to employment and communication to interpersonal connections and relationships. If differences exist in the overall experience and impact of SMU among different racial/ethnic groups, it will

be important to understand these differences and translate them into effective screening and equitable treatment of patients.

If it is found that the design of social media platforms may contribute to inequitable SMU experiences or unhealthy behavioral outcomes, technology companies will have the opportunity to respond with design changes that promote greater equity and more positive mental health outcomes. In 2019, the social media platform Instagram started testing the potential value of hiding *like* counts to reduce user exposure to social evaluations that might threaten users' self-esteem. Instagram's chief executive officer Adam Mosseri promised, "We will make decisions that hurt the business if they help people's well-being and health." [65] In May 2021, after 2 years of testing, Instagram announced that although removing *likes* was beneficial for some users, it annoyed others, and it did not *meaningfully depressurize* their platform [66]. As a result, Instagram and parent company Facebook decided to offer users the option of turning off *likes* but leaving them viewable to others by default. Similar observations of different affective experiences of SMU by various racial/ethnic groups and considerations of design changes could improve digital wellness.

Limitations

The study's limitations include the relatively small sample size, which reduces the generalizability of the results. However, the sample included a diverse group of participants drawn from a population of patients with evidence of at least mild depression, which is an at-risk group of great clinical interest. In addition, our analyses were performed at the moment level, thereby increasing the statistical power.

Although the overall EMA survey response rate (approximately 50%) was similar to that of other studies using this methodology with adolescents, it does represent a potential selection bias. Participants with higher response rates could provide qualitatively different responses than those with lower response rates. For instance, participants with higher levels of social anxiety exhibited higher EMA response rates. In addition,

adolescents may have avoided answering surveys during SMU, especially when they were actively engaged in it. However, EMA measures essentially eliminate recall bias, which likely greatly enhances the reliability of patient reports.

Another limitation of this study was the inability to prove that SMU contributes to mental health problems. Given the dynamic nature of social media, our results may be sensitive to the specific period during which the study was performed. Study participants' SMU characteristics and affective experiences may be highly dependent on news stories that happened to be trending at a given point, creating the potential for chronology bias.

Future Research

Moving forward, it will be important to measure momentary affective responses to SMU in more detail, with larger populations, with different social media designs, and over longer periods to achieve greater granularity and demonstrate the stability of these findings. Given the significant differences in affective experiences among racial/ethnic groups, future research should broaden to include gender, culture, and other experience-influencing user characteristics.

Conclusions

At a time marked by increasing trends in mental health problems and unprecedented levels of interactive media use among children and adolescents, there is a real urgency to achieve a better understanding of the relationships between different media use behaviors and mental health problems. Identifying helpful and harmful digital design features and risk and protective factors in users will be of paramount importance, as will be the continued study of the role of racial/ethnic identities and other individual factors as potential moderators of media use experiences. As the nature of our social interactions continues to evolve in an increasingly digital landscape, so too must our understanding of the potential influence of these behaviors on the health and well-being of the children, adolescents, and young adults we serve.

Abstract

Background: As mobile phone uptake in India continues to grow, there is also continued interest in mobile platform-based interventions for health education. There is a significant gender gap in mobile phone access—women's access to mobile phones is constrained by economic and social barriers. Pregnancy and postpartum care is one of many targets for mobile health (mHealth) interventions that particularly rely upon women's access to and facility with mobile phone use.

Objective: We aimed to describe the dynamics and patterns of married pregnant and postpartum women's mobile phone access and use (among both phone owners and nonowners) who participated in an mHealth postpartum care intervention and to identify potential barriers to their participation in mobile platform-based interventions.

Methods: A secondary analysis was performed on mixed methods data obtained for a pilot mHealth intervention for postpartum care of mothers in rural Punjab from July 2020 to February 2021. Two formative sources included exploratory in-depth interviews among postpartum women (n=20; 1-3 months postpartum) and quantitative maternal health survey among women who were pregnant or who had recently given birth (n=102). We also utilized mixed methods intervention assessment data from early postpartum women who participated in the pilot intervention (n=29), including intervention moderator perspectives. Qualitative and quantitative analyses were performed, and pertinent findings were grouped thematically.

Results: The majority of women owned a phone (maternal health survey: 75/102, 74%; demographic survey: 17/29, 59%), though approximately half (53/102, 52%) still reported sharing phones with other family members. Sharing a phone with female family members typically allowed for better access than sharing with male family members. Some households had strict preferences against daughters-in-law having phones, or otherwise significantly restricted women's phone access. Others reported concerns about phone use-related health hazards for mother and infant during the pregnancy or postpartum period.

Conclusions: These findings suggest nuance regarding what is meant by women's phone ownership and access—there were numerous additional constraints on women's use of phones, particularly during pregnancy and the postpartum period. Future

research and mHealth interventions should probe these domains to better understand the dynamics governing women's access, use, and fluency with mobile phones to optimally design mHealth interventions.

Introduction

Mobile phone use is growing dramatically globally, including in India. India's subscriber base for mobile devices in 2015 was 867.8 million (64.8% of the country's population) and was slated to rise exponentially by 2019 due to a 4-fold increase in mobile commerce sales. [1]. In the Indian states of Punjab and Haryana alone, over 70% of internet users access wireless networks through mobile devices [2]. Smartphone penetration was predicted to rise to 800 million users before the end of 2019 [1]. Younger people are even more likely to use mobile phones; over 25% of retail transactions in India are web-based using mobile phones, with the highest reported use being in the age group of 18- to 34-year-old adults [3].

Mobile phone use has expanded to health care as well in India, with more people opting for telehealth provider interactions [3]. Thus, there is increased possibility for reaching people, including women, with health care information and support using mobile phones through mobile health (mHealth) interventions. mHealth approaches encompass interventions that use some type of mobile phone-based technology to provide health information or services. There have been a plethora of mHealth interventions globally that have targeted pregnancy, maternal, child, and reproductive health using approaches that include text messages, hotlines, and communication platforms that connect women to community health workers, doctors, or each other [4]. mHealth interventions have been shown to successfully improve dietary intake in pregnant women [5] and health service utilization during pregnancy, delivery, the postpartum period, and for child health [4,6]. mHealth interventions have particular potential value for women in the postpartum period in India where postpartum visits are below recommendations [7]. Significant logistical barriers prevent mothers from physically attending postnatal care appointments at facilities or other locations that may be far from their homes, particularly in India [8]. Common logistical challenges, such as difficulty obtaining transportation and with scheduling, are exacerbated in India by rural geographic distances, cultural and linguistic barriers to care, women's practice of postnatal seclusion, and generally low levels of mobility for married women [9-11]. Further intergenerational and gender-based hierarchical roles structure decision-making in Indian households, particularly for couples living in extended-family households, with decision-making largely outside of the hands of mothers [12], especially those who are young and newly married. Despite women's physical mobility limitations in this setting, there is broad access to mobile telephones in India with 88% of households nationally owning a mobile phone [13].

Despite high household phone ownership, substantial gender disparities in phone ownership and use exist in India. In fact, South Asia has the largest gender gap in phone ownership of any region globally [14]. A 2019 report [15] highlighted some of these gaps, finding that 75% of men and only 51% of women owned mobile phones in India. This gap is even more pronounced for smartphone ownership, with 37% of men owning smartphones in 2019 compared to only 14% of Indian women [16]. Men are more likely not only to own a phone, but also to make calls, receive calls and text messages, and access the internet [15]. Women phone users may be expected to spend small amounts of time on the phone and to do so mostly within their homes. Unequal gender norms and conceptions of women's roles in the household impact phone use as well, as phone use may be considered to be associated with risks to women's purity or reputation, and can also be seen to be in conflict with women's household responsibilities. Other research has suggested that women are perceived to not need a phone or that their use should be censored [17]. The gender gap in phone use is highest in adolescence and early marriage—when fears about women's reputations are most pronounced [15].

While there is this large gender gap in ownership of phones, Indian women often do report access to a shared phone within the household [15]. This access to a shared phone, alongside the growing population of women phone owners, has been the basis for numerous mHealth interventions targeting women, including those pertaining to maternal health [4-6,18-25]. However, because men are often the gatekeepers to these shared phones, women often have less access to these phones, either indirectly, because the men take the phones with them and are apart from women while at work, or directly, because men choose to limit how much women use the phone [15,26]. While there is increasing information about the gender gap in phone ownership and its impact on access to phones, we know little about how gender norms and inequalities around mobile phones specifically impact women's ability to participate in mHealth interventions, including those targeting women themselves.

We aimed to explore how gender, mobile phone access, and mobile phone use patterns intersected to structure women's participation in an mHealth intervention to improve access to high quality postpartum care and social support for women in rural India.

Methods

We developed an intervention to improve access to postpartum care and social support for women in rural India that included group calls over the phone and additional interaction and content over WhatsApp. We followed a human centered design process;

initial stages included a formative mixed methods phase and a pilot [27] of the intervention, which also included mixed methods evaluation.

We conducted secondary analysis of these data—exploratory in-depth interviews, a maternal health survey, and intervention assessments (Table 1). We developed interview guides and survey questions and pilot tested the tools among respondents from the same population in which we aimed to collect data; respondent feedback was used to improve the interview guides and survey questions. For the quantitative survey, where possible, validated measures were used, such as items from the National Family Health Survey of India [7]; however, we ultimately developed most items, since there were no standardized validated measures for phone use patterns specific to this population of women.

Participants for the exploratory in-depth interviews and for the maternal health survey were recruited from antenatal and birth registries in the study area and over the phone by study team members. In-depth interviews were scheduled and conducted in person (usually lasting 45 minutes and conducted at the participant's home). The interview guide included questions on conception, women's experiences across the continuum of perinatal care (ie, antenatal, childbirth, and postnatal), neonatal experiences, and women's acceptability of and preferences regarding mobile phone-based interventions. Maternal health survey participants were recruited over the phone; the survey was also administered over the phone and included questions regarding mobile phone access and use and regarding recent pregnancy and childbirth care experiences.

Participants for the mHealth postpartum information and social support pilot intervention were recruited from birth registries. Inclusion criteria were having their residence in study area, having given birth within the prior 2 weeks, being <40 years of age, and having a live neonate >1500 grams. Exclusion criteria

were complications for the mother during or after childbirth warranting hospital stay and continued medical care at the facility, stillbirth, twins, significant birth defects, inability to provide informed consent, and lack of phone access if they were unwilling to accept a phone from the study team. A study researcher explained the study procedures in detail over the phone, including the risks and benefits of participation. Participants provided verbal consent. Where requested, assent was obtained from the husband or another family member (in alignment with local norms). Participants were sequentially enrolled into 3 groups (total: n=29 women; group 1: n=7, group 2: n=10; group 3: n=12) based on their child's birth date. They completed a short demographic questionnaire at enrollment that included questions about mobile phone ownership (none, individually owned, shared with another household member), mobile phone type (smart versus feature phone), and willingness to accept a mobile phone from the study team if they did not have their own mobile phones. We conducted a brief phone-based survey on a weekly basis regarding participants' experience with the intervention, what they liked, what they did not like, and any challenges that they experienced. In-depth interviews were conducted with a subset (n=15) of participants after the 6-week intervention had been completed. Research team members moderating group sessions tracked what worked and what did not work after each group call in a structured text format.

Quantitative data were analyzed descriptively (i.e. frequencies and proportions, by data collection source). For qualitative data, we followed a 2-stage systematic process: (1) deductive and emergent coding, and (2) thematic analysis (the different dimensions and commonalities, their distribution across sociodemographic variables, and the patterns and linkages between themes). Qualitative data were coded in Dedoose cloud-based software. Findings and interpretations were discussed by the full research team.

Table 1. Mixed methods data sources combined for phone use analysis.

Source	n	Participants	Time frame
Exploratory in-depth interviews	20	1-3 months postpartum	July to December 2020
Maternal health survey	102	Pregnant or early postpartum	January to February 2021
Demographic survey	29	Early postpartum women participating in our pilot intervention	November to December 2020
Weekly check-in surveys	29	Early postpartum women participating in our pilot intervention	December 2020 to January 2021
Postintervention in-depth interviews	15	Early postpartum women participating in our pilot intervention	January 2021

Results

Phone Owners

The majority of women reported having a phone (maternal health survey: 75/102, 74%; demographic survey: 17/29, 59%). Most had access to a smartphone (87/102, 85% in maternal health survey and 29/29, 100% in demographic survey); in some cases, women themselves owned a feature phone but had access to a household smart phone. However, even when women

reported owning a phone, 53 of the 102 women (52%) in the maternal health survey reported they still had to share it with others, typically with other women in the household (such as sister-in-law or mother-in-law). When women reported they did not own a phone but had shared access to one, the owner was most commonly their husband.

The maternal health survey found that almost all phone owners use their phone for voice calls (68/75, 91%) and WhatsApp (57/75, 76%) (Table 2). Only approximately 1 in 5 used it for

internet (15/75, 20%) or for videos (14/75, 19%), and less than 10% used SMS or texting (6/75, 8%).

Table 2. Phone use by maternal health survey respondents from northern India.

Type of use	Respondents with phones (n=75), n (%)
Voice calls	68 (91)
SMS or text	6 (8)
WhatsApp	57 (76)
Facebook	21 (28)
Internet	15 (20)
Watching videos	14 (19)
Other	17 (23)

Nonphone Owners

Of the 102 respondents to our maternal health survey, 27 (26%) women did not have their own phone. However, even these nonowners had household access to phones, with 11 (41%) reporting daily use ranging from 15 to 60 minutes per day, 5 (19%) reporting only once weekly use, and another 11 (41%) reporting less than weekly use.

Women who participated in the in-depth interviews reported sharing access to phones owned by husbands, sisters-in-law, mothers-in-law, and other family members. They generally reported a single phone (as the shared phone) in the household, though some shared access to multiple household phones as the need arose. Among those who shared a phone, they often reported limited use, in some cases only to receive or make calls to their family. One respondent explained that she could use her mother-in-law's phone just to make a call but had to give it back right away and that she did not use messaging or any other phone features.

Husband's Ownership of Phone

For women whose mobile phone access was through their husband, the husband's work outside the home and his own phone use often precluded women's phone use, especially during their husband's working hours. One woman described the various approaches she used to try to participate in the intervention and the barriers she had faced:

I have only attended the first call. I attended that call on my neighbor's phone. Now they go for work. This is my husband's number. He is also always at work.

Women's travels to their natal homes, which is common in pregnancy and the postpartum period, limited their access to husbands' phones. Even in a woman's natal home, if only men had phones, the woman's access to their brother or father's phone would be similarly limited by the hours the male relative was in the home. When women shared phones with another female household member (sister-in-law or mother-in-law) they were more likely to have better access throughout the day.

Communications intended for women who were not the primary owners of a device were sometimes subject to censoring or control by the primary owner. Some women reported that their husband listened to the information and passed it along to her. Other husbands sometimes did not relay messages or contact

attempts to their wife, or acted as a barrier to direct contact by conveying messages rather than offering alternative contact numbers for their wives. Additionally, in some cases, husbands left the messaging groups intended to provide information or support for their wife.

Women noted that phone access was more restricted in their husbands' homes than in their natal homes (before they were married). One woman described how

...before marriage I had my personal phone and used it, but after marriage I have not kept any personal phone.

When asked if she felt she still needed a phone, she replied,

no, not too much. There is always someone or the other at home so I don't feel the need of it.

Family Attitudes Against Women's Phone Ownership

Some women said that their family explicitly stated that they would not allow women's phone ownership. One woman explained that her

in-laws will not agree (with my phone ownership). They do not like if we keep a phone.

Another woman initially was amenable to phone ownership, then consulted her husband and declined, stating that

it is looked down upon if women in the family (keep a phone). No women in the family, including the mother and sisters-in-law, keep a phone.

Notably, several women who were unsure about the acceptability of phone ownership explained that they would have to ask for permission from their husband or in-laws to accept a phone or to join a WhatsApp group. Even some women who were phone owners noted they would need to obtain permission to participate in a WhatsApp group.

Beliefs About Phones and Maternal and Child Health

Some mothers articulated beliefs about mobile phones and other electronics being harmful to the health and development of a fetus or young child. One woman explained that

doctors do not permit use of mobile phones during pregnancy and near a child. I don't have a smartphone but my husband has one, so when he is home I use it a little bit to watch videos... [My

husband] permitted me only one hour to use the phone, not much, because its rays are harmful for the development of the child's heart.

When asked which doctor had told her this, she said it was a doctor at a dispensary.

Another mother shared that

...[my in-laws] would say that during [pregnancy I should] keep the phone away from me as it affects the baby. Now I keep the ringtone off since she was born. Before that also I would keep vibration off and would keep it away.

Another woman reported that she had not used a mobile phone during pregnancy at all, and that

[my husband] also stopped T.V. and all for me saying that you shouldn't use anything like this that will affect the baby. Even after she was born I haven't seen that much. Now that it has been 3-4 months, I have started checking phone a little bit. He didn't allow me to watch even a little bit and said our safety is in our hands. Tomorrow if any problem arises then also it will affect us. He said that if I will see phone then I will get addicted to it and it will become the habit of the baby. I didn't use the phone for 9 months.

This concern about the child getting habituated to a phone was shared by another mother as well, who noted that

[my husband] was saying to me also to get a phone but I am not getting one because of the baby. You know that it spoils the habits of the children. Right now my brother-in-law shows [my child] the phone and he keeps on staring at it. I feel that he will get used to it and will have this habit.

Women's Household Responsibilities

Women reported household responsibilities as a significant and frequent barrier to phone use, which precluded availability even during scheduled weekly times. One woman shared

there was lot of work at home. My mother-in-law is sick already and with two kids, I barely get time for anything.

Participants in our intervention, who had recently given birth, reported childcare and household responsibilities as being substantial barriers to their participation.

Concern for Mobile Fraud

Some women reported that they were concerned that they would receive calls or messages on mobile devices from unknown numbers due to experiences with mobile fraud personally or having heard about people seeking financial information over the phone. One woman mentioned that

actually I may have missed the first 1-2 calls as my sister-in-law was hesitant and she told me so. But then I thought let's pick up and see what happens. Then we got confident that it's not a fraud call.

Discussion

General Context

We focus on the implications of these findings for future researchers and implementors designing mobile platform-based interventions for women in South Asia. Women's access to and ownership of mobile phones in India continues to increase, promoting optimism about the associated benefits to women's agency, economic empowerment, access to education, access to health resources, and opportunities for mobile platform-based interventions for health alongside other fields [15,22]. However, there have recently been some calls for caution in designing mHealth and other mobile platform-based interventions, given awareness of gender inequities in mobile phone use and access, and concern that these interventions may have potential to exacerbate these inequalities [21,22,28].

Principal Findings

Consistent with previous studies [15,17,28], in our study, we found that women reporting access to but not ownership of mobile phones may have very limited use of the device. Women whose phone access occurred through their husbands may lack access to a phone during the day when husbands are out of the house for work, thus they cannot be reached and cannot participate in mHealth interventions during that time. The same physical and logistical barriers that have been found to limit women's ability to participate in phone surveys can also hinder women's ability to participate in mHealth interventions [15].

Existing mHealth literature tends to dichotomize women's phone access based on phone ownership, where ownership may be assumed to portend greater autonomy and access than simply having access to a shared phone. However, we found there may also be significant constraints to women's use of their own phones, particularly if their phone they own is still shared. Of note, when women reported ownership of a phone that was shared, they more often shared with other female relatives rather than with male relatives. When phones were shared among women, they tended to maintain better access to the phone as compared to sharing with their husband, both indirectly because men left for work during the day, and directly because of some husbands' attempts to restrict or control women's phone access. These findings suggest that future researchers should probe all women, including phone owners, to determine whether they share a mobile device and should understand who the phone is being shared with in order to understand a fuller picture of women's mobile access.

Our findings also highlight that gender norms that have previously been identified as having an impact on women's phone ownership and use are also barriers to their participation in mHealth interventions. As in previous studies [15,17,28], our participants described challenges due to household responsibilities as well as perceptions about if, when, and how much women should be using phones. In particular, we encountered specific concerns about phone use during pregnancy and in the postpartum period, and its impact on the health and habits of the mother and infant. While these beliefs did not appear to be widespread, they had the potential to dramatically alter a woman's phone access during pregnancy and the

postpartum period, with one woman reporting almost complete avoidance of technology for the duration of her pregnancy and 3 months postpartum. We also identified concerns over potential fraud, as others have found [15], despite the fact that our initial recruitment and interaction for the intervention was through trusted and known institutions. This suggests that fears and myths about fraud over the phone might be a substantial barrier. Our findings extend the literature by describing how women in pregnancy and in the postpartum period may be especially limited in their ability to engage with mobile phones due to beliefs about the health and safety of women using phones while pregnant or infants being close to mobile phones. These types of beliefs act as substantial barriers and must be considered and explored further. Of note, some mHealth intervention designs include the option of providing a mobile phone or smartphone to participants. While this may address economic barriers to a participant's phone ownership, it does not address, and in fact may grate against, sociocultural barriers to women's phone use [21].

We also observed surprising phone use patterns in our survey of pregnant and postpartum women. Almost half (11/27, 41%) of nonowners who reported shared access to a phone actually used a phone less than weekly. We are not aware of previous recent studies characterizing frequency of phone use among women reporting shared access, and a recent meta-analysis of literature on women's mobile phone access similarly did not address frequency of use [17]. This is an important future avenue to explore in order to better characterize the diversity of experiences represented by Indian women who report shared phone access. Even smartphone owners report relatively low utilization of internet services other than WhatsApp, consistent with prior findings that the gender gap widens with sophistication of task (eg, taking calls vs using WhatsApp vs surfing the web) [15,17,28]. This has important implications for the development of maternal mHealth interventions that may rely on some level of fluency with app interfaces and other more sophisticated tasks.

Limitations

This study had several limitations. First, data came from different data sources, collected from women who were pregnant or had recently given birth, including both participants in our intervention as well as nonparticipants. The data were not collected synchronously, though they were all collected within 6 months of each other. We also included data collected from participants after completion of the intervention pilot. These

differences in participant populations and time points of data collection may limit the generalizability of our findings. Additionally, the generalizability of our findings is constrained by the study population being only recruited in rural Punjab, and our observed use patterns and beliefs may not be applicable to women living in urban areas or other regions of India.

Of note, the question addressed by this paper—describing women's mobile phone use patterns—was not one of our initial research questions. The themes surrounding women's mobile phone beliefs and use emerged from data being collected for the intervention design and evaluation. While this limits both the specificity and the breadth of our findings, we present only what women organically shared with us in the process of discussing the themes that we probed, with some additional quantitative context provided by our surveys. We are also accordingly constrained by collecting data only from women, whereas truly exploring this question of gender norms surrounding women's mobile phone use would benefit from the perspectives of other family members. Future exploration of this space can build on our findings by incorporating these familial perspectives as well as additional measures of empowerment to better characterize women's use of mobile phones especially for mHealth interventions during and after pregnancy.

Conclusion

As mobile technology access continues to expand in India and other countries, mobile platform-based interventions remain a promising avenue for education and information dissemination, particularly for health-related topics that carry significant potential to improve individual and population health and well-being, such as maternal and reproductive health. Pregnancy and postpartum care, in particular, have been targeted due to the high risks to mother and infant during this time, and significant room for improvement in meeting care milestones set by the Indian government and World Health Organization [7,29]. Our findings suggest that additional attention should be paid to women's phone access beyond reports of ownership or access to phones, as there may be considerable variation and constraints in the duration and timing of women's access, beliefs around mobile phone health hazards, and women's degree of facility with mobile phone functions. A better understanding of these nuanced factors will facilitate maternal mHealth intervention design and success, and may have implications for other health topics, although more research is needed.

Acknowledgments

We would like to acknowledge and thank our participants for sharing their experiences with us.

Abstract

Background: Several treatments for anxiety are available, which can make treatment decisions difficult. Resources are often produced with limited knowledge of what information is of interest to consumers. This is a problem because there is limited understanding of what people want to know when considering help for anxiety.

Objective: This study aimed to examine the information needs and preferences concerning treatment options for anxiety by assessing the following: what information people consider to be important when they are considering treatment options for anxiety, what information people have received on psychological and medication treatment in the past, how they received this information in the past, and whether there are any differences in information needs between specific samples and demographic groups.

Methods: Using a web-based survey, we recruited participants from a peer-support association website (n=288) and clinic samples (psychology, n=113; psychiatry, n=64).

Results: Participants in all samples wanted information on a broad range of topics pertaining to anxiety treatment. However, they reported that they did not receive the desired amount of information. Participants in the clinic samples rated the importance of information topics higher than did those in the self-help sample. When considering the anxiety treatment information received in the past, most respondents indicated receiving information from informational websites, family doctors, and mental health practitioners. In terms of what respondents want to learn about, high ratings of importance were given to topics concerning treatment effectiveness, how it works, advantages and disadvantages, what happens when it stops, and common side effects.

Conclusions: It is challenging for individuals to obtain anxiety-related information on the range of topics they desire through currently available information sources. It is also difficult to provide comprehensive information during typical clinical visits. Providing evidence-based information on the web and in a brochure format may help consumers make informed choices and support the advice provided by health professionals.

Introduction

Background

Anxiety disorders are one of the most common classes of mental health problems in the community [1]. Several treatment options are available for anxiety, which can make treatment decisions difficult for consumers. A way to support the treatment decision-making process is by providing high-quality information [2]. However, information about many health treatments (including treatment for anxiety) is seldom addressed and is difficult to access using currently available resources [3]. The internet is an important source of support, especially with the recent COVID-19 pandemic [4]. Unfortunately, available information on the internet tends to focus on descriptions of health problems and treatment options and provides little research-based evaluation of treatment options [5]. Professionals commonly produce resources for the public with limited knowledge of what information is of interest to consumers [3]. Indeed, existing resources often focus on a narrow range of options (ie, one or two) while overlooking others [5,6]. Making a wide range of information available to those seeking treatment for a health problem is an important step that can be taken to support treatment decision-making in individuals with different information needs and preferences.

There is a limited understanding of what people want to know when considering help for anxiety disorders, which is problematic because many people have unanswered questions not covered by currently available materials [7-9]. A recent systematic review of 12 studies on information and decision-making needs for mental health problems, such as depression and schizophrenia, revealed that *basic facts*, *treatment*, and *coping* were the most frequently cited information needs [10]. Tlach et al [10] emphasized the importance of discussing these topics with one's health care provider to gather information and make informed decisions. Liebherz et al [3] conducted a web-based study of a German sample of individuals with anxiety disorders that examined patients' information and decision-making needs and how they might inform the development of patient decision aids. These authors found that individuals with anxiety disorders reported receiving insufficient information from health care providers. Previous work by our research group has explored information needs and preferences concerning treatment options for depression, anxiety, and stress in young adults from community and college samples [7-9]. Our findings suggested that people dealing with these mental health issues want information on a broad range of topics to support their treatment decisions. Cunningham et al [8] also reported that individuals differ widely in the information they want and how they prefer to receive this information. By determining information preferences, health care providers can understand how to best deliver information to consumers.

Objectives

This study addresses the following gap in the literature: there is a limited understanding of what persons with anxiety want to know about anxiety treatment. Furthermore, increasing health care providers' understanding of patient information needs will enhance the shared decision-making process. In this study, we

evaluated the information needs of adults (aged ≥ 18 years) seeking support and treatment information for problems with anxiety. We built on earlier research exploring information needs by our research group by recruiting individuals seeking information on the web or from mental health treatment clinics and asking questions about the amount of information individuals had received on different topics. Our goal was to examine the following questions: (1) What information do people consider to be important when they are considering treatment options for anxiety? (2) What information have people received on psychological and medication treatment in the past? (3) How did they receive this information in the past? (4) Are there any differences in information needs between specific samples and demographic groups?

Methods

Participants and Procedures

Clinic Recruitment

Individuals referred by their family physician for anxiety problems to either a hospital-based anxiety clinic offered through psychology or a hospital-based psychiatric consultation service were invited to participate. Participants recruited from each clinic (before treatment) were provided with information explaining the study's procedures and a URL address they could use to access and complete a web-based survey. The response rates for the psychology and psychiatry samples were 23.2% (113/487) and 21.3% (64/300), respectively.

Website Recruitment

To provide a comparison with those seeking treatment for anxiety in hospital-based clinics, we also recruited a *self-help* sample from visitors to the Anxiety Disorders Association of Manitoba (ADAM) website (a local peer-support association). This website is widely visited by public members searching for information concerning anxiety disorders and treatment or peer-support services provided by the ADAM. Typically, more than 2000 visitors visit the ADAM website per month. A link to the survey was posted on the ADAM website, inviting interested people to click on a link to the survey.

The web-based consent form was the first webpage viewed by the participants when they visited the survey URL address. The consent form described the study's purpose and highlighted that the choice to participate would not have an impact on the care they received from the treatment settings. Participants were asked to click "yes, I consent" (and then taken to the survey) or "no, I do not consent" (asked to close the browser).

Ethics Approval

This study was approved by the University of Manitoba Psychology and Sociology Research Ethics Board (protocol 2018:011) and St Boniface Hospital Research Review Committee (RRC/2018/1753).

Measures

Information Needs Questions

Many of the questions in this section of the survey were adapted from previous research by our group on information needs and

preferences concerning mental health issues [7,9], allowing for the replication and extension of this work. Participants were first asked, “If you were having anxiety problems and considering getting help, what information would be important to you in considering the kinds of help available?” They were presented with a list of 20 information topics, including treatment options (eg, medication and psychological treatments) and information related to treatment, such as cost and side effects. These topics were rated on a scale from 0 (*not at all important*) to 8 (*very important*). Following these questions, participants were asked if they had previously received psychological treatment for anxiety. If they answered yes, they were presented with 12 information topics and asked what specific information they had received in the past regarding psychological treatment, along with an additional question regarding the information received about the use of medication. These questions were rated on a scale ranging from 0 (*none*) to 8 (*just the right amount*). If they answered no, they skipped to the next set of questions, which addressed whether participants had previously received medication treatment for anxiety problems. If they answered yes to this question, they were asked which of the 13 information topics regarding medication treatment they had received information about in the past (eg, cost and how long it takes to produce results), along with an additional question about the amount of counseling or therapy information they had received. These questions were rated on a scale ranging from 0 (*none*) to 8 (*just the right amount*). If they answered no, they skipped to the final section, where they were asked, “When you have been considering treatment options for anxiety in the PAST, how much information did you receive from each of following sources?” The 10 items in this section were rated on a scale from 0 (*none*) to 8 (*a lot*).

Sample Characteristics

Participants were asked to provide information concerning their gender, age, marital status, education level (ie, sum of years of education in high school, college, university, and apprenticeship categories), the main activity in the past 12 months (ie, work and school), and country of birth. In addition, they were asked if they had previously been diagnosed with an anxiety disorder by a health care professional. They were also asked if they had previously received psychological or medication treatment or if there was a time when they felt they would have benefited from either treatment but did not receive it. Finally, they were asked about their experience with self-help approaches (eg, exercise and meditation).

Anxiety Symptoms

Participants' current level of anxiety symptoms was assessed using the PROMIS (Patient-Reported Outcomes Measurement Information System) Anxiety Scale (short form), which is a validated measure of anxiety symptoms [11]. The survey uses the following introductory statement: “In the past 7 days...” This is followed by 8 items rated on a 5-point rating scale ranging from 1 (*never*) to 5 (*always*). This scale has good internal consistency with a Cronbach α of .93 reported in previous work [11], similar to the internal consistency found for these items in this study (Cronbach α =.92). This scale also has good validity (divergent, $r=0.72$, and convergent, $r=0.80$).

Statistical Analysis

Overview

We computed and tabulated descriptive statistics for sociodemographic variables and responses to questions about information experiences and preferences. Sociodemographic data obtained from different groups of respondents were compared using 1-way ANOVA tests for means and chi-square tests for proportions. CIs for mean ratings on the survey items were reported, allowing for convenient comparisons within and across different survey questions and groups of respondents.

In addition, we computed a composite *information importance* score, which reflected the number of topics receiving a high rating (≥ 6) for topic importance, and 2 composite *information received* scores, which reflected the number of topics pertaining to counseling or therapy or medication treatment that participants felt they had received their desired (or *appropriate*) amount of information in the past (rating ≥ 6 for the amount of information received). This cutoff of ≥ 6 was selected, as the ratings were on a 9-point scale from 0 (*not at all important*) to 8 (*very important*). Therefore, a rating of 6 through 8 was considered a high rating of importance and suggested a strong interest in receiving this type of information. These composite scores were used as outcome variables in forced-entry multiple linear regression analyses that included the following predictors: gender, age, birthplace, marital status, education level, anxiety symptoms, anxiety diagnosis, and treatment experience. We ran separate regressions for the self-help and (combined) clinic samples, given that, as outlined in the *Sample Characteristics* Results section, the self-help group differed from the clinic samples on a variety of measures. The regressions conducted on the combined clinic sample included an additional predictor, namely, whether the individual was recruited from the psychology or psychiatric clinic.

Power

Before data collection, we conducted an a priori power analysis to determine the sample size required for a power of 0.80, a significance level of .05, and an effect size of Cohen $d=0.50$. The analysis yielded an intended sample size of 102. The medium effect size was selected based on the Cochrane collaboration review of the effects of decision aids for the treatment of health issues [12]. The goal of this study was to enroll a sample of 100 from each clinical group and, for comparison, enroll 200 nonclinical participants. Given that there was some difficulty enrolling participants from the psychiatry sample, we conducted a sensitivity power analysis after data collection. These analyses were on the ANOVAs, used to compare the demographic characteristics, and on the regressions, used to predict information importance sum scores, to determine the effect detectable given the sample sizes included in the study analyses. For the ANOVA, using a power of 0.80, a significance level of .05, and a total sample size of 465 led to a detectable effect size of Cohen $d=0.14$. For the self-help regression analyses, using a power of 0.80, a significance level of .05, and a self-help sample size of 283 led to a detectable effect size of Cohen $d=0.06$. For the clinic regression, analyses using a power of 0.80, a significance level of .05, and a clinic sample size of 170 led to a detectable effect size of Cohen $d=0.10$.

Results

Sample Characteristics

Most participants in all 3 groups were Canadian born. Most had previously been diagnosed with an anxiety disorder, and most reported that they felt they could have benefited from counseling or therapy from a professional for anxiety in the past but had not received it. Despite these similarities, there were several differences in the sample characteristics, particularly between the self-help sample and the 2 clinic samples (Table 1). The mean age of the self-help sample (32.2, SD 9.0 years; range 18-77 years) was significantly lower than that of the clinic samples (mean_{psychology} 38.2, SD 13.9 years; range 18-80 years; mean_{psychiatry} 37.6, SD 14.9 years; range 18-65 years; $F_{2,458}=14.8$; $P<.001$; $\eta_p^2=0.06$). Compared with the clinic samples, the self-help sample also had the highest proportion of men (138/288, 47.9%; $\chi^2_2=14.4$; $P=.001$), had more

individuals who reported being married ($\chi^2_2=22.6$; $P<.001$), were more likely to have been working full-time in the year before completing the survey ($\chi^2_2=55.0$; $P<.001$), and reported more years of education (an average of 5 years after high school, compared with 2 years in the clinic samples; $F_{2,458}=32.1$; $P<.001$; $\eta_p^2=0.13$). Compared with the clinic samples, a higher proportion of the self-help sample also indicated that there was a time when they felt that medication for anxiety would have been helpful, but they did not receive it ($\chi^2_4=24.9$; $P<.001$). Both the self-help and psychology samples reported more symptoms of anxiety (a PROMIS *T* score >50) compared with the psychiatry sample ($\chi^2_4=8.3$; $P=.02$). Finally, compared with the self-help and psychiatry samples, a higher proportion of the psychology sample reported that they had received counseling or therapy ($\chi^2_4=10.9$; $P=.004$) and medication ($\chi^2_4=10.7$; $P=.005$) for anxiety in the past.

Table 1. Sociodemographic characteristics of survey respondents.^a

	Self-help sample (n=288)	Psychology sample (n=113)	Psychiatry sample (n=64)	<i>P</i> value
Age (years), mean (SD)	32.2 (9)	38.2 (13.9)	37.6 (14.9)	<.001

^aValues in italics are significantly different from corresponding values in other samples.

^bPROMIS: Patient-Reported Outcomes Measurement Information System.

Information Importance

Table 2 provides the mean importance ratings given by those considering anxiety treatment in the future for 20 information topics concerning it. All 3 samples rated nearly all the information topics as *important* (mean ratings of ≥ 6). The mean ratings of importance and proportion of each sample that rated

each topic as important were slightly higher in the clinic samples than in the self-help sample. In addition, the clinic samples rated the importance of information pertaining to the goal or outcome, common side effects, serious side effects, and advantages and disadvantages of treatment significantly more highly than members of the self-help sample.

Table 2. Ratings of the importance of information topics when considering the kinds of help available for anxiety problems.^a

Information topic	Weighted mean rating	Self-help sample (n=288)		Psychology sample (n=113)		Psychiatry sample (n=64)	
		Mean rating (95% CI)	With a mean rating ≥ 6 , n (%)	Mean rating (95% CI)	With a mean rating ≥ 6 , n (%)	Mean rating (95% CI)	With a mean rating ≥ 6 , n (%)
Effectiveness of treatment	6.6	6.4 (6.2-6.7)	219 (76.0)	6.9 (6.6-7.2)	74 (83.6)	6.8 (6.4-7.3)	54 (84.4)

^aInformation was considered *important* if it received a mean rating of ≥ 6 on a scale ranging from 0 (*not important*) to 8 (*very important*). The second column provides the weighted average (across samples) of the ratings for each topic. Values in italics denote a CI that differs from the corresponding CI of one or both of the other samples.

^bDenotes that the CI for a clinic sample is nonoverlapping with the CI of the self-help sample (at 2 decimal places).

^cDenotes a CI for the self-help sample that is nonoverlapping with the CI of both clinic samples (at 2 decimal places).

Information Received Among Those With Counseling or Therapy Experience

Table 3 provides ratings of the amount of information that respondents with psychological treatment experience had received when deciding to start this form of treatment for anxiety. Overall, the findings highlight that individuals in all 3 samples received, at best, a moderate amount of information on the different topics (all mean ratings ≤ 5.0). No topic received the highest rating, confirming that participants were generally dissatisfied with the amount of information they received. Thus, respondents in the self-help sample reported accessing

significantly more information than those in the psychiatry sample on 9 of the 12 topics and significantly more information than the psychology sample on all the topics. Moreover, whereas the proportion of individuals in the self-help sample who felt that they had received an *appropriate* amount of information (rating ≥ 6) ranged from 22% to 52% across topics, the proportion of individuals in the 2 clinical samples who felt this way was much lower, ranging from 2% to 27% across topics. All groups reported receiving the largest amount of information regarding available medication treatments, what the consumer has to do as part of the treatment, the goal or outcome of treatment, how

treatment works, and how long treatment takes to produce results.

Table 3. Ratings of how appropriate the amount of information received was when making decisions about starting counseling or therapy for an anxiety problem.^a

Information topic	Weighted mean rating	Self-help sample (n=194)		Psychology sample (n=94)		Psychiatry sample (n=41)

^aOnly participants who received previous psychological treatment for anxiety were included in the analyses. The weighted mean collapses across samples. The amount of information received was considered appropriate if it received a mean rating ≥6 on a scale with the following anchors: 0 (none), 2 (too little), 4 (moderate amount), 6 (quite a bit), and 8 (just right amount). Values in italics denote a CI that differs from the corresponding CI for one or both of the other samples.

^bDenotes that the CI for the self-help sample is nonoverlapping with that of both clinic samples.

^cDenotes a clinic sample CI that is nonoverlapping with the CI of the self-help sample.

Information Received Among Those With Medication Experience

Table 4 provides ratings of the amount of information that respondents who had previously undergone medication treatment for anxiety had received when deciding to start this form of treatment. Once again, individuals in all 3 samples reported receiving, at best, a moderate amount of information on the different topics. None of the topics received a mean rating >4.8, suggesting that the participants were generally dissatisfied with

the amount of information received. All groups reported receiving the greatest amount of information on how long it takes for treatment to produce results, the goal or outcome of treatment, what the consumer has to do as part of the treatment, how treatment works, and common side effects. Respondents in the self-help sample provided higher ratings than the other 2 groups regarding the amount of information available about counseling or psychological treatments, the cost to the consumer and the health care system, and treatment effectiveness.

Table 4. Ratings of how appropriate the amount of information received was when making decisions about starting medication for an anxiety problem.^a

^cDenotes that the CI for the self-help sample is nonoverlapping with that of both clinic samples.

Amount of Information Received From Different Sources

Table 5 indicates the amount of information respondents received from different sources when considering anxiety treatment options. The internet was the highest-rated source,

followed by family doctors. In line with the previously discussed findings, the self-help sample indicated receiving more information from 8 of the 10 sources than the clinic samples. Respondents in all samples indicated receiving the least amount of information from nurses.

Table 5. Ratings regarding the amount of information received from different sources.^a

^aThe weighted mean collapses across samples. The amount of information received was considered *appropriate* if it received a mean rating ≥6. Values in italics denote a CI that differs from the corresponding CI for one or both of the other samples.

^bDenotes that the CI for the self-help sample is nonoverlapping with that of both clinic samples.

^cDenotes a clinic sample CI that is nonoverlapping with the CI of the self-help sample.

Predictors of Information Importance and Information Received

Table 6 describes the regression analyses examining the predictors of the number of information topics considered *important* by participants (information importance composite score) and the number of topics for which an *appropriate* amount of information was received regarding either counseling or therapy or medication treatments (information received composite scores). The results are presented separately for the self-help sample and the combined clinical samples. The partial correlations (*r*) reported in the table, when squared, indicate the unique proportion of the variance in a given outcome variable that is accounted for by each predictor when all other predictors and their shared variance have been accounted for in the relevant model.

In the self-help sample, gender and marital status were significant predictors of all 3 outcome variables. Men and married participants were more likely than women and unmarried participants (respectively) to rate a higher number

of information topics as being important and feel that they had received an appropriate amount of information about both counseling or therapy and medication treatments after accounting for other predictors. Being born in (vs outside of) Canada emerged as an additional predictor of the number of topics found to be important, and both younger age and higher educational attainment emerged as additional predictors of how appropriate the amount of information received regarding medication treatment was found to be.

Gender was a less important predictor in the regressions performed on the combined clinic sample. Indeed, after accounting for other predictors, men were only more likely than women to report that they had received an appropriate amount of medication information. In contrast, years of education proved to be a somewhat more important predictor in the combined clinic (vs self-help) sample, with higher educational attainment predicting the number of topics found to be important and how appropriate the amount of information received regarding counseling or therapy (and, to a lesser extent, medication) was found to be.

Table 6. Predictors of composite scores for information importance, information received on counseling or therapy, and information received on medication for the self-help and combined clinic samples.^a

^aThe number of important topics was defined as the number of topics that received a rating of ≥ 6 for topic importance. The number of topics for which the right amount of counseling or therapy or medication information was provided equaled the number of topics receiving a rating of ≥ 6 for amount of information received. Values in italics are significant at $P < .05$.

^bPROMIS: Patient-Reported Outcomes Measurement Information System.

^cTherapy received or needed refers to the number of individuals who indicated that they had previously received counseling or therapy for anxiety in the past or who felt they would have benefited from doing so.

^dMedication received or needed refers to the number of individuals who indicated that they had previously received medication for anxiety in the past or who felt they would have benefited from doing so.

^eB: unstandardized beta.

^fClinic sample membership is not applicable to the analyses within the self-help sample.

^gpr: partial correlation.

Discussion

Principal Findings

This study addressed a gap in the literature in that it is one of the first to explore anxiety treatment information needs and one

of the first to assess these needs in samples enrolled via different routes (ie, from psychology or psychiatry clinics vs on the web). Although individuals from both clinic and self-help samples are seeking information, we can speculate that they are likely at different points on their treatment-seeking journey.

Specifically, whereas individuals in the clinic samples may have been actively engaging or preparing to engage in a specific form of treatment, individuals in the self-help sample may have still been seeking information about various treatment options, either for themselves or for another person (eg, family member or friend).

The 2 clinical samples comprised individuals with similar demographic characteristics. They also had a higher proportion of women than the self-help sample. This is congruous with the idea that women are more likely than men to seek treatment for mental health problems [13], even if men desire such information. The clinic samples were also significantly older than the self-help sample, which may simply reflect the fact that younger people are more regular users of the internet [14] and may therefore have been more likely to view our survey link posted on the ADAM website. Previous research also suggests that younger people are more likely to participate in shared decision-making [15], which may make them more interested in accessing information about topics such as anxiety and its treatment. Interestingly, most of the self-help sample reported a previous diagnosis of an anxiety disorder and had either received or felt they would have benefited from counseling or therapy *and/or* medication for anxiety in the past. This suggests that they may have been interested in participating in the survey because of their personal struggles regarding how best to manage symptoms of anxiety.

Not surprisingly, the psychology sample had the highest proportion of individuals with counseling or therapy experience. People who have previously received therapy may be more likely to continue to seek out therapy in the future, given that they tend to behave in a way consistent with their past behavior [16]. Interestingly, the psychology sample also had the highest proportion of individuals who had previously received medication treatment for anxiety. A possible explanation for this finding may be that the clinic from which the psychology sample was recruited has a long waitlist, and some individuals may have tried medication or another treatment for their anxiety before they were seen by this service. Finally, although more than three-quarters of individuals in each sample felt that they had not received counseling or therapy in the past when it might have been beneficial to do so, members of the self-help sample were more likely than those recruited through clinics to report feeling that they might have benefited from receiving medication in the past. This supports the view expressed earlier in the Discussion section that members of the self-help group were more ambivalent about what the best course of treatment for anxiety is likely to be. Overall, the sample differences described above support the view that people currently seeking *treatment* differ from those currently seeking *information* in terms of their information needs.

All 3 samples viewed information on a wide range of topics as important, consistent with our group's earlier work involving information needs related to stress, anxiety, and depression [7,9]. This is also consistent with the information needs for people with other health issues such as cancer [17]. The ratings of the importance of specific information topics in this study were also similar to those in our earlier research. The mean ratings of topic importance and proportion of individuals who

rated a topic as important were slightly higher in the clinic samples than in the self-help sample. These findings may be related to the fact that those in the clinic samples were actively seeking or engaged in a course of treatment. In their *Stages of Change* model, Prochaska and DiClemente [18] outlined several stages of behavior change, including *precontemplation* (more than 6 months until intended action), *contemplation* (action in the next 6 months), *preparation* (action in the next month), *action* (action begins), *maintenance* (at least 6 months into an action), and *termination* (during which an individual will not return to old habits). As suggested above, the clinic samples may be quite far along in this process, having made a decision to seek treatment (preparation) and having met with health care providers, such as family physicians, to obtain a clinic referral (action). The discussions that they may have had with health care providers may have helped them reflect on the kind of information they would want concerning anxiety treatment. In contrast, members of the self-help sample may primarily be at the precontemplation or contemplation stages and be focused on finding general information for themselves or on behalf of another person.

An area unique to this study was the examination of the amount of information previously received. Overall, the self-help sample provided higher ratings regarding the amount of information received when considering starting counseling or therapy or medication treatment for anxiety. The fact that the psychology clinic sample reported greater treatment experience than the self-help group and that both clinic samples had likely had more opportunities to speak with health care providers about anxiety treatment may have meant that these groups had a better sense of whether they had received *the right* amount of information on the different topics at the time of the survey, compared with the self-help group. If so, this would suggest that despite seeing a mental health treatment provider, these individuals may still feel inadequately informed about treatment options. In contrast, if the self-help sample was at an earlier stage of the information gathering or treatment-seeking process, they may have (1) been less certain about how much information was actually available on certain topics, (2) had less need for information, or (3) sought information from fewer sources. These factors, alone or in combination, might have led them to feel more satisfied with the amount of information they received. In either case, it is important to note that none of the groups provided high ratings for the appropriateness of the amount of information they received.

It is noteworthy that the clinic samples did not report feeling adequately informed about medical treatments if they were currently seeking counseling or therapy or vice versa. This suggests that people are not necessarily given a choice when starting a treatment, despite the efficacy of both therapy and medication in treating anxiety problems [19-21]. An important clinical implication of these findings is that health care providers need to have more in-depth discussions with their patients about a broad range of topics, including different treatment options, to help their patients decide on the best course of action.

Respondents in the self-help sample indicated that they had received more information from a range of different sources than the clinic samples. Again, this might suggest that members

of the self-help group are interested in gathering much information, whereas the clinic samples are at a stage where they have a better idea of the type of information they want or need and where to obtain it. We also found that in the self-help sample, being a man and being married positively predicted the number of information topics rated as important and the appropriateness of the amount of counseling or therapy and medication treatment information received. Men in this sample may have had less treatment experience than women, which could have influenced their ratings in these areas. It may also be that married people are often interested in gathering information to help them understand or support a spouse who is struggling with anxiety, rather than for themselves. In such cases, it may be useful to include the spouse in an initial treatment session designed to provide psychoeducation about anxiety and its treatment.

All 3 study groups reported that their family physicians were important sources of information. This is not surprising given that the family physician is likely to be one of the first health care providers one sees when struggling with mental health problems such as anxiety. However, it does speak of the importance of family physicians engaging in continuing education to ensure that the information they provide is current and that they can address their patients' questions. Given the range of topics identified as being of interest, one can imagine how difficult it would be to review all of these topics in a typical primary care visit of 10 to 15 minutes or even in a specialist visit of 20 to 50 minutes. More importantly, from the patient's perspective, it would be very challenging to process and remember large amounts of information if presented orally, especially for those struggling with anxiety. For these reasons, it would be helpful for health care providers to deliver information in the form of patient-oriented brochures or web-based information that can be reviewed over a longer period and revisited as needed [3,5,8]. A limitation of paper-based formats is that it would take considerable space to address all the topics identified as important in this study and to provide context regarding the quality of the available scientific evidence. An advantage of websites is that they can incorporate drop-down menus and links that allow the consumer to obtain more detailed information about topics of interest. However, research by our group suggests that internet sources are of variable quality [22]. This is of concern, given that all 3 groups in this study reported that the internet was an important source of information. More effort should also be made to ensure that high-quality print and web-based resources are available. Ensuring that the reading level of these materials is low and the clarity of the writing is high is important to ensure that less well-educated members of the public can process them.

Limitations

Although this study addresses gaps in the literature by assessing what information people view as important in considering help for anxiety and what anxiety information they have received in the past, it is not without limitations. A limitation of this study is that it examined the objectives from a quantitative methods perspective. Other useful information may be obtained by collecting open-ended responses in semistructured interviews and using a qualitative approach to data analysis. Another

limitation is that this sample may not generalize to individuals not seeking help or information, as many individuals with anxiety do not seek help [23]. A third limitation is that participants in the clinic and self-help samples were individuals in the process of seeking help or information; therefore, the generalizability of the results to all individuals with anxiety problems may be limited. Furthermore, the clinic participants who responded to the survey may not truly reflect those seeking treatment within each clinic. Compared with those who did not participate, those who did were likely individuals who desired more information and aimed to engage in various methods of obtaining information, such as completing a survey related to anxiety treatment. Another limitation of the information needs questions is that they did not undergo a series of reliability and validity tests. This could be a subject of future research. Finally, we were unable to determine the response rate for the self-help sample. Some individuals may have clicked on the link to the survey but decided not to complete it. This is an issue because it is not possible to determine how the sample of respondents compared with the total population of those visiting the website.

Implications

These results indicate that people are interested in a wide range of information topics on anxiety treatment. This is similar to the information needs for people with other health issues such as cancer [17]. However, individuals often do not receive the amount of information that they desire. Health care providers' understanding of information needs and preferences for persons with anxiety (and other health problems) provides a better appreciation of the patient-preferred role in the treatment decision-making process. This study also demonstrated differences in preferences for the amount of information among individuals. A way to deal with such differences is to produce information focused on each topic and allow consumers to choose their areas of interest. Our research group is currently developing evidence-based materials to treat anxiety. Another issue raised by the findings of this study is that persons with anxiety may not be provided information on different treatment options when seeking treatment. This leads to the question of whether there are any barriers to discussing different options with their health care providers. A hypothesis is that there is a lack of high-quality, evidence-based information that can be used by consumers and health care providers to allow consumers to make informed decisions. Another hypothesis is that health care provider knowledge may vary across providers. For example, general health care providers may not have the in-depth knowledge of treatment options that specialists do [24]. Overall, increasing public knowledge and the use of health information results in more positive attitudes toward help-seeking [2].

Conclusions

This study fills an important gap in the literature by examining the information needs of people with anxiety. The results suggest that people with anxiety are interested in information developed to answer important questions concerning anxiety treatment. Information needs for other common mental health problems have been found to be similar [7,9,25]. Of particular interest to consumers is information about treatment goals and

effectiveness and what happens when the treatment stops [7,9,25]. The wide range of topics judged to be important by individuals with anxiety suggests that it would be very difficult to address these information needs via oral communication

during health care visits or using currently available materials. Therefore, it is imperative that high-quality, evidence-based resources be created to assist individuals in making decisions about treatment for problems with anxiety.

Acknowledgments

MTB received funding from the Canadian Institutes of Health Research for this work. The authors also thank John R Walker and the Family Research Fund for their support of this work.

Authors' Contributions

MTB participated in conceptualization, methodology, formal analysis, investigation, resources acquisition, data curation, all aspects of writing, and funding acquisition. Abstract

Background: Affective characteristics are associated with depression severity, course, and prognosis. Patients' affect captured by clinicians during sessions may provide a rich source of information that more naturally aligns with the depression course and patient-desired depression outcomes.

Objective: In this paper, we propose an information extraction vocabulary used to pilot the feasibility and reliability of identifying clinician-recorded patient affective states in clinical notes from electronic health records.

Methods: Affect and mood were annotated in 147 clinical notes of 109 patients by 2 independent coders across 3 pilots. Inter-coder discrepancies were settled by a third coder. This reference annotation set was used to test a proof-of-concept natural language processing (NLP) system using a named entity recognition approach.

Results: Concepts were frequently addressed in templated format and free text in clinical notes. Annotated data demonstrated that affective characteristics were identified in 87.8% (129/147) of the notes, while mood was identified in 97.3% (143/147) of the notes. The inter-coder reliability was consistently good across the pilots (inter-annotator agreement [IAA] >70%). The final NLP system showed good reliability with the final reference annotation set (mood IAA=85.8%; affect IAA=80.9%).

Conclusions: Affect and mood can be reliably identified in clinician reports and are good targets for NLP. We discuss several next steps to expand on this proof of concept and the value of this research for depression clinical research.

Introduction

Background

Depression is associated with affective characteristics generally insensitive to change [1-3]. Evolutionary theories suggest that affective insensitivity to context or inflexibility to change is an adaptive response that helps preserve energy, a core evolutionary function of depressed mood [3,4]. Unfortunately, contextually insensitive affect appears to have long-term costs for mood, with persistently low reactivity to negative and positive stimuli predicting a poorer depression course with some consistency [5]. Despite these advancements in affective science for understanding depression, these theories have yet to be integrated into clinical practice [6]. Further, clinical practice is still in need of clinical markers that better capture patient-desired outcomes. Current practice guidelines for depression use a symptom management approach to gauge recovery [7]; however, patients place less value on symptom reduction as an outcome and more value on achieving psychological well-being [8]. Based on work consistently showing links between affective flexibility and psychological well-being [2], this paper outlines how clinician-documented affect, which is observed during mental health encounters, may assist in tracking patient-desired depression outcomes over time.

One promising avenue to test this hypothesis is to use data from sequential clinical notes stored in electronic health records (EHRs). EHRs provide temporal information regarding a patient's affective functioning. As a result, these notes can be used to map a trajectory of outcomes relevant to the depression course. EHRs include significant data from clinical interviews, clinician observations of patients' affective demeanor, which can capture affective behavior (eg, patient appears unresponsive, incongruent with the emotional content of a verbal report, or agitated), self-reported experiences, and manifestations of physiological affective activation (eg, increased breathing rate and perspiration). Given that affective dysregulation (protracted low mood or anhedonia) is a core aspect of depression, clinicians likely capture relevant affective information in clinical notes and mental health assessment templates, although this is an empirical question that we will revisit in this paper. This information that is already being recorded, through systematic extraction and evaluation, could aid in the development of a measure that incrementally improves how we assess depression, which can ultimately improve clinical practice.

Using data available in the EHR to improve how we capture the depression course and depression outcomes offers mental health care providers a creative solution for bridging clinical science with practice. One way to make use of the EHR and provide a unique opportunity for efficient large-scale investigation is through the development of analytics tools, such as natural language processing (NLP; a method to extract meaningful data from clinical notes) and machine learning (a process to make sense of the data extracted through predictive analyses), both of which can assist with clinical decision-making and make an endeavor, such as the one we are proposing, feasible.

NLP as a Tool for Understanding Depression

NLP research focuses on developing computational models for understanding natural language [9]. NLP, in its many forms, is used to perform information extraction, which is the extraction of predefined information from texts such as clinical notes [10]. Using tools built around ontologies (controlled vocabularies), like SNOMED-CT (Systematized Nomenclature of Medicine-Clinical Terms) [11], NLP has enabled researchers to automate the capture of information in clinical narratives [10]. This data mining of EHRs can be useful for detecting patterns in patient care, such as choice of treatments, adherence, and changes in functioning and well-being over time [12], which can predict patient treatment habits and their symptom outcomes [13], as well as patient outcomes [14].

The application of analytics tools (eg, NLP) has enabled accurate and efficient determination of longitudinal outcomes. For example, a study by Perlis et al [15] applied NLP using notes from 127,504 patients with a billing diagnosis of major depressive disorder. The NLP classification was developed by a panel of expert clinical psychiatrists who reviewed 5198 patient narrative records to define a classification including 34 terms from the clinical annotations that could distinguish patients who were no longer depressed from those who had treatment-resistant depression. The study found that the NLP models were superior to those relying on billing data alone in classifying a patient's current mood and longitudinal outcome.

Given that information extraction is based on the extraction of predefined information, the first step in developing a new NLP system is defining the constructs of interest. Specifically, we are interested in what constructs may be relevant to the depression course and outcomes. Currently, the gold standard in clinical practice is monitoring of depression symptom severity. However, this does not adequately capture patient-desired outcomes [8]. Given that depression is conceptualized as an affective disorder based on its 2 core symptoms of protracted negative affect and anhedonia [16], we focused on affective functioning in this study. We expect that affect information would be prevalent in mental health care notes because most major types of therapies for depression tackle some aspect of affective functioning, given that depression is an affective disorder.

Using Affective Theories of Depression and Empirical Evidence to Guide NLP Development

In this study, we drew from depression and affective theory and research to predefine our main constructs, affect and its characteristics. First, it is important to define the distinctions between emotions and affect. Emotions are immediate and often quick responses to stimuli and environmental changes or events, while affect may be a more diffuse response over the course of minutes and even an hour. Relative to emotions and affect, moods are generally thought to be longer, slower moving, and less tied to specific objects or elicitors [17]. In our analyses, we define affect as encompassing fleeting emotions and states that may be captured during a therapeutic session or clinic visit, while moods are defined as capturing long-lasting affective states that may last days or weeks.

The next key step in developing an NLP tool is understanding how depression may impact affective characteristics. This will help generate a set of adjectives that are expected to be seen in notes when affect is described. For example, anecdotally, people struggling with depression complain that their emotional world is undifferentiated, flat, dull, and empty [18], and behavioral observations from inpatient settings document that depression can diminish motivated activity to the point of immobility, even catatonia in severe cases [19], while others have characterized depression as a syndrome marked by inflexibility and stereotypy in cognition, behavior, and physiology [20]. Results from a meta-analysis of 19 laboratory studies on currently depressed individuals revealed a pattern that was termed “emotion context insensitivity” [21,22], in which major depressive disorder was characterized by reduced emotional reactivity to both positively and negatively valenced stimuli, with the reduction larger for positive stimuli ($d=-0.53$) than for negative stimuli ($d=-0.25$). Importantly, the meta-analysis revealed similar depression-related differences in emotional reactivity across the following 3 major emotion-response systems: self-reported experience, expressive behavior, and peripheral physiology, reinforcing our current interest in capturing clinician-reported patient affect during clinical sessions. In clinical depression, emotions and affect are often incongruent with mood, in that depressed mood seems to facilitate flat, context insensitive affect, rather than particularly sad emotions [21], a disconnect which seems to strengthen as depression becomes more severe [23].

Our Study

While the Veterans Affairs (VA) EHR contains information about patient clinical and functional characteristics at the time of a visit, much of it is stored in text notes and is not easily extracted or summarized and readily available to clinicians. Thus, NLP could provide a useful solution to making this information accessible and useable. To facilitate the development of an NLP tool that could be applied to affect information in mental health clinical notes, we conducted a series of 3 pilot studies with the following goals: (1) to identify the major constructs associated with depression as indicated by theory and empirical findings to date; (2) to determine if the targeted constructs can be reliably found in the EHR; and (3) to test the feasibility and reliability of an initial NLP system.

Methods

Requesting and Extracting Data

Ethics Statement

The Institutional Review Boards at the Department of VA Research and Development (VA R&D) and the University of South Florida approved this study protocol (approval number: IRBPro00029453) and granted waivers of individual consent based on the absence of individually identifying data. The Department of VA provided a waiver of Health Insurance

Portability and Accountability Act authorization for research conducted in this study.

Data Source and Cohort Selection

The sample for this pilot was extracted from a larger study. We obtained data from the VA Corporate Data Warehouse (CDW), an administrative data source that contains electronic medical records of all Veteran patients who receive care through the VA. The patient cohort included Operation Enduring Freedom/Operation Iraqi Freedom Veteran patients aged 18 to 66 years at the time of their initial elevated Patient Health Questionnaire-9 (PHQ-9) score (≥ 10) indicative of probable depression, which was recorded anytime during fiscal years 2006 to 2016. During data extraction, we excluded patients who were diagnosed with bipolar disorder, personality disorders, psychotic disorders, and pervasive developmental disorders (to be consistent with the National Committee on Quality Assurance measure of quality of care, the Healthcare Effectiveness Data and Information Set), as well as substance abuse and dependence. The rationale for the exclusion criteria is the divergent treatment practices in the presence of these disorders relative to unipolar depression treatment in the absence of these conditions.

Measures

Structured Medical Record Data

Patient (N=109) demographic data extracted from the CDW included age, gender, race, and Hispanic ethnicity. Depressive disorder diagnoses and comorbid posttraumatic stress disorder (PTSD), other anxiety disorders, and adjustment disorders were all captured through ICD-9 (International Classification of Diseases, Ninth Revision) codes. PHQ-9 scores obtained during health care visits at the VA were extracted. Finally, we extracted mental health services data associated with a depressive disorder diagnosis, including note and provider type.

Unstructured Medical Record Data

Mental health clinical notes (N=147) were randomly selected for our sample of VA (N=109). Two annotators (including ARD) were trained, and they independently annotated each document using Extensible Human Oracle Suite of Tools (eHOST) annotation software developed as part of the VA Consortium for Healthcare Informatics Research project [24]. Notes were grouped into 3 sets so that spot checks could be performed on agreement scores to ensure consistency. An iterative process leading to an agreement of at least 0.70 was used.

Annotation Guidelines

To support the completion of the annotation process, we developed annotation guidelines and a schema based on depression and affective theories and the literature. The annotation guidelines were developed like those traditionally used for chart review but included more explicit detail about the specific text strings that should be coded (Table 1).

Table 1. Affect characteristics as identified in clinical notes.

Construct	Affect	Mood
Theory	Emotion context insensitivity [21]; evolutionary theory [4]	Emotion context insensitivity [21]; evolutionary theory [4]
Definition	A superordinate category for all valenced states [25]. Often used interchangeably with affect is emotion, a subtype of affect, which refers to coordinated responses that occur when an organism encounters meaningful stimuli. Can be indexed by cognitive, experiential, central and peripheral physiological responses, and overt behavior.	Mood is a diffuse construct encompassing emotional experiences (defined by behavioral, psychological, physiological, and cognitive aspects) over the course of days/weeks. It is often not context specific like affect, and it can be impacted by pervasive affect and vice versa.
Characteristics	Descriptive: Blunted, broad, flat, restricted, constricted, less constricted, mood/topic congruent, appropriate to thought/speech content, inappropriate to content, wide ranging, reactive, euthymic, dysthymic, intensity, neither increased nor decreased, irritable, nervous, anxious, sad, angry, tense, labile, within normal limits Behavioral: Crying, laughing, smiling Physiological: Sweating, rapid respiration Timeline of emotional experiences: affect is defined by being observed or expressed during the session.	Descriptive: Depressed/low, dysphoric, anxious, irritable, euphoric, angry Timeline of emotional experiences: mood is defined by a timeline that expands beyond the session.
Examples (from notes)	“patient appeared sad even when talking about his daughter’s accomplishments,” “patient teared up when remembering his lost mother,” “affect is constricted and at times tearful,” “affect is reserved, but reactive,” “affect is tightly controlled, comes across as somewhat blunted,” “affect: tearful at times when appropriate,” “affective expression was serious and melancholic,” “appears sad,” “broader range of affect than yesterday,” “congruent, less flat,” “consistent with mood and topics discussed,” “crying easily,” “difficulty controlling his temper,” “easily tearful,” “easily emotional,” “easily aggravated,” “episodically tearful during the session today,” “expressed frustration and anger multiple times during the assessment,” “feeling emotionally distant,” “his affect seems to be brighter,” “no acute distress noted,” “no emotional response,” “non-labile throughout the session,” “not tearful during the session today,” “patient smiles appropriately,” “poor frustration tolerance,” and “was also able to smile on occasion as appropriate”	“anger/irritable moods,” “anhedonia,” “patient reports anxious mood that varies from daily to weekly,” “anxious, sometimes depressed,” “become anxious in crowds,” “decreased interest,” “devoid of feeling,” “down moods,” “emotional numbing,” “dysphoric/dysthymic,” “emotionally flattening,” “fluctuations in mood,” “feeling unhappy,” “has mood swings (irritable, anxious, depressed),” “he frequently becomes frustrated,” “he has been in a foul mood,” “I am not depressed, I am just angry,” “improved mood,” “inability to express positive emotions,” “increased anxiety over the past few weeks,” “lack of interest in activities,” “lack of pleasure,” “lacks sexual interest,” “less mood instability,” “little interest or pleasure in doing things,” “mood described as <i>ok</i> ,” “mood has remained somewhat depressed,” “mood is described as <i>better</i> ,” “mood was neutral,” “not as depressed as he says he feels,” “moody,” “my mood is ok and I am not depressed as much now,” “no mood lability,” and “sustained low/down mood”

Affect

Affect is a class that can encompass emotional responses to immediate stimuli and therefore is context dependent. Affect can capture immediate responses as well as responses over the course of minutes to an hour. Affective experience is often multi-component involving behavioral, psychological, physiological, cognitive aspects. This class captures the clinicians’ observations of the patients’ affect (which can be a summation of observations of portrayed emotional behaviors, such as crying and laughing; outward expression of physiological symptoms, such as sweating and rapid respiration; and verbalized cognitions and experiences related to affect, such as expressed distress and worry).

Mood

Mood is a diffuse construct encompassing emotional experiences (defined by behavioral, psychological, physiological, and cognitive aspects) over the course of days and weeks. It is often not context specific like affect, and it can be impacted by

pervasive affect and vice versa. This class captures patients’ self-report or clinicians’ observations.

NLP Procedure

As a proof of concept, we conducted a pilot of a simple NLP system using a named entity recognition approach on 147 documents using the final annotations as a reference set. The NLP system, implemented in the Python programming language, first parsed the note for sentences and then checked each sentence for occurrences of the terms or phrases identified as “mood” or “affect” in the text. After the initial NLP extraction, each occurrence was recorded in a data set and compared to the annotated reference set. An error analysis was performed by the clinical psychologist. If an instance found by NLP was not originally in the reference set, but was deemed valid, it was added to the reference set and was counted as a true positive. If it was not a valid instance, it remained a false positive.

Results

Structured Medical Record Data

Note Characteristics

Out of 147 notes, 64 (43.5%) were written by psychology and

83 (56.5%) by psychiatry mental health providers. The large majority of the notes (119/147, 81.0%) were generated by clinical providers conducting outpatient visits in a VA mental health clinic (ie, specialty clinic), and only 28 (19%) notes were generated in a primary care outpatient setting with an integrated mental health provider. The types of notes are presented in [Table 2](#).

Table 2. Types of clinical notes where affect and mood were documented.

Type of note	Value (N=147), n (%)
Mental health consult	16 (10.9)
Mental health note	38 (25.9)
Mental health outpatient note	5 (3.4)
Psychiatry medication management	33 (22.4)
Psychiatry note	27 (18.4)
Psychology note	11 (7.5)
Other types	17 (11.6)

Patient Characteristics

The notes included in this pilot were extracted from 109 patients. Patients were on average 40.7 years old (SD 8.2 years; range 27-66 years). Moreover, 100 (91.7%) were male and 57 (52.3%) were married. Clinically, all patients had probable depression (PHQ-9 ≥ 10). Mean depression severity was 16.1, which is indicative of moderately severe depression (SD 4.1; range 10-25). Diagnostic information suggested that 100 (91.7%) patients had received a depression diagnosis in their charts, 97 (89.0%) had a PTSD diagnosis, and 46 (42.2%) had another anxiety or an adjustment disorder diagnosis.

Unstructured Medical Record Data

Annotation Findings

As noted in [Table 3](#), coding reliability was consistently good across our 3 pilots (range of *F* measure 70%-80%). The language processing data demonstrated that affect characteristics were identified in 123 (83.7%) notes, while mood characteristics were identified in 143 (97.3%) notes. Affect was recorded in 71.9% (46/64) of all notes reported by a clinical psychologist and 92.8% (77/83) of all notes recorded by a psychiatrist. Of those notes reporting any affect during a visit, 37.4% (46/123) were psychology notes and 62.6% (77/123) were psychiatry notes.

Table 3. Pilot reliability results.

Variable	Pilot 1 (N=54)		Pilot 2 (N=49)		Pilot 3 (N=44)	
	Percentage present in notes	IAA ^a	Percentage present in notes	IAA	Percentage present in notes	IAA
Affect	83.3%	79.6%	90.0%	76.1%	90.9%	80.0%
Mood	94.4%	70.1%	98.0%	76.9%	100%	73.1%

^aIAA: interannotator agreement.

NLP Accuracy

An overall accuracy of 84.4% was achieved by the NLP system relative to a final reference set of annotations of the 2 concepts. Individually, NLP accuracy in identifying “mood” reached 85.8%, while NLP accuracy in identifying “affect” reached 80.9%.

Discussion

Principal Findings

Our preliminary main findings suggest that (1) our theory-driven vocabulary describing affect is indeed captured in patient records with regularity; (2) our vocabulary captured affect in a manner that led to reliable coding by 2 independent coders across 3 pilot samples of clinical notes; and (3) a proof-of-concept NLP system

showed good accuracy in capturing affect relative to human coding. Other observations are that affect is frequently present in mental health notes, especially as documented by psychologists and psychiatrists in specialty clinics; clinicians more often documented negative affect, while positive affect was rarely observed in our pilot. Although much of the characteristics were static, in that they were describing emotional expressions specific to the session being documented, on occasion, clinicians did use words suggestive of change, such as comparative adjectives (eg, improved, better, and less).

The pilot findings provide preliminary proof of our concept. Affective characteristics of depressed patients that are theoretically relevant to the depression course and outcomes are frequently reported and reliably identifiable in clinical notes. Our findings showed that clinicians regularly report on patient

characteristics that are theoretically and empirically relevant to depression. Although this stored information is not readily accessible to use for outcome research or treatment planning purposes, it appeared to be reported frequently and in a manner that led to reliable coding. Finally, this initial pilot NLP effort showed that we will be able to reliably identify “mood” and “affect” in patients’ medical records.

This work also provided preliminary evidence that affect is described in a variable yet consistent manner, which likely contributed to affect being reliably extracted. Our initial annotation scheme was developed by extracting affect characteristics gleaned from theory and empirical evidence. Both anecdotal accounts [18] and theory of affective functioning in depression [3,4] describe depressed persons reporting their experience of the world as undifferentiated, dull, and generally in a manner that is unresponsive or insensitive to changing contexts. Similarly, many of the patients captured in our pilot data were described as exhibiting “constricted affect, or tightly controlled, coming across as blunted.” Conversely, few patient accounts could be described as labile. Lability of affect appeared more often related to anger, rather than uncontrollable fits of crying spells, for example. Although crying was the most often cited emotional behavior, it was often described as episodic, and the intensity was rarely recorded and mostly implied by therapists’ use of words such as tearful versus crying spell. In future work, it will be important to evaluate whether signs and evidence of reactivity, even when temporary, are related to depression improvement. This work suggests that evidence of emotional reactivity to emotional stimuli is generally related to a more benign course of depression [5]. Finally, positive affect, although theoretically [26] and empirically [2,22] (meta-analyses showing larger effects for positive than negative affect in relation to depression) relevant to the depression state and course [5], was rarely recorded in clinical notes describing patient affect in the session.

The findings that only one-third of the notes documenting affect were written by a psychologist and only two-thirds of all psychologist-written notes documented affect were moderately surprising. This was in part because the gold standard therapy for depression, cognitive behavioral therapy, focuses on developing affective awareness as a major component of the early stages of the therapy. The capacity to distinguish among negative affects is instrumental in the successful deployment of appropriate affect regulation strategies [27]. The fact that psychologists do not always record affect may be important to monitor, especially for studies evaluating consistency in how patients present across clinicians who see patients within the same day. It may also be important to evaluate whether there are qualitative and quantitative differences in the manner that affect is being recorded by psychology and psychiatry notes. Although the high overall accuracy of our NLP tool was reassuring, future work on a larger corpus of notes should look at variability in accuracy based on note characteristics.

Furthermore, although our pilot work was limited in scope, the richness of language observed to be used in clinical notes suggests that tracking *change* will also be feasible on a larger scale. Relevant to capturing affective changes over time that may map onto depression progress and outcomes, we also

observed in our annotations language that implied change. Specifically, clinicians used comparative adjectives, such as better and less, to describe observed affective change and record noticeable change from prior sessions. Comparative adjectives will be an important new class of annotations in the next step of this area of research, as they will help with tracking affective and mood changes over time, which are both important to understanding the depression course and possibly depression outcomes.

Implications of This Work for Understanding and Predicting Depression Outcomes

There is a need for better affective theories that make predictions of the role of affect in the course and outcomes of depression, building on strong evidence showing the implication of affective changes in the course and outcomes of depression [5]. Across various measures of affect, both reduced positive affect and reduced state negative affect predicted a poor depression course. Based on prior work, greater affective responsiveness to sad [21] and amusing [23] laboratory stimuli predicted a more benign course of major depression. Conversely, lack of affective response predicted long-term heightened depression severity. For example, greater endorsement of positive, but not negative, words predicted depressive symptoms 9 months later [28], and people with depression exhibiting the lowest behavioral reactivity to an amusing film showed worse depression severity 1 year later [23]. Affective reactivity to daily life events was predictive of symptomatic change at 1 month after treatment [29]. This body of work suggests that signs of positive and negative affect dysregulation are likely to be germane to the prediction of long-term outcomes in depression.

Finally, affective characteristics also appear to fluctuate with the depressed state and history, such that remitted depressed individuals look more like healthy controls than currently depressed individuals on various measures of affective reactivity (measured through physiological and behavioral measures) [30,31]. Prospective links between affect and depression outcomes make good sense within a functionalist perspective on affect [32], given that affect represents dynamic adjustments to environmental challenges and opportunities across time. Nevertheless, we do not yet know how observable affective characteristics within the context of naturalistic mental health visits are important in predicting the depression course in the context of mental health care. While other studies have demonstrated success using NLP to detect treatment-resistant depression [15], we propose that future work may build on our findings by specifically relating affect-related measures to depression outcomes in adults.

Future Directions

Despite research indicating the potential for improvements in depression outcomes, there is a dearth of research on outcome enhancement through the use of analytics tools. Using NLP to develop methods to reliably extract the routine documentation of affect by mental health care providers in clinical notes and structure it for use in health services research is a foundational step. We would like to offer the following suggestions for future research that could help this field move forward:

1. The development of NLP analysis that may predict depression outcomes is the ideal extension of this work. Hence, the evaluation of affect over time is a crucial next step. Specifically, the next meaningful question is as follows: Are we able to detect meaningful change in affect across sequential notes? Practically, is affect reported and recorded in a way that will translate to an observable and clinically meaningful change? Extraction of affect over time within the patient is key for this step. Based on the literature reviewed in this proof of concept and our pilot work, we believe this will be a fruitful endeavor.
2. Another necessary step entails validation of our “measure.” Does our measure converge with measures we assume it intersects with, such as measures of depression symptoms, well-being, and functioning? Such work not only would provide a preliminary validation for this clinical tool, but also may highlight potential discriminant validity.
3. To further validate this tool, collection of patient behaviors during clinical sessions and evaluation of the alignment or misalignment with provider coding of affect would initiate an evaluation of the pieces of information that providers account for when coding a patient’s affective state during a session.
4. Ultimately, our work sets the preliminary steps to developing an NLP tool. Automating the extraction and interpretation of affective information from mental health session notes would provide a monitoring tool that could benefit patients and clinicians alike by highlighting clinically meaningful changes. This information could inform clinical decision-making.

Abstract

Background: The COVID-19 pandemic has resulted in unprecedented uptake of telepsychology services; however, clinicians have mixed attitudes toward virtual technologies.

Objective: This study (1) explored clinicians' experiences of and intentions to use video, telephone, and in-person services, and (2) tested the utility of the unified theory of acceptance and use of technology (UTAUT) to predict clinicians' intentions to offer telepsychology after the COVID-19 pandemic.

Methods: Clinician satisfaction and therapeutic alliance were compared across in-person, video, and telephone services, while technology attitudes and intention to use after the pandemic were compared across video and telephone services among 118 addiction and mental health clinicians during the COVID-19 pandemic.

Results: Clinicians reported more positive experiences with in-person services than both virtual technologies; further, clinicians reported greater positive experiences, attitudes, and intentions to use video services than telephone services across measures. Based on the UTAUT, performance expectancy positively predicted concurrent intentions to use video services ($\beta=0.46$; $P<.001$) and telephone services ($\beta=0.35$; $P<.001$) after the pandemic. Social influence ($\beta=0.24$; $P=.004$) and facilitating conditions ($\beta=0.19$; $P=.03$) additionally predicted the intention to use telephone services.

Conclusions: Clinicians rated in-person services more positively than virtual technologies, with video services perceived more positively than telephone services. Performance expectancy was the primary facilitator of the uptake of both virtual modalities.

KEYWORDS

mental health; telepsychology; clinician attitude; unified theory of acceptance and use of technology; therapeutic alliance

Introduction

The COVID-19 pandemic has triggered an unprecedented shift toward virtual health care delivery [1]. Telepsychology is the provision of addiction and mental health (AMH) care from a

physical distance and includes psychiatric evaluations, therapy, psychoeducation, and medication management [2]. While evidence supports the effectiveness of telepsychology [3-7], clinician hesitancy impedes uptake [5,8,9]. Because telepsychology is expected to play a continued role in service

delivery after the pandemic [1,10,11], it is critical to understand clinicians' perceptions of and attitudes toward telepsychology.

A clinician's experience with telepsychology may also contribute to uptake. Perceived weakened therapeutic alliance may be a contributor to poor uptake of telepsychology [4,5], with therapists perceiving poorer therapeutic alliance in virtual than in-person settings [12]. In contrast, client ratings of therapeutic alliance are comparable across virtual and in-person services [13-15]. Clinicians also remain divided in their satisfaction with telepsychology services [9,10,16,17].

The unified theory of acceptance and use of technology (UTAUT) [18] predicts uptake of new technology into practice from the following 4 factors: (1) performance expectancy, the degree to which a technology is expected to improve performance; (2) effort expectancy, the user's self-efficacy with the technology; (3) social influence, the perceived norms of technology use; and (4) facilitating conditions, including availability of training and technology fit [18-22]. The UTAUT is based on the theory of planned behavior, wherein attitudes predict intentions, which predict behavior [23]. While the postpandemic behavior of clinicians cannot yet be measured, their intention to use technology serves as a proxy.

The utility of technology may vary considerably depending on whether the clinician is using telephone or videoconferencing. The literature offers comparisons of telepsychology (either telephone or video) [13,24] to in-person services, but few comparisons *between* telepsychology modalities. One meta-analysis indicated that videoconferencing was more effective than telephone for depression and posttraumatic stress disorder in veterans [25], yet a comparison between telepsychology modalities is a major gap in the literature.

This study directly compared the experiences of different modalities (ie, in-person, telephone, and video) and further explored factors pertinent to the uptake of telephone- and video-based services in an AMH setting. Specifically, we predicted the following: (1) Clinicians would have the most positive experiences (ie, satisfaction and therapeutic alliance) with in-person sessions, followed by videoconferencing and then telephone; (2) Clinicians would have a greater intention to use videoconferencing than telephone after the pandemic; (3) Clinicians would have more positive technology attitudes toward video than telephone; and (4) Greater performance expectancy, effort expectancy, social influence, and facilitating conditions would predict greater clinician intentions to use virtual services after the pandemic.

Methods

Ethics Approval

This study was approved by the University of Alberta Health Research Ethics Board (Pro00114433).

Procedures

Secondary data were obtained from a virtual health program evaluation conducted from November 16 to December 21, 2020, using an online survey within the publicly funded AMH service in Alberta, Canada. Clinicians who provided services using both telephone and videoconferencing during the pandemic were included in the sample (n=118; see Table 1 for available sample characteristics). Included clinicians were in AMH practice for 13.7 years on average. They reported seeing 64.1% of their virtual clients previously in-person, with individual virtual sessions being the most frequent format (69.7%), followed by group (47.0%) and couple/family (25.4%) sessions.

Table 1. Sociodemographic characteristics of participants.

Characteristic	Value (N=118 ^a), n (%)
Clinician profession	
Psychologist	44 (37.3)
Social worker	22 (18.6)
Nurse	16 (13.6)
Occupational therapist	7 (5.9)
Psychiatrist	6 (5.1)
Other	22 (18.6)
Populations served (categories not mutually exclusive)	
Children	22 (18.6)
Adolescents	32 (27.1)
Young adults	39 (33.1)
Adults	89 (75.4)
Older adults	17 (14.4)
Families	18 (15.3)
Theoretical orientation	
Cognitive behavioral	42 (35.6)
Integrative/eclectic	23 (19.5)
Existential/humanistic	6 (5.1)
Interpersonal/systemic	6 (5.1)
Other	19 (16.1)
Prior experience with telepsychology^b	
Do not provide therapy	22 (18.6)
Telephone	70 (59.3)
Video	21 (17.8)

^aOf the total 153 clinicians who completed the survey, 35 used only telephone and were excluded from the analysis to focus on the comparison between telephone and video.

^bClinicians who reported “some or quite a lot” were included in this frequency. The remaining participants reported “none or very little.”

Measures

Modifications to measures are displayed in [Multimedia Appendix 1](#). Table S1 in [Multimedia Appendix 1](#) provides the internal consistencies reported in previous literature and this study. The below measures were repeated across video, telephone, and in-person, where applicable.

The Agnew Relationship Measure-5 (ARM-5) [26] assessed therapeutic alliance in virtual settings on a scale of 1 (strongly disagree) to 7 (strongly agree), and was modified to reflect perceived therapeutic alliance for telephone, video, and in-person sessions in general (ie, across sessions and clients).

Clinicians rated their satisfaction with telephone, video, and in-person sessions on a custom scale of 1 (not at all satisfied) to 10 (very satisfied).

Clinicians' intentions to use technology after the pandemic were measured by the question, “Given the choice, I would offer

telephone [video] sessions,” on a scale of 1 (strongly disagree) to 7 (strongly agree).

The UTAUT-Therapist Version [22] assessed technology acceptance using 13 items based on the original UTAUT, on a scale of 1 (strongly disagree) to 5 (strongly agree), with subscales for performance expectancy, effort expectancy, social influence, and facilitating conditions.

Results

Differences Between Telephone and Video Services

Normality assumptions were tested with the Shapiro-Wilk test, and outliers were assessed by boxplots for all analyses. Adjustments based on violated assumptions are described below.

A one-way repeated measures analysis of variance (ANOVA) tested differences in therapeutic alliance among telephone, video, and in-person services. Epsilon ($\epsilon=0.850$ [27]) adjusted for a violation of the sphericity assumption ($\chi^2_2=22.359$;

$P < .001$). Therapeutic alliance was significantly different among modalities ($F_{1,700, 197.163} = 46.67$; $P < .001$; partial $\eta^2 = 0.287$). Post-hoc analysis with a Bonferroni adjustment revealed that

all pairwise differences between modalities were significant ($P < .001$), with in-person services having the greatest therapeutic alliance followed by video services and then telephone services (Table 2).

Table 2. Clinicians' attitudes toward telepsychology variables for in-person, video, and telephone services.

Variable	In-person, mean (SD)	Video, mean (SD)	Telephone, mean (SD)	Difference	95% CI

^aLL: lower limit.

^bUL: upper limit.

^cN/A: not applicable.

^d $P < .001$.

^eUTAUT: unified theory of acceptance and use of technology.

A one-way repeated measures ANOVA tested differences between clinicians' satisfaction with in-person, video, and telephone services. There were significant differences in clinician satisfaction across modalities ($F_{2,228} = 82.32$; $P < .001$; partial $\eta^2 = 0.419$; Table 2). Post-hoc analysis with a Bonferroni adjustment revealed that all pairwise differences between modalities were significant ($P < .001$), with in-person services having the greatest satisfaction, followed by video services and then telephone services.

A paired samples t test evaluated the difference between clinicians' intentions to use video and telephone after the pandemic. Clinicians reported significantly greater intention to use video than telephone after the pandemic ($t_{117} = -5.393$; $P < .001$; $d = 0.50$; Table 2).

A paired samples t test assessed the difference between UTAUT-T total scores for video and telephone. Clinicians reported significantly greater scores for video than telephone

($t_{117} = -4.200$; $P < .001$; $d = 0.39$). Paired samples t tests revealed significant differences in each of the UTAUT predictors in favor of video ($P \leq .001$), except effort expectancy ($P = .75$) (Table 2).

UTAUT Prediction of the Intention to Use

A multiple regression was performed to predict the intention to use video, with concurrent performance expectancy, effort expectancy, social inclusion, and facilitating conditions. The model significantly predicted the intention to use video ($F_{4,113} = 14.072$; $P < .001$; adjusted $R^2 = 0.31$). Performance expectancy was the only unique predictor ($P < .001$) (Table 3).

A multiple regression was performed to predict the intention to use telephone, with concurrent UTAUT factors. The model significantly predicted the intention to use telephone ($F_{4,113} = 24.348$; $P < .001$; adjusted $R^2 = 0.44$). Performance expectancy ($P < .001$), social influence ($P = .004$), and facilitating conditions ($P = .03$) were unique predictors (Table 4).

Discussion

This study explored the differences in clinicians' perceptions of in-person, video, and telephone services, and the prediction of the intention to use telepsychology after the pandemic. As hypothesized, clinicians had more positive experiences with

in-person services, followed by video services and then telephone services across measures. Additionally, clinicians reported greater intention to continue using video services over telephone services. These findings suggest that the perceived utility of technologies varies in AMH care [25], and the merits of and attitudes toward each require consideration when integrating them into routine practice.

Consistent with previous work, this study demonstrated the utility of the UTAUT for predicting the intention to use telephone and video technologies [12,16,22,24]. Specifically, performance expectancy was predictive of the intention to use both video and telephone services, while social influence and facilitating conditions were additionally predictive of the intention to use telephone services. Because telephone services are so different from in-person services (ie, no visual information), the intention to use may be related to how well it fits for a particular service (eg, medication refills [28]) and how much it is supported by the clinician's profession. Thus, facilitating conditions and social influence may be more relevant to the uptake of telephone services than video services.

The limitations of this study include its cross-sectional design, which prevents causal conclusions. Further, clinicians' intentions to use telepsychology are a proxy for actual postpandemic technology use. In addition, the study's small self-selected sample of public AMH clinicians, with underrepresentation of some professions and service settings, limits the generalizability of the findings. For example, our sample did not include urgent settings, where virtual care may present additional challenges [29]. While this study did not include private practitioners, its

focus on public health is unique, compared with previous studies focusing primarily on private practice [1,12,16].

In this study, clinicians reported consistently more positive experiences with video services than telephone services, suggesting that the uptake of videoconferencing will face fewer barriers than telephone; however, an overall preference for in-person sessions may result in a return to prepandemic practices. For some clinicians, misgivings about videoconferencing may stem from low performance expectancy. Education on the establishment of a strong therapeutic alliance and the effectiveness of video-based care could decrease clinician hesitancy [3,6,7,30]. Regarding telephone uptake, improved facilitating conditions, such as training, and positive social influence (ie, promotion) may aid uptake. Exploration of how clinicians' demographic characteristics (eg, age, gender, and prior experience) relate to telepsychology uptake would clarify necessary training or support. For example, those with minimal prior experience may require greater support [24]. In conclusion, while there has been a practice shift to telepsychology during the COVID-19 pandemic, AMH clinicians will likely require ongoing support to maintain this practice change.

Abstract

Background: India has the greatest burden of tuberculosis (TB). However, over 15% of the people on antitubercular therapy (ATT) in India are nonadherent. Several adherence monitoring techniques deployed in India to enhance ATT adherence have had modest effects. Increased adoption of mobile phones and other technologies pose potential solutions to measuring and intervening in ATT adherence. Several technology-based interventions around ATT adherence have been demonstrated in other countries.

Objective: The objective of our study was to understand the acceptance of mobile phone adherence supports for ATT using self-administered quantitative measures among patients with TB in South India.

Methods: This exploratory study was conducted at a TB treatment center (TTC) at a tertiary care center in Thrissur District, Kerala, India. We recruited 100 patients with TB on ATT using convenience sampling after obtaining written informed consent. Trained study staff administered the questionnaire in Malayalam, commonly spoken in Kerala, India. We used frequency, mean, median, and SD or IQR to describe the data.

Results: Of the 100 participants diagnosed with TB on ATT, 90% used mobile phones routinely, and 84% owned a mobile phone. Ninety-five percent of participants knew how to use the calling function, while 65% of them did not know how to use the SMS function on their mobile phone. Overall, 89% of the participants did not consider mobile phone-based ATT adherence interventions an intrusion in their privacy, and 93% did not fear stigma if the adherence reminder was received by someone else. Most (95%) of the study participants preferred mobile phone reminders instead of directly observed treatment, short-course. Voice calls (n=80, 80%) were the more preferred reminder modality than SMS reminders (n=5, 5%).

Conclusions: Mobile phones are likely an acceptable platform to deliver ATT adherence interventions among individuals with TB in South India. Preference of voice call reminders may inform the architecture of future adherence interventions surrounding ATT in South India.

KEYWORDS

adherence; tuberculosis; antitubercular therapy; mHealth; mobile health; digital health; South India; technology acceptance; health intervention

Introduction

Tuberculosis (TB) continues to be a significant public health problem globally, with an estimated 10 million new cases in 2019 [1]. It contributes significantly to global mortality, with an estimated 1.2 million TB-related deaths in HIV-negative individuals and 208,000 deaths among people living with HIV. Globally, India accounted for 26% of new cases of TB and carries the greatest burden of multidrug-resistant TB (MDR-TB; 27%). It also ranks first among the countries in which more than 15% of patients with TB and their households have catastrophic expenditures (>20% of total annual household income) on health in terms of total TB cases [1].

Management of TB centers around adherence to antibiotic regimens. Treatment adherence reduces the risk of developing MDR-TB while treating TB. Despite the promise of antitubercular therapy (ATT), nonadherence continues to be a significant problem due to various issues including access to medication, duration of treatment, syndemics such as AIDS and substance use disorder, and lack of routine medication taking behavior [2-6]. In India, it is estimated that >15% of patients with TB on ATT are nonadherent during their treatment regimen [7]. Given the importance of adherence in TB treatment, multiple strategies including mobile phone notifications, digital pillboxes, and ingestible sensors have been employed to ensure access to ATT, adherence to therapy, and persistence of adherence [8-11].

Since 2015, India has enacted national TB guidelines to promote mobile technologies such as 99DOTS, Video Directly Observed Therapy (vDOT), or medication event monitoring systems (MEMS) to support ATT adherence. These strategies are generally linked to mobile or smartphones where users are asked to call a phone number uncovered after opening a pill blister pack to note adherence (99DOTS) [12], use the smartphone video camera to connect or record video of ATT ingestion (vDOT), or link an adherence device to access ATT ingestion patterns (MEMS). In parallel with an emphasis on digital health technologies to measure ATT adherence in India has been a rise in mobile phone and smartphone usage. Currently there are over 1 billion mobile phone users and over 600 million internet users in India [13,14]. In contrast, a lack of familiarity with phones, unstable cellular networks outside of large metropolitan centers, and cost of phones continue to be significant barriers to mobile phone uptake in India.

Given the increasing uptake of mobile phones and their critical role in ATT adherence strategies, we undertook this pilot study in Thrissur District, Kerala, India, to explore the acceptability of adherence support for ATT delivered via mobile phones. The results of this study would help in continued research in developing an ATT adherence monitoring using mobile phones and cumulatively could help in the deployment of such a system in the community in future.

Methods

Recruitment

We conducted a descriptive survey study of 100 patients diagnosed with TB actively on ATT at TB treatment centers (TTCs) in a tertiary care center and other neighboring urban TB treatment centers in Thrissur. These centers manage approximately 300 patients initiated on ATT annually. Participants visiting the TTC were screened and enrolled in the study consecutively if they were over 18 years old and enrolled in the directly observed treatment, short-form (DOTS) program for at least 2 weeks. Minors and individuals who did not speak Malayalam or English were excluded. Potential participants were approached by study staff who confirmed eligibility criteria and described study procedures. Written informed consent was obtained from participants. Next, we administered a quantitative questionnaire to the participant in their local language to understand the use of mobile phones, willingness to engage with mobile phone-based ATT adherence support, and the duration and type of mobile support that would be most acceptable to participants. We also collected baseline demographics and clinical details of the participant from the TB registry at the clinic (Multimedia Appendix 1). The survey was adapted from a previous study conducted in Karnataka, India, that sought to understand the acceptance and feasibility of mobile phone-based interventions for ATT adherence [15]. The adapted survey was tested among the study team members for clarity prior to deployment.

Ethical Considerations

Ethical approval for the study protocol and written consent was obtained from the institutional ethics committee of Amala Institute of Medical Sciences, Thrissur (AIMSEC/21/2018).

Data Analysis

Data were entered into Microsoft Excel and analyzed using SPSS (version 23; IBM Corp). The data were described using frequencies and measures of central tendency (mean and median) and dispersion (SDs and IQRs) as appropriate.

Results

Overview

During the study period, we screened 115 individuals, of whom 100 met the inclusion criteria, signed consent forms, and completed all study procedures. We excluded 15 participants with TB who did not speak Malayalam or English. The mean age of our participants was 44.48 (SD 16.40) years; 69 were male, and 80 were residents of Thrissur. Five reported no formal education, while 79 of individuals reported having less than graduate training. Finally, 57 were currently unemployed. General demographics are described in Table 1.

^aAny schooling less than a college education.

^bA patient who has never had treatment for tuberculosis or has taken antituberculosis drugs for less than 1 month.

^cA patient previously treated for tuberculosis who has been declared cured or completed in their most recent treatment episode and is presently diagnosed with bacteriologically confirmed or clinically diagnosed tuberculosis.

^dA patient who was previously treated for TB but was lost to follow-up for 2 months or more in their most recent course of treatment and is currently diagnosed with either bacteriologically confirmed or clinically diagnosed tuberculosis.

^eA patient who has been previously treated for tuberculosis and whose sputum smear or culture was positive at 5 months or later during treatment.

^fNew smear-positive patients with pulmonary tuberculosis.

^gSputum smear-positive patients who have relapsed, experienced treatment failure, or are receiving treatment after treatment interruption.

^hDOTS Plus: DOTS + diagnosis, treatment, and management of multidrug-resistant tuberculosis.

ⁱAny management other than DOTS.

Tuberculosis Characteristics

Eighty-six of our study participants were newly diagnosed with tuberculosis within the past 6 months, and 9 had experienced recurrence after category 1 treatment. Over half (n=64) of the participants were diagnosed with pulmonary TB, of whom 58 were diagnosed with sputum-positive TB and others with sputum-negative chest-symptomatic TB. There were 3 participants with an HIV-TB coinfection. Most participants (n=57) were in the intensive phase of ATT (ie, were taking isoniazid, rifampicin, pyrazinamide, and ethambutol for 2 months), and the rest were in the continuation phase (ie, were taking isoniazid and rifampicin for 4 months) of the treatment. Sixty-four of our participants reported traveling to DOTS centers using public or personal transport and reported spending an average of INR 17.3 (US \$0.2) to reach the nearest TTC for each visit. Sixteen participants reported that they had missed

their DOTS appointments at least once prior to the survey. The TB characteristics are described in [Table 1](#).

Ownership and Basic Mobile Phone Functionality

Of the 100 participants, 90 reported routine use of mobile phones, among whom 39 did not have a camera on their phone, 37 did not know how to use the camera, and 54 did not use any phone function other than calling. Of those who used mobile phones, 84 were the primary owner of the phone and owned at least one phone for a median duration of 6 (IQR 3, 10) years ([Table 2](#)). The majority (n=95) reported competence with using voice calls, but 65 did not know how to operate the text messaging function on their phone. When asked about participants usage of mobile phones for connecting with health care facilities, 62 among reached out to their health care provider when they were unwell and 34 of them used it to know the

availability of their doctors. Ownership and basic mobile phone functionality are described in [Table 2](#).

No use of phones for any health-related purposes	2

Acceptability of Mobile Phone Interventions for ATT Adherence

Next, we asked participants about their willingness to use mobile phones to receive messages surrounding ATT adherence (Table 3). Eighty-nine participants were accepting of mobile phone ATT adherence supports, and 93 participants did not fear stigma if ATT adherence reminders were received by someone else. Seventy-four participants reported that they would prefer to use mobile phone reminders as a mode of ATT adherence monitoring, and 95 participants preferred mobile phone reminders instead of current DOTS therapy. Additionally, 78 participants reported that they would be willing to discuss their medical care and adherence with their ATT provider using their

mobile phone. When asked around ideal methods for reminders, the majority (n=80) preferred telephone call reminders. When asked about the frequency of reminders, 79 participants reported that they would prefer daily reminders. Malayalam was the preferred language for telephone call (n=79) and text message (n=71) reminders, and they would like to receive it during morning hours between 6 AM and 10 AM (n=80).

We additionally asked about participant preferences to engage with a mobile app to manage and promote ATT adherence. Forty participants indicated they would also use such an app for communication with a counselor or health care providers and 52 would seek information on their prescribed pharmacotherapy via the app (Figure 1).

Discussion

Principal Findings

Over the past 10 years, there has been an exponential increase in ownership and usage of mobile phones in India with 1 billion wireless subscribers, expanding possibilities for mobile health-based interventions to address chronic disease [14,16]. Digital health technologies that leverage the use of mobile phones may therefore become widely accessible and used in the Indian context, given the mixed literacy rates and low income [16-18]. Among disease states, adherence to ATT is an attractive target for intervention using mobile phone technology [15,19]. Traditional directly observed treatment, short-course (DOTS) has had suboptimal uptake during the COVID-19 pandemic due to public health measures, and while relaxation of these measures may improve DOTs access, the use of digital health-mediated ATT adherence monitoring is promising [20]. Therefore, it is essential to identify, develop, and implement interventions that support adherence remotely. This study demonstrates a high uptake of mobile phones among patients with TB in Thrissur and their willingness to accept it as a method to provide mobile phone-based reminders such as voice calls to ensure treatment adherence to ATT. The results of this investigation also suggest that a structured intervention supporting ATT adherence using mobile devices in rural setting, such as that in our study, may need to use voice calls as their mainstay.

We found high uptake of mobile phones consistent with literature from India, which has reported up to 81% mobile

phone uptake in remote areas of the country [15,21-23]. The study also confirms the high uptake of mobile phones in Thrissur in which the majority of the population is from a rural setting, suggesting the development of mobile phone-based ATT adherence supports could reach individuals on ATT. Importantly, most participants own their phone (84%), can operate the calling function (95%), and would be willing to interact with ATT adherence interventions on their phones (95%). Even individuals who leverage phones shared among multiple family members were willing to receive ATT adherence messages despite the fact that they may be received by another family member. Among these interventions, participants identified the ability to receive reminders and communication from health care providers as highly desirable. This suggests that future interventions could seek to leverage mobile phones as a platform to understand and reinforce ATT adherence.

Importantly, we discovered that most of the participants' reminder preference is voice calls. Although daunting, the deployment of call center-based adherence reminders and monitoring may be a potential avenue through which population-level adherence interventions around ATT can be enacted. Although phone call-based adherence monitoring may be an indirect measure of adherence, it represents a universal platform that is accessible to those who may potentially most need adherence monitoring compared to other programs such as 99DOTS and smart pill bottles. Only a third of the participants reported competence with the SMS function, and 61% could use the camera function on their phones. ATT support via mobile phones as voice calls would be feasible and effective in Kerala. The SMS or camera or video-based

interventions might require additional support for patients with TB in Kerala. For interventions that rely on SMS text messaging, instruction and support for SMS may need to be integrated into training modules prior to deployment. Voice-based interventions may be feasible in Kerala and eliminate the need for all individuals to travel to the DOTS clinic, thus eliminating this barrier to adherence. A potential system may deploy a call center-based ATT adherence system for individuals on ATT. In order to scale up, programs may consider prerecorded messages or potentially interventions grounded in a voice chat bot that delivers empiric ATT adherence interventions through voice calls. These systems should additionally consider downstream measures to address nonadherence or nonresponse to voice calls. For example, instead of using DOTS for all individuals on ATT, voice calls could potentially identify individuals who have the most difficulty with adherence, and in-person DOTS may be selected an alternative adherence measure.

In our survey, most of the participants were willing to receive adherence support through mobile phones, and they do not think that it invades their privacy. In addition, many of our participants do not fear the stigma of disclosure of their illness if a reminder about their treatment happens to be seen or received by others. These findings could be attributed to the success of support services offered to patients with TB, creating awareness about the disease among them [24]. Previous studies conducted in other rural areas of India have also reported similar responses [15,23]. However, investigations conducted among the general

population found that the stigma surrounding TB still exists. Hence, continued awareness and support programs among patients with TB and the general population are necessary [25,26].

If given a choice, three-fourth of the study population would prefer to use mobile phone technology instead of conventional DOTS. Previous investigations have also shown that the users of 99DOTS reported a need for increased mobile phone support and potential willingness to use mobile phone reminders to improve adherence and ATT monitoring [15]. Based on our findings, enhancing the current 99DOTS program with more human interactions including direct phone calls or automated phone call reminders may be a possible avenue to overcome the pitfalls and strengthen the program.

Limitations

Given that this study was a pilot study carried out only in a single city in South India, it may not be generalizable to the rest of the country. Similar study conducted in another state in South India shares similar results [15]. However, when India as a whole is considered, mobile phone uptake is only 40%; so, generalizability is a concern [27]. We only enrolled people coming to the TB treatment centers, thus resulting in missing nonadherent individuals whose responses could have been different. Further, as the study staff involved in administering the questionnaire were health care personnel, social desirability is likely to have influenced some of the responses, especially those focusing on acceptance of mobile phone-based ATT support.

Abstract

Background: Digital health interventions have been shown to improve data quality and health services in low- and middle-income countries (LMICs). Nonetheless, in LMICs, systematic assessments of time saved with the use of digital tools are rare. We ran a set of cluster-randomized controlled trials as part of the implementation of a digital maternal and child health registry (eRegistry) in the West Bank, Palestine.

Objective: In the eRegTime study, we compared time spent on health information management in clinics that use the eRegistry versus the existing paper-based documentation system.

Methods: Intervention (eRegistry) and control (paper documentation) arms were defined by a stratified random subsample of primary health care clinics from the concurrent eRegQual trial. We used time-motion methodology to collect data on antenatal care service provision. Four observers used handheld tablets to record time-use data during one working day per clinic. We estimated relative time spent on health information management for booking and follow-up visits and on client care using mixed-effects linear regression.

Results: In total, 22 of the 24 included clinics (12 intervention, 10 control) contributed data; no antenatal care visits occurred in the other two clinics during the study period. A total of 123 and 118 consultations of new pregnancy registrations and follow-up antenatal care visits were observed in the intervention and control groups, respectively. Average time spent on health information management for follow-up antenatal care visits in eRegistry clinics was 5.72 minutes versus 8.10 minutes in control clinics (adjusted relative time 0.69, 95% CI 0.60-0.79; $P < .001$), and 15.26 minutes versus 18.91 minutes (adjusted relative time 0.96, 95% CI 0.61-1.50; $P = .85$) for booking visits. The average time spent on documentation, a subcategory of health information management, was 5.50 minutes in eRegistry clinics versus 8.48 minutes in control clinics (adjusted relative time 0.68, 95% CI 0.56-0.83; $P < .001$). While the average time spent on client care was 5.01 minutes in eRegistry clinics versus 4.91 minutes in control clinics, some uncertainty remains, and the CI was consistent with eRegistry clinics using less, the same, or more time on client care compared to those that use paper (adjusted relative time 0.85, 95% CI 0.64-1.13; $P = .27$).

Conclusions: The eRegistry captures digital data at point of care during client consultations and generates automated routine reports based on the clinical data entered. Markedly less time (plausibly a saving of at least 18%) was spent on health information management in eRegistry clinics compared to those that use paper-based documentation. This is likely explained by the fact that the eRegistry requires lesser repetitive documentation work than paper-based systems. Adoption of eRegistry-like systems in comparable settings may save valuable and scarce health care resources.

Introduction

Digital health interventions (DHIs) have the potential to close critical health system gaps toward achieving universal health coverage in low- and middle-income countries (LMICs) [1]. The 2019 World Health Organization (WHO) guideline on DHIs recommends 9 digital interventions for health system strengthening, given certain context-specific implementation considerations [1]. With the release of the guideline, the WHO highlighted the need for better evidence not only on effectiveness of DHIs but also on other policy-relevant questions such as feasibility, cost-effectiveness, and efficiency [1]. A systematic review summarizing evidence on the time efficiency of electronic health records showed that health workers spent less time on documentation [2], while another review showed an increase in documentation time [3]. Both these reviews were conducted in hospital settings in high-income countries. Such evidence is scarcely applicable in LMICs, where clinical tasks and workflow processes as well as the design and purpose of the DHIs are vastly different. We did not find any systematic reviews of studies of efficiency of DHIs in LMICs.

Despite several demonstrated benefits of using DHIs such as improved service quality and coverage [4], data use and information exchange [5], and health outcomes [6,7], challenges such as increased workloads and stress for care providers have also been reported [1]. In LMICs, client loads are heavy and human resources for health care are scarce [8]. In addition to documenting clinical data, health workers in LMICs typically spend considerable amounts of time on reports of aggregate data to their own Ministries of Health and, in many instances, also to donors and program-based funding agencies [9,10]. While DHIs have the potential to save health workers' time and thereby improve efficiency of the health system, realizing efficiency goals depends on the implementation strategy. Explicit efforts should be made to reduce health workers' documentation burden, such as removing duplicate and repetitive documentations on paper [11]. In many health systems in LMICs, health workers using DHIs continue to record the same information both digitally and on paper, resulting in longer times spent in data management activities [1]. Compounded with high client loads, such inefficiencies may adversely affect time spent on patient care.

An eRegistry is a digital health information system consisting of client records for tracking clients longitudinally [12]. In Palestine, a Maternal and Child Health eRegistry has been implemented for antenatal, postnatal, and newborn care services in governmental primary health care clinics. The longitudinal data captured in the eRegistry drive health worker clinical decision support based on national guidelines. Embedded in the implementation was a set of cluster-randomized controlled trials; the eRegQual trial assessed the effectiveness of eRegistry's clinical decision support versus paper-based client records for improving the quality of antenatal care [13,14].

The aim of the eRegTime study was to evaluate the time spent on health information management in eRegistry clinics compared to clinics performing paper-based documentations.

Methods

Study Design, Data Collection, and Outcome Measures

Detailed descriptions of the eRegTime study methodology have been published in the protocol [15]. Briefly, the eRegTime study was conducted in public primary health care clinics providing antenatal care services in the West Bank, in the setting of a cluster-randomized controlled trial (eRegQual), where the eRegistry's clinical decision support system for antenatal care was evaluated. Of the 119 clusters (primary health care clinics) included in the eRegQual trial, 60 were included in the intervention arm and received the eRegistry with clinical decision support. Built in the District Health Information Software 2 (DHIS2) tracker [16], the eRegistry is accessed through a web-based browser on desktop computers, where care providers enter clinical information in digital client records. The remaining 59 clusters, included in the control arm, continued to use paper-based documentation. The primary health care clinics in the West Bank are staffed by different cadres of health workers including nurses, midwives, and doctors with training in maternal and child health, and obstetricians. The nurse-midwife has the responsibility for most of the documentations in client records and compiling aggregate public health reports for the Ministry of Health, Palestine, and was the only group included for observations in the eRegTime study.

For inclusion in the eRegTime study, two criteria were applied to the primary health care clinics in the eRegQual trial: (1) having only 1 nurse or 1 midwife providing antenatal care services on a given workday (to maintain a 1:1

subject-to-observer ratio) and (2) having, on average, at least 1 booking visit per workday (to capture sufficient antenatal booking visits). A total of 41 clinics were eligible for the time-motion study (20 intervention clusters and 21 control clusters). Of these, 24 clinics (12 eRegistry clinics and 12 paper clinics) were selected by random sampling stratified by laboratory availability, which we reasoned could affect care providers' activities and clinical workflow. Sampling of clinics was done by researchers independent of the study team. Data on clinic staffing and number of antenatal care visits were derived from an inventory assessment of primary health care clinics in the West Bank, conducted in 2014.

Prior to the eRegTime study, we mapped the workflow in clinics using paper-based documentations (control group), and in clinics using the eRegistry (intervention group) [17]. Our findings showed that a typical workday consisted of client consultations in the mornings, when the nurse or midwife provided routine antenatal care and referred clients to higher levels of care, if appropriate. Clinical documentations were carried out in digital client records in the eRegistry in the intervention group. In the control group, paper-based client records were used. Care providers in intervention and control groups maintained a register book of key indicators for reporting purposes. In addition, in both groups, essential clinical information was documented in a client-held handbook for maternal and child health. Apart from the format (ie, digital vs paper), the eRegistry's digital client records and the paper-based records contained identical documentation requirements. Afternoon sessions were typically reserved for compiling public health reports, and the nurse or midwife gathered the required information from the client records and registers to calculate aggregate indicators. In the intervention group, automated aggregate reports could be generated in the eRegistry, while in the control group, the reporting was paper-based. Booking visits, when registrations of new pregnancies occur, as well as follow-up antenatal care may be conducted in the primary health care clinics on a given day.

The data collection tool was designed on the basis of the findings from the mapping; a Microsoft Access template from the US Agency for Healthcare Research and Quality [18] was customized for our context. A total of 10 task categories were included in the data collection tool, with each task accompanied by a time stamp. The tool was designed to capture the full range of activities performed by a nurse or midwife in providing antenatal care on a typical workday.

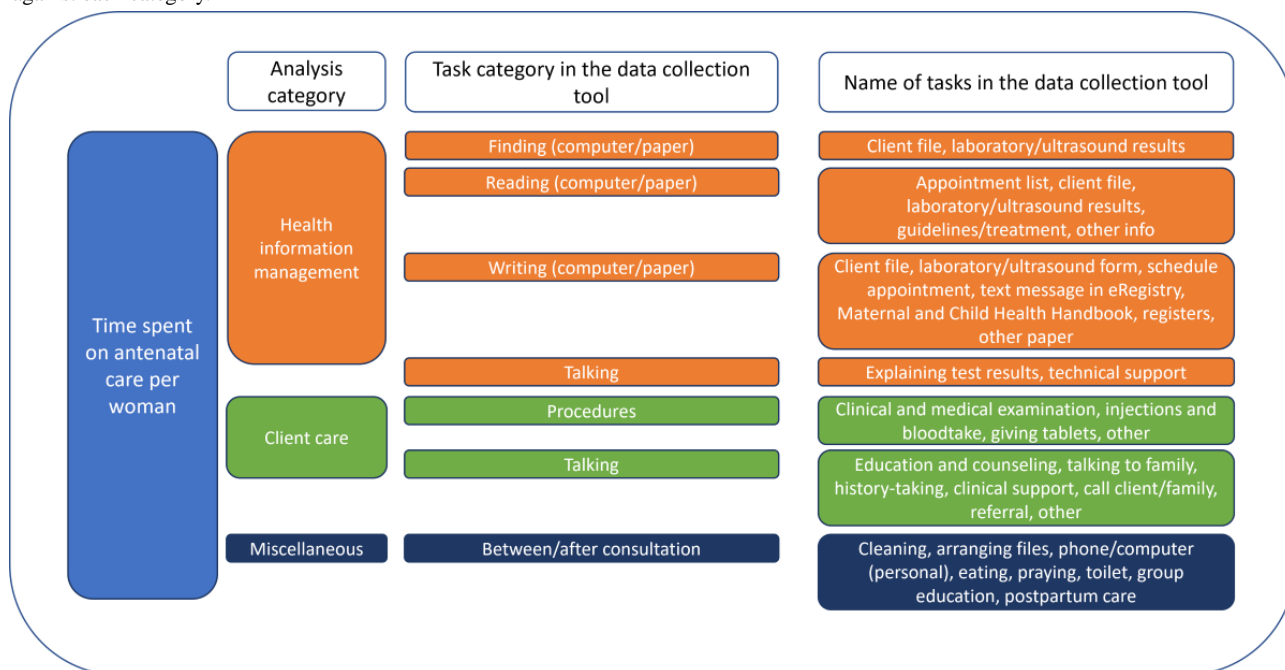

Four data collectors were trained in the use of the data collection tool using the time-motion methodology. Following training, two data collectors individually conducted pilot observations on the same antenatal care consultations in clinics that were not part of the study. That is, 2 observers gathered data on the same day from a clinic using paper-based documentations (control group), while the other 2 observers gathered data from an eRegistry clinic (intervention group). The observers were instructed to only record the primary task in the data collection tool, in case of multitasking by the care provider.

We categorized the tasks in the data collection tool into one of the following six activity types: finding, reading, writing, client care, talking, and miscellaneous [19]. Each antenatal care consultation consisted of differing compositions of the activity types (Figure 1). We applied the task definitions to the final data set and classified each task under one of the following analysis categories: health information management, client care, or miscellaneous (Figure 1). The primary outcome was the time spent on health information management per consultation, defined as the time spent per client consultation on all tasks involving "finding," "reading," "writing," and some tasks listed under "talking" (Figure 1). Time spent on documentation in registers after consultation hours was averaged across the client consultations and added to the health information management time.

In addition to time-motion data, we collected a predefined set of characteristics of clinics and care providers included in the study. No identifiable data were collected on care providers or clients.

It was not possible to blind data collectors, care providers, or clients with respect to allocation owing to the nature of the intervention (eRegistry versus paper-based documentation). However, it was possible to blind them with respect to outcome measurement; that is, data collectors, care providers, and clients were not informed of what was being measured. To reduce possible bias due to lack of blinding to allocation, data collectors were instructed to observe full working days and record data beyond that needed for the computation of the study outcomes. The statistician (CJR) was not involved in data collection and was blinded to treatment allocation for the analyses of relative differences in time used on health information management (primary outcome), client consultation, and client care. It was not possible to blind the statistician to treatment allocation for the analyses of time used finding, reading, and writing files because the treatment allocation was obvious (care providers in the control group could not use a computer for these tasks).

Figure 1. Analysis categories that constitute an antenatal care consultation, task category in the data collection, and name of the task in the data collection tool against each category.

Statistical Analysis

We calculated the sample size by assuming that clinics in the control group (paper-based documentation) spend an average of 10 minutes on health information management per client and that time use would vary more in the intervention (SD 5 minutes) than control clinics (SD 2 minutes). We calculated that a minimum sample size of 8 observations per clinic from each of the 24 clinics would be needed to detect a 25% difference (judged to be clinically meaningful) with 90% power and 5% significance.

We checked data from pilot observations prior to the study for mean (SD) values of time spent on each consultation, health information management, and client care for observations as recorded by each of the observers. We calculated interrater reliability using Cohen κ [20] for the total number of task categories per consultation recorded by each pair of observers.

We present sample means for total consultation time, health information management time, and time spent on client care in the control and intervention groups. We transformed time use to the logarithmic scale and used mixed-effects linear regression to estimate relative time use. Use of the logarithmic scale facilitates estimation of relative time and addresses the issue that time use is a nonnegative quantity that is often positively skewed (ie, many consultations are of “typical” duration, but some are much longer). We adjusted for the variables used to stratify [21] and constrain randomization (cluster size and lab availability) [22], which we modeled as fixed effects. We reasoned that booking visits (new pregnancy registrations) are fundamentally different to follow-up antenatal care visits (we anticipated that they would be of longer duration); therefore, we also adjusted for visit type as a fixed effect. We used random intercepts at the level of clinic to model the cluster-randomized design and used clustered sandwich estimation to account for possible within-observer clustering. We exponentiated to obtain

estimates of relative time use. To aid interpretation of the estimated quantities, we computed marginal mean times used in total and on health information management, client care, finding, reading, and writing, with respect to cluster size, laboratory availability, and visit.

We followed the intention-to-treat principle for all analyses: clusters (and hence participants) were analyzed in the arms to which they were randomized, and all clusters and participants were included in the analyses. No data were missing. Sample size calculations and statistical analyses were performed using Stata 16 (StataCorp LLC). Protocol deviations are documented in [Multimedia Appendix 1](#).

Ethics Approval

Approvals for conducting the eRegTime study were obtained from the Palestinian Health Research Council (PHRC/HC/208/17) and the Regional Committee for Medical and Health Research Ethics in Norway (2017/400), and from the Ministry of Health, Palestine. Participating clinics and care providers were informed of the data collection. Owing to the inherent hesitancy of clients in the study area in placing signatures on documents, verbal informed consent was obtained from all clients prior to start of observation of antenatal care in the study clinics. This study is reported in accordance with the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and onLine TeleHealth) guidelines ([Multimedia Appendix 2](#)).

Results

During the pilot data collection prior to the study, observers 1 and 3 recorded slightly different mean times spent on a consultation (18.3, SD 2.2 minutes vs 17.5, SD 1.3 minutes), on health information management (9.9, SD 2.8 minutes vs 8.9, SD 2.4 minutes), and on client care (8.3, SD 2.3 minutes vs 8.3, SD 1.8 minutes). Interrater reliability (Cohen κ) for the total

number of task categories per consultation was 0.67, indicating substantial agreement [23]. Recordings of observers 2 and 4 were closer in terms of mean times spent on consultation (11.5, SD 7.9 minutes vs 11.2, SD 7.7 minutes), on health information management (5.7, SD 3.7 minutes vs 5.1, SD 3.1 minutes), and on client care (5.4, SD 4.5 minutes vs 5.8, SD 5.0 minutes). Interrater reliability (Cohen κ) for the total number of task categories per consultation was 0.78, indicating substantial agreement as before.

From August to December 2018, data collection was completed at 10 control clinics and 12 intervention clinics, corresponding to a total observation time of 66 hours 26 minutes, and 61 hours 17 minutes, respectively. Four clinics in the control group and 2 in the intervention group were observed for 2 working days,

while the remaining were observed for 1 working day. Data could not be collected from 2 control clinics, since they were small clinics that neither registered new pregnancies nor provided follow-up antenatal care during the data collection period. A total of 118 antenatal care consultations were observed in the control group, of which 19 were booking visits, while 123 antenatal care consultations were observed in the intervention group, of which 11 were booking visits (new pregnancy registrations) (Figure 2).

The age and years of experience of nurses and midwives providing routine antenatal care were comparable across the control and intervention groups (Table 1). A laboratory was available in 6 control clinics and 7 intervention clinics.

Figure 2. Participant flow diagram.

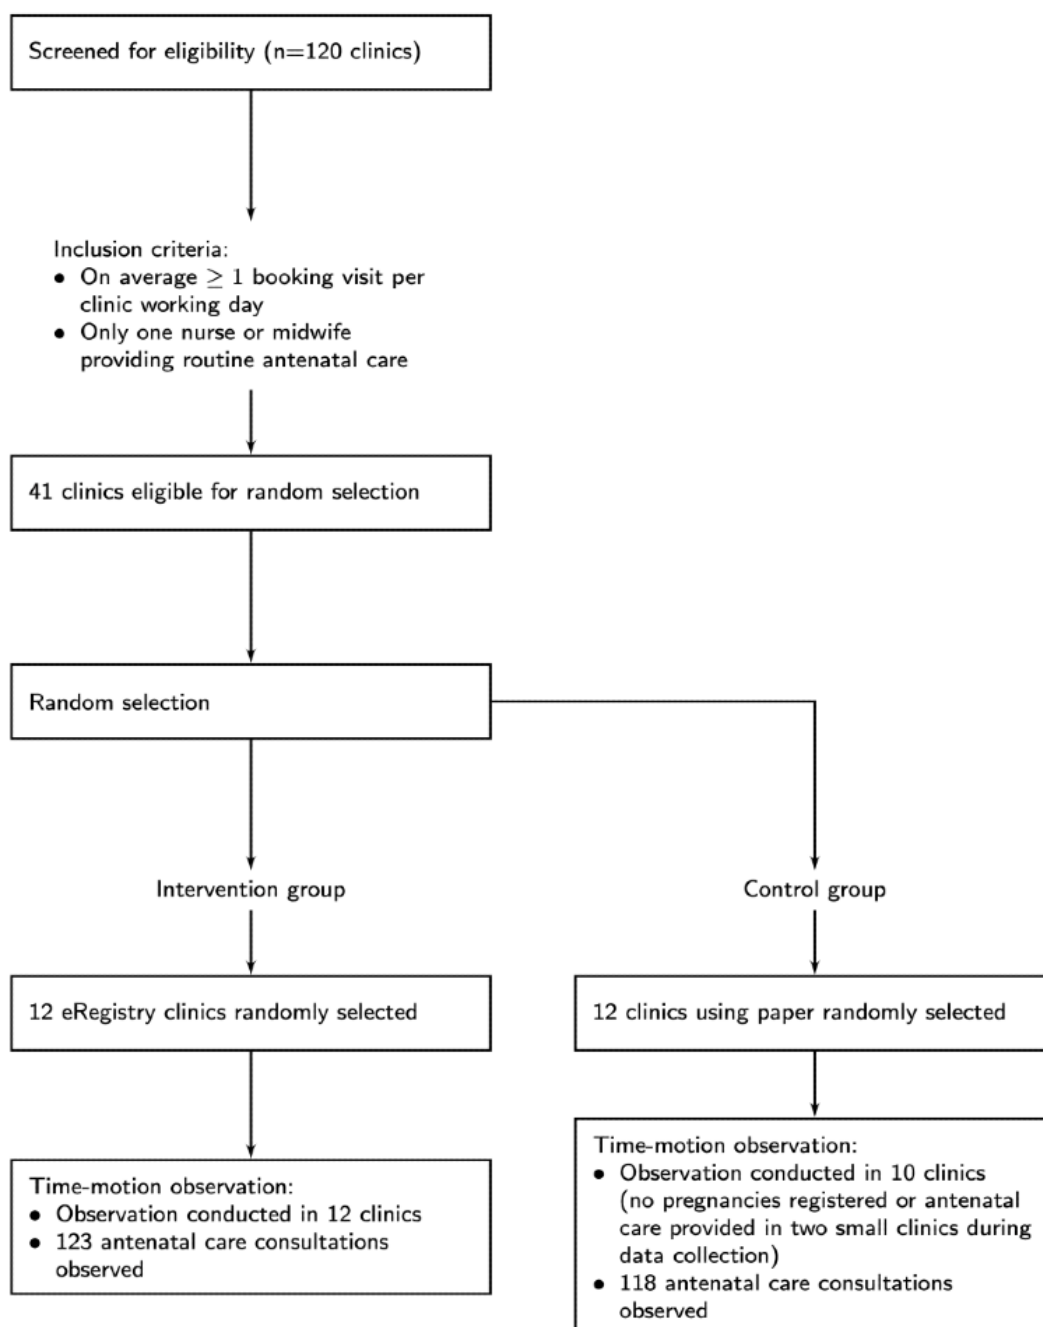

Table 1. Characteristics of clinics and care providers included in the eRegTime study.

Characteristics	Control group, mean (SD)	Intervention group, mean (SD)
Age (years) of the care provider ^a	42.6 (9.3)	43.1 (8.7)
Care provider's years of experience	16.0 (8.1)	17.4 (8.8)
New pregnancy registrations per month during the data collection period	5.5 (2.2)	5.8 (4.9)
Days of service provision per week	1.7 (1.3)	2.0 (1.5)

^aNurse or midwife providing routine antenatal care in primary care clinics.

Table 2 presents comparisons of control and intervention groups of total time spent per consultation, on health information management (primary outcome) and on client care, for booking visits (new pregnancy registrations), follow-up antenatal care visits, and overall. Total consultation time was shorter in the intervention group (sample mean 11.99 minutes) than the control group (sample mean 15.56 minutes). The intervention group spent 74% (adjusted relative time 0.74, 95% CI 0.60-0.90; $P=.003$) of the time spent per client consultation in the control group. The intervention appears to have reduced consultation

times of follow-up antenatal care visits (adjusted relative time 0.72, 95% CI 0.58-0.90; $P=.004$), but not booking visits (**Table 2**). Health information management time per client consultation was shorter in the intervention group (sample mean 6.64 minutes) than in the control group (sample mean 9.84 minutes), with an adjusted relative time of 0.70 (95% CI 0.59-0.82; $P<.001$). Client care was not different in the intervention group compared to that in the control group overall (sample mean 5.01 minutes vs 4.91 minutes; adjusted relative time 0.85, 95% CI 0.64-1.13), or for booking or follow-up visits (**Table 2**).

Table 2. Analysis of total time use and time use on health information management and client care in the intervention and control groups.

	Sample means (minutes) ^a		Relative time (intervention/control)			
	Control	Intervention	Sample (unadjusted)	Adjusted ^b	95% CI ^c	<i>P</i> value ^c
Total time^d						
Any visit	15.56	11.99	0.77	0.74	0.60-0.90	.003
Booking ^e	29.36	24.80	0.84	0.96	0.66-1.39	.82

Follow-up	4.22	4.66	1.10	0.84	0.60-1.19	.33

^aSample means were not computed on the log scale.

^bEstimates of relative time use were adjusted for the stratification variable, cluster size, lab availability, and booking visit.

^c95% CIs and *P* values were adjusted for possible cluster effects due to the cluster-randomized controlled trial design and observer.

^dTotal time includes activities not accounted for in health information management and client care.

^eBooking refers to a new pregnancy registration.

Table 3 shows the relative differences in time used on activities such as finding, reading, and writing—the main activity types that constitute health information management per client consultation—in the intervention versus control groups. The mean time spent on finding files and laboratory test results was longer in the intervention than in the control group (sample

means 0.92 vs 0.68 minutes; adjusted relative time 1.30, 95% CI 1.16-1.45) (**Table 3**). On the other hand, we estimated that the intervention group used only 68% of the time as the control group on writing tasks overall (adjusted relative time 0.68, 95% CI 0.56-0.83) and for follow-up antenatal care visits (adjusted relative time 0.65, 95% CI 0.59-0.72).

Table 3. Analysis of time used in finding, reading, and writing (components of health information management) in the intervention and control groups.

^aSample means were not computed on the log scale.

^bEstimates of relative time use were adjusted for the stratification variable, cluster size, lab availability, and booking visit.

^c95% CIs and P values were adjusted for possible cluster effects due to the cluster-randomized controlled trial design and observer.

^dBooking refers to a new pregnancy registration.

Discussion

Principal Findings

We conducted a continuous observation time-motion study in the setting of a cluster-randomized controlled trial. The intervention, a digital maternal and child health registry (eRegistry), reduced the time spent on health information management without affecting time spent on client care. More time was saved on health information management for follow-up antenatal care visits compared to booking visits (new pregnancy registrations). Our results suggest that adoption of digital tools like the eRegistry in antenatal clinics in LMICs would be expected to meaningfully reduce time spent by care providers on writing tasks.

Comparison With Prior Work

The intervention group in our study had significantly shorter consultation times. In contrast, an assessment in primary care clinics using paper versus electronic health records in Jordan did not show a significant difference in consultation times [24]. However, this result is likely explained by inadequate sample size, since consultation times in clinics using paper records showed wide variations. A multicountry study conducted in Tanzania and Ghana showed that a digital clinical decision support system resulted in increased time spent on antenatal care, although a nonsignificant increase in time was also observed in the nonintervention sites [25]. Booking visits (new pregnancy registrations) typically take longer than follow-up antenatal care visits, as also shown by the results of our study. The eRegistry provides longitudinal digital client records of pregnancies [12], and the care provider can review information from all prior antenatal contacts and proceed with only

documenting new information. This is likely to have resulted in time saved on health information management during follow-up antenatal care visits in the intervention group. A time-motion study in Uganda conducting an evaluation of the effect of client summaries, equivalent to eRegistry's longitudinal client records, found a reduction in time spent on client consultation [26].

Of the subcategories constituting health information management, we estimated a reduction in time spent on writing tasks in the intervention group (sample mean 5.50 minutes vs 8.48 minutes; relative time 0.68, 95% CI 0.56-0.83), amounting to substantial time saved for care providers and the health system. Similar to our results, a systematic review of time efficiency of computer- versus paper-based documentation systems showed a reduction in documentation times with the use of electronic health records of up to 25% for nurses using digital point-of-care tools [2]. In our study, nurses in the control group documented the same information in paper-based client records during consultations and in reporting forms after consultation hours. Redundancies in documentations due to this common practice of maintaining parallel paper-based systems in settings with DHIs have proven to be time-consuming for care providers [10,25]. The eRegistry can generate automated aggregate reports based on digital data entry, and the reduction in time spent on health information management may be attributed to the elimination of some of the dual documentations in the intervention group. A similar digital system in Kenya, which replaced dual documentations, also resulted in time saved for health workers [11]. Further elimination of redundant documentation in register books in the intervention clinics can potentially result in more time saved.

Decreased time spent on patient care owing to the use of DHIs such as digital client records is a commonly cited concern among care providers [27,28]. In our study, there was no difference in the time spent on direct patient care between the two groups. Finding client files and test results was the only activity type that the intervention group appeared to spend more time on than the control group, possibly because of the fundamental differences in doing digital versus paper-based searches; client searches in the eRegistry require 2 or more personal identifying information.

Strengths and Limitations

Time-motion observations, as in our study, have been shown to be more precise in capturing time data as well as less prone to self-report biases compared to other methodologies such as work sampling and self-reporting surveys [29,30]. Since we sampled from a cluster-randomized controlled trial, clinics using paper-based documentations (control group) were likely to be comparable to the eRegistry clinics (intervention group) in all aspects except for the intervention. Time since first implementation is a crucial factor in the evaluation of time efficiency. A systematic review showed that evaluations of electronic health records performed soon after implementation tend to show reduced documentation times compared to those performed later [31]. The eRegTime study was conducted 18 months after the rollout of the eRegistry. We believe that this

allowed sufficient time for care providers to acclimatize to the eRegistry such that our estimates reflect differences with respect to routine clinical practice rather than excessively large effects attributable to a new system. Unlike many other LMICs, the West Bank has no vertical, donor-driven programs for maternal and child health, which demand separate reporting from primary health care. A unified system of automated digital public health reports was relatively easy to roll out—a process that might be challenging in many LMICs.

The study has some limitations. First, our inclusion criteria were based on clinic characteristics from 2014. The sample size was slightly smaller than planned since 2 clinics did not have any antenatal care visits during the data collection period. Second, we conducted only one interrater reliability assessment prior to the study and did not conduct any during the data collection period; however, we did adjust for possible within-observer clustering (see *Statistical Analysis in Methods* and protocol deviations in [Multimedia Appendix 1](#)).

Conclusions

The eRegistry with clinical decision support and automated reporting results in reduced time spent on health information management, possibly without adversely affecting client care time. DHIs that reduce workloads for care providers are perceived as more acceptable, which is crucial for scaling up and sustainability of implementations.

Acknowledgments

This study was funded by grants from the European Research Council (grant agreement 617639; project title: A New Paradigm for Public Health Surveillance: Unlocking the Potential of Data to Empower Woman and Health Systems; project acronym: HEALTMPOWER) and the Research Council of Norway (grant agreement 234376; project title: Harmonized Reproductive Health Registry Communication Strategies: Using Health Data to Empower Women and Health Systems). We also received monetary and in-kind support from the Centre for Intervention Science in Maternal and Child Health (CISMAC), University of Bergen (project 223269). In particular, the contributions of MV and JFF were funded by the CISMAC, University of Bergen. We thank the Ministry of Health, Palestine, for extending support for the eRegistry implementation and research, and for this data collection. We are grateful to the nurse-midwives who were data collectors of the study. The workflow mapping and the design of the data collection tool was conducted as part of a master's thesis submitted by Marie Hella Lindberg to the University of Oslo. We thank the care providers and pregnant women in the primary health care clinics for their co-operation.

Authors' Contributions

JFF is the principal investigator of the eRegistry trials in Palestine and conceptualized the study. MV, KM, ZN, and JFF designed the study. BG is the project leader for the eRegistry implementation in Palestine and coordinated the research and data collection. BG, RK, MI, KAK, EA, TA, and TH trained the data collectors, supervised the data collection, and contributed to critical interpretation of results in the study context. RK performed data curation. MV and ZN analyzed the data; CJR performed the formal analysis. MV and CJR drafted the manuscript. KM and JFF edited the manuscript. All authors reviewed the manuscript and approved of the final version.

Abstract

Background: “Essential Coaching for Every Mother” is a Canadian text message–based program that sends daily messages to mothers for 6 weeks after they give birth. There is a need to explore the program’s effectiveness in terms of the participants’ experience to guide refinement and modification.

Objective: This study aimed to describe the process evaluation of the Essential Coaching for Every Mother randomized controlled trial through an evaluation of the research implementation extent and quality.

Methods: Participants were recruited from Nova Scotia, Canada, between January 5 and August 1, 2021. Enrolled participants were randomized into the intervention or control group. Participants randomized to the intervention group received standard care along with the Essential Coaching for Every Mother program’s text messages related to newborn and maternal care for the first 6 weeks after giving birth, while the control group received standard care. Usage data were collected from the SMS text message program used, and participants completed web-based questionnaires at 6 weeks after birth. Quantitative data and qualitative responses to open-ended questions were used to triangulate findings. Quantitative data were summarized using means, SDs, and percentages, as appropriate, while qualitative data were analyzed using thematic analysis.

Results: Of the 295 unique initial contacts, 150 mothers were eligible and completed the baseline survey to be enrolled in the study (intervention, n=78; control, n=72). Of those randomized into the intervention group, 75 (96%) completed the 6-week follow-up survey to provide feedback on the program. In total, 48 (62%) intervention participants received all messages as designed in the Essential Coaching for Every Mother program, with participants who enrolled late missing on average 4.7 (range 1–12) messages. Intervention participants reported an 89% satisfaction rate with the program, and 100% of participants would recommend the program to other new mothers. Participants liked how the program made them feel, the format, appropriate timing of messages, and content while disliking the frequency of messages and gaps in content. Participants also provided suggestions for future improvement.

Conclusions: Our process evaluation has provided a comprehensive understanding of interest in the program as well as identified preference for program components. The findings of this study will be used to update future iterations of the Essential Coaching for Every Mother program.

Trial Registration: ClinicalTrials.gov NCT04730570; <https://clinicaltrials.gov/ct2/show/NCT04730570>

Introduction

Mothers undergo significant changes during the postpartum period, physically as well as emotionally and relationally, as they adjust to their new mothering role [1,2]. Rates of postpartum anxiety and depression are high, with approximately 17% of mothers reporting postpartum depression symptoms [3] and 15% reporting postpartum anxiety symptoms [4], suggesting the postpartum period is a particularly vulnerable time period for mothers' mental health. During this critical period, mothers learn the skills of motherhood, which can influence how mothers see themselves in relation to their new infant [5] and influence their perception of maternal self-efficacy [6]. During the postpartum period, mothers can often feel undersupported, unsure about their new role as a mother and struggle to find reliable information about caring for their infant [7,8]. Mothers who do not have enough support nor information to help in the transition to motherhood may experience challenges in their psychosocial adjustment and conceptualization of their self-efficacy as a mother [8,9].

To assist with the transition after birth, interventions that target postpartum adjustment and health outcomes are important, with mobile health (mHealth) being one innovative strategy that can be used to provide postpartum education directly to mothers. mHealth is defined as the use of mobile devices, such as mobile phones or smartphones, to transmit various health content and services [10] and can be used across multiple health outcomes and conditions. In the current context, mHealth interventions can be used to complement existing postpartum care, enhancing maternal self-efficacy and feelings of social support through the provision of standardized, time-appropriate, and evidence-based information.

Globally, mHealth interventions have been used to target the perinatal period, with varied impact on maternal psychosocial and newborn outcomes [11-14]. One systematic review on mHealth interventions in high-income countries (n=21) found significant variation in approach and intervention, with positive impacts on postpartum depression for mHealth interventions targeting this outcome [11]. While there are some mobile health interventions targeting the antenatal period [15], there are none currently available that have been evaluated that target the postpartum period in Canada [11]. In the abovementioned systematic review [11], only one study was conducted in Canada, which made phone calls to women with postpartum depression [16]. In a recent study in the Maritime provinces, which includes Nova Scotia where the current study was conducted, 61% of women reported low parenting self-efficacy, 31% had high postpartum anxiety, and 52% had depressive symptoms [17], suggesting that there is a need for a targeted intervention in this area.

While evidence suggests that mHealth innovations can improve health outcomes in the postpartum period [11], there is a need to further explore a program's effectiveness, through the participant's experience, to guide refinement and modification. While the use of a randomized controlled trial (RCT) design is considered to be a gold standard to examine the effect of an intervention, a limitation of this design can be that the findings fail to explain the underlying process and context associated with the implementation of the intervention [18]. There is growing recognition that it is not enough to know "if a health intervention is effective; it is also necessary to understand why the intervention works, how, for whom and in which contexts" [19]. The goal of process evaluation in RCTs is to identify the factors that influence success or failure during implementation by taking into account the complexity of health behavior interventions to identify contextual factors associated with variation in outcomes [20-22].

As part of a hybrid type 1 effectiveness implementation RCT [23], this study aims to describe the process evaluation component of the Essential Coaching for Every Mother RCT; in particular, (1) the research implementation extent (eg, number of participants recruited, timing of recruitment) and (2) implementation quality measured through the likes and dislikes of the program from the perspective of participants and suggestions for further improvement.

Methods

Intervention

To capitalize on the potential of mHealth to support postpartum mothers, we developed the Essential Coaching for Every Mother program, which includes 53 SMS text messages sent over the first 6 weeks after birth, which are related to newborn care and maternal mental health [24]. The program is designed to send 2 SMS text messages per day in the first 2 weeks and a daily message for weeks 3 through 6. Messages are sent automatically on the basis of the newborn's date of birth. In both the pilot feasibility study [25] and the RCT (currently under review), the Essential Coaching for Every Mother program was found to improve maternal self-efficacy and decreased postpartum anxiety.

Participants

Participants were recruited from Nova Scotia, Canada, between January 5 and August 1, 2021, for an RCT on the Essential Coaching for Every Mother program. Participants were eligible if they (1) were between 37+0 weeks pregnant and 10 days postpartum, (2) had daily access to a mobile phone with texting capabilities, (3) were over 18 years of age, (4) lived and gave birth in Nova Scotia, and (5) spoke and could read English. Participants were excluded if (1) their newborn died or was expected to die prior to leaving the hospital, (2) they did not have access to a mobile phone (either personal or shared), (3)

they were unwilling to receive SMS text messages, (4) declined or withdrew by not completing the baseline survey, or (5) previously participated in the development or feasibility phase of this project. Additional details about the study are reported elsewhere [23].

Of note, the use of the term “mothers” is in its broadest sense to refer to any birthing individual, recognizing that not all birthing individuals identify as mothers and not all mothers identify as women [26,27]. All individuals who physically gave birth were recruited to participate in this study, regardless of gender identity.

Ethics Approval and Study Registration

This study was approved by the IWK Health Research Ethics Board (1024984) and Nova Scotia Health Research Ethics Board (1026534) and is registered with the ClinicalTrials.gov Protocol Registration System (NCT04730570).

Study Procedures

This was a 2-group, stratified, parallel-arm RCT following a predefined protocol [23]. Recruitment occurred remotely using both web-based platforms and posters for study promotion. Participants could initiate contact during pregnancy (considered antenatal recruitment) or after the birth of their infant (considered postpartum recruitment). All contact with participants occurred through a predesigned SMS text message flow system in TextIt [28], with sending facilitated through Twilio [29]. TextIt is a web-based interface platform where messages can be preprogrammed in a time-based flow, which is compatible with Twilio, a gateway service that offers virtual phone numbers that send and receive messages on behalf of TextIt [28,29]. A researcher only engaged with a participant

during recruitment if they asked a question that was not understood by the predesigned program. No interaction with participants occurred while they were in the program. All eligibility criteria were self-reported by potential participants as they passed through screening questions via SMS text messages prior to enrollment in the study. Participants also self-reported the date that they gave birth to their infant, which was prompted at set times if a participant was recruited antenatally (eg, weekly between 39 and 42 weeks) or during the recruitment flow if recruited postpartum.

Recruitment

Recruitment occurred through study posters at local hospitals, paid and unpaid social media advertisements (eg, Facebook, Instagram, and Twitter), sharing through family resource centers, and relevant organizations (eg, local public health units and baby stores). Figure 1 illustrates the antenatal and postpartum recruitment posters that were used in hospitals and clinics, with Figure 2 illustrating the modified version that was used with social media advertisements and posts. For the paid Facebook advertisements, approximately CAD \$780 was spent over the campaign. These paid advertisements targeted women aged 18-45 living in Nova Scotia.

After recruitment, participants provided consent and were randomized into the intervention group (Essential Coaching for Every Mother program) or standard care. Participants in both the intervention and control group were requested to complete the consent form, baseline survey (enrollment after birth), 6-week follow-up survey, and 6-month follow-up survey. Additional details about study procedures and the RCT are available elsewhere [23].

Figure 1. Recruitment posters for antenatal and postpartum recruitment for hospitals.

Figure 2. Social media images for antenatal and postpartum recruitment.

Outcome Measures

To measure the extent of implementation of the Essential Coaching for Every Mother program, output data available through the Twilio and TextIt platforms [28,29] were collected per participant, including the enrollment rate (ie, percentage contacted compared to percentage enrolled, and number of withdrawals), enrollment timing (ie, postpartum or antenatal and days post partum), and numbers of messages received based on enrollment timing (per participant). These data were collected throughout the trial.

To measure implementation quality, in the 6-week survey, mothers in the intervention group were asked about user experience, perspectives on the frequency and timing of messages, and what did they like and not like about the Essential Coaching for Every Mother program. Using these two approaches together seeks not only to obtain data on the implementation extent but also on the quality through open-ended questions where mothers provided feedback on their experience with the Essential Coaching for Every Mother program in practice.

Data Analysis

Summative data were reported through means, SDs, and percentages as appropriate. Open-ended questions from the survey were analyzed using thematic analysis [30] led by the first author.

Results

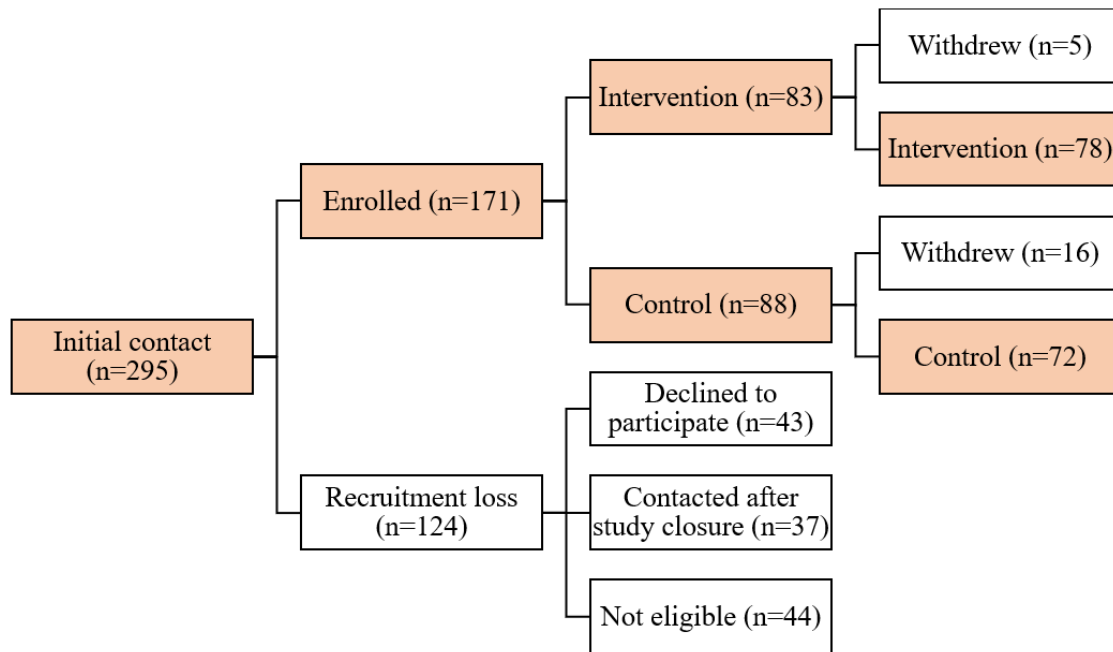

Implementation Extent

During the recruitment period, 295 initial contact messages were sent to the study phone number. Of them, 43 declined to participate (ie, did not complete the screening process), 37 contacted the study number after recruitment was concluded, and 44 did not meet the eligibility criteria.

Of the 171 participants randomized, 83 were randomized to the intervention arm and 88 to the control arm. Two participants texted “STOP” to withdraw from the program and 19 did not complete the baseline survey and were thus considered to have withdrawn from the trial after randomization. Of them, 16 were from the control arm and 5 were from the intervention arm. Figure 3 shows the enrollment flow diagram. In total, 150 participants (50.8%) who contacted the study number were randomized and completed the baseline survey.

For these 150 participants, the mean age of the newborn at enrollment was 2.1 (SD 2.6) days and mothers had a mean age of 31.4 (SD 4.5) years. Most participants identified as White (n=132, 88%) with 18 participants (12%) identifying as landed immigrants. Most participants contacted the study number (n=100) antenatally, with 50 having contacted the study number during the postpartum period. Most enrolled participants found out about the study through posters at the IWK Health Centre in the postpartum rooms (n=64, 42.7%) or perinatal clinics (n=7, 4.7%), followed by Facebook, either posts in groups (n=38, 25.3%), paid advertisements (n=17, 11.3%), or on Marketplace (n=2, 1.3%). Other approaches included word of mouth from family or friends (n=11, 7.3%), family resource centers (n=4, 2.6%), Instagram (n=3, 2.0%), or Kijiji (n=1, 0.1%). Three participants (2.0%) did not specify where they heard about the study.

Of the 78 participants who were randomized to the Essential Coaching for Every Mother program, 48 (61.5%) received full SMS text messages. Of them, 39 (81.3%) were antenatally recruited and 9 (18.7%) were recruited postnatally. The 30 participants who enrolled after the program was designed to start, missed on average 4.7 (SD 3.9, range 1-12) messages. This corresponds to missing on average 2.5 days of messages, on average starting the messages on day 5 post partum. Of them, 18 (60.0%) were antenatally recruited and 12 (40.0%) were recruited postnatally.

Figure 3. Enrollment flow for participants who completed baseline assessment.

Implementation Quality

Among the participants who received the Essential Coaching for Every Mother program and completed the 6-week follow-up survey (n=75), 65 (86.7%) felt that the number of messages was just right, while 6 (8.0%) felt that there were too few messages, and 4 (5.3%) felt that there were too many messages. Overall, participants reported an 89.2% satisfaction rate with the program, and 100% of participants would recommend the program to other new mothers.

Most participants (n=65, 86.7%) felt that the messages reflected all the information needs they had related to their own postpartum experience. Areas of additional informational need related to the maternal postpartum experience were sleep, physical recovery after childbirth (both vaginal and caesarian), breast milk pumping, return of menses, and where to go for postpartum support. Similarly, most participants (n=66, 88.0%) felt the messages reflected all the information needs that they had related to caring for their newborn. Additional information areas requested were primarily related to breastfeeding or pumping as well as newborn sleep, secure attachment, soothing, infant cardiopulmonary resuscitation (CPR), and when to seek medical help.

When asked what participants liked most about the Essential Coaching for Every Mother program, responses fell into four categories: general praise, how the messages made them feel, the format, and the appropriateness of message timing and content. In terms of general praise, participants provided nonspecific appreciation for the program, stating that the information provided was “amazing” and “informative.” Participants also commented on how the program made them feel, in that they felt reassurance and support from the program, with some even commenting that it felt like a daily check-in. One mother said the following: “As a first-time mom, it was reassuring to see some of the information and to get resources,”

while another said, “I liked that it made me feel connected to something.”

Participants also commented that they appreciated the format of the program, particularly liking that the information came via SMS text message and at standard times. One participant explained the following:

Initially when I was receiving two a day, I was excited for 10am and for 5pm... I was sad when I realized the 5pm ones stopped! I enjoyed receiving the texts because it was something to look forward to.

The timing and content of messages was another area that participants really liked about the program. Participants commented that the messages were timely and contained information relevant to their stage of their newborn:

Sometimes I would be thinking about something and receive a text about that exact subject matter! It was almost like they read my mind.

Participants also provided praise on the general content of the information and that links were provided for additional sources of support. One participant appreciated that the program was “Concise, Canadian, [with] good information conveyed.” Another participant said, “I also liked the links to more information that were provided, like the video about purple crying and pelvic floor therapy.”

Among the 75 participants who received the program, 41 (55.7%) provided feedback about what they did not like about the program. The primary areas that participants did not like fell into two main categories: frequency of messages and gaps in content. In relation to the frequency of messages, some participants felt that there were too many messages, some were repetitive, and that the messages were sent in batches of 3, rather than as 1 long message. One participant said, “It came in multiple messages. I would have preferred if it came in one big message, so I didn't get as many notifications.” On the other

hand, a few participants desired more messages: “I would have liked more messages as it was very comforting.”

In terms of content gaps, participants commented on some missing content, such as additional information on breastfeeding, newborn sleep, or on postpartum health for the mothers. Some participants commented that not all information was relevant to them, or they would have liked additional information or support on some topics. One mother said, “some texts didn’t provide enough detail or where to find additional information,” while another explained that she wanted to know “If there was a way to seek further support besides just a public health nurse.” A few participants felt that information regarding the COVID-19 pandemic was too much. Furthermore, others wished that the program was more interactive: “I wish I could text back and forth and ask questions.”

Finally, participants were asked to provide areas where the Essential Coaching for Every Mother program could be improved, which were categorized into 4 main areas. The first related to extending the program, both beyond 6 weeks and to other family members and care providers. One participant said, “I would have liked to continue to get messages further than 6 weeks as they were very helpful.” The second area for improvement was to provide the option to tailor the content, whether to reduce or increase the frequency of messages, or to provide more, or less, content about a particular topic. Some participants preferred to receive more messages—“maybe texts twice a day to get more information”—while others preferred fewer messages—“1 message a day.” One mother suggested, “Maybe tailored to mothers pre-existing knowledge or some specifics for second time moms.” The third area for improvement was to provide additional links or areas for external support for web-based or local resources. Participants wanted more information about accessing support—“including more links for follow up information”—and more information in the texts themselves—“Maybe more links to pdf files with basic information. Not everything can be conveyed via text but sometimes more info is required.” The final area for improvement was to provide an interactive component, where participants could respond to the SMS text messages or engage with other mothers. One participant summarized, “The information was all amazing but being able to interact would be great as well. If there’s any questions to be able to respond to the texts or speak to other mothers.”

Discussion

Principal Findings

This paper presents the process evaluation of the Essential Coaching for Every Mother RCT conducted in Nova Scotia, Canada. Almost two-thirds of participants received the full program as it was designed, with participants who enrolled later missing, on average, approximately 2.5 days of messages. Participants who received the program were generally satisfied and all would recommend it to other new mothers. Likes and dislikes related to the program were identified, along with areas for future improvement.

Comparison With Other Studies

Similar to the feasibility study [25], there was significant interest in the Essential Coaching for Every Mother program. Recruitment occurred quickly (8 months) through the use of completely remote, passive strategies. It appears that posters in the hospital were the most successful strategy, followed by posts and advertisement through Facebook. Several reviews have identified that the use of Facebook to recruit for health research can prove fruitful, especially for hard-to-reach populations [31-33]. This is particularly relevant given that this study’s recruitment occurred during the COVID-19 pandemic, which significantly limited the ability to carry out in-person recruitment in hospital as was originally planned. However, a limitation of recruitment via social media is the lack of generalizability and overrepresentation of White, middle-higher-income participants [31-33]. Therefore, the supplementation of remote recruitment through posters in the postpartum unit of local hospitals allowed for the promotion of the study without requiring physical interaction with potential participants by research staff.

In the feasibility study examining the program, less than half of the participants received the full messages [25], compared to almost two-thirds in this study. This could be partially explained as this study specifically targeted recruitment during the antenatal period on the basis of lessons learned during the feasibility study, which seems to have worked in terms of ensuring that more participants received the full design of messages. What is interesting is that even though two-thirds of participants were recruited antenatally, almost half of participants indicated that they heard about the study via the study poster in the postpartum room. This suggests that participants actually heard about the study earlier and enrolled while they were still pregnant but were reminded about the study through the poster in their room after they gave birth, triggering their engagement with the program shortly after birth. The question about where participants heard about the study occurred in the baseline survey after they gave birth, making the study poster the most recent reminder about the study, potentially influencing their response. Nevertheless, 38.5% of participants enrolled after the program was designed to start (ie, the evening of the second day after birth), starting on average on day 5 post partum, suggesting that perhaps a reconsideration for the design start time may be needed. While the missed messages did not impact outcomes in the feasibility study, and the study team did see improvement in enrollment timing between the feasibility and RCT, this is a large number of participants who did not receive the full program as designed.

Responses from the 6-week follow-up survey were positive and demonstrate that the Essential Coaching for Every Mother program was valuable to mothers. Overall, 89% of participants felt that the number of messages was just right and most of the content addressed what they needed to know related to caring for themselves and their newborn after birth. Identifying the appropriate length and frequency of an SMS text message program is a challenge as there is no standardized evidence of what would be a perfect length for SMS text message programs in relation to the length of the program and frequency of messages. Another Canadian SMS text message program providing general mental health support found that a daily,

consistent message was appreciated by most participants [34]. Preferences may vary among individuals and during the targeted postpartum behavior change period versus the maintenance phase, making it difficult to identify the perfect length [35].

However, as suggested by some participants, the option of more tailored content could help reduce some of these challenges. The inability to tailor content has also been noted in other mental health [34] and maternally focused [36] SMS text message programs, with a desire for more personalization and interaction expressed by participants. Perhaps in future iterations, the Essential Coaching for Every Mother program could be designed to allow participants to opt in for additional messaging around certain topics, such as breastfeeding or sleep, and opt out of messaging if they feel they are receiving too much information. For instance, a Canadian antenatal text message program called SmartMom found a similar need from participants, resulting in them creating different streams of messages in which participants could opt in if they wanted more information on, for example, smoking or pregnancy after previous cesarean [34]. This could be an option for future iterations of the Essential Coaching for Every Mother program as well. Furthermore, a preference for interaction has been found in other SMS text message-based mental health programs [37]. While interaction was considered in the initial development of the Essential Coaching for Every Mother program, this was originally decided against to minimize personnel need and to allow for independent operation. Furthermore, challenges exist for scalability as providing direct access to health care providers would require significant funding to create a dedicated position to allow for this type of interaction. However, if interaction is a key component that participants feel is lacking, this may need to be revisited to determine if and how an interactive component could be added to improve the program's success.

One interesting piece of feedback from participants was that messages were sent in blocks of 3, rather than 1 long message, which was done purposefully. The TextIt platform that was used to program the messages has an upper limit of 160 characters per message, and if a longer message was sent, it may be sent out of order, making it more confusing for participants. Thus, long blocks of content were purposely split into messages under 160 characters to ensure that messages were sent in order, with the goal of improving readability and legibility of health information. A different platform that can send out longer threads of messages could be explored in the future to keep the information in order while minimizing the number of notifications that participants receive when the messages are delivered.

In both the feasibility study [38] and this study, participants requested that the program go on longer than 6 weeks and be available to other care providers, such as their partner. A study by Demirci et al [37] providing SMS text message-based breastfeeding support in the postpartum period also identified that their participants wanted the program to extend beyond 8 weeks and provide similar messaging for partners [39]. The team is currently working on a version for partners as well as an extension beyond 6 weeks. The extension beyond 6 weeks could also address additional content concerns, as there would be more time to offer information without including additional

messages in the first 6 weeks. In terms of messages for partners, evidence from SMS4Dads, a postpartum SMS text message program for Australian fathers, shows preliminary effectiveness and positive uptake by fathers [39,40], suggesting that a targeted intervention for Canadian fathers or partners may have similar positive impacts.

Finally, participants also discussed areas where they wanted additional information related to both maternal health (ie, sleep, physical recovery after childbirth, breastmilk pumping, return of menses, and where to go for postpartum support) and newborn care (ie, breastfeeding or pumping, newborn sleep, secure attachment, soothing, infant CPR, and when to seek medical help). The postpartum period has a lot of changes and information needs for women. The Essential Coaching for Every Mother program was originally designed as a 6-week program, requiring a need to balance provision of information and not overwhelming new parents with information. As most participants appreciated the frequency of messages, it would be difficult to add more messages in the base program. However, if an extension of the Essential Coaching for Every Mother program was designed out to 6 months post partum, the addition of these information needs could easily be added.

Limitations

While this study is able to shed important light on the process evaluation of the RCT, there are limitations. First, owing to unclear variation in reporting between the TextIt program and Twilio program, we were unable to ascertain which messages, if any, were undelivered to participants. Furthermore, owing to the way the SMS text messages are delivered, we were also unable to ascertain if participants read the messages upon delivery. While we anticipate that most participants received and read the text messages, we are unable to confirm that the messages were all read within the designed time frame and as planned. Additionally, there was no fidelity issues reported by the participants (eg, letting us know that they were not receiving the messages and provided feedback on technological challenges faced) and most participants did complete the 6-week follow-up survey, which was primarily sent via SMS text message to participants. This suggests that participants likely received the messages as intended.

Another limitation relates to possible recall bias as participants were asked to provide feedback about the program only after it ended at 6 weeks rather than throughout the program. However, because the program was offered over a short period of time, we anticipate this bias to be limited. We were unable to ascertain why participants withdrew after signing up (ie, they texted "STOP") and why participants did not complete the baseline survey, which may have provided insight into reasons for study withdrawal.

Finally, we did not collect information on other languages spoken or comprehension of the messages, thus limiting our ability to assess for cultural or language barriers in future iterations of the intervention. Nevertheless, the messages were targeted at an eighth-grade reading level [24], thus increasing the accessibility of the messages to the general population. The sample is also quite heterogeneous in terms of race, with 88% of participants identifying as White and only 12% identifying

as landed immigrants. While our sample is slightly more diverse than the current demographics of Nova Scotia, where 6% of Nova Scotia's population identify as a visible minority and 6% as immigrants [41], the findings of the study must be interpreted in this light, with further exploration needed on the impact of the program on non-White, immigrant mothers.

Conclusions

This process evaluation for the Essential Coaching for Every Mother RCT suggests that the implementation extent and quality

were satisfactory. Nearly two-thirds of participants received the full program as it was designed. Participants were generally satisfied and all were willing to recommend it to other new mothers. The information provided by participants on the likes and dislikes of the program along with areas for improvement will be used in future iterations of the Essential Coaching for Every Mother program.

Abstract

Background: Depression is a major global cause of morbidity, an economic burden, and the greatest health challenge leading to chronic disability. Mobile monitoring of mental conditions has long been a sought-after metric to overcome the problems associated with the screening, diagnosis, and monitoring of depression and its heterogeneous presentation. The widespread availability of smartphones has made it possible to use their data to generate digital behavioral models that can be used for both clinical and remote screening and monitoring purposes. This study is novel as it adds to the field by conducting a trial using private and nonintrusive sensors that can help detect and monitor depression in a continuous, passive manner.

Objective: This study demonstrates a novel mental behavioral profiling metric (the Mental Health Similarity Score), derived from analyzing passively monitored, private, and nonintrusive smartphone use data, to identify and track depressive behavior and its progression.

Methods: Smartphone data sets and self-reported Patient Health Questionnaire-9 (PHQ-9) depression assessments were collected from 558 smartphone users on the Android operating system in an observational study over an average of 10.7 (SD 23.7) days. We quantified 37 digital behavioral markers from the passive smartphone data set and explored the relationship between the digital behavioral markers and depression using correlation coefficients and random forest models. We leveraged 4 supervised machine learning classification algorithms to predict depression and its severity using PHQ-9 scores as the ground truth. We also quantified an additional 3 digital markers from gyroscope sensors and explored their feasibility in improving the model's accuracy in detecting depression.

Results: The PHQ-9 2-class model (none vs severe) achieved the following metrics: precision of 85% to 89%, recall of 85% to 89%, F_1 of 87%, and accuracy of 87%. The PHQ-9 3-class model (none vs mild vs severe) achieved the following metrics: precision of 74% to 86%, recall of 76% to 83%, F_1 of 75% to 84%, and accuracy of 78%. A significant positive Pearson correlation was found between PHQ-9 questions 2, 6, and 9 within the severely depressed users and the mental behavioral profiling metric ($r=0.73$). The PHQ-9 question-specific model achieved the following metrics: precision of 76% to 80%, recall of 75% to 81%, F_1 of 78% to 89%, and accuracy of 78%. When a gyroscope sensor was added as a feature, the Pearson correlation among questions 2, 6, and 9 decreased from 0.73 to 0.46. The PHQ-9 2-class model+gyro features achieved the following metrics: precision of 74% to 78%, recall of 67% to 83%, F_1 of 72% to 78%, and accuracy of 76%.

Conclusions: Our results demonstrate that the Mental Health Similarity Score can be used to identify and track depressive behavior and its progression with high accuracy.

Introduction

Background

The American Psychiatric Association defines depression as a “common and serious medical illness that negatively affects how you feel, the way you think, and how you act” [1]. It comprises symptoms such as low mood, guilt, suicidal ideation, and cognitive decline [1,2]. According to *The Global Burden of Diseases, Injuries, and Risk Factors Study (GBD) 2019*, depression is one of the most disabling mental health disorders [3], and it poses a significant economic and medical burden. A study by Greenberg et al [4] calculated an increase in economic cost related to depression of 37.9% from US \$236.6 billion to US \$326.2 billion in 2020. These costs comprised direct, suicide-related, and workplace costs [4]. There also has been a global increase in the prevalence of depression. The percentage of adults in the United States with major depressive disorder increased by 12.9%, from 15.5 to 17.5 million, between 2010 and 2018 [4]. To further add to these increasing numbers worldwide, the COVID-19 pandemic has led to a substantial increase in mental health conditions, including depression [5], which has been aggravated by the uncertainty associated with the disease, isolation, and overall decreased social interaction [6,7]. Given this rise in depression rates and the immense costs associated with it, adequate diagnosis and timely intervention have become a pressing and urgent need [8].

Depression, as most other mental illnesses, is diagnosed via the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) [9], or the International Classification of Diseases, 11th Revision [10]. However, there is growing skepticism regarding their validity [11,12]. In a groundbreaking research study by Newson et al [11] in 2021, they were able to quantify the degree of heterogeneity within and across the DSM-5 symptom profile in that the DSM-5 criteria “fails to diagnose *patients* by symptom profile any better than random assignment.” This strongly supports Zimmerman et al [13], who found that there are 227 different ways to diagnose depression. The problem is further exacerbated by heterogeneity among scales used for depression screening and diagnosis [14,15], illustrated by a cross-sectional study that found that, in a small sample of 309 patients, there was a misdiagnosis in 55% of these cases [16]. In addition, there are no approved biomarkers as part of the diagnostic criteria for depression [17]. Compounding factors that contribute to the hurdles associated with adequate screening and monitoring of depression are lack of primary care physicians, low recognition of depression in primary care [18], delayed response to treatment [19], 12-week waiting period in the absence of a response, other comorbidities, and patient fear of stigma attached to depression [20]. There are several instruments for detecting depression in primary care [21], one of which is the Patient Health Questionnaire-9 (PHQ-9), which has been adopted as the gold standard for detecting depression and grading its severity [22].

To overcome these many challenges associated with traditional methods for the detection, management, and monitoring of depression, smartphone-based interventions have advanced as an available and alternate option. Middleweerd et al [23] found that the use of digital tools for physical health monitoring, such as fitness-based smartphone apps, was becoming increasingly popular. The use of digital tools for the management of mental health conditions became a key resource as the demand for mental health support exceeded the supply when the COVID-19 pandemic led to a rise in depressive disorders worldwide [6]. In addition to telehealth and remote therapy, a solution that emerged was digital health assessment using smartphones and their sensors [24], also known as digital phenotyping. Torous et al [25] define the term as “moment-by-moment quantification of the individual-level human phenotype in-situ using *data* from smartphones and other personal digital devices.” The use of passive sensors in the mental health industry has the potential to detect real-time changes in psychological factors, and this can be used to increase access to care [26], reduce stigma [27] improve diagnosis [28], and enable remote monitoring [29] as has been established by previous and ongoing research.

Previous Work

There is a growing body of research on passive data sensing and its use in modeling human behavior [30]. Previous work has shown that monitoring these digital biomarkers using machine learning models to assess passive smartphone data can aid in the screening, treatment, and remote monitoring of mental health disorders. In a study by Wang et al [31], the app Student Life was used to show the correlation between depression and accelerometer- and screen use-based biomarkers. In another study, Saeb et al [32] found significant correlations between depression and passive data such as phone use and GPS in a sample of 40 participants. Asare et al [33] found that age group and gender as predictors led to improved machine learning performance. Their study concluded that behavioral markers indicative of depression can be unobtrusively identified using smartphone sensor data [33]. Taking a machine learning approach, a study found that the predictive power of mobile device use patterns was significant to continuously screen for depressive symptoms or monitor ongoing treatments [34]. In line with this study, another study used the Remote Monitoring Application in Psychiatry to explore the validity of smartphone-based assessments for self-reporting mood symptoms and found high compatibility with nonsmartphone-based assessments [35], thus proving such tools to be helpful for clinicians and research.

This study focused on South Korea as it has consistently reported a low number of depression cases despite high suicide rates [36] and the dramatic worldwide increase in depression. In 2005, a study reported that the annual prevalence rate of depression in South Korea was 1.7%, whereas rates of depression were reported to be much higher in that 25.3% scored positive for depression in a nationwide sample study [37].

Researchers have debated various reasons for the low prevalence rates, including the difference in cutoff scores in South Korea versus other countries and the associated stigma [37] attached to mental health conditions, but have not yet reached a conclusion as to the cause. Digital phenotyping and passive monitoring can provide a timely opportunity to target issues such as low access to mental health diagnoses, stigma, and associated health consequences in South Korea and similar countries.

Objective

Smartphone sensors and passive data, when coupled with relevant statistical and machine learning models, provide an avenue to capture behavioral changes associated with mental health disorders in naturalistic settings [30,38]. Much of the previous work in this field has used sensors that are invasive and privacy-related such as GPS, call logs, SMS text message logs, and keyboards. This study demonstrates a novel mental behavioral profiling metric termed Mental Health Similarity

Score (MHSS), derived from analyzing passively monitored nonintrusive and nonidentifiable smartphone use data, to identify and track depressive behavior.

Methods

The Study Design

We collected active and passive data in a longitudinal observational study using the Behavidence (Behavidence, Inc) mobile app, derived from a cohort of anonymous participants in South Korea. Participants were invited to take part in this study through social media advertisements and campaigns, which is an effective tool for recruitment in research studies [39]. The advertisement used a research code that the interested individual could use to enter the study by downloading the app (Figure 1). The data set was collected from 558 participants between November 2021 and December 2021. All the participants were Android-based smartphone users.

Figure 1. The Behavidence app screen showing the daily Mental Health Similarity Score.

Participant Inclusion Criteria

The inclusion criteria were as follows: (1) they must be aged >18 years and (2) they must have an Android device.

Measure (PHQ-9)

Depression severity was assessed using a patient-reported outcome measurement questionnaire. When the participants registered with a research code and enrolled in the study, they answered the PHQ-9 [40] in the app. The PHQ-9 scale is the gold standard for detecting and measuring the severity of depression worldwide [41]. It has been validated for use in community-based and general population settings and has sound psychometric properties [42]. Although the depression assessments were self-reported, the PHQ-9 has been clinically validated for the assessment of depression severity owing to its high internal reliability (Cronbach $\alpha=.89$) and has been used in multiple studies as a self-reported questionnaire [22]. The PHQ-9 measures depression severity over the preceding 2 weeks. Each item of the PHQ-9 is scored on a scale of 0 (not at all) to 3 (nearly every day). The total PHQ-9 score ranges from 0 to 27, with a score of ≥ 10 indicating a major depressive disorder [22]. A score of < 5 indicates no depression, 5 to 9 indicates mild depression, 10 to 14 indicates moderate depression, 15 to 19 indicates moderately severe depression, and 20 to 27 indicates severe depression [40]. The PHQ-9 has also been established to have good psychometric properties in the South Korean population, which is the focus of this study [43].

Smartphone App (Behavidence)

Behavidence [44] is a mental health screening app that passively collects personal device use data with zero respondent burden and no use of identifiable information. The app works as an always-on solution and can be downloaded from the Google Play store. Individuals can register or log in to the app with no supervision, and any required onboarding information was easily made available to the study participants remotely. In addition, demographic user profile information questions (gender, age bracket, and existing mental health indication) were answered within the app.

The Behavidence Research App was developed for smartphones running Android version 5 or higher and requires connectivity to send data to the back end for analysis and receive data analysis outcomes. It does not require connectivity to collect the data. For an app to run as a background process, it must obtain the *Battery Optimization* and *Usage Data Access* permissions from the user. These permissions are obtained during the onboarding process.

The app uses the principle of digital phenotyping to track user behavior. It displays an MHSS developed from phone use metrics such as time spent on various apps on a daily and weekly basis. The MHSS displays how similar the user's digital behavior is to the digital behavior of someone who has been diagnosed with depression. This similarity score is a range from 0% to 100% (Figure 1). The MHSS is generated every 24 hours. The app also shows the user their weekly history of similarity scores. In this study, gyroscope readings from each participant's smartphone device were collected in addition as sensor features

measuring the direction and speed at which the phone was spinning around its axis.

The app and back end use strict data privacy and security protocols. The solution is compliant with the Health Insurance Portability and Accountability Act and the General Data Protection Regulation.

Data Inclusion and Exclusion

The data set used for model training only included participants aged ≥ 18 years with at least 24 hours of complete passive, nonsensor, personal device use data. The final data set contained 399 participants with an average of 10 (SD 25.21) days of mobile data. The addition of the use of gyroscope readings, measuring angular velocity as phone sensor features, was tested to improve the accuracy of the model. The purpose of this is to test whether sensor features provide additional insights than using only nonsensor features. The data set used specifically for the gyroscope model training had a reduced individual participant number of 193, in which at least 24 hours of raw device use with the additional sensor readings was available. This reduced number of participants was due to the inability to collect gyroscope readings from specific Android phones.

Feature Extraction

The raw data set collected contains daily behavioral patterns that were data-cleaned and transformed to reach independent features such as opening and closing apps with the start and end times in Coordinated Universal Time in milliseconds. These data were preprocessed by converting the time stamps to local dates and times according to the user's time zone. Digital biomarkers, used as machine learning features in this study, were calculated per user, taking daily behavioral patterns on a 24-hour basis starting from midnight every day. The 3 main types of nonsensor features were *average time on the phone per day*, *frequency of events per day*, and *app category use per day*. The mapping of various apps into specific categories can be found in [Multimedia Appendix 1](#). In addition, gyroscope data were collected and processed daily to generate sensor features such as *mean activity*, *average gap activity*, and *total activity*. In the end, a total of 37 features were extracted and merged on a per-user, per-day basis. Explanations of each feature can be found in [Multimedia Appendix 2](#).

Procedure

The participants downloaded the Behavidence app and answered a simple demographic questionnaire along with the informed consent form. They then completed the PHQ-9. The questionnaire was answered only as a 1-time data point and, thereafter, they were free to use the app on their own. The app generated a daily MHSS. The app added no further respondent burden and, therefore, the participants were able to check the score whenever they felt the need to or not at all.

Data Analysis

Imbalanced Data Handling

A total of 24 hours of raw data each day were binned for every participant and considered separate observations in this study. Therefore, an individual with depression who had 10 days of complete 24 hours of passive data was considered as 10

depression-labeled observations. To correct for the imbalanced training data of the *none* and *severe depression* categories, the cohort with the smaller number of observations was randomly sampled to match the number of observations in the other. In this case, more observations were found in the *none* (ie, not depressed) group and, thus, it was randomly split into equal subsets. In addition, bootstrapping with 15-fold cross-validation was performed to assess the overall model performance.

Machine Learning to Predict Depression

A mental health profiling metric termed MHSS was derived from the features extracted from the raw data to classify whether a user's daily digital behavior mimicked the digital behavior of mobile users who are depressed. This metric is a direct output of a machine learning model trained to classify 24 hours of digital behavior into the different thresholds of the PHQ-9, screening positive for severe depression versus no depression. A variety of machine learning models were compared to detect major digital behavioral differences between *none* and *severe* category participants. The algorithms tested in this study include random forest regression, multivariate adaptive regression splines, random forest classification, extreme gradient boosting, and support vector machines with a radial basis function kernel. After the top algorithm was chosen based on the highest predictive accuracy, 4 machine learning models were created and compared: the PHQ-9 binary nonsensor model, the PHQ-9 binary gyroscope sensor model, the PHQ-9 3-class model, and the PHQ-9 question-specific models.

The PHQ-9 binary nonsensor model was intended to classify participants who scored as severe (scores ≥ 20) on the PHQ-9 against those who scored as having no indication of depression (scores < 5). The 3 main feature categories (average time on the phone per day, frequency of events per day, and app category use per day) were the main components input into this model. The PHQ-9 binary gyroscope sensor model had the same specifications as the PHQ-9 binary nonsensor model; however, 3 features (mean activity, average gap activity, and total activity) were added to the training to assess whether the gyroscope sensors had higher accuracy than the PHQ-9 binary nonsensor model. The PHQ-9 3-class model was intended to classify participants who scored as severe (> 20), moderate (10-14), and no depression (< 5) to help with predicting the progression toward severe depression. Finally, a model was built using specific PHQ-9 items that had the highest correlations with the nonsensor passive digital biomarkers to detect specific symptoms of depression rather than classifying them into *none* and *severe* categories.

Model Validation

The main metric used to validate the models built in this study tested whether most days of data collected had either high or low MHSSs. The training cohort was taken at a specific time point during the study's recruitment in December and, thereafter, all additional days of data collected were used for the machine

learning validation set. The metrics were tested on both a 1-week data majority and an overall majority on all days of data that were collected from the user by the app. If most days had high MHSSs, defined as having scores $> 50\%$, the user was classified as having depression. If most days had low MHSSs, defined as having scores $< 50\%$, then the user was classified as not showing signs of depression. This, in addition to the model accuracy and recall rates, will be used to assess whether digital biomarkers can detect and track depression.

Correlation Analysis

Further analysis of all items (questions) from the PHQ-9 was conducted to determine which symptoms of depression could be identified from the passive digital data collected through the app. A Pearson correlation and Spearman correlation were assessed to determine whether there was either a linear correlation or a monotonic relationship where the rate was not constant. Correlations were conducted on all 9 questions of the PHQ-9 scale with an MHSS as well as a combination of different questions.

Software

The Amazon Web Services platform was used for data storage, whereas data processing, feature engineering, model training, and poststatistical analysis were written in Python 3.8 programming language (Python Software Foundation). The packages used include pandas, stats models, and scikit-learn random forest classifier.

Ethics Approval

Consent was voluntarily given on the participants' smartphones once they were informed of the purpose of the study. The data set does not contain personally identifiable or any personal health information. The advertisement, informed consent, and study protocol were approved by the independent Western Institutional Review Board-Copernicus Group, Institutional Review Board (approval number: 20216225).

Results

Participants

Self-reported demographic data from the 558 participants (Table 1) show that, of these, 286 (51.3%) identified as women, 254 (45.5%) identified as men, and 18 (3.2%) identified as nonbinary or preferred not to disclose their gender. Regarding the participants' age distribution, of the 558 participants, 474 (84.9%) were aged between 18 and 25 years, 29 (5.2%) were aged between 26 and 35 years, 42 (7.5%) were aged between 36 and 55 years, 10 (1.8%) were aged between 56 and 64 years, and 3 (0.5%) were aged ≥ 65 years. The PHQ-9 questionnaire was administered to users in both English and Korean, with most of the participants belonging to the Korean-speaking population (487/558, 87.3%).

Table 1. Demographic distribution showing the numbers for age, gender, and language of the answered Patient Health Questionnaire-9 (N=558).

Variable	Value, n (%)
Age (years)	
18-25	474 (84.9)
26-35	29 (5.2)
36-55	42 (7.5)
56-64	10 (1.8)
>64	3 (0.5)
Gender	
Male	254 (45.5)
Female	286 (51.3)
Prefer not to say	18 (3.2)
Language	
Korean	487 (87.3)
English	71 (12.7)

Smartphone Data and PHQ-9 Distribution

[Table 2](#) presents the distribution of the PHQ-9 scores of the 558 participants. The PHQ-9 was collected at the start of recruitment at a single time point during this study. The distribution of the PHQ-9 scores was as follows: 11.3% (63/558) were in the *none* category (ie, they were not depressed) with PHQ-9 scores <5, whereas 88.7% (495/558) showed signs of depression by scoring between *mild* and *severe*. The mean PHQ-9 score was 12.5 (SD 6.29).

There is an imbalance in the gender distribution when looking into each severity group of depression. For the *none* and *mild* cohorts, men represented the majority, whereas, in the *moderate*, *moderately severe*, and *severe* cohorts, there was a female majority, as shown in [Table 3](#).

Out of the 558 participants, 499 (89%) answered “no previous diagnosis” in the demographic questions collected at onboarding. Moreover, 65% (323/499) of the participants who reported that they had no previous diagnosis of any kind obtained a PHQ-9 score of at least moderate (≥ 10) to severe depression, as shown in [Table 4](#).

Table 2. Distribution of the participants' PHQ-9^a scores (N=558).

PHQ-9 score category and score	Participants, n (%)

Features Engineered From Smartphone Data

A total of 37 features were computed from the raw passive smartphone data. Of the 37 features, 29 (78%) showed statistical significance in the 1-tailed *t* test results between the *none* and *severe* cohorts. Overall, 8 of the significant nonsensor and

gyroscope (sensor) features are displayed in [Table 5](#). The remaining list can be found in [Multimedia Appendix 3](#). Effect size analysis showed that the most important features had moderate to high effect sizes when comparing the *none* and *severe* category populations [45].

Table 5. The *t* test (1-tailed) results of the none versus severe cohorts with *P* values and Cohen *d* statistic.

Feature	Cohort, mean (SD)		<i>P</i> value	Cohen <i>d</i>
	None	Severe		
Nonsensor				
Mean session time	1.1 (0.5)	2.5 (4.8)	<.001	0.4257
Total session	300.0 (145.0)	416.7 (233.3)	<.001	0.5811
Number of opens	305.7 (137.9)	240.8 (169.6)	<.001	0.4248
Sleep	266.7 (183.3)	300.0 (216.7)	<.001	0.1947
Average gap	3.2 (3.5)	4.3 (6.2)	<.001	0.2495
Gyroscope (sensor)				
Average activity	28.5 (67.5)	57.0 (101.0)	<.001	0.2053
Average gap activity	7.6 (13.9)	23.8 (47.5)	<.001	0.3191
Total activity	1181.6 (436.7)	1165.0 (446.7)	.68	0.0859

Predicting Depression From Features

Among the classification algorithms, random forest proved to have the highest predictive accuracy (87%). Extreme gradient boosting followed with an accuracy of 86%, whereas the support vector machine classifier had the lowest accuracy (44%), as shown in [Table 6](#).

The top-performing algorithm, the random forest classifier trained on the PHQ-9 binary nonsensor model (none vs severe on the depression rating scale) on 34 of the nonsensor features mentioned in [Table 5](#), achieved a precision of 85% to 89%,

recall of 85% to 89%, F_1 of 87%, and overall accuracy of 87%, as shown in [Table 7](#).

The feature importance plot based on Gini Impurity measurement analysis indicates the top passive digital features indicative of differentiating between *none* and *severe* cohort participants ([Figure 2](#)). The top 5 features are mean session time on the phone within a 24-hour period, average session time in the social interaction apps (app category 1), average session time within a 24-hour period in the miscellaneous and additional passive recreational apps (app category 11), number of times

active messaging and communication apps (app category 3) were opened within a 24-hour period, and average time spent on unofficial or unregulated apps (app category 0). The top 5 features had Gini Impurity values ranging from 0.6 to 0.1.

The top 5 features from the feature importance list achieved statistical significance with $P < .001$, as shown in Table 8. Average overall session time and average time spent on social interaction apps, miscellaneous and additional passive recreational apps, and unregulated apps had greater mean values for the participants who scored as *severe* compared with the participants who scored as *none* on the PHQ-9. *None* participants opened active messaging and communication apps 110 times on average (SD 7.02), whereas *severe* participants opened this app category 74 times on average (71.05).

In addition, the model was tested to see whether it could accurately predict participants who had reported a previous diagnosis of depression. The model achieved an accuracy of 80% in detecting depression but only 26% in detecting the *none* group.

Additional validation of whether the PHQ-9 binary nonsensor-based model (none vs severe) could accurately predict the progression of depression was performed by calculating the

percentage of participants in each group who had a majority of days with high MHSSs (>50%), with the MHSS as the model's prediction of class probabilities. As shown in Table 9, the majority increases as severity increases, indicating that participants with severe depression had a majority of days with high MHSSs, supporting the model's prediction ability.

When the gyroscope features were added as additional markers, the overall accuracy dropped to 76% with a precision of 74% to 78%, recall of 67% to 83%, and F_1 of 72% to 78%. This model was also tested on the self-proclaimed diagnosis cohort and achieved 27% accuracy in detecting depression and 0% accuracy in detecting the *none* group. When age and gender were added to see if demographics played a role in classifying *none* (not depressed) versus *severe* (depressed) cohort participants, the overall accuracy decreased slightly from 87% to 84%, precision increased from 82% to 87%, recall increased from 83% to 86%, and F_1 increased from 84% to 85%.

An additional random forest classifier trained on the PHQ-9 3-class model—none (PHQ-9 <5), moderate ($10 \leq \text{PHQ-9} < 15$), and severe ($\text{PHQ-9} \geq 20$) depression on the 34 nonsensor features—achieved a precision of 74% to 86%, recall of 76% to 83%, F_1 of 75% to 84%, and overall accuracy of 78%, as shown in Table 7.

Table 6. Accuracy metrics of the 3 classification algorithms tested in this study: random forest, extreme gradient boosting (XGBoost), and a support vector machine with radial basis function kernel.

Mean session time: average session length that a user interacts with their mobile device within a 24-hour period (minutes)	1.07 (3.58)	2.49 (4.97)	<.001
App 1: average time a user spent on apps that fall into app category 1—social interaction apps—within a 24-hour period (minutes)	1.41 (4.40)	3.58 (1.16)	<.001
App 11: average time a user spent on apps that fall into app category 11—miscellaneous and additional passive recreational apps—within a 24-hour period (minutes)	1.56 (1.94)	3.37 (5.11)	<.001
App 3 opens: number of times a user opened apps that fall into app category 3—active messaging and communication apps—within a 24-hour period (counts)	110.49 (70.10)	74.45 (71.05)	<.001
App 0: average time a user spent on apps that fall into app category 0—nonofficial or unregulated apps—within a 24-hour period (minutes)	0.34 (0.60)	0.83 (2.34)	<.001

Table 9. The PHQ-9^a binary nonsensor-based model validation results showing the majority of days with high MHSS^b across all days of data collected.

PHQ-9 severity	Participants, n (%)	Majority of days of data with MHSSs >50% (%) ^c
None	38 (18)	15.84
Moderate	116 (55.5)	75.02
Severe	55 (26)	95.82

^aPHQ-9: Patient Health Questionnaire-9.

^bMHSS: Mental Health Similarity Score.

^cEach participant has a different total number of days of data collected. Hence, each PHQ-9 group has a different total number of days. Therefore, the majority of days mentioned is the total percentage of days that group participants had MHSS greater than 50%.

PHQ-9 Specific Questions and Smartphone Data

A significant positive Pearson correlation was found among PHQ-9 questions 2, 6, and 9 within the *severe* category users and the mental health behavioral profiling metric ($r=0.73$), as shown in [Table 10](#). When a gyroscope sensor was added as a feature, the Pearson correlation among questions 2, 6, and 9 dropped from 0.73 to 0.46.

A binary model trained on questions 2, 6, and 9 was constructed to complement the PHQ-9 binary nonsensor model. The participants who scored 0 on all 3 questions were considered as the *none* class, whereas the participants who scored 3 on every question were considered as the *depression symptoms* class. The PHQ-9 questions model achieved an overall accuracy of 78% with a precision of 76% to 80%, recall of 75% to 81%, and F_1 score of 78% to 79%, as shown in [Table 7](#). [Figure 3](#) shows the feature importance plots for this prediction model. Top features include (1) number of times active messaging and communication apps (app category 3) were opened within the 24-hour period, (2) number of times active messaging and communication apps were opened or longer than 1 SD from the mean session time within the 24-hour period (app 3 upper), (3)

number of passive information consumption apps (app category 2) opened within the 24-hour period, (4) average time spent on general utilities apps (app category 6), and (5) average time spent on passive information consumption apps (app category 2).

[Table 11](#) displays the mean values of the top 5 features of the random forest model for PHQ-9 questions 2, 6, and 9. The number of times the participants opened active messaging and communication apps that had greater session lengths than the average was calculated for both the *none* and *severe* participants and proved to be both statistically significant ($P<.001$) and a top feature in the questions model. The *none* participants opened this app category 6.47 times on average compared with the *severe* participants, who opened it 3.25 times. In addition, *none* participants opened passive information consumption apps 2.13 times on average compared with *severe* participants, who opened them 0.46 times on average. Finally, *severe* participants had general utilities apps opened for longer (0.57 minutes) on average than the *none* participants (0.40 minutes), but *none* participants had passive information and consumption apps opened for longer (0.29 minutes) on average than *severe* participants (0.18 minutes).

Table 10. Correlation analysis within the severe cohort between baseline per-item scores and Mental Health Similarity Scores on the day of baseline assessment.

PHQ-9 ^a item	Pearson correlation	Spearman correlation
Question 1: “Little interest or pleasure in doing things?”	-0.078	-0.075
Question 2: “Feeling down, depressed, or hopeless?”	0.596	0.607
Question 3: “Trouble falling or staying asleep, or sleeping too much?”	0.004	0.0
Question 4: “Feeling tired or having little energy?”	-0.101	-0.045
Question 5: “Poor appetite or overeating?”	-0.017	0.059
Question 6: “Feeling bad about yourself—or that you are a failure or have let yourself or your family down?”	0.492	0.543
Question 7: “Trouble concentrating on things, such as reading the newspaper or watching television?”	-0.214	-0.213
Question 8: “Moving or speaking so slowly that other people could have noticed? Or the opposite—being so fidgety or restless that you have been moving around a lot more than usual?”	0.064	0.093
Question 9: “Thoughts that you would be better off dead, or of hurting yourself in some way?”	0.479	0.447
Question 1+Question 2+Question 6+Question 9	0.655	0.580
Question 2+Question 6+Question 9	0.727	0.698

^aPHQ-9: Patient Health Questionnaire-9.

Figure 3. Feature importance plot of the random forest model for Patient Health Questionnaire-9 questions 2, 6, and 9. The x-axis represents the feature importance metric, Gini Impurity, which can range from 0.0 to 0.5. The y-axis represents the list of features ordered from greatest to least importance.

Table 11. Mean values of each cohort and *P* values from 1-tailed *t* tests of the top 5 important features in the random forest model for Patient Health Questionnaire-9 questions 2, 6, and 9.

Feature	Cohort, mean (SD)		<i>P</i> value
	None	Severe	
App 3 opens: number of times a user opened apps that fall into app category 3—active messaging and communication apps—within a 24-hour period (counts)	110.49 (73.47)	74.45 (77.25)	<.001
App 3 upper: number of times a user opened apps that fall into app category 3—active messaging and communication apps—and had session times greater than the average session time of that app category within a 24-hour period (counts)	6.47 (5.77)	3.25 (3.98)	<.001
App 2 opens: number of times a user opened apps that fall into app category 2—passive information and consumption apps—within a 24-hour period (counts)	2.13 (5.24)	0.46 (1.2)	<.001
App 6: average time a user spent on apps that fall into app category 6—general utilities apps—within a 24-hour period (minutes)	0.40 (2.11)	0.57 (0.48)	<.001
App 2: average time a user spent on apps that fall into app category 2—passive information and consumption apps—within a 24-hour period (minutes)	0.29 (0.70)	0.18 (0.20)	.008

Discussion

Principal Findings

The study objective was to demonstrate a novel machine learning mental behavioral profiling metric termed MHSS, derived from analyzing passively monitored and nonintrusive smartphone use data, to identify and track depressive behavior. This objective was met as the MHSS models reached an overall accuracy of 87%. In this study, an average of 10 days of smartphone data were used in addition to PHQ-9 results from 399 participants to demonstrate the ability to detect digital behavioral markers quantified from the participants' smartphones to detect depression severity. We further focused on using these digital behavioral markers to develop predictive models to classify *none* (not depressed) and *severe* (depressed) symptom severity scores.

A mental behavioral profiling metric termed MHSS, developed from digital markers extracted from the participants' smartphone data, was able to predict the participants' depression state (ie, none or severe) with high predictive performance using machine learning models.

Demographic analysis found a higher number of women in the *severe* group compared with the *none* group, which is in line with previous literature on the prevalence of depression in South Korea [46]. Studies conducted in South Korea have shown that, in a sample, women were more depressed than men across all age groups [47]. Both regression (random forest regression and multivariate adaptive regression splines) and classification (random forest classification, extreme gradient boosting, and support vector machines) machine learning models were tested to evaluate the highest predictive accuracy between none and severe depression. The PHQ-9 binary nonsensor model (none vs severe) achieved the highest accuracy using a random forest classification algorithm with the following metrics: precision of 85% to 89%, recall of 85% to 89%, F_1 of 87%, and overall accuracy of 87%. The PHQ-9 3-class (none vs mild vs severe) model achieved the following metrics: precision of 74% to 86%, recall of 76% to 83%, F_1 of 75% to 84%, and overall accuracy of 78%. The effect size of the nonsensor features was moderate, and the effect size of the sensor features was low. The PHQ-9

gyroscope sensor model achieved the following metrics: precision of 74% to 78%, recall of 67% to 83%, F_1 of 72% to 78%, and overall accuracy of 76%. Although the results of this study have similar accuracies to previous studies [24,48], these models indicate that invasive features such as GPS tracking and audio information are not necessarily required to detect behaviors in individuals with depression.

The feature importance list was extracted based on the Gini Impurity measurement. In the PHQ-9 binary nonsensor model, results found that *mean session time* was the most important feature in predicting severe depression using nonintrusive passive sensors. Mean session time was higher in participants with *severe depression* compared with *none*. This result is in line with previous findings that people with higher phone use have a positive correlation with self-reported depression [49]. Another study found that high mobile phone use was associated with symptoms of depression in men and women at 1-year follow-up compared with people with low phone use [50]. Going down the feature importance plot, it was observed that app category 1 (social interaction apps) had higher use in participants with severe depression compared with participants with no depression. This aligns with studies that have shown that social media use is higher in people with depression [51,52] and that limited use can lead to a decline in self-reported feelings of depression [53]. In the PHQ-9 questions model, it was interesting to find that mean session time on active messaging and communication apps was lower in participants with *severe depression* (ie, their use of this app category was low compared with the *none* group). This finding is in line with previous findings that web-based communication is reported to be low in people with depression [54].

A per-item correlation was performed, and a significant positive Pearson correlation was found between PHQ-9 questions 2, 6, and 9 within the *severe* category users and the mental health behavioral profiling metric, that is, the MHSS ($r=0.73$). Users who had higher scores in the 3 questions also had higher MHSSs (>50%). Previous research has shown that items 2, 6, and 9 comprise the affective-cognitive component of the PHQ-9 scale [55]. The highest-correlated PHQ-9 items—2, 6, and 9—were the questions that indicated affective symptomatology; therefore,

a separate PHQ-9 questions model was created, achieving a precision of 76% to 80%, recall of 75% to 81%, F_1 of 78% to 89%, and overall accuracy of 78%. This 2D PHQ-9 questionnaire (the other being the somatic component) approach has been used in previous studies and shown to have sound psychometric reliability and validity [55-57]. Thus, the results of this study add to the literature as, to the best of our knowledge, no previous studies have explored the 2-factorial approach of the questionnaire and used it to create digital behavioral markers.

We chose South Korea as the study site as there are low levels of reported depression despite the high number of cases of suicide. The study found that, of the 469 individuals who reported having *no diagnosis* as their current status in their demographics questionnaire, 307 (65.5%) scored as moderate to severe depression (PHQ-9 score ≥ 10). This result fits previous literature that states that the population in South Korea is often less likely to seek treatment and diagnosis for depression because of low awareness and stigma [58]. Our results also complement our intention to study a South Korean sample as a previous study on the prevalence rates of depression in South Korea found that, despite the high suicide rate in the country [59], the prevalence of depression has been reported to be much lower compared with other countries [60]. This can be mainly due to 2 factors: the access rate to services for depression has been reported to be low and the mental health treatment gap for major depression is 56.3% [61]. It is also interesting that studies have shown that the prevalence of depression rates is lower in Asian countries, such as South Korea, when compared with Western countries [62,63] owing to the stigma surrounding psychiatric illnesses [64]. This result demonstrates the feasibility of a daily mental health profiling metric using smartphone-based passive data to monitor symptoms, administer tests at home, and schedule interventions, which will help overcome the limitations hindering traditional methods of assessment such as stigma [64] and hesitation toward accessing mental health services because of low education levels [58].

This study also evaluated the use of another passive sensor (ie, gyroscope) to improve the accuracy of our models. This study found that, when a gyroscope sensor was added as a feature, the Pearson correlation among questions 2, 6, and 9 decreased from 0.73 to 0.46. Mean activity ($P < .001$) and average gap activity ($P < .001$) features from the gyroscope sensors showed statistically significant differences between *none* and *severe* individuals. Therefore, although gyroscope sensor data show some distinction between the 2 cohorts when including them as an additional feature, the gyroscope as a sensor alone does not add predictive power.

Previous researchers have established a relationship between depression and digital phenotyping using identifiable passive information such as GPS and HealthKit information [8,48] and have a high respondent burden, such as daily mood surveys and multiple assessments [24,48]. Our study adds an approach in which we show that high-accuracy models to detect depression can be achieved using nonintrusive data such as average time on the phone per day, frequency of events per day, and app category use per day, with only 1 baseline assessment and no

further respondent burden. The behavioral profiling metric, called the MHSS, is easy to understand by the user and, therefore, is easily incorporated into various clinical and therapeutic scenarios. The findings about various app category uses provide a dive into behavior patterns of depressed and not depressed groups, which can be useful for risk profiling. This study also further complements the idea shared by Onnela [65] in his research that private passive data collected from smartphones present a big challenge and should be anonymized. The app used in this study collects only nonintrusive, passive data, and the data are encrypted from the time they are collected and then re-encrypted when they are stored in the servers, thereby guaranteeing an accurate and safe MHSS. To further address any concerns about security, the app provides the ability to obtain daily MHSSs as a completely anonymous user, ensuring zero traceability.

In the everyday clinical scenario, the MHSS can help with remote monitoring of symptoms as well as treatment or intervention efficacy. It is a simple, affordable, and accessible form of technology that is easily scalable. This proves especially useful in low- and middle-income countries, where there are multiple barriers to mental health care access. In our study, we found that the MHSS can detect individual patterns of behavior as well as population-based trends. However, further research is required to establish its use on an epidemiological level.

Strengths

The strength of the study can be found in using nonintrusive, passive behavioral data to generate digital phenotypes for depression and, in the future, for more mental health disorders. In addition, web-based recruitment was used, which eased the onboarding process and allowed the users to participate in the study at their own comfort. This study design is easy to replicate for other digital phenotyping indications where it is possible to administer web-based self-report questionnaires and generate results.

Limitations and Future Work

The first limitation of the study was that the PHQ-9 was administered only once; thus, the depression symptom status was only collected at baseline. Future studies should aim to assess the symptoms at 2 time points and observe the changes in questionnaire scores alongside the changes in digital behavior. Another limitation was that our data were heavily inclined toward the 18 to 25-year age group, with 84.9% (474/558) of the participants belonging to it. Our study did not have *clinical diagnosis of depression* as an inclusion criterion, only a self-reported clinical diagnosis and the self-reported PHQ-9 scale. Using a more diverse age group in a more proportionate number could provide a better overview of how digital behavior symptom severity could change with age as a factor. Although the PHQ-9 as a patient-reported outcome measure is the gold standard method for diagnosing depression and is used worldwide to screen for depression, the results of this study will be further consolidated when tested in a clinically diagnosed population. This study was available only for Android users; therefore, further studies should look at incorporating the iOS operating system. Furthermore, future studies can include other locations and questionnaires.

Conclusions

Nonidentifiable passive smartphone data prove to be a suitable tool to assist with the remote screening and monitoring of depression. The strong privacy metrics and low respondent

burden pave the way for further exploration in not only screening and even triaging patients but also measuring therapeutic outcomes through the MHSS as a metric. Finally, the aggregated measurement of a group as a health metric could further support larger epidemiological studies.

Abstract

Background: The COVID-19 pandemic accelerated drivers for virtual health adoption and triggered the US federal government to implement regulatory changes to reduce barriers to virtual health implementation. Consequently, virtual health solutions have been increasingly adopted, and health systems in the United States have been reorganizing their care delivery process with unprecedented speed.

Objective: This study aimed to assess and make recommendations on the strategy, business model, implementation, and future considerations for scaling and sustaining virtual health solutions based on the views of executives from the largest health systems in the United States.

Methods: In September 2020 and October 2020, the Health Management Academy conducted 29 quantitative surveys and 23 qualitative interviews involving 58 executives from 41 of the largest health systems in the United States. Participating health systems were approximately equally distributed across size categories (small, medium, and large, defined as annual total operating revenue US \$2-3 billion, \$3-6 billion, and >\$6 billion, respectively) and US Census Bureau regions (Northeast, Midwest, South, and West).

Results: Based on the Health Management Academy's assessment of approaches to governance, financing, data infrastructure, and clinical integration of virtual health, most participating health systems (13/24, 54%) had a mid-stage level of maturity in virtual health implementation. Executives reported the pandemic is forcing health systems to re-examine strategic priorities; the most commonly raised key impacts were increased access (15/21, 71%) and flexibility (10/21, 48%) as well as lower costs of care delivery (9/21, 43%). Most executives (16/28, 57%) reported their organization had a defined budget for virtual health, and many noted that virtual health is best supported through value-based payment models. Irrespective of health system maturity, reimbursement was consistently rated as a key challenge to virtual health scaling, along with patient access to and understanding of virtual health technology. The success of virtual health implementation was most commonly measured by patient satisfaction, health care provider engagement, and proportion of health care providers using virtual health solutions (reported by 7/8, 88%; 6/8, 75%; and 7/8, 75% of information technology executives, respectively). Almost all health systems (27/29, 93%) expect to continue growing their virtual health offerings for the foreseeable future, with user-friendliness and ease of integration into the electronic medical record as key factors in making go-forward decisions on virtual health solutions (each selected by 9/10, 90% executives).

Conclusions: The increased demand for virtual health solutions during the COVID-19 pandemic is expected to continue postpandemic. Consequently, health systems are re-evaluating their current platforms, processes, and strategy to develop a sustainable, long-term approach to virtual health. To ensure future success, health system leaders need to proactively build on their virtual health solutions; advocate for payment, site flexibility, and reimbursement parity for virtual health; and demonstrate continued engagement and boldness to evolve care beyond established models.

KEYWORDS

virtual health; eHealth; mHealth; telemedicine; telehealth; COVID-19; health system; care delivery; strategy; business model

Introduction

Virtual health is a rapidly evolving field, encompassing a range of information and communication technologies and forms of care delivery. Although there is no static and universally agreed definition of virtual health, the World Health Organization has defined eHealth in the following way: “the cost-effective and secure use of information and communications technologies in support of health and health-related fields, including health-care services, health surveillance, health literature, and health education, knowledge and research” [1].

Virtual health, as well as telemedicine or telehealth, could be considered as components of eHealth, with virtual health focused on modalities of care delivery. For the purposes of this research, we defined virtual health to include the following components.

- Live (synchronous) videoconferencing: a 2-way audiovisual link between a patient and health care provider
- Store-and-forward (asynchronous) care delivery: transmission of a recorded health history to a health care provider or patient
- Remote patient monitoring: the use of connected electronic tools to record personal health and medical data in one location for review by a health care provider in another location, usually at a different time
- Mobile health (mHealth): health care and public health information provided through mobile devices. The information may include general educational information, targeted texts, and notifications about disease outbreaks.

Over recent years, there have been trends toward an increase in virtual care solutions for patients [2]. However, prior to the COVID-19 pandemic, health systems across the United States faced several barriers to the expanded use of virtual health, including a lack of reimbursement, uncertainty around workflow integration, resistance to change, and concerns about quality and efficacy [3,4]. The COVID-19 pandemic accelerated drivers for virtual health adoption, as maintaining continuity of care during “stay at home” orders necessitated increased use of virtual health to minimize exposure to and spread of the virus during care delivery. The pandemic also triggered the US federal government to implement multiple regulatory changes to reduce barriers to virtual health implementation. Pandemic emergency orders allowed for cross-jurisdictional recognition of licensure, enabling health care providers licensed in one state to work in any other state [5-8]. The Coronavirus Preparedness and Response Supplemental Appropriations Act of 2020 waived many of the geographic and site restrictions on Medicare reimbursement [9]. The US Department of Health and Human Services loosened enforcement of some rules under the Health Insurance Portability and Accountability Act of 1996 during COVID-19, giving health care providers more flexibility in the use of telehealth solutions [10]. Consequently, virtual health solutions have been increasingly adopted, and health systems

in the United States have had to reorganize their entire care delivery process with unprecedented speed [11,12].

Although the pandemic has catalyzed significantly higher virtual health utilization, health care providers and academics in the field are predicting a fundamental, enduring shift in how health systems deliver care [12-14]. Although health systems scaled virtual health out of necessity, innovating to meet the needs of an immediate crisis is different from sustainable, long-term transformation. Consequently, health systems are beginning to re-evaluate how the virtual health strategies implemented during the COVID-19 surge in virtual health utilization will meet the needs of the system, health care providers, and patients going forward. The pandemic quickly demanded that patients, health care providers, and health systems adapt virtual care at an unprecedented pace of change. Continuing to manage this rate of change will continue to be a challenge postpandemic. Maintaining these elevated levels of virtual health adoption among health systems into the future will depend on key factors, including sustained payment mechanisms, regulatory flexibility around site-of-service requirements, and development of a virtual care delivery model that wins the confidence of patients, health care providers, and health systems with regard to quality, safety, and cost. With 637 separate health systems across the United States [15], sharing learnings and best practices between health care providers is important for ensuring consistency and equity in health care delivery across the nation. Sharing information can also assist health systems with decision-making and implementation of the most effective solutions. Some of these learnings may also be applicable to health care systems in other countries.

In this study, we aimed to assess and make recommendations on the strategy, business model, implementation, and future considerations for scaling and sustaining virtual health solutions based on the views of executives from the largest health systems in the United States.

Methods

Overview

The Health Management Academy (referred to herein as The Academy) comprises over 3500 members, including C-suite executives and principal leaders from more than 150 of the largest health systems in the United States (each with an annual operating revenue of at least US \$2 billion), as of July 2021 [16]. In September and October of 2020, The Academy distributed a survey and interview request to members with clinical, operational, or informatics roles with role titles that included Chief Medical Officer (CMO), Chief Nursing Officer, Medical Group President, Chief Operating Officer, Chief Financial Officer, Chief Information Officer, Chief Medical Information Officer, and Chief Nursing Information Officer.

The survey and interviews included questions on health systems’ strategic approach, implementation, and future outlook on their

virtual health modalities. Surveys were distributed by email and included 18 multiple choice questions divided into 4 sections: general quantitative survey, clinical, strategy and operations, and information technology (IT)/data (Multimedia Appendix 1). The questions included under the General Quantitative Survey section were given to all participating executives, whereas the sections on clinical, strategy and operations, and IT/data were sent to targeted executives with expertise on those topics. Interviews ran for 30 minutes to 60 minutes, were conducted virtually through Microsoft Teams, and included questions based on a qualitative interview guide containing 31 questions divided into 6 sections: strategy, structure, implementation, finance, data, and consumerism (Multimedia Appendix 2). Questions from each section were asked as relevant to the interviewee's role; for example, only C-suite executives in IT were asked questions in the data section. Executives from the same health system were allowed to attend the same interview if preferred.

The Academy collected responses and analyzed results. For the quantitative survey data, percentages were calculated for each question, with the total number of responses to each question as the denominator. For the sections on clinical, strategy and operations, and IT/data, the denominator was the number of executives with the relevant experience who answered each question. If a respondent skipped a question, then the denominator for that question would be reduced by 1. Due to

the small sample sizes involved, statistical analyses of survey data were not feasible. Responses from the interviews were qualitatively assessed, and observations were summarized in the report. Quotes were blinded and included as spoken by interview participants.

Data were segmented by health system size, geographic region, percent of revenue from government pay, and virtual health maturity. Health system size was defined based on annual total operating revenue (TOR), including all revenue from both patient care and health plan if applicable; large systems were those with >US \$6 billion TOR, medium systems were those with \$3-\$6 billion TOR, and small systems were those with <\$3 billion TOR. Geographic regions were based on the US Census Bureau regions [17] and were defined as Northeast, Midwest, South, and West (Figure 1). Government pay was defined as the proportion of payer mix coming from Medicare, Medicaid, or other government sources, with high and low categories of greater than or less than the median of the survey group, respectively. Virtual health maturity was defined and assessed by The Academy based on responses to survey and interview questions in 4 categories: virtual health governance, finance, data/IT, and clinical. General features of health systems at early stage, mid-stage, advanced, and innovative levels of virtual health maturity are shown in Figure 2. Selected subgroup analyses are presented for qualitative comparison.

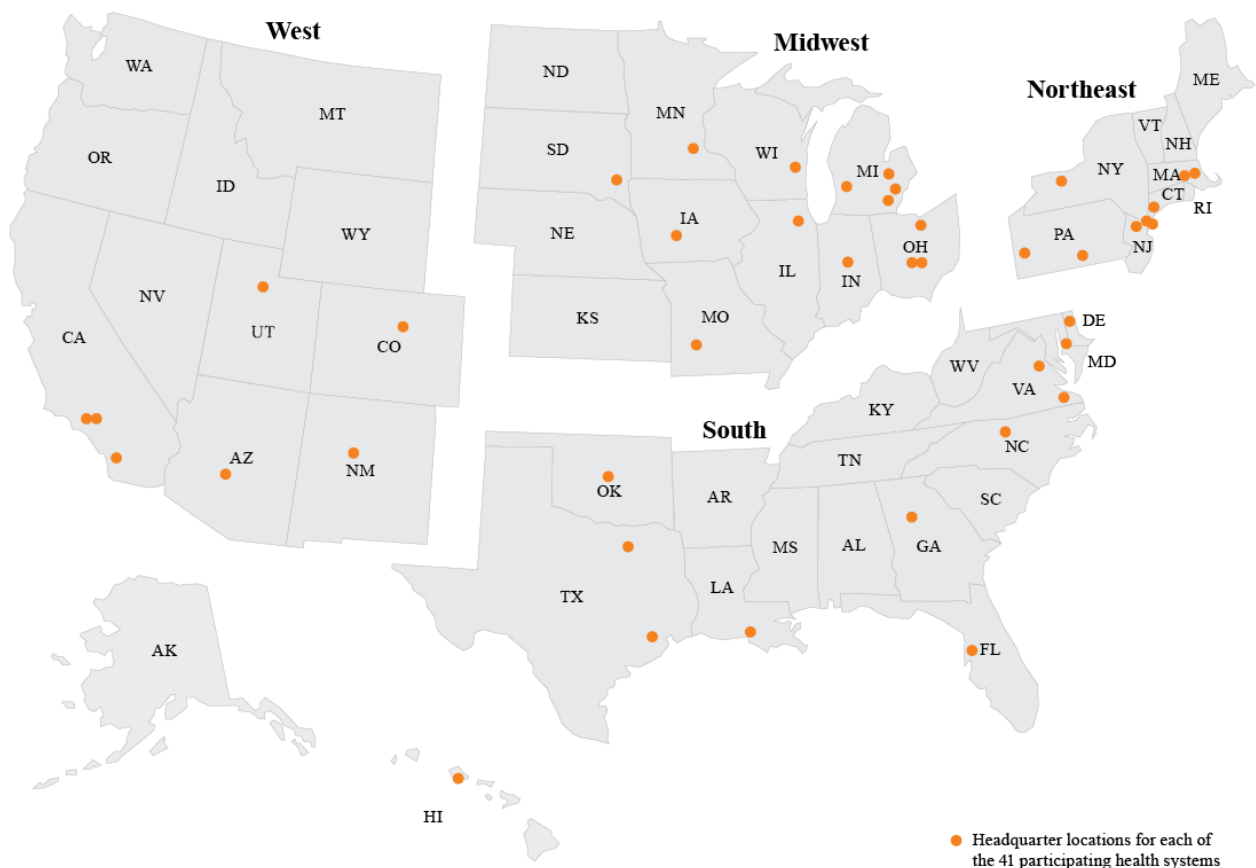

Figure 2. Overall health system maturity across virtual health programs. AI: artificial intelligence; IT: information technology.

Ethical Considerations

This research was considered exempt from institutional research board review according to the US Department of Health and Human Services, Office for Human Research Protections, §46.101, (b)(2) [18] because it involved survey procedures, and the information obtained could not be linked to the participants and did not place them at risk.

Results

Participating Health Systems

Study participants included 58 executives from 41 separate health systems in the United States. There were 29 quantitative survey responses and 23 qualitative interviews (some interviews involved more than 1 executive).

Participating health systems represent a mean TOR of US \$5.5 billion. Participating health systems were approximately evenly distributed across the size categories: 32% (13/41) were large, 39% (16/41) were medium, and 29% (12/41) were small. Participating health systems were also approximately evenly distributed across the different US regions: Northeast (9/41, 22%), Midwest (13/41, 32%), South (11/41, 27%), and West (8/41, 20%). The median government pay across these systems was 42% (range 23%-66%). Based on their approaches to governance, financing, data infrastructure, and clinical integration of virtual health, most participating health systems (13/24, 54%) were categorized as being at a mid-stage level of overall maturity in virtual health implementation (Figure 2). Health systems tended to be at a more advanced level of maturity in their approach to strategy/governance and finance and less mature in their data and IT infrastructure and clinical integration (Figure 3).

Figure 3. Virtual health maturity by domain. IT: information technology.

Virtual Health Strategy

Prior to the COVID-19 pandemic, most health systems had implemented some form of virtual health solution for specific use cases, most commonly tele-stroke, tele-intensive care unit, or within behavioral health. However, most health systems did not have defined infrastructure, processes, or strategies to leverage virtual health on a large scale. Most health systems reported a neutral to conservative approach to pursuing virtual health modalities pre-COVID-19 (60% to $\geq 70\%$ across modalities). Reimbursement difficulty and lack of integration with the electronic medical record (EMR) were cited as the main barriers to virtual health implementation.

Executives reported that the pandemic is forcing health systems to re-examine strategic priorities, and executives raised multiple key impacts on health systems and health care providers. In light of the virtual health “new normal,” health systems are forced to re-examine the cost structure of their business model and the composition and skills of their workforce, as well as the need for brick-and-mortar facilities. There is also a push for health systems to incorporate insights from consumer-facing industries (eg, banking, finance) in digital front door strategies. Health systems and health care providers are being pushed to develop a strategy to partner with patients to design and implement virtual health solutions from a consumer lens, address the social determinants of health that impact patient access to virtual health, and ensure equity and access in moving beyond traditional (eg, phone, video) telehealth services. Health care providers are also being forced to adopt virtual health and learn how to modify their workflows accordingly.

In order to scale existing virtual health modalities to meet surging demand, many health systems found building on their

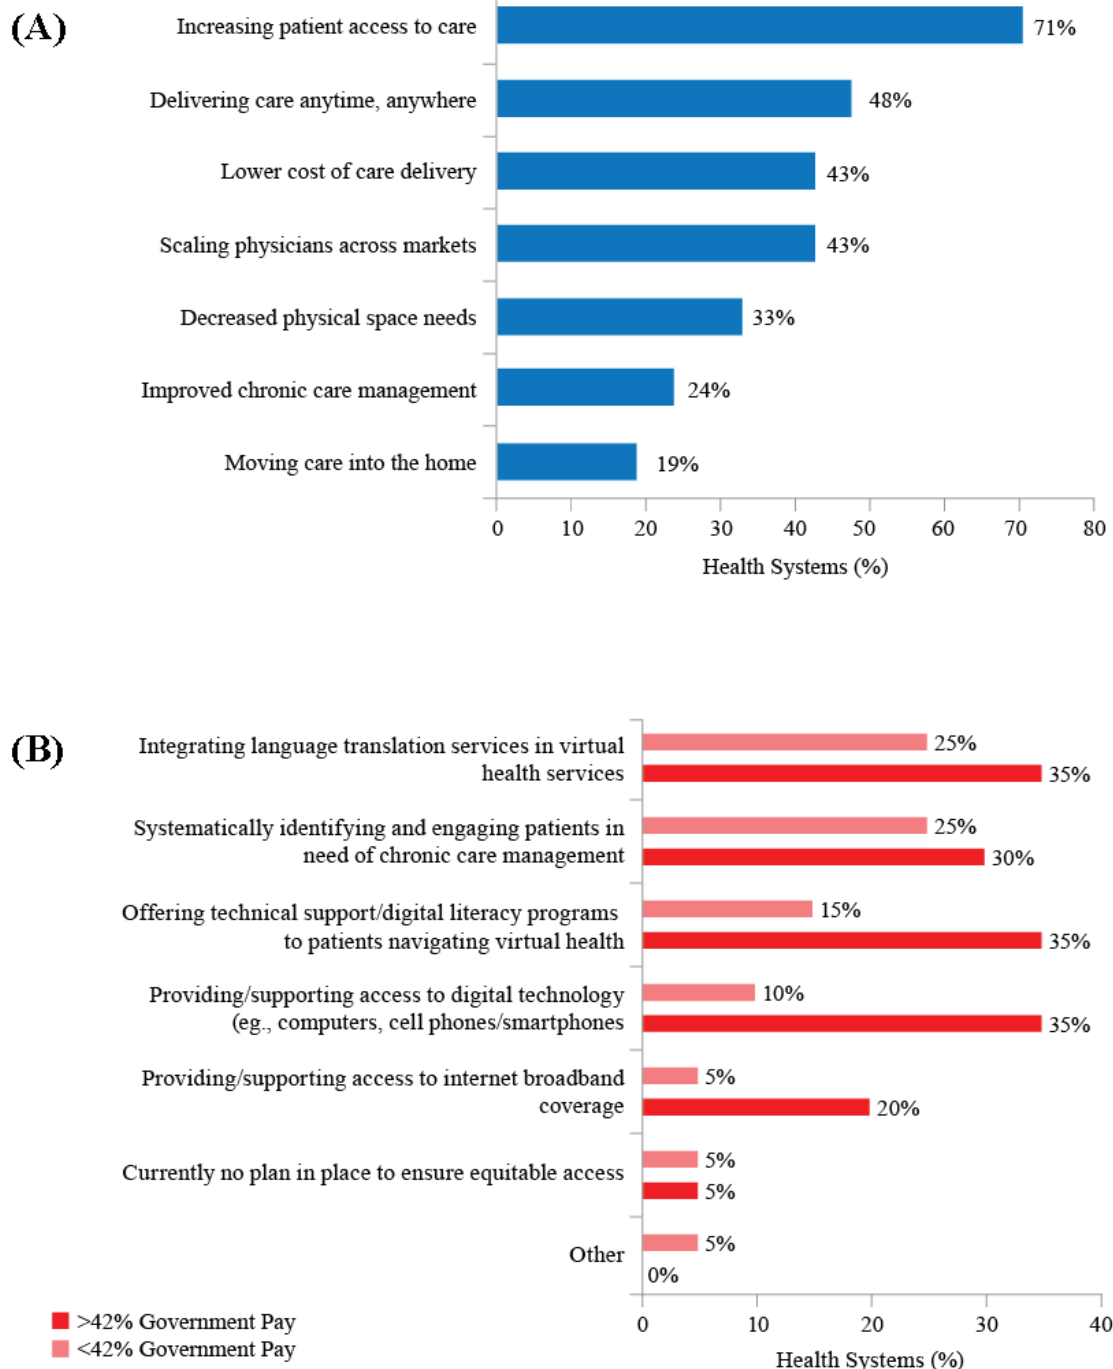

existing platforms—regardless of how small—was the best choice for rapidly scaling virtual health to meet the needs of their patients and health care providers:

We have had a telehealth option since 2012, and the growth had historically doubled each year from a very small base. But that growth is now exponential—we went from about 70,000 virtual health visits a year in 2019, to nearly 70,000 per week by early April (2020). [Chief of Medical Technology]

Health system executives reported that, during the COVID-19 pandemic, immediate priorities included maintaining patient and staff safety by keeping health care providers and patients remote whenever possible and sustaining revenues to support the business. As health systems look to develop a long-term strategy for virtual health, executives are beginning to set new goals for enterprise-level virtual health and, in particular, increasing flexible, consumer-friendly care; improving access and expanding market share; broadening the suite of digital health technologies; and building new virtual health business models.

Areas in which executives expect virtual care to have the greatest impact include increasing access and flexibility of care delivery and lowering costs (Figure 4A). It will be essential for health systems to leverage technology to develop a model of a continual ongoing relationship with the patient across the health care journey of their lifetime, as compared with a previous model of episodic care. As virtual health expands, executives are prioritizing equity in access and outcomes. Health systems do not want virtual health to exacerbate existing divides in patients’ ability to access and benefit from care and are taking steps to monitor and address equity concerns (Figure 4B).

Figure 4. Impacts and strategies for virtual health implementation, including (A) areas in which participating health systems expect the greatest impact from virtual health (n=21) and (B) strategies in place to support equitable access to virtual health (n=20); the segmenting point of 42% government pay represents the median across participating health systems.

Many health system executives considered virtual health to form part of both their care delivery strategy and consumer strategy. This is because improved access, flexibility, and convenience are increasingly sought by consumers, and virtual solutions may assist health systems in meeting these expectations. However, health system executives recognize the opportunity to improve the consumer-friendliness of their current virtual health systems. Most executives from large health systems (5/9, 55%) rated their organization’s virtual health systems as either consumer-friendly or very consumer-friendly.

For medium and small health systems, only 20% (2/10) and 14% (1/9) of executives, respectively, rated their virtual health systems as consumer-friendly or very consumer-friendly.

Virtual Health Business Model

Health systems will likely focus on development of a hybrid model of virtual and in-person care, with efforts focused on population health and value-based reimbursement. Most executives (16/28, 57%) reported their organization had a defined budget for virtual health (Figure 5).

Figure 5. Virtual health budget types by health system size, as provided by executives (n=28).

Many executives expressed concern that a retraction to a pre-pandemic lack of payment and site-of-care restrictions on virtual health would significantly detract from their ability to deliver care virtually:

If payment parity for virtual visits goes away, expenses will have to decrease to meet the corresponding decrease in that revenue stream... We're not going to stop doing virtual, because we believe it's the right thing to do for our patients, and it's about continuing to evolve with the future of healthcare. [Senior Vice President, Finance]

Executives saw virtual health as a strategy best supported through a value-based payment model:

Going forward, we're trying to get to a more value-based world where we're only bringing patients onsite if they need complex care. That's a large transformation that is underway, and virtual is an important component of that, but there's still a long way to go. [Chief Medical Information Officer]

Most health systems in the United States are predominantly fee-for-service and have only a small proportion (an average of 29%) of revenue coming from value-based payment models. Executives reported that their organization would not shift to a fully value-based model until a larger proportion of revenue comes from these models.

The [value-based payment] tipping point is probably 40%, but we're not near that now; we're at 10% or less, and many value-based arrangements start with fee for service. [Senior Vice President and CMO of Ambulatory Service]

Health systems are restructuring their operations to adapt to the increased use of virtual health. For example, most health systems

(6/10, 60%) intend to use technology to automate certain tasks associated with virtual services, such as clinical documentation during virtual visits. This increased automation can also assist with cost management. Other strategies to address cost management in response to the shifting business model include reducing or consolidating the physical clinic's square footage (5/10, 50% of health systems), adjusting the workforce by reducing or reassigning staff (3/10, 30%), and redesigning health care provider compensation (2/10, 20%). Health systems may also be able to manage costs by aligning and partnering with other health systems to provide financial support for necessary technologies.

Health system executives stressed that the federal government's actions to maintain payment for virtual health and promote flexibility in care delivery during the pandemic will need to be sustained for health systems to continue to provide virtual care. These responders were optimistic about these benefits being extended, and some health systems have developed "legislative teams" willing to align efforts with other health systems to help drive government support, at both state and federal levels, for sustained reimbursement for virtual care. Despite these efforts, uncertainty remains:

The maintenance of virtual visits is dependent on a payment model remaining in place for them, I can't stress that enough. If there isn't payment parity between virtual and in-person, we'll have to re-examine how to manage our costs. [President, Medical Group]

Implementing Virtual Health Solutions and Workflows

Health systems experienced a rapid surge in virtual health utilization during the peak of the COVID-19 pandemic; during spring and summer 2020, 58% of total visits to participating

health systems were virtual. As in-person care resumed, the proportion of virtual visits declined, reaching 21% at the time of the survey (September-October 2020).

As they exit the COVID-19 surge, health system executives report a shift in focus to medium- and longer-term virtual health strategy, with key concerns of payment mechanisms and the ability to practice across state lines. Going forward, 67% (6/9) of participating health systems have a defined target for the percentage of health visits occurring virtually. Almost one-fourth (2/9, 22%) of health systems reported that they want 21% to 30% of all care to be delivered virtually going forward, and one-third (3/9, 34%) of health systems expect 11% to 20% of care delivery to be virtual.

As health system executives consider their long-term virtual health strategy, many expect to leverage the governance structures established during the pandemic moving forward. For medium and large health systems, almost all executives reported that their organization had a centralized governance structure for virtual health implementation (Figure 6A). These central committees were typically composed of multiple key stakeholders and representative groups (eg, clinical leadership, regulatory, patient experience), and many executives reported their organization had a formal leadership role established for virtual health (eg, CMO of virtual health). Virtual health governance structures most commonly fell within the IT and/or population health division (14/29, 49% and 10/29, 34%, respectively), and most participating health systems created a dedicated virtual health committee or taskforce, which will remain post-COVID-19.

Key considerations around creating these new governance structures included centralization versus decentralization of authority, defined versus undefined accountability, and outsourcing versus insourcing committee members. High-maturity approaches tended to feature a multistakeholder governance structure that clearly delineated responsibilities for virtual health strategy and implementation.

During the COVID-19 surge in virtual health utilization, the higher a health system was on the virtual health maturity curve, the more likely they were to scale up existing solutions rather than implement new technology. Patient and health care provider usability was reported as being the primary criteria for selecting virtual health solutions. Health care provider acceptance and adoption of virtual health increased during the pandemic; however, health system executives reported less success in developing and integrating virtual health into existing clinical workflows in a sustainable and comprehensive way.

Health system executives and leaders are considering whether their existing EMR and IT capability will be positioned to sufficiently support and adapt to telehealth efforts moving forward or whether a partnership with an outside vendor would be a more viable option long term. Most (7/9, 77%) IT executives reported their organization currently uses multiple virtual health platforms; however, 44% (4/9) aim to streamline operations and move to one base platform in the next 1 year to 2 years (Figure 6B). Most health systems (19/29, 66%) used Epic as their primary virtual health software solution, and most

(15/29, 52%) used Zoom as their primary synchronous video platform. All IT executives reported that their organization had at least some success in integrating virtual health data into the EMR, with 22% (2/9) rating this integration as very successful. There will need to be a focus on developing platforms that are friendly and affordable to patients and health care providers.

The expansion of virtual health has caused some organizations to consider reshaping their clinical pathways from being EMR-centric to more consumer-focused:

Our EMR plays an important role, but when we launched our virtual health app, we made the decision to shift away from EMR-focused processes to consumer-focused ones. What's easy and intuitive for the consumer is not the same as the way the EMR wants you to do things. [Chief Strategy Officer]

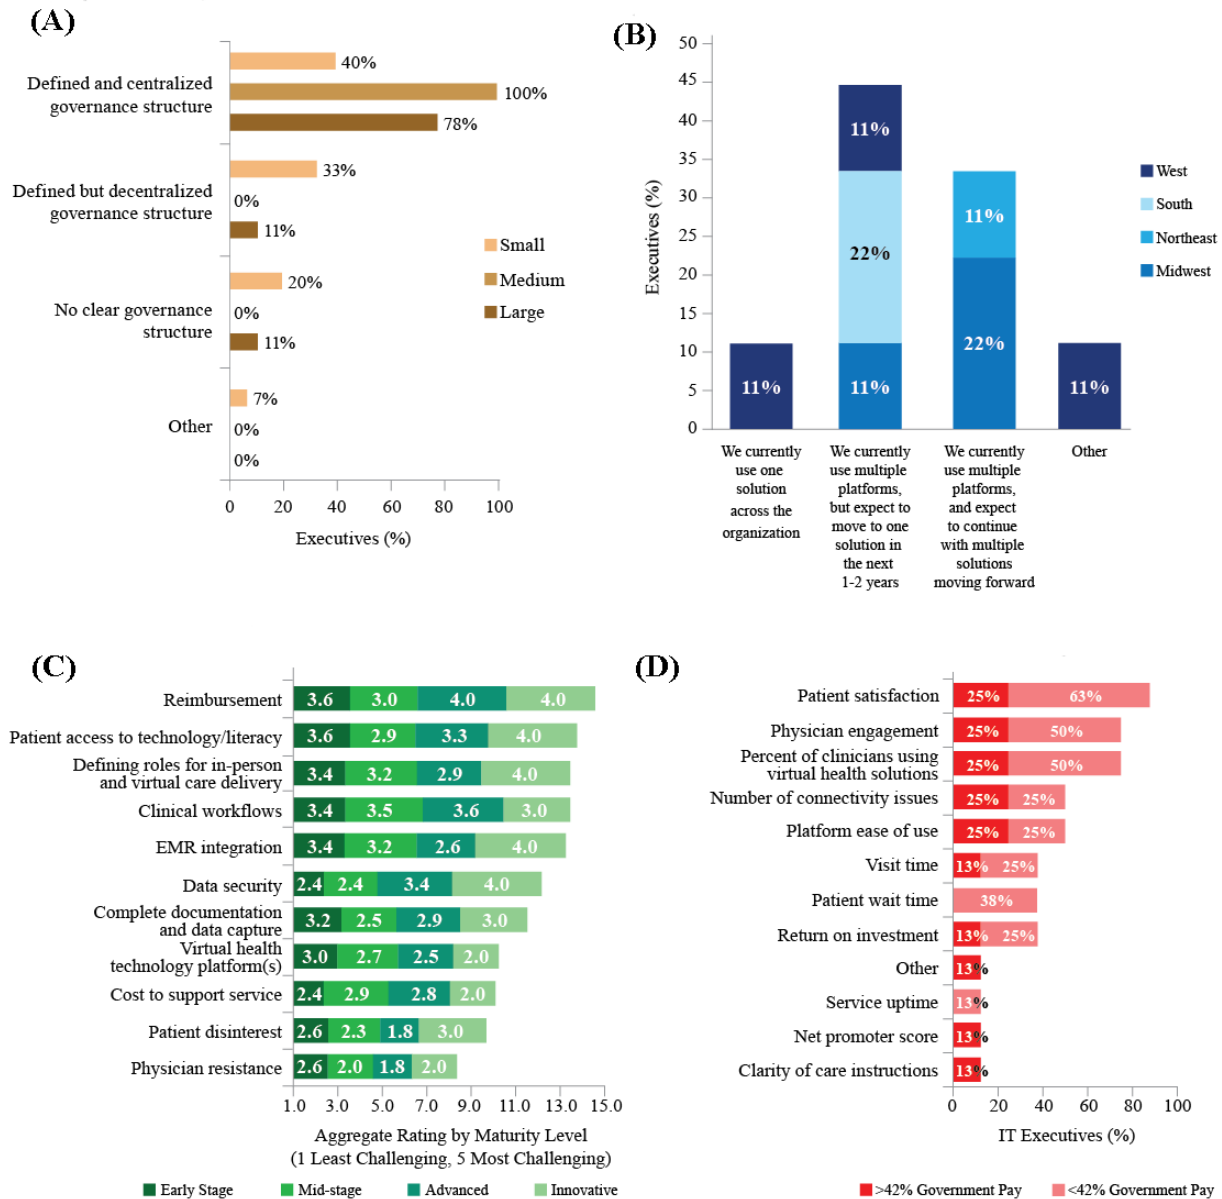

Executives were generally less confident in their IT capabilities (eg, interoperability, technology, data analytics) than some of the process components of virtual health implementation (eg, adoption by health care providers). Executives were most confident in their cybersecurity proficiency and the distinct virtual health technology solutions, with leaders rating their proficiency within these components as "at goal and advancing." Executives noted that, to effectively implement virtual health enterprise-wide, it is critical to ensure that virtual health solutions effectively support both patients and health care providers with frictionless, accessible care at each step of the patient journey, from finding care to managing care, and paying for care:

Our digital front door aims to help patients solve their inconvenient pain points – where am I in my deductible? How much do I owe? To do that, we're focused on empowering the patients to answer three questions: how do I find the care I need, how do I manage the care I need, and how do I pay for it. [Chief Strategy Officer]

Some health system executives reported using virtual health to supplement and extend the reach of their existing care infrastructure. For example, one health system used physicians' offices as specialty access hubs where the primary care physician could connect virtually with specialists in a single appointment. In another example, the health system's virtual health platform was incorporated into ambulances, enabling emergency department staff to connect virtually and triage patients to the most appropriate care venue according to the level of care needed. Approximately 50% of the time, health care providers were able to make decisions to monitor patients at home, reducing the number of emergency department visits, and thereby reducing potential exposure to COVID-19 and conserving personal protective equipment.

Irrespective of health system maturity level, reimbursement was consistently rated as a key challenge to virtual health scaling, along with patient access to and understanding of virtual health technology (Figure 6C). To improve patient and health care provider understanding, health systems may need to develop and provide training for virtual care to both their patients and health care providers.

Figure 6. Features of virtual health implementation, as reported by executives, including (A) virtual health governance structure by health system size (n=29), (B) use of multiple virtual health platforms by region (n=8), (C) challenges to virtual health scaling by health system maturity level (n=29), and (D) metrics to measure the success of virtual health implementation, by proportion of government pay (n=8). EMR: electronic medical record; IT: information technology.

Defining Metrics to Measure the Success of Virtual Health Implementation

Patient and health care provider satisfaction and health care provider engagement are the most commonly prioritized virtual health metrics among participating IT executives (Figure 6D). Health system executives reported a need to increase the tracking and measurement of virtual health-specific metrics.

Health metrics differed slightly between health systems with high and low government pay, with low government pay systems more likely to prioritize patient satisfaction and wait time (Figure 6D). Organizations used a variety of different metrics, including measures of patient and health care provider satisfaction, clinical and screening metrics, platform and follow-up metrics, and financial metrics. Health system executives commonly reported they have not yet settled on their

key metrics but recognize their importance for virtual health validation.

Several health systems are using pilot projects to better evaluate the success of their virtual health initiatives on metrics such as total cost of care, readmissions, and follow-up rates. Health systems plan to build on these projects to understand how they can continue to optimize their use of virtual health. These pilot projects enable health systems to maintain the “fail fast” mentality that they developed during the pandemic.

Health system executives stated they have a narrow window of time to collect sufficient data on virtual health’s efficacy and efficiency compared with in-person care, in order to make the case to regulators and payers for why supporting virtual health’s financial sustainability is a must. There were some differences of opinion between executives on whether in-person measures can or should be transferred over to digital modalities.

Future Considerations

Almost all health systems (27/29, 93%) expect to continue to grow most or all of their virtual health offerings for the foreseeable future:

What's here to stay is the adoption of it, acceptance that care is not always in person. People have trepidation around payment, but what I've said is we're not going to have a choice. It's not going to matter. Health systems and physicians will learn how to adopt this, or they will go out of business or be purchased. You have maximum two to three years. If you're not aggressively adopting these services, you will fail. [Executive Director, Virtual Care]

Health system executives' degree of satisfaction with their current virtual health system varied between US regions, with executives from health systems in the Western region most

likely to rate the organization's virtual health system as sufficient for most or all of their needs (Figure 7A). Many health systems are reevaluating existing virtual health infrastructure, with user-friendliness and ease of information sharing or integration with the EMR as the 2 most commonly reported key factors (9/10, 90% of operations executives) in making go-forward decisions on virtual health initiatives (Figure 7B). Other factors in making go-forward decisions included to ensure data-driven decision-making; maintain patient confidence in a trusting, confidential patient-health care provider relationship; and a focus on how to best leverage technology to support a hybrid model of virtual and in-person care. This will require both patients and health care providers to rethink their relationship and the journey of providing consumer-focused health care. Alternate payment models driven by population health and value-based reimbursement will require adaptability and change in health care provider contracts.

Figure 7. Future considerations for virtual health implementation, as reported by executives, regarding the (A) sufficiency of current virtual health systems by region (West: n=5; Midwest: n=13; South: n=11; Northeast: n=9) and (B) factors in making go-forward decisions on virtual health initiatives (n=10). EMR: electronic medical record.

Executives raised a number of key challenges moving forward, including transparency and flexibility in health care provider licensing, maintaining the “move fast” cultural shift, integrating patient-generated health data with the EMR, determining which types of visits should be virtual versus in-person, and maintaining relationships between health care providers and their patients. Other unknowns and challenges included the pandemic trajectory, aid and politics, macroeconomic factors, demand for services, impact of regulations, and operational resilience. Addressing burnout and health needs of health care providers were also identified as issues going forward, with most (13/20, 64%) health system executives describing their care team as “tired and frustrated” with the COVID-19 journey. About one-third (6/20, 32%) were in a state of “acceptance of the new normal,” and 5% (1/20) described their status as “return to hope.”

Health system executives commented that, although the future outlook is uncertain, a proactive mindset is needed to create the future they want for their patients and their health care providers. This includes key actions such as executing and building on the established continuum of virtual care; advocating for payment, site flexibility, and reimbursement parity for virtual care; and continued engagement and boldness from leadership to evolve care beyond established models. Such care models are evolving toward a hybrid model of virtual, in-person care supported by changing the mindset of both patients and health care providers of what the new patient-health care provider relationship is seen as across the continuum of the patient care journey and not just episodic care as it may have been before the pandemic.

Discussion

Principal Findings

Through surveys and interviews with executives from many of the largest health systems in the United States, this study assessed and makes recommendations on the strategy, business model, implementation, and future considerations for implementing virtual health solutions in the United States. The key findings were (1) the main impacts of increased demand for virtual health solutions on health systems were increased access and flexibility and lower costs of care delivery; (2) health system executives commonly believe that virtual health is best supported through value-based payment models; and (3) almost all health systems expect to continue growing their virtual health offerings for the foreseeable future, with reimbursement being the key challenge to virtual health scaling.

A robust, patient-centric virtual health offering is now a standard expectation for health system executives. Health systems are evaluating whether their current virtual health system meets the differing needs of the system, health care providers, and patients and are identifying the mission-critical goals of a long-term virtual health strategy. Although the external shock of COVID-19 disrupted care models, all participating health systems are expecting to continue virtual care moving forward.

A key consideration in maintaining virtual care is to establish its safety and efficacy relative to traditional in-person care. The efficacy and safety of virtual care would be dependent on the

nature of the solution and circumstances of use. For example, a Cochrane review of admission avoidance–hospital-at-home programs showed no differences in mortality between patients treated using admission avoidance–hospital-at-home programs compared with conventional inpatient hospital care [19]. On the other hand, virtual solutions such as a chatbot have proved more controversial, and experts have raised concerns about efficacy [20]. Delivering care virtually can also impact the patient-health care provider relationship, as physical touch and eye contact can communicate interest and empathy. In one study, patients who did not previously have a relationship with their health care provider reported feeling less comfortable with clinical video telehealth than those who had previously visited in person [21].

Current virtual health platforms were sufficient for participating health systems' COVID-19 response but far from perfect. These health systems are reevaluating their current platforms, processes, and strategy to develop a long-term approach to virtual health that addresses key challenges, including adjusting clinical and operational workflows that meet clinical and operational needs with one user-friendly, integrated, scalable platform to ensure patients' access to technology and avoid exacerbating existing health equity disparities. Early adopters of new medical technologies commonly have high socioeconomic status due to differences in access (the digital divide) and differences in use (due to factors such as health literacy) [22]. The transition towards increased adoption of virtual health solutions has the potential to either relieve or exacerbate existing health care disparities. The decisions that health systems make now in the types of solutions they offer, and the strategies they choose to minimize disparities, are important in shaping health care equity for the future. For example, apps that are difficult to use could make accessing care disproportionately more difficult for people who are older, have a lower level of education, or are from a diverse racial or ethnic background, who may have lower digital literacy [23]. Alternatively, health equity disparities may decrease over time for technologies that simplify treatment, as innovations gradually diffuse through society [22]. Another concern is fragmentation of patient care due to the expansion of non-health system–affiliated virtual care options. This could erode relationships between health care providers and patients and reduce the effectiveness of care due to a lack of communication between affiliated and nonaffiliated health care providers. There is also a lack of clarity on which clinical and financial metrics are most valuable to validate virtual health's cost and efficacy compared with in-person care. With one estimate showing that US physicians spend approximately 15 hours per week on quality metrics [24], it is important to focus on the most valuable metrics to minimize the time and effort these require.

Participating health systems report significant uncertainty around changes to payment models and regulatory policy (eg, reduction in payment parity, eliminating payment for phone-only visits, persistence of site-of-care, and state licensing restrictions) as they try to plan for the financial sustainability of their virtual health offerings. A lack of payment parity for virtual and in-person visits could be a disincentive to offer virtual visits, because if insurers reimburse telehealth appointments at a lower

rate than in-person visits, health systems may have to operate telehealth services at a loss or not offer these services at all. Regulatory policies also differ substantially by state; for example, 43 states and Washington DC have payment coverage laws for telehealth, but only a subset of these have payment parity laws [25]. Health system executives have a role to play in shaping the financial sustainability of virtual health solutions going forward, as they can proactively advocate for continuation of many of the regulations and payment structures that have enabled increased virtual health adoption during the pandemic.

Health system executives are concerned that current virtual health modalities are not sustainable if regulations regress toward prepandemic status; however, many note that accelerated movement toward value-based payment models would support virtual health expansion. Health systems that proactively seek alternate payment models could benefit in the long-term with payment structures that are more sustainable in a post-COVID-19 world. The use of value-based payment models is predicted to increase due to incentives created by the 2015 Medicare Access and CHIP Reauthorization Act [26]. Under this act, stakeholders are able to propose alternative payment models to the Physician-Focused Payment Model Technical Advisory Committee. An example of an alternative payment model is the bundled hospital-at-home and 30-day postacute transitional care program at the Icahn School of Medicine at Mount Sinai in New York City, which led to improved patient outcomes and care ratings compared with traditional inpatient care [27]. In this payment model, health care providers were able to charge a base payment for hospital-at-home services and fee-for-service charges for other services, demonstrating the feasibility of this alternate payment model.

To establish a sustainable, enterprise-wide approach to virtual health that addresses the challenges and barriers laid out in this research, health systems are working through key components, including governance structures, finance, data/IT, and clinical operations. As health systems evolve in their virtual health maturity, governance structures tend to become more centralized, with the most mature health systems having explicit C-level support for virtual health. Virtual health budgets become more defined and high-level, wherein advanced and innovative health systems have system-level budget lines for virtual health, and work with payers to develop and advocate for virtual health payment structures. With increasing maturity, data and IT systems become more advanced, and health systems proactively seek cutting-edge technologies, move beyond standard metrics, develop interconnectivity between platforms, and proactively

monitor for cybersecurity threats. Additionally, health care providers become increasingly empowered and able to seamlessly integrate virtual and in-person care. As health systems evolve in their virtual health maturity, their market impact is expected to increase.

Strengths and Limitations

This analysis has several strengths and limitations. One strength is the breadth of executive types that inform this study. Participants included executives from the 3 categories of clinical, operations, and data/IT, which may assist in understanding virtual health from different perspectives. In addition, survey participants represent a variety of health systems, differing by size, region, degree of government pay, and virtual health maturity level. This even distribution of health system features suggests that the sample is likely to be representative of the health system landscape in the United States, which is further supported by the substantial portion of the total US health system market represented by these systems. These surveys do, however, only represent a subset of systems, and these findings may not be applicable to every health system. Also, these findings represent the views of individual executives, and there may be differences of opinion within individual health systems. In addition, by including only US-based health systems, some of the issues raised are specific to the United States, such as concerns around state licensing requirements. Although this analysis is limited to US health systems, the COVID-19 pandemic has precipitated a trend toward increased adoption of virtual health in countries around the world [11], and it is likely that many of the trends and challenges highlighted by this study would be applicable in other countries. Additionally, the timing of the study in late 2020 allows the authors to only document health systems' early response to the pandemic.

Conclusions

The COVID-19 pandemic saw a substantial increase in virtual health adoption, and this increase is expected to continue postpandemic. Consequently, health systems are reevaluating their current platforms, processes, and strategy to develop a sustainable, long-term approach to virtual health. Health system leaders need a proactive mindset to create the future they want for their patients and their health care providers, including executing and building on the established continuum of virtual care; advocating for payment, site flexibility, and reimbursement parity for virtual care; and continued engagement and boldness to evolve care beyond established models.

Abstract

Background: Social media platforms such as YouTube are integral tools for disseminating information about health and wellness to the public. However, anecdotal reports have cited that the human gut microbiome has been a particular focus of dubious, misleading, and, on occasion, harmful media content. Despite these claims, there have been no published studies investigating this phenomenon within popular social media platforms.

Objective: The aim of this study is to (1) evaluate the accuracy and reliability of the content in YouTube videos related to the human gut microbiome and (2) investigate the correlation between content engagement metrics and video quality, as defined by validated criteria.

Methods: In this cross-sectional study, videos about the human gut microbiome were searched for on the United Kingdom version of YouTube on September 20, 2021. The 600 most-viewed videos were extracted and screened for relevance. The contents and characteristics of the videos were extracted and independently rated using the DISCERN quality criteria by 2 researchers.

Results: Overall, 319 videos accounting for 62,354,628 views were included. Of the 319 videos, 73.4% (n=234) were produced in North America and 78.7% (n=251) were uploaded between 2019 and 2021. A total of 41.1% (131/319) of videos were produced by nonprofit organizations. Of the videos, 16.3% (52/319) included an advertisement for a product or promoted a health-related intervention for financial purposes. Videos by nonmedical education creators had the highest total and preferred viewership. Daily viewership was the highest for videos by internet media sources. The average DISCERN and Health on the Net Foundation Code of Conduct scores were 49.5 (SE 0.68) out of 80 and 5.05 (SE 2.52) out of 8, respectively. DISCERN scores for videos by medical professionals (mean 53.2, SE 0.17) were significantly higher than for videos by independent content creators (mean 39.1, SE 5.58; $P<.001$). Videos including promotional materials had significantly lower DISCERN scores than videos without any advertisements or product promotion ($P<.001$). There was no correlation between DISCERN scores and total viewership, daily viewership, or preferred viewership (number of likes).

Conclusions: The overall quality and reliability of information about the human gut microbiome on YouTube is generally poor. Moreover, there was no correlation between the quality of a video and the level of public engagement. The significant disconnect between reliable sources of information and the public suggests that there is an immediate need for cross-sector initiatives to safeguard vulnerable viewers from the potentially harmful effects of misinformation.

KEYWORDS

microbiome; social media; YouTube; misinformation; content analysis; gut health; misinformation; public

Introduction

Over the past decade, governments, health organizations, and private sector companies have increasingly endorsed the use of social media platforms as a trusted means of disseminating information on health and wellness [1-3]. Of the available platforms, YouTube has arguably emerged as the standout modality for accessing comprehensive health care information. As of December 2021, YouTube boasts over 1 billion hours of watched content daily, over 2 billion unique users monthly, and is commonly accessed by both health professionals and the public alike for a wide range of health-related queries [4]. Although YouTube usually hosts factually accurate content, there have been reported instances where inaccurate information has been hosted for public viewing [5]. This issue came to prominence during the COVID-19 pandemic as inaccurate content about COVID-19 vaccines and national vaccination programs rapidly gained global viewership. This, in turn, led to YouTube's implementation of a COVID-19 medical misinformation policy, which disallowed COVID-19 content that contradicts the policies of health authorities [6]. Since its implementation in September 2020, the platform has removed over 130,000 videos, a staggering figure highlighting the scale of misinformation on vital public health matters. However, a similarly specific policy has not been extended to other areas of health-related content in which there may be a history of misinformed content. In these cases, the responsibility of determining the veracity and applicability of the encountered information is placed upon the individual [7].

As increasing understanding develops around the "digital determinants of health" [8], there is concern that unverified content may lead to instances of clinical harm to viewers who cannot independently discern content quality [9-11]. In turn, these users may share misinformed content with their social networks, resulting in misinformation within epistemic bubbles and, more concerning, "echo chambers" [12,13]. One topic that is highly vulnerable to this phenomenon is the human gut microbiome. The gut microbiome is a consistently popular topic for content creators on YouTube, particularly as greater understanding develops around its regulatory role in anxiety, mood, cognition, and pain through the gut-brain axis. Despite the paucity of high-grade evidence on the mechanisms through which the microbiome may be reconfigured to optimize human physiology, there has been a sharp rise in videos that promote lifestyle-based strategies which purport to modify the gut microbiome for health and well-being benefits [14,15]. Without rigorous standards related to scientific accuracy, these videos often stretch the applications of existing scientific evidence to advocate treatments that are advertised as helpful but instead may have no effect or potentially cause overall harm. Hence, if not properly caveated with scientific resources and disclaimers, these videos can distract viewers from empirically sourced medical advice and protective health-seeking behaviors.

To date, no studies have evaluated the quality of the microbiome-related content available on social media. Moreover, it is not known whether the engagement metrics associated with microbiome-related content correlate with the quality of the information provided. As such, this study aims to (1) evaluate the accuracy and reliability of YouTube content pertaining to the human gut microbiome and (2) investigate the correlation between social media engagement metrics and video quality, as defined by validated criteria.

Methods

Ethical Considerations

The institutional review board of Imperial College London determined this study does not constitute human subjects research and was therefore exempt from the associated ethical requirements.

Selection of Videos

The phrases "microbiome", "gut microbiome", and "microbiome health" were searched on the United Kingdom (UK) version of YouTube on September 20, 2021. The search terms were chosen to ensure appropriate coverage of any videos related to the role of the gastrointestinal microbiome in health and well-being. The search was conducted using an incognito browser (Google Chrome, Google LLC) to avoid biased suggestions based on cookies or previous search histories. The results were ranked according to view count as this is the most sensitive means of identifying videos that have had the greatest impact and are the most likely to trend. The 200 most-viewed videos (10 pages) of each search were deduplicated and subsequently extracted. Video titles and channels were first screened for relevance and English language before further full-video screening. Videos were included if they described at least 1 of the following: (1) components of the gut microbiome; (2) the role of the microbiome in gut health, including cancers, inflammatory bowel conditions, and infectious bowel conditions; (3) methods of altering the gut microbiome for the purpose of broader health-related effects; and (4) side effects or the safety of interventions used. Videos that did not discuss the human gut microbiome or were not in the English language were not included. Videos >5 years old were also excluded to represent the current body of work about the microbiome more accurately. In cases of uncertainty on whether a video should be included, a consensus was sought between authors, with a tendency to include the video for full assessment.

Data Extraction

The characteristics of the videos were independently extracted by 2 authors (SC and YM). This included the video's URL, country of origin, duration, age, and channel name. Engagement metrics that assess the use of a video by the public were also extracted; this included the number of likes, dislikes, comments, and the view count. The videos were subsequently classified

into the following 6 categories based on their content and purpose: educational channels produced by medical professionals (eg, the American Society for Microbiology); educational channels produced by nonmedical professionals (science education or explanatory media, eg, The Sheekey Science Show), independent producers (eg, Tom Bilyeu – QUEST nutrition), internet media (magazines or talk shows, eg, Health Via Modern Nutrition), news agencies (clips from network news programs, eg, King 5 news), and nonprofit or medical organizations (hospitals, government organizations, or universities eg, Mayo Clinic, UCLA Health, Hopkins Kimmel).

Outcome Measures

The primary outcome measure was the quality of the videos assessed, which is graded using the DISCERN tool as well as by assessing the video's adherence to the Health on the Net Code of Conduct (HONcode). Secondary measures included engagement metrics, which were classified as total viewership (total number of views the video accrued), daily viewership, and preferred viewership (number of likes received by the video). Correlations between video characteristics, engagement metrics, and quality assessment scores were analyzed using linear regression models.

The DISCERN Score

The DISCERN tool is an instrument that is designed to help users assess consumer health information. The criteria were originally drafted based on the analysis of a random sample of consumer health information on the treatment choices for 3 medical conditions (myocardial infarction, endometriosis, and chronic fatigue syndrome). The tool consists of 3 categories of items, scored between 1 (worst) and 5 (best), that assess the reliability (8 questions, 40 attainable points), quality of Information (7 questions, 35 attainable points), and overall impression (1 question, 5 attainable points) of the information source, thus accounting for a total attainable score of 80. The DISCERN criteria have enabled the assessment of various aspects of video quality, including completeness, understandability, relevance, depth, and accuracy of information. The shortlisted videos were rated independently by 2 authors

(SC and YM). Any discrepancies were resolved through discussion with a third author (VS).

The HONcode

The HONcode certification is an ethical standard aimed at offering high-quality health information. It demonstrates the intent of a website to publish reliable and high-quality information with maximum transparency. The HONcode consists of 8 principles that evaluate the reliability and credibility of health information, including the justification for and balance of claims, citations of sources used, details of funding, and clear distinguishment of advertising from editorial content [16]. Videos were rated with a score of 1 (adherent) or 0 (nonadherent) for each of the 8 principles, for a total score of 8.

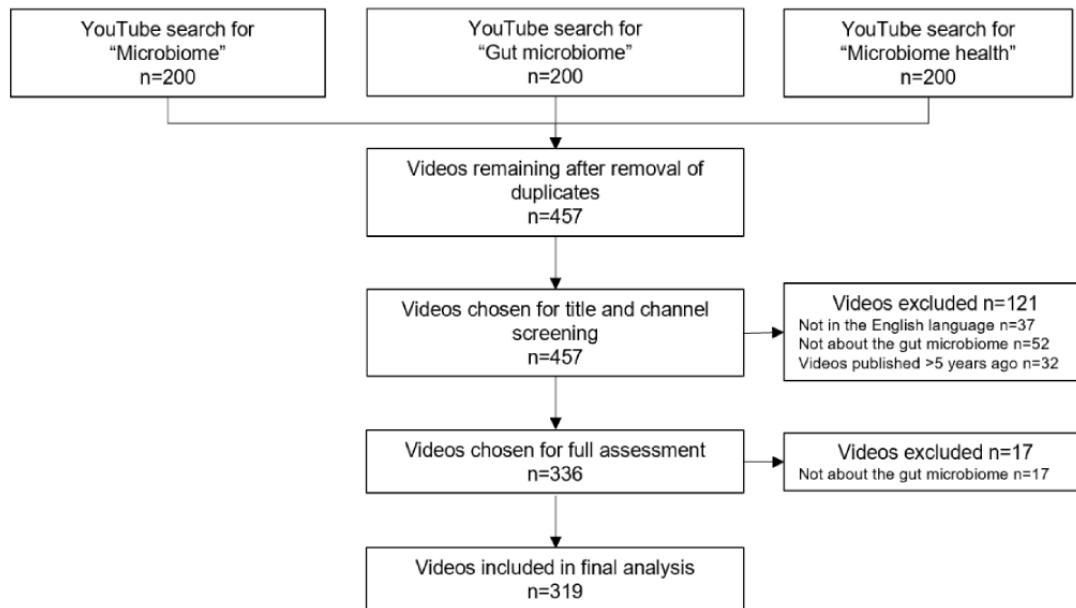

Statistical Analysis

The statistical analysis was performed using SPSS (version 27; IBM Corp). All data are presented as means and SEs of means unless otherwise stated. The interrater reliability was assessed using the Cohen κ statistic. A DISCERN score of 1 or –1 was considered agreement for each category in accordance with previous studies. Data were assessed for normality using the Shapiro-Wilk test. The 1-way ANOVA and Kruskal-Wallis tests were used to assess the relationships between categorical variables, such as channel type, and DISCERN scores with parametric and nonparametric distributions, respectively. The associations between engagement metrics and DISCERN scores were evaluated using linear regression. Statistical significance was set at $P < .05$.

Results

Video Selection and Characteristics

We identified 600 videos in total based on the 3 search terms. Following deduplication, 143 videos were removed, yielding 457 videos. After the initial screening of video titles and channels, 138 videos that did not meet the inclusion criteria were removed. This led to 319 videos being included in the final analysis. The video review process is illustrated in [Figure 1](#).

Figure 1. The results of searches for microbiome-related videos on YouTube and the video selection process for inclusion in the study.

Of the 319 videos included in this study, the majority originated from North America (234/319, 73.4%), followed by Europe (46/319, 14.4%) and Australasia (32/319, 10%). A total of 41.1% (131/319) of the videos were produced by nonprofit organizations, 15.4% (n=49) were created by independent creators, and 11.9% (n=38) were produced by nonmedical educational organizations. In total, only 19.4% (62/319) of the videos were produced by a medical professional, of which a

smaller minority had proven expertise in the human microbiome. The mean duration of videos was 21.2 (SE 1.25) minutes. A majority (251/319, 78.7%) of the videos were uploaded in the last 3 years, with a median age of 2.22 years. Of note, 16.3% (52/319) of the videos included an advertisement for a product or promoted a health-related intervention for financial purposes. The characteristics of the included videos are summarized in [Table 1](#).

Table 1. Characteristics of the sample videos (N=319).

Characteristic	Value
Country of origin, n (%)	
Australia	28 (8.8)
Canada	10 (3.1)
France	2 (0.6)
Germany	3 (0.9)
Hungary	1 (0.3)
India	3 (0.9)
Ireland	3 (0.9)
Italy	1 (0.3)
Lebanon	1 (0.3)
The Netherlands	1 (0.3)
New Zealand	4 (1.3)
Russia	1 (0.3)
South Africa	3 (0.9)
Spain	1 (0.3)
Switzerland	1 (0.3)
United Kingdom	32 (10)
United States of America	224 (70.2)
Channel type, n (%)	
Educational (nonmedical)	38 (11.9)
Educational (medical)	62 (19.4)
Independent users	49 (15.4)
Internet media	32 (10)
News agency	7 (2.2)
Nonprofit	131 (41.1)
Duration in minutes, mean (SE)	21.2 (1.25)
Days since upload, mean (SE)	962 (40.1)
Engagement	
Views, mean (SE)	195,469 (43,985)
Views per day since upload, mean (SE)	245 (47.8)
Likes, mean (SE)	3954 (909)
Dislikes, mean (SE)	90.8 (21.2)
Containing advertisements or serving a promotional purpose, n (%)	52 (16.3)

Quality Assessment Scores

The average DISCERN and HONcode scores were 49.5 (SE 0.68) out of 80 and 5.05 (SE 2.52) out of 8, respectively. Of the various video characteristics, the regression analysis shows that only the channel type and the presence of promotional materials were indicative of content quality, as per DISCERN scoring (Figure 2). Figure 2A shows the effect of the channel type on the mean DISCERN score, and Figure 2B shows the effect of promotional materials on the mean DISCERN score. Videos with promotional materials had significantly lower DISCERN

scores than videos without any advertisements or product promotion ($P<.001$). The highest DISCERN scores were recorded for videos by medical professionals (mean 53.2, SE 0.17), whereas lower DISCERN scores were recorded for videos by independent content creators (mean 39.1, SE 5.58). Scores for each of the DISCERN subsections (completeness, understandability, relevance, depth, and accuracy of information) followed a similar trend.

The linear regression analysis revealed no correlation between the quality of a video based on the DISCERN score and any engagement metric, including total viewership, daily viewership,

and preferred viewership (number of likes; Figure 3). There was some agreement between the HONcode and DISCERN scores. For example, the HONcode score was the highest for videos by medical professionals, which also had the highest

DISCERN scores. However, this was not a consistent correlation as HONcode scores were significantly lower ($P < .001$) for videos by internet media sources, at a mean of 1.28 (SE 0.81), relative to the mean DISCERN score of 47.7 (SE 4.18).

Figure 2. The relationships between video characteristics and DISCERN scores. All values are presented as averages with 95% CIs.

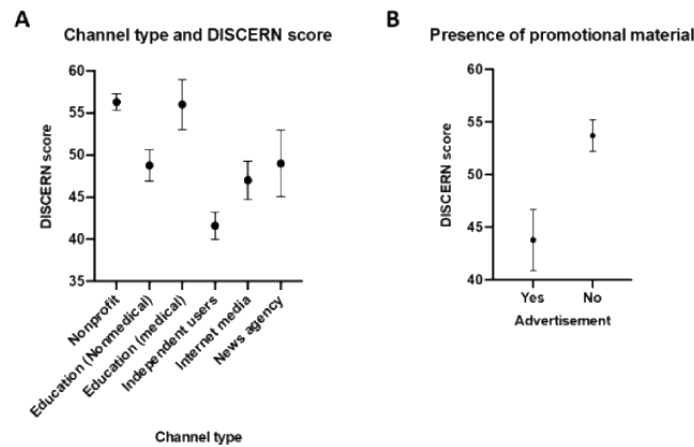

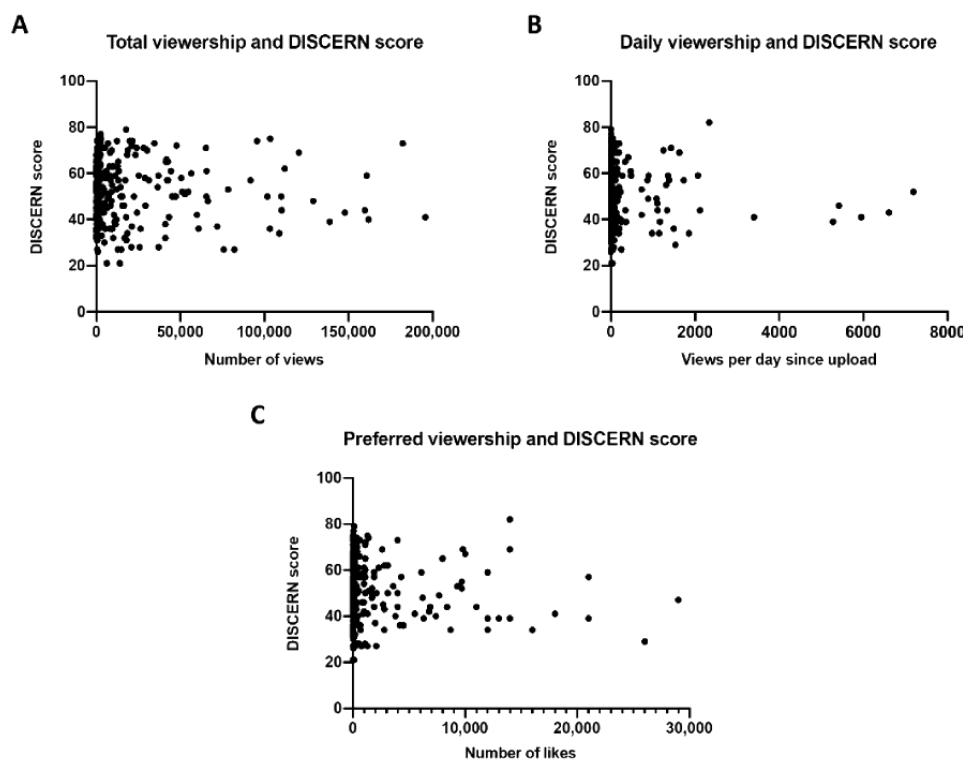

Figure 3. The relationship between engagement metrics and DISCERN scores, highlighting the correlation between the total number of views (A), daily viewership (B), and number of likes (C).

Engagement Metrics

Overall, the videos accrued a total of 62,354,628 views since being uploaded. The highest mean number of views was achieved by nonmedical education creators. The viewership per video for content produced by medical professionals was 136,606, which was significantly lower than the average of 195,469 views for all videos. Preferred viewership followed a similar trend, in which the highest value of 10,920 likes was registered for videos made by nonmedical education creators;

this was 3 times the value for videos by health care professionals (n=3480) and 5 times the value for videos from nonprofit organizations (n=2954). In contrast, daily viewership (n=1067) was the highest for internet media sources and was thrice that achieved by medical professionals (n=321). In parallel, videos by internet media sources were liked (n=6020) to a greater extent relative to total viewership and compared to other channel types, reflecting greater approval among the audience. Summary data of engagement metrics are included in Table 2.

Table 2. Engagement metrics, adherence to the Health on the Net Foundation Code of Conduct, and DISCERN scores for YouTube videos on the gut microbiome.

Parameter	Value for each channel type						Value for all channel types
	Educational (non-medical)	Educational (medical)	Independent nonmedical users	Internet media	News agencies	Nonprofit organizations	
Videos, n	38	62	49	32	7	131	319
Total views, n	16,786,496	8,469,633	5,909,797	3,014,580	727,969	27,446,153	62,354,628
Views per video, n	441,749	136,606	120,608	94,205	103,995	209,512	1,106,675
Daily views, n	436	321	234	1067	40	156	2254
Likes, n	10,920	3480	3196	6020	1162	2954	27,732
Dislikes, n	228	31	54	245	17	98	673
HONcode adherence score (out of 8), mean (SE)	2.36 (0.16)	2.77 (0.8)	2.48 (0.35)	2.03 (0.17)	1.28 (0.81)	2.67 (0.13)	5.05 (2.52)
DISCERN total score (out of 80), mean (SE)	46.4 (1.85)	53.2 (0.17)	39.1 (5.58)	44.9 (2.25)	47.7 (4.18)	53.6 (0.91)	49.5 (0.68)
DISCERN reliability score (out of 40), mean (SE)	24.6 (0.96)	27.4 (0.8)	18.5 (2.65)	22.6 (1.23)	22.6 (2.29)	27.6 (0.47)	25.2 (0.38)
DISCERN quality score (out of 35), mean (SE)	18.9 (0.91)	22.3 (0.63)	18.1 (2.58)	19.6 (1.02)	21.7 (0.35)	22.4 (0.45)	21.0 (0.31)
DISCERN overall impression score (out of 5), mean (SE)	2.84 (0.1)	3.51 (0.09)	2.51 (0.35)	2.75 (0.16)	3.42 (0.35)	3.61 (0.06)	3.24 (0.05)

Discussion

Principal Findings

This study highlights the importance of YouTube as a medium for sharing content surrounding the human gut microbiome. We demonstrate increasing public interest in this field, with over 62 million cumulative views on the videos that were shortlisted. However, this study also highlights that there is significant variation in the quality of the information provided by most videos. A content analysis revealed that the quality of the information was dependent on factors such as the profile of the content creator and the presence of a financial slant. Interestingly, videos with the most reliable information did not consistently receive the highest ratings or engagement. The disconnect between content quality and public engagement suggests that less informed videos are being viewed in lieu of more balanced content, which could lead to the propagation of misinformation.

Our analysis showed an inverse relationship between channel type, quality of content, and viewership. Videos created by recognized institutions, such as universities, hospitals, and charities, provided more accurate information than videos from independent producers, some of whom were also qualified medical practitioners. However, both the total and average viewership was significantly higher for nonmedical content

creators, even after accounting for the duration of the videos and date of upload. The number of likes given to videos reflected a similar pattern, indicating that viewers expressed a more positive reception of videos that were lower in quality. This highlights the alarming phenomenon that low-quality, unreliable, and potentially misinformed content may be more readily acquired, processed, and positively viewed by an audience who may otherwise be unaware of existing literature on the microbiome [17].

Furthermore, the majority of videos made by independent creators captured in this study usually promoted a specific form of health care intervention, such as a dietary product, to “reengineer” the microbiome [18]. Although the microbiome inarguably plays a crucial role in a wide range of common medical conditions, there is a paucity of high-grade evidence demonstrating a risk modification effect of a reconfigured microbiome or that the advertised interventions can modify the microbiome to a clinically significant extent. These videos, often with no declaration of financial interests, frequently lacked evidence or misrepresented the literature by making a significant leap in the interpretation of the results of existing literature on the microbiome. Thus, given the far-reaching effects of web-based misinformation, there is a pressing need for key stakeholders, such as content creators, governments, health organizations, and hosting platforms, to proactively implement

policy, regulatory, and educational interventions to protect susceptible members of the population.

Policy Implications

Particularly in the postpandemic era, digital technologies are increasingly commonplace in the delivery of public health and well-being educational materials and interventions. Although younger cohorts may have embraced this shift, there is evidence to suggest that many segments of the population were poorly prepared for this rapid digitization of services [19]. Equity across the population in the ability to access, interpret, and appraise information is both under-reported and overlooked. Targeted interventions need to empower the end-user as well as serve a custodial role over the production of content. As such, strategies to mitigate the spread of nonfactual health information on social media can be approached at 3 levels: government, industry, and consumer.

At the government level, there is laudable tightening in protective legislation globally. The proposed UK legislation (the Online Safety Bill) aims to combat harmful web-based content through increased regulatory oversight [20]. Similarly in the United States, the proposed Health Misinformation Act and Justice Against Malicious Algorithms Act aim to hold web-based platforms accountable for posting content with misinformation related to an existing public health emergency (eg, COVID-19) or contributing to physical or severe emotional injury [21-23].

Additionally, in the context of COVID-19 and the spread of anti-vaccination misinformation, technology corporations have already begun to remove and monitor nonfactual and harmful content on their sites. YouTube's search algorithm has historically recommended videos that attracted the most views or clicks. However, the recent heightened concerns regarding harmful misinformation on YouTube have prompted algorithm changes, which have reportedly reduced the consumption of borderline content by 70% [24]. Further potential action through increasing the ranking and visibility of health content from reputable scientific sources, such as universities, hospitals and health charities, would increase consumer exposure to high-quality and reliable health information. To appraise content, platforms need to generate criteria for evaluating the credibility and reliability of a source; evaluate which assessment tools such as the HONcode, URAC certification or the Credibility, Reliability, Authority, and Purpose test best fit their model; and incorporate them into their quality appraisal methods. As part of this, platforms can also necessitate that content creators disclose potential conflicts of interest to minimize instances where content is skewed for the purpose of commercialization. The ground layout (ie, content guidelines) where a social media platform has outlined clear criteria for credibility and ways to achieve it will be useful for content creators to follow when producing their content. In this way, social media platforms can actively elevate high-quality content while reducing misinformation from poorer-quality content. A summary of recommendations for content-hosting platforms is displayed below (Textbox 1).

Textbox 1. A summary of recommendations for content-hosting platforms to increase the quality and reliability of visible health-related content.

- Evaluate content with assessment tools (eg, Health on the Net Foundation Code of Conduct, URAC, or Credibility, Reliability, Authority, and Purpose test).
- Increase ranking, and therefore visibility, of health content from reputable scientific sources.
- Necessitate disclosure of conflicts of interest from content creators.
- Flag content from nonmedical independent creators with content warnings.
- Provide external links to health content from validated sources of health information (eg, United Kingdom National Health Service, World Health Organization, US Centers for Disease Control and Prevention).
- Outline clear criteria for content creators to achieve increased credibility.

Consumers also have a responsibility to identify nonfactual information and discern high-quality and reliable information on the internet. Often, social media sites allow users to tailor their preferences and see information from only the sources they select, leading to “bubbles” and echo chambers that reinforce any false information users encounter. Given the vast amount of content that is uploaded to the internet on a continuous basis, it is unrealistic for content hosts to review all material for nonfactual or harmful content. Thus, the provision of educational material for the general public is crucial, especially given that health information resources are increasingly being migrated to the internet. Globally, the World Health Organization, in partnership with local governmental agencies, has introduced several initiatives to improve public awareness and education regarding web-based health misinformation, with a particular focus on COVID-19 and vaccination misinformation [25,26]. Additionally, the UK

government has recently published its Online Media Literacy Strategy, with one of the key aims being to improve the ability of members of the public to identify misinformation and assess the reliability of a web-based information source [27]. Similar to likes and ratings, social media platforms can employ verified users who have prior experience in using validated tools to assess video quality to provide their feedback. Videos identified can be checked by the platform before consideration for removal as well. It is important that the crude censorship of these videos does not foray into impeding free speech and still allows the user at the heart of the consumption process to make the final decision. With an increasing reliance on digital health technology that is only expected to rise in the future, it is critical to ensure the public is adequately equipped with the skills to use it, and the ability to recognize and manage misinformation forms a significant component of this.

Strengths and Limitations

This study has several strengths. Firstly, to our knowledge, this is the first study to report on the accuracy and quality of the most widely viewed YouTube videos about the gut microbiome. Furthermore, we have analyzed the videos' content accuracy and reliability using a combination of objective measures, including the DISCERN criteria. Our sample size is extensive and covers up to 400 of the most-watched videos on this topic, capturing over 62 million views. As such, our study provides a broad assessment of the mismatch between content quality and viewership, which provides important insights into channels through which key stakeholders may codesign interventions to deliver high-quality information to an evidently receptive audience. Limitations of this study include its inherent selection bias given that only videos in the English language were included, which reduces the generalizability of our results to videos produced in other languages and originating from different geographical regions. In addition, our search was

limited to YouTube. Other social media platforms such as Facebook, TikTok, Instagram, and Twitter were not included in this study, although these remain a target for future research due to high use as well.

Conclusions

There is a significant degree of variation in the quality of health-related YouTube videos on the gut microbiome. Both the channel type and the presence of financial intent were significant factors in the quality, reliability, and transparency of the information provided. There is little correlation between viewership and information quality, reflecting a mismatch in public engagement and discernment of good-quality health advice from misinformation. This calls for greater scrutiny of health-related information provided on social media platforms. Further work should aim to impose more stringent regulations as well as policies and educational resources to ensure accurate and reliable information is accessible in a transparent manner with the interests of the general public in focus.

Abstract

Background: Hypertension (HTN) affects millions of Americans. Our Whole Lives: an eHealth toolkit for Hypertension and Cardiac Risk Factors (OWL-H) is an eHealth platform that teaches evidence-based lifestyle strategies, such mindfulness and cooking skills, to improve self-management of HTN.

Objective: The primary goal of this pilot study was to evaluate the feasibility of OWL-H combined with teaching kitchen medical group visits (TKMGVs) in a low-income population of participants with HTN.

Methods: We conducted a pre-post 8-week study to assess the feasibility of a hybrid program (a web-based 9-module self-management program, which includes mindfulness and Mediterranean and Dietary Approaches to Stop Hypertension diet) accompanied by 3 in-person TKMGVs among patients with HTN. Data including demographics, platform use, and satisfaction after using OWL-H were examined. Outcome data collected at baseline and 8 weeks included the Mediterranean Diet Questionnaire, Hypertension Self-Care Profile Self-Efficacy Instrument, Blood Pressure Knowledge Questionnaire, and the number of self-reported blood pressure readings. For the statistical analysis, we used descriptive statistics, paired sample *t* tests (1-tailed), and qualitative methods.

Results: Of the 25 enrolled participants, 22 (88%) participants completed the study. Participants' average age was 57 (SD 12.1) years, and 46% (11/24) of them reported a household income <US \$30,000 per year. Among the 22 participants who logged in to OWL-H, the average number of mindfulness practices completed was 7 and the average number of module sessions accessed was 4. In all, 73% (16/22) of participants reported that they were "very satisfied" with using OWL-H to help manage their HTN. Participants' blood pressure knowledge significantly increased from baseline (mean 5.58, SD 1.44) to follow-up (mean 6.13, SD 1.23; *P*=.03). Participants significantly increased their adherence to a Mediterranean diet from baseline (mean 7.65, SD 2.19) to follow-up (mean 9, SD 1.68; *P*=.004). Participants' self-efficacy in applying heart-healthy habits, as measured by the Hypertension Self-Care Profile Self-Efficacy Instrument, increased from baseline (mean 63.67, SD 9.06) to follow-up (mean 65.54, SD 7.56; *P*=.14). At the 8-week follow-up, 82% (18/22) of the participants had self-reported their blood pressure on the OWL-H platform at least once during the 8 weeks.

Conclusions: The eHealth platform for HTN self-management, OWL-H, and accompanying in-person TKMGVs have the potential to effectively improve lifestyle management of HTN.

Trial Registration: ClinicalTrials.gov NCT03974334; <https://clinicaltrials.gov/ct2/show/NCT03974334>

Introduction

Hypertension (HTN) affects millions of Americans, with a disproportionate burden falling on both those within the lowest socioeconomic status (SES) demographic and on people of color [1]. Currently, to increase access and self-efficacy, there is a heightened need for technology targeted toward delivery of HTN self-management strategies. However, few studies have tested the use of internet-delivered self-management interventions within lower SES populations [2-7].

HTN is a complex disease, with both external and internal factors affecting its control, including healthy diet, stress management, and medication use [8]. From the patient's standpoint, it requires an understanding of basic physiology and the concept that one's behavior (dietary habits, physical activity, and stress) has an impact on blood pressure levels [9]. Although treatment options such as dietary and behavior change counseling can increase healthy dietary habits that can reduce HTN, only 35% of adults with HTN receive such interventions [10]. These factors, coupled with external factors such as food insecurity; decreased access to fruits and vegetables and locations to exercise; and high-stress jobs, likely play an important role in significantly poor HTN control [8,11-14].

Adults are increasingly seeking dietary information from internet sources and apps, and these digital health tools present scalable ways to improve lifestyle changes [15,16]. Furthermore, as of 2019, up to 71% of Americans who earned <US \$30,000 owned a smartphone and 56% had home broadband service [17]. However, there has been little research conducted with low-income individuals accessing web-based tools to improve HTN self-management [18,19]. Before embarking on a large-scale trial, appropriate methodologies must be adapted or developed and tested for feasibility in a target population consisting of individuals with HTN and other cardiac risk factors and low SES. Therefore, this study examines the feasibility of a web-based multimodal self-management platform called Our

Whole Lives: an eHealth Toolkit for Hypertension and Cardiac Risk Factors (OWL-H), combined with a teaching kitchen medical group visit (TKMGV) in a low-income population.

Originally adapted from mindfulness-based stress reduction [20-22], the Our Whole Lives (OWL) web-based platform was created as a patient-derived web-based self-management toolkit named Our Whole Lives: an eHealth Toolkit for Chronic Pain (version 1). It was created in 2014 as part of a Patient Centered Outcomes Research Institute randomized controlled trial for patients with chronic pain and depression. OWL was designed with a patient advisory group and beta-tested with diverse groups to ensure that patients from varied racial, ethnic, generational, and low-health literacy backgrounds could comprehend its information [20]. The OWL curriculum introduces patients to the principles of mindfulness practices, nutrition, stress reduction, and movement [22,23]. In 2017, OWL (version 2) was tested to determine its effectiveness as a stand-alone intervention for patients with chronic pain; participants showed significant reduction in depression, pain interference, and average pain impact, accompanied by 13% reduction in opioid use ($P=.03$) [24].

Using the proven OWL platform and with funding from the University of Massachusetts Medical School's Center for Advancing Point of Care Technologies in Heart, Lung, Blood, and Sleep Diseases, this pre-post study was powered to test the feasibility (though not the clinical outcomes) of OWL (version 3), Our Whole Lives for Hypertension and Cardiac Risk Factors. This was combined with accompanying in-person medical group visits and hands-on cooking classes in a teaching kitchen (ClinicalTrials.gov NCT03974334). Using the principles of adult education, the new adapted platform provides content and experiential activities to increase self-management of HTN through regular blood pressure monitoring and self-management strategies to reduce cardiac risk factors such as sodium consumption, stress, and unhealthy eating. [Figure 1](#) shows the OWL-H curriculum on the platform.

Figure 1. Our Whole Lives: an eHealth toolkit for Hypertension and Cardiac Risk Factors patient curriculum diagram.

Methods

Setting

This study was conducted at the University of Massachusetts Memorial Health Care system, which provides access to the large and diverse patient population in central and western Massachusetts. The city of Worcester, Massachusetts, itself allows access to a diverse local population, with >13% of the city's residents being Black or African American, 7% being Asian, and 21% being Hispanic or Latino, with 21% of the population living below the poverty line [25].

Study Design

This feasibility trial enrolled participants with a current diagnosis of HTN to test OWL-H. Totally, 2 cohorts of patients (N=24) participated in an 8-week clinical trial testing of hybrid live cooking classes or medical group visits, combined with a web-based self-management platform (OWL-H). Participants' qualitative comments and feedback were used to revise the OWL-H platform for the next iteration.

Recruitment and Enrollment

Inclusion criteria were as follows: people with a current diagnosis of HTN who were aged >18 years, could provide informed consent, and can understand educational materials written in English and whose physical and mental health status were sufficient to comprehend instructions and participate in the interventions. Participants also had to have access to computer technology (mobile phone, desktop, or laptop) and the internet to use the web-based OWL-H platform. Exclusion criteria were as follows: people with serious underlying comorbid physical, cognitive, or psychiatric disease, including psychotic or manic symptoms, which precluded full participation in the intervention; those involved in active substance abuse; pregnant women or those who were actively trying to become pregnant; and those not willing to participate in the intervention or attend medical group visits. In addition, those planning to begin new HTN treatments within 2 weeks from the beginning

of the protocol or who were planning a major medical treatment within 4 months from being screened were not eligible to participate.

Participants were recruited from the Worcester area with a focus on adult primary care clinics and were either self-referred (via flyers and brochures distributed around the clinics) or referred by their primary care providers. They spoke in person or over the phone with the study research coordinator (RC) to complete the self-report portion of the screening process and review the study objectives and eligibility criteria. If eligibility was confirmed, the study RC read a study consent fact sheet to the participant and obtained verbal consent.

Intervention Web-Based Platform

OWL-H is a password-protected website hosted on a Health Insurance Portability and Accountability Act-compliant server that can be accessed via a computer, tablet, or mobile device. It contains an orientation session (for training purposes) and 8 unique educational sessions (Figure 1; Table 1). One session is released each week, across 8 weeks, and participants can access these unlocked sessions at any time [26-31]. The study team (licensed dietician or nutritionist [BO], a culinary-trained family medicine physician [LJM], and a mindfulness-trained family physician [PG]) adapted the content from OWL (version 2) to create OWL-H. Most of the original content of OWL (version 2) created for patients with chronic pain was used (Table 1 outlines the new content that was added to strategies to reduce HTN) [24]. The third version added evidence-based self-management strategies for reducing HTN and cardiac risk factors such as cooking videos and recipes using the Dietary Approaches to Stop Hypertension (DASH) [32,33] and Mediterranean diets. The new content developed specifically for OWL-H was completed with the input of patients in the clinic, who were attending a medical group visit at University of Massachusetts Memorial Health Care, to ensure appropriate literacy levels and diverse patient engagement. In addition, curriculum changes were made based on participant feedback between cohort 1 and cohort 2.

Table 1. Summary of the OWL^a website and the in-person teaching kitchen medical group visit.

Week and title of the session	Theme or activity	Home practice and recipes
1		
Teaching kitchen 1–micronutrients=building blocks ^b	Sodium, potassium, and calcium and changing tastes; introduction to fiber and healthy carbohydrates; eating more fruits, veggies, herbs and spices; drinking more water; knife skills and safety; and basic cooking skills	Pear, spinach, and walnut salad, salsa, oil-free pesto, chia seed pudding, and water bar
OWL–orientation to our group	Awareness of breath M ^c , ground rules, introduction to mindfulness, and video on how to measure BP ^d (3.54 minutes)	Engage group members on community tab and set up home practice space
OWL–what is HTN ^e ? ^b	Summary of HTN, how HTN is measured and treated, introduction to HTN management lifestyle habits ^b , introduction to BS, and video on what is HTN? (12 minutes)	Self-monitoring BP, journal ^b , and BS ^f on 6 out of 7 days
2		
OWL–eat for your health ^b	Introduction to DASH ^g and Mediterranean eating plans (video 17.52 minutes) ^b and the healthy plate method and video on introduction to M	Eat one meal mindfully, share healthy plate pictures ^b , BS on 6 out of 7 days, and M on 6 out of 7 days
3		
OWL stay active ^b	Setting SMART ^h movement goals, exercise education and guidance ^b introduction to MM ⁱ , and video on stay active (12:30 minutes)	Come up with a 3 day/week exercise plan ^b and alternate BS and MM on 6 out of 7 days
4		
Teaching Kitchen 2–what do we have with our veggies tonight? ^b	Fats-saturated, omega 3s; protein and all its sources (plant based); fiber; sugar; traffic light foods, glycemic index, hunger, and portion control; alcohol and other enjoyments; vegetable entrees; and what is “mise en place”?	Three-bean salad, roasted chickpeas, avocado ice cream, and zucchini noodles
OWL–foods to reduce inflammation and spotlight on healthy fats ^b	Nonpharmacological approaches to treating inflammation, tips to reduce salt intake and increase healthy fat consumption ^b , video on inflammation (4:07 minutes), and spotlight on salt (4:36 minutes)	Post a recipe on the community tab, create a plan to substitute salt for spices ^b , and alternate BS and M on 6 out of 7 days
5		
OWL–stress less, live more	Nonpharmacological approaches to reducing stress and video on our reaction to stress (4:08 minutes)	Create a stress reduction plan, alternate BS and MM, and M on 6 out of 7 days
6		
Sleep, sleep, it’s good for your heart	Nonpharmacological approaches to sleep and video on the importance of healthy sleep (5:15 minutes)	Create healthy sleep space and share plan on the community tab, alternate BS and MM, and loving kindness M on 6 out of 7 days
7		
OWL-HTN medications and supplements ^b	Discussion of common classes of HTN medications and common side effects, research-supported supplements for HTN ^b introduction to loving kindness M, and videos on vitamins and minerals (4:08 minutes) and food as pharmacy (19:38 minutes)	Notice any physical sensations when taking the prescribed BP medications ^b and choice of BS, MM, M, or loving kindness M on 6 out of 7 days
8		
OWL–practical ways to eat healthy ^b	A review of important food groups for patients with HTN, tips for grocery shopping and eating out at restaurants ^b , and video on practical eating (8:21 minutes)	Create a heart-healthy plate shopping list and share on the community tab ^b
Teaching kitchen 3–cooking <i>competition</i> ^b	Putting it all together; eating out–how to order; meal planning; planning ahead–batch cooking and freezing; shopping list–staples for your pantry; budget cooking and shopping; reading nutrition labels; trying new foods; and cooking <i>competition</i>	Quick lemon and garlic quinoa salad; carrot and beet salad; Asian salad; cocoa banana smoothie; spinach, cucumber, and mint smoothie; and kale, coconut, and pineapple smoothie

^aOWL: Our Whole Lives.

^bThough all sessions’ pictures, formatting, and content were updated in some way, this denotes brand new content created specifically for OWL for Hypertension and Cardiac Risk Factors.

^cM: meditation.

^dBP: blood pressure.

^cHTN: hypertension.

^fBS: body scan.

^gDASH: Dietary Approaches to Stop Hypertension.

^hSMART: Specific, Measurable, Achievable, Realistic, and Timely.

ⁱMM: mindful movement.

Upon logging in to OWL-H, participants were greeted with a 4-item *check-in* box asking them to rate their mood (ranging from 0-10, with high numbers indicating positive mood) and physical comfort (ranging from 0-10, with high numbers indicating high levels of comfort); record their current blood pressure and pulse; and answer whether they had taken their high blood pressure medication today, if applicable. Within OWL-H, the measurement record charted these daily readings throughout the duration of the program so that participants and staff can track their progress. All the participants received an Omron 7 Series upper-arm blood pressure monitor with an appropriately sized cuff.

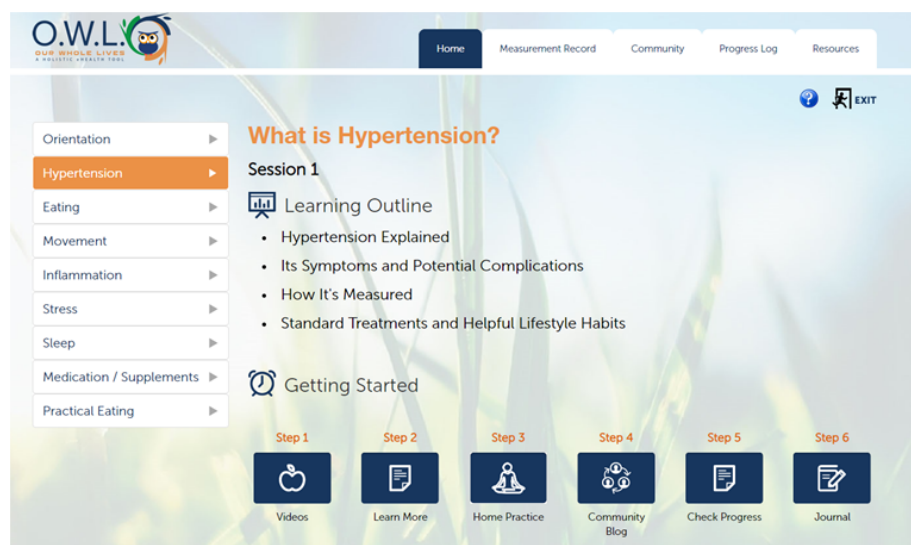

After completing the check-in process, participants had the option to navigate through OWL-H session modules, tools, or resource pages. Each session included 1-2 videos on health topics, with duration ranging from 2-20 minutes, covering the week's topic (Figure 1). Next, the participants completed a home practice (eg, meditation, body scan, and mindful movement) and posted it on the community board or journal. When any media item was played and completed, a comment box appeared to facilitate collection of real-time qualitative feedback from the participants ("What are your thoughts and feelings after completing this video?").

Home practices, assigned at each session, included mindful movement (a video with duration of 24 minutes or audio with duration of 32 minutes), meditation with a focus on the breath (3 audio options with duration of approximately 20 minutes each), and body scans with a focus on noticing sensations in different areas of the body (3 audios with duration of 23 minutes or 12 minutes). Each mind-body practice was recorded by a certified yoga or meditation teacher. As participants progressed

through the sessions, they were slowly introduced to new techniques or longer meditations to enhance their experience, and after completion of each, they were asked to provide feedback on the session. The mind-body progress log, which can be accessed from within the session or the upper taskbar, added a gamification element to OWL-H by tracking the completion of these practices. The participants received 1 checkmark and puzzle piece to fill in their week's progress on the log. By practicing for 6 out of 7 days, the participants can earn enough puzzle pieces to complete the week's reward image.

The journal is a private feature that allows participants to write about their daily events, thoughts, and reactions at their own time. In addition, the home practices periodically asked the participants to follow up on a lesson learned that week through a written journal assignment, such as writing about common stresses or creating a healthy shopping list. Participants were asked to participate in the monitored web-based discussions hosted on the community board of the website. OWL-H's extensive resource library contains 12 unique content areas, all derived through participant feedback and requests (focus on health, mind and body, poems, quotes, nutrition resources, nutrition tips, healthy eating, recipes, integrative medicine, support services, videos, and audios). Each area contains information and tools that support what is learned in the main session content, either directly linked from within a session's written materials or as stand-alone supplemental material. It also contains information on local resources (eg, affordable gyms, food pantries, free meals, and community resources), spotlights on foods of interest (eg, salt, whole grains, fruit, and vegetables), information on mindfulness and mental health, and motivational content (eg, poems; Figure 2) [33-37].

Figure 2. Our Whole Lives: an eHealth toolkit for Hypertension and Cardiac Risk Factors (OWL-H) version 3 platform.

Overview of In-Person TKMGV

TKMGV Session 1 (Week 1)

During the first in-person session, all participants were welcomed to the room and asked to sit in a circle and complete an individual medical check-in form before meeting the clinician one-on-one in a side room. In a group setting, participants were taught to use an Omron Series 7 upper-arm cuff that was lent to them for the duration of the study and were provided a binder containing the cooking class recipes, their OWL-H log-in information, user manual, printed resource documents, and a welcome letter. The participants were trained in and observed

Figure 3. Teaching kitchen next to group visit room.

TKMGV Session 2 (Week 4)

For week-4 TKMGV, the program check-in structure remained the same, and clinicians led an in-person interactive presentation on the DASH and Mediterranean diet. Once the check-in and teaching-kitchen portion was completed, the participants reviewed any technical issues or questions they had about OWL-H.

TKMGV Session 3 (Week 8)

For the final TKMGV, the program check-in structure was the same as the first class: (1) participants completed the postintervention outcomes and feedback surveys, and physical outcome measures were collected by the study staff and (2) after completing the cooking portion of TKMGV, participants could stay and participate in an optional focus group to facilitate further collection of qualitative feedback; all in attendance chose to do so. Participants could receive US \$50 in the form of an Amazon gift card for completing all aspects of the study, US \$25 for completing the 8-week program and all questionnaires, and another US \$25 for participating in the optional focus group. All the participants who completed the study also received a certificate of completion.

Self-report Outcome Data Collection

As a feasibility study, the primary outcomes were centered around confirming whether OWL-H is a feasible tool to deliver and facilitate self-management of HTN and other cardiac risk factors. The second primary outcome was to characterize participants' use of and feedback on OWL-H to further adapt

measuring their own blood pressure. Next, the study staff assisted participants in accessing and bookmarking OWL-H on the device of their choice (ie, smartphone, tablet, or laptop). Participants then logged in to the OWL-H for the first time, following a live demonstration of the website by the study staff. The remainder of the session was conducted in the teaching kitchen in the next room (Table 1; Figure 3). The recipes and cooking classes were facilitated by a culinary-trained physician (LM). One week after this first class, the RC called each participant to assess whether there were any issues with using OWL-H and to answer any questions.

and revise the content and platform for use in a large study. These data were collected through surveys administered at baseline and 8 weeks (or web-based through REDCap [Research Electronic Data Capture; version 9.3.0; Vanderbilt University] [38] if a participant was not able to attend in person). Questions regarding participants' preintervention and postintervention blood pressure monitoring habits were asked, and a blood pressure entry log was collected using the OWL-H system to provide quantifiable self-management data. Using these outcomes, we evaluated preintervention and postintervention effects.

Demographic information included the following: age, sex, race, ethnicity, country of birth, marital status, health insurance status, education level, employment status, and yearly household income. Other questions assessed the status of social and cardiac determinants of health such as food security ("In the last 12 months, the food that I bought just didn't last, and I didn't have the money to get more" and "In the last 12 months, I couldn't afford to eat balanced meals"), access to healthy food ("In the last 12 months, I couldn't afford to buy fresh fruit and vegetables"), prescribed blood pressure medication ("Do you currently take a prescribed blood pressure medication?"), whether they smoke cigarettes or drink alcohol ("How often do you practice non-smoking [tobacco]?" and "How often do you practice moderation in drinking alcohol daily [2 glasses or less for men; 1 glass or less for women]?"), and their recent level of stress ("Stress means a situation in which a person feels tense, restless, nervous, or anxious, or is unable to sleep at night

because of his or her mind is troubled all the time. Within the last 30 days, how often have you felt this kind of stress?”).

The Blood Pressure Knowledge Questionnaire (BPKQ) [39,40] was used to assess the participants' level of knowledge regarding risk factors of HTN. It consists of eight items covering topics such as common symptoms, white coat syndrome, and the amount of salt consumed by the average American individual, with a mix of multiple-choice (6 items) and true or false questions (2 items). The total number of correct items determines the score, which ranges from 1 to 8, with high scores indicating high level of knowledge. The information needed to answer each item correctly was covered in the OWL-H's curriculum.

The Hypertension Self-Care Profile (HTN-SCP) consists of three separate instruments designed to assess self-care behavior, motivation for self-care, and self-efficacy in people with HTN. It was developed and validated in 2014 [41]. The self-efficacy instrument (HTN-SCP–Self-Efficacy [HTN-SCP–SE]) used in this study consisted of 20 items assessing the respondent's confidence, on a scale of 1 (not confident) to 4 (very confident), to regularly engage in lifestyle habits that are recommended for patients with high blood pressure. This resulted in a total confidence or self-efficacy score ranging from 20 to 80, with high scores indicating high levels of confidence in engaging in heart-healthy lifestyle habits.

The Mediterranean Diet Questionnaire consists of 14 yes or no items that assess the participant's consumption of heart-protecting or heart-harming foods, such as various healthy proteins (eg, legumes, nuts, and fish) and commercial sweets or pastries, respectively. It was originally developed in Spain in 2004 to briefly assess adherence to a Mediterranean diet [42] for patients at risk for cardiac complications and has been validated in multiple studies [43]. Items assess not only the type of food consumed but also whether the appropriate serving size is consumed, on a weekly basis. The number of “yes” responses are totaled, resulting in a score ranging from 0 to 14, with high scores indicating high adherence to the Mediterranean diet.

To assess the blood pressure self-monitoring before and after the intervention, we asked the following question at baseline, “Are you regularly (at least once per week) able to measure your blood pressure outside of your doctor appointments?” Those who said “yes” were asked, “How often, in a regular week, do you measure your blood pressure outside of your doctor appointments?” In their postintervention surveys, they were again asked to estimate their average weekly number of entries. Along with the self-reported numbers, the OWL-H platform also maintains a log of every blood pressure reading entered by each participant across the 8 weeks. Surveys were administered either in person, over the phone, or via an email invitation through REDCap—a password-protected research tool.

OWL System Outcome Data

Self-reported blood pressure and pulse data were collected each time the participants logged in. Collected data included

participant's use of the OWL-H website, such as the number of minutes spent on the site, use of home practices, or number of health videos completed; any text that was inputted in the website through the comment boxes, journals, and community board; and any resource content that was accessed.

Qualitative Data Collected on OWL-H

Qualitative data were gathered in real time through written comments in media comment boxes. Qualitative feedback was also collected from the participant entries into the journal and through surveys on both the specific sessions and the overall OWL-H content and platform. The video comments and journal entries were collected to gain an understanding of reflections, reactions, and opinions about the OWL-H project and to ascertain their impact on the overall satisfaction of the patients.

Data Analysis

Descriptive statistics were used to analyze the survey information. Means, SDs, frequencies, and percentages were calculated for demographic characteristics. To compare the results between baseline and follow-up, we used paired sample *t* tests (1-tailed) and descriptive statistics. We carried the missing values forward from the pretest measurements to account for missed survey items. Means and SDs were calculated for the BPKQ, Mediterranean Diet Questionnaire, HTN-SCP–SE, and blood pressure self-monitoring at baseline and 8 weeks. All quantitative analyses were conducted using SPSS (version 26, IBM Corp).

For OWL use data, we tracked and summed the average and total number of accessed mind–body practices, number of times the participants used the journal, and total duration of time spent on OWL-H.

Qualitative data analysis methods were used to identify themes that were related to participants' OWL-H platform use. The media comments and journal entries were reviewed and independently coded by 2 research assistants (LCK and AC). Using modified grounded theory, the coders inductively generated new codes. After the media comments and journal entries were coded, the 2 research assistants (LCK and AC) reconciled the codes with the RC and resolved any differences through consensus and review. The coders identified high-density codes and combined similar codes into categories and themes, which were shared with the research team.

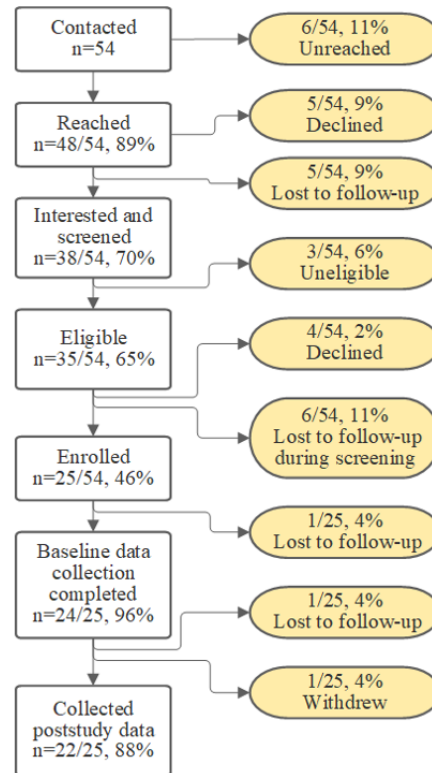

Ethics Approval

This study was approved by the University of Massachusetts Medical School institutional review board (H00015619).

Results

Overview

The study flow, screening, and study enrollment are illustrated in [Figure 4](#).

Figure 4. Study enrollment CONSORT (Consolidated Standards of Reporting Trials) diagram.

The study team contacted a total of 54 candidate participants of which 38 (70%) participants agreed to be screened (3/38, 8% participants were screened and found ineligible), 35 (65%) participants were eligible, and 25 (46%) participants consented. After enrollment and consent (25/54, 46%), 4% (1/25) of the participants voluntarily withdrew from the study and 8% (2/25) of the participants were lost to follow-up (1 before baseline data collection; N=24). Of the 24 participants, 22 (92%) participants completed follow-up data collection. Specifically, in cohort 1, there were 42% (10/24) of participants in the beginning and 41% (9/22) of participants at the end, whereas for cohort 2, there were 63% (15/24) of participants in the beginning and 59% (13/22) of participants in the end.

Table 2 lists all the demographic factors. In this study, the average age was 57 (SD 12.1) years, most participants were

women (21/24, 88%), and 33% (8/24) of participants identified as belonging to a race other than White, and 17% (4/24) of participants identified as Hispanic. In all, 46% (11/24) of participants' annual household incomes were <US \$30,000, with 79% (19/24) of participants reporting they "have just enough money to make ends meet" or "do not have enough money to make ends meet or prefer not to answer" on a monthly basis. Participants responded "often true or sometimes true" that "the food that I bought just didn't last, and I didn't have the money to get more" (7/24, 29%); that they "couldn't afford to eat balanced meals" (8/24, 33%); and that they "couldn't afford to buy fresh fruits and vegetables" (9/24, 38%). Totally, 46% (11/24) of participants reported having used a food insecurity service (eg, Supplemental Nutrition Assistance Program; Women, Infants, and Children program; and food pantries).

^bFood insecurity service includes Supplemental Nutrition Assistance Program or food stamps (7/11, 64%); Women, Infants, and Children program (5/11, 45%); food pantries (4/11 36%); community free meals (1/11, 9%); and Church programs (1/11, 9%).

^cA total of 1 response was missing.

Survey Outcomes

Table 3 lists the baseline and follow-up mean values and comparisons for all the outcomes. Participants' HTN knowledge, measured using the BPKQ, significantly increased from baseline (mean 5.58, SD 1.44) to follow-up (mean 6.13, SD 1.23; $P=.03$). Participants' self-efficacy in applying heart-healthy habits, as

measured by the HTN-SCP-SE, increased from baseline (mean 63.67, SD 9.06) to follow-up (mean 65.54, SD 7.56), but there was no significant change ($P=.14$). Participants showed a significant increase in their adherence to a Mediterranean diet from baseline (mean 7.65, SD 2.19) to follow-up (mean 9, SD 1.68; $P=.004$).

Table 3. Survey outcome measures (N=24).

Items	Baseline total sample, n (%)	Baseline value, mean (SD)	Postintervention total sample, n (%)	Postintervention value, mean (SD)	<i>t</i> test (<i>df</i>)	<i>P</i> value
Blood Pressure Knowledge Questionnaire	24 (100)	5.58 (1.44)	22 (92)	6.13 (1.23)	-2.07 (21)	.03
Hypertension Self-Efficacy Questionnaire	24 (100)	63.67 (9.06)	22 (92)	65.54 (7.56)	-1.13 (21)	.14
Mediterranean Diet Questionnaire	23 (96)	7.65 (2.19)	22 (92)	9 (1.68)	-2.96 (21)	.004

At baseline, of the 24 participants, 10 (42%) participants reported being able to measure their blood pressure at home. For those 10 participants, the mean of the self-reported baseline number of blood pressure measurements per week was 2.8 (SD 1.31; minimum=1, maximum=5). At the 8-week follow-up, 82% (18/22) of the participants had reported their blood pressure in OWL-H at least once during the 8 weeks. The self-reported average weekly blood pressure measurement of these participants was 4.78 (SD 1.90; minimum=1, maximum=7), with the OWL-H platform data reporting the mean weekly entries as 2.74 (SD 2.02). Across 8 weeks, the mean total number of measurements logged was 22.22 (SD 16.54; minimum=1, maximum=54). When considering only the participants who completed the entire 8-week protocol (22/24, 92%), the mean total log of blood pressure was 24.05 (SD 16.14; minimum=1, maximum=54). When dividing the total number of measurements logged for the same 92% (22/24) of the participants across the 8 weeks, the weekly logged blood pressure mean was 3 (SD 2.02). There was no difference in the change between baseline blood pressure 131/88 mm Hg (minimum=110/68 mm Hg, maximum=167/123 mm Hg; SD

17 systolic pressure and SD 11 diastolic pressure) and 8-week blood pressure 134/84 mm Hg (minimum=104/58 mm Hg, maximum=160/103 mm Hg; SD 16 systolic pressure and SD 11 diastolic pressure).

Participants' average mood score across the 8 weeks was 7.23 (SD 1.70) and average physical comfort score was 6.63 (SD 2.11). After accounting for those who did not complete the study (2/24, 8%) and those not taking blood pressure medication (2/24, 8%), the average adherence to taking a prescribed blood pressure medication across the 8 weeks was 85% (17/20).

Of the 9 modules, the average number of modules accessed was 4 (minimum=0, maximum=9). The average number of unique educational documents accessed from the resource library was 8.27 (minimum=0, maximum=51). Of the 24 participants, 11 (46%) participants attended all 3 cooking classes, whereas 3 (13%) participants attended only 1 class. Of the 24 participants, 2 (8%) participants did not spend time on OWL-H after the orientation class, and the remaining 22 (92%) participants used OWL-H on their own at least once. For those 22 participants, the average number of minutes spent in using the site was

approximately 30 hours or 1773.64 minutes (minimum=101 minutes, maximum=4789 minutes). Participants' average number of mindfulness home practices completed was 7 (minimum=0, maximum=40) and average number of completed videos on health topic was 7 (minimum=0, maximum=22). In terms of participation in mind-body practices at home, on average, participants completed 3 body scans (minimum=0,

maximum=16), 2 meditations (minimum=0, maximum=18), and 1 yoga session (minimum=0, maximum=12). Further analysis of platform use is shown in [Figure 5](#) (video use). These results show a trend of decreased use over time ([Multimedia Appendix 1](#) reports mind-body activity schedule and [Multimedia Appendix 2](#) reports mind-body activity use rates).

Figure 5. Summary of completed video views by session (S). DASH: Dietary Approaches to Stop Hypertension.

Overall, participant satisfaction and feedback about OWL-H was positive. From the survey feedback, we found that 73% (16/22) of the participants reported that they were “very satisfied” with using OWL-H to help manage their HTN. In all, 73% (16/22) of the participants reported that it was “very helpful” in “helping [you] to take and record [your] blood pressure at home.” Totally, 82% (18/22) of participants said that they “feel like OWL provided support and encouragement to reach [your] goals,” 73% (16/22) of them said that they would “like to use OWL again,” and 82% (18/22) of them said that they “would recommend OWL to someone they know.” Further participant feedback is presented in [Textbox 1](#).

The main themes that emerged from the content feedback were centered on the health benefits of the mind-body practices, self-reflection on healthy behaviors, behavior change, and nutrition knowledge and skills ([Textbox 1](#)). Participants who practiced the body scans, meditations, or mindful movements overwhelmingly felt beneficial effects on their health. Of the

22 participants, 11 (50%) participants expressed that the practices had effects on their stress, pain levels, or blood pressure. Specifically, regarding blood pressure, a participant remarked, “Very effective. Dropped my systolic 15 pts.”

After watching the videos or participating in home practices, most participants (13/22, 59%) reflected on their own behaviors and beliefs. Videos on health topics such as *Practical Eating* and *Stay Active* had participants writing about their current or past health behaviors, and often ended with them deciding to reinforce a health habit, make a change, or discuss barriers to change. Participants said that they learned a variety of new nutrition skills to help them make healthy choices, such as “I will try ginger root tea. I will introduce turmeric into my cooking more as well. I could add a bit of flaxseed to my steel cut oats too.”

A mild adverse event was reported during the study; however, it was determined to be unrelated to the study.

Textbox 1. Summary of qualitative Our Whole Lives for Hypertension and Cardiac Risk Factors media content (eg, videos and audios) feedback.

Theme and original quotes

- Participants who practiced the body scans, meditations, or mindful movement activities overwhelmingly felt beneficial effects on their health, such as stress reduction, pain awareness and reduction, and actual decline in measured blood pressure.
 - “I found the meditation very relaxing and calming and definitely something I would use as a tool to relieve some stress- which I do. I breathe in and out and it seems to help a great deal” [participant 1].
 - “Yesterday I fell and hurt my knee and back. So today when I did the body scan it helped with locating my exact pain locations, so I was able to relax those areas to cut down the pain” [participant 2].
 - “Tried taking BP before and after body scan. Before: 165/92 After: 113/53 That’s really impressive” [participant 3].
- After watching videos or practicing activities, many participants reflected on their own behaviors and beliefs or on how the material has impacted their lives.
 - “I totally love her voice and the meditation. Sometimes people get angry at family members, but that is just a waste of energy. So sending them love will make you feel better” [participant 4].
- Participants found that the material in the videos and practices encouraged them to try healthy behaviors or reinforced their already healthy behaviors.
 - “I really enjoyed listening to this video. I already have put into practice much of the tips that were shared, however, I learned a few new things too. Things like cutting more veggies and fruits than needed, looking at the top and bottom of supermarket shelves to find the best bargains, and looking at the UNIT price of an item to see if I am really saving money. I knew about staying on the outer perimeters of markets for finding healthier choices too. This program has really changed the way I think about food and I have seen great results in the weight I have lost and my blood pressure medication being reduced. Thank God for this program!!” [participant 5].
- Patients learned a variety of new health and nutrition knowledge and skills to help them make healthy lifestyle choices.
 - “I really liked how the doctor explains high blood pressure (HBP) in easy terms what it is, so anyone can understand. I didn’t know about the mm of mercury being the standard measurement for it, for everyone. There are many devastating heart problems associated with HBP, and I often forget that if not controlled, could lead to a stroke, heart attack and so forth. But the good news is, to be aware it truly is the silent killer. My mother had three a heart attacks, and one of my sisters had one, and had stents put in. Knowledge is power to change my life. Thankful for the doctor and her team, to teach me, and eager to learn new healthier ways to lower my HBP” [participant 6].

Discussion

Principal Findings

The importance of using technology to encourage self-management and self-monitoring for patients with cardiac risk factors and HTN has become even more important during the COVID-19 pandemic, especially for those with health disparities in access to high blood pressure treatment [44]. We recruited participants with HTN to engage with the OWL-HTN platform combined with attending a TKMGV and found that 73% (16/22) of participants were highly satisfied with using OWL-H to manage their HTN. Participants’ blood pressure knowledge and adherence to a Mediterranean diet significantly increased. There was an increase in self-efficacy in applying heart-healthy habits. In all, 82% (18/22) of the participants reported their blood pressure in OWL-H at least once during the 8 weeks.

During the pandemic, the importance of internet access and health delivery technologies to assist with self-monitoring and social connection, such as mobile phones, computers, and tablets, has increased [17,45]. For example, in a recent study by Lustria et al [46], the prevalence of internet use was 72% among those with self-reported HTN or diabetes, which translates to 63 million US adults. Technologies present a way to create a community, educate, and sustain engagement in health practices. However, patients with low income and

experiencing high blood pressure may not have access to the internet and spaces to exercise and have increased stress and food insecurity, further exacerbating disparities in HTN risk [47-49]. Furthermore, low diet quality is even more prevalent among adults with food insecurity, and diet quality is directly related to morbidity and mortality of cardiovascular diseases [47,49-51]. Therefore, it is important that this population have increased patient education and skills, such as healthy shopping and cooking, stress reduction, and regular monitoring of their blood pressure.

Studies have shown a link between knowledge about HTN and blood pressure outcomes [52]. Insufficient knowledge about HTN could lead to less optimal blood pressure control through lower rates of adherence to prescribed medications and engagement in lifestyle practices [53-57]. We found that the participants’ knowledge of common blood pressure and cardiac risk factors significantly increased after the intervention. High knowledge of HTN was associated with healthy lifestyle practices, including eating smaller portions to lose weight and reducing dietary sodium. Abu et al [58], in a study of adults with HTN who attended 2 primary care clinics in the city of Baltimore, Maryland, found that patients with low knowledge about HTN were less likely to be engaged in heart-healthy lifestyle practices than patients with high knowledge about HTN.

Both the Mediterranean dietary pattern and the DASH diet have been shown to improve blood pressure in adults and have been

linked to reduced cardiac injury [59-62]. Our intervention presented engaging content, cooking demonstrations using a teaching kitchen, and recipes from the Mediterranean and DASH diets (high in fruits, vegetables, whole grains, and lean proteins, and low in red meats, sweets, saturated, and total fat) [63] and we showed an increase in adherence to a Mediterranean diet. There is very little research on the use of teaching kitchen or culinary skills as an intervention to reduce blood pressure [64-66]. In a study by Razavi et al [67], families living in New Orleans, Louisiana, were randomized to a hands-on teaching kitchen culinary education class or non-kitchen-based dietary counseling for 6 weeks. Compared with families receiving traditional dietary counseling, those participating in hands-on kitchen-based nutrition education were approximately 3 times as likely to follow a Mediterranean dietary pattern [67]. Qualitative findings from OWL emphasized themes that included healthy shopping on a budget, cooking one's own food, and adapting the DASH and Mediterranean diets to appeal to diverse ethnic groups and income levels.

There is strong evidence that mind-body techniques such as meditation are linked to low blood pressure [68-70]. The main themes that emerged from the video content feedback were centered on the health benefits of the mind-body practices, self-reflection on healthy behaviors and beliefs, behavior change or reinforcement of healthy behaviors, and new health and nutrition knowledge and skills (Textbox 1). Participants who practiced the body scans, meditations, or mindful movements overwhelmingly felt beneficial effects on their health. In addition, the most widely viewed videos were on the topics of stress and inflammation, 2 videos assigned after the second in-person TKMGV; hence, more research is needed on how patients interact with live or web-based curriculum and which component leads to behavior change.

We found that participants increased their blood pressure monitoring. At the 8-week follow-up, 82% (18/22) participants had reported their blood pressure in OWL-H at least once during the 8 weeks. In the Framingham Health eHeart study, women were more likely than men to enroll in a digital intervention that tracked weekly blood pressure and activity with a Fitbit device, with high rates of device use through the 5-month intervention [71,72]. We showed that it is feasible to deliver the intervention at a teaching kitchen as part of a medical group visit and use web-based tracking, content, and experiences (eg, meditation) to reinforce self-management of HTN. Our future research direction includes a large fully powered randomized controlled trial that will allow us to test which parts of the intervention have the greatest impact or whether there is synergy in the different components that lead to behavior change.

Limitations

As a feasibility pilot study, the sample size was not powered to detect reductions in blood pressure. External factors such as the variability in internet connectivity and type of device, such as smartphones, computers, or tablets, may have impacted the results. No valid methodology exists to measure and account for these external factors. In addition, the engagement of male participants was low (3/24, 13%), a limitation reported in other studies of similar nature [73-75]. The future upgrade of OWL-H will aim to include study materials in non-English languages with a goal to increase efficacy of the intervention for ethnically diverse participants.

Conclusions

As these technologies are associated with healthy behaviors, they present a way to create a community, educate, and sustain engagement in health. The flexible access to remote learning platforms creates a convenient and cost-efficient way to reach patients who are under geographic, pandemic, and economic burdens that prevent health care access.
