HRV home trainer devices differ in terms of form, feedback mechanisms, data storage, training guidelines, and underlying software, all of which may affect user experience and effectiveness. For this study, biofeedback devices were selected based on evidence of their use in previous research. To explore whether these aspects were of any concern, participants were allocated to 1 of 2 different biofeedback devices (Figure 2).

Group A participants were provided with a home trainer biofeedback device that used PPG ear sensors [62]. Group B participants were provided with a home trainer biofeedback device that used a fingertip PPG sensor contained within a stand-alone device [63]. A wireless single-lead ECG recorder, worn on the chest, was used to measure participant heart rate and HRV from a single lead before and after the intervention [64]. This lightweight device is battery powered and does not require any external leads or Velcro to connect to the recorder.

Figure 2. We used 2 personal home trainer devices to provide biofeedback during pilot testing: StressEraser, left, and Inner Balance, right (Inner Balance image reproduced with permission of HeartMath).

Measures

Participants were invited to complete anxiety and depression questionnaires before and after the intervention. The measures included *Beck Anxiety Inventory* [65], *Beck Depression Inventory-II* [66], and *Beck Youth Inventories-II* for people aged 13 to 17 years [67] as appropriate to age. The parent or family carer was also invited to complete short before-and-after interviews, rating any changes in participant behavior over the course of the intervention period.

During the intervention period, participants were asked to complete short daily reports on stress levels and device use. This enabled us to track participant stress levels and monitor perceived usefulness of the device. The progress report was devised based on initial phase 1 evaluations and served a 2-fold purpose: tracking participant stress levels and monitoring use of the device over the course of the intervention. This short

report asked questions on sources of stress, levels of stress, and use of the biofeedback device.

At the end of the intervention, participants and carers independently completed a short debriefing interview, and participants completed equipment usability ratings using the *System Usability Scale* [SUS]. This questionnaire provides a standardized assessment of the usability of different technology products [68]. The scale comprises 10 short statements rated on a 5-point scale. Item scores are summated and then rescaled in the range from 0 to 100, with higher scores indicating higher usability. Empirical evaluations of the SUS indicate good reliability [69]. A summary of the measures used is provided in [Multimedia Appendix 2](#) [70,71,65,66,67,72,73,68].

Intervention

All participants were offered initial assessment and training in their own home, with their carer present. This was carried out

by a chartered clinical psychologist with certified training in HRV biofeedback (HC). The training involved sending video clips and written instructions produced by the device manufacturers to participants before an agreed home visit in which a direct demonstration of device use was given. Participants were then all seen and assessed by the first author (HC) who offered 2 training sessions (lasting for 30 minutes each) of home instruction in use of the allocated biofeedback device. No other intervention regarding anxiety management was provided. The HRV biofeedback intervention was available to use daily for a period of 12 weeks. Self-tailoring of intervention intensity was allowed to gauge acceptability and record self-reported compliance. Use was encouraged by the first author (HC) at the outset and indirectly through monitoring uptake. Information on participant anxiety and depression was collected through questionnaire measures completed before and after the intervention.

Participant HRV was measured in the home through a psychophysiological stress profile assessment using a single-lead ECG recorder before and after the intervention. Once the intervention commenced, remote monitoring continued daily, using SMS text message prompting at preset intervals agreed with participants. Questions used to monitor use of the intervention were sent to participants at an agreed time in the evening, recording whether they had used the device that day and whether it had been perceived as useful. Finally, additional information on risks, perceived problems, and benefits of the intervention and equipment usability was collected in face-to-face interviews with participants and their carers at the end of the intervention. This information was also collected from those who dropped out and those whose pre-post data were excluded, provided they consented to provide these data. This was seen as crucial to capture information on any potential difficulties and ensure a representative assessment of risks and benefits. Further details on the intervention are presented in the CONSORT (Consolidated Standards of Reporting Trials) and Template for Intervention Description and Replication checklists ([Multimedia Appendices 3 and 4](#)) and the study protocol ([Multimedia Appendix 5](#) [68,74,75,76,64,77,73,78,79,24,80,81,82]).

Results

Demographic Information

All participants were nonsmokers, and none reported taking illegal drugs. Of the 20 participants, 10 (50%) reported prescribed medication. Of these 10 participants, 6 (60%) were prescribed selective serotonin reuptake inhibitor antidepressants, and 4 (40%) took stimulant medication. Sleep disturbance was reported by 75% (15/20) of the participants; 15% (3/20) reported

needing to carry auto injectors with adrenaline (EpiPen). Of the 20 participants, 16 (80%) were employed or were students.

Carers were asked standardized questions regarding their main concerns about participant behavior, including whether there were any triggers for participant anxiety attacks or *meltdowns* and any strategies used to manage anxiety. The main concern reported was anxiety. The main triggers for anxiety attacks reported by 70% (14/20) of the families were sensory issues such as “loud noise,” “bright lights,” or “touch”; other triggers reported were “changes in routine” and increases in workload or examinations. Busy or crowded places, for example, “shopping centers” or *school*, were also mentioned as frequent triggers for anxiety by 55% (11/20) of the families. The most frequently reported strategy to help manage anxiety described by 85% (17/20) of the families involved reducing sensory information; for example, “reduce noise” or “turn down lights.” Other strategies reported were engaging in favorite activities or physical activity, spending time with parent or carer or pet, listening to music, and escaping from the source of stress by fighting or running away. All carers and participants reported more than one strategy for managing anxiety.

Participant Anxiety and Depression

Of the 20 participants, 4 (20%) were excluded after randomization because of the identification of cardiac concerns ($n=3$, 75%) and significant mental health concerns ($n=1$, 25%), whereas 1 (5%) dropped out and declined further questionnaire and physiological assessment, leaving 15 participants ($n=11$, 73%, male participants and $n=4$, 27%, female participants) for before-and-after data analysis ([Figure 1](#)).

Statistical analyses were carried out using SPSS software (version 24.0) to assess mean group differences in reported anxiety and depression. Parametric statistical tests were conducted using paired sample 2-tailed t tests. Anxiety scores at baseline did not deviate from normality on either the Kolmogorov-Smirnov test ($P=.20$) or the Shapiro-Wilk test ($P=.23$). As different measures were necessarily used for children and adults, separate analyses were performed for these groups.

Of the 15 participants, 1 (7%) adult participant did not complete the initial depression questionnaires: 14 sets of depression data were analyzed. Parametric statistical tests were also conducted using paired sample 2-tailed t tests. Again scores at baseline did not deviate from normality on either the Kolmogorov-Smirnov test ($P=.20$) or the Shapiro-Wilk test ($P=.78$).

Data collected from children and adults showed statistically significant reductions in mean score for anxiety after the intervention; the results for both adults and children showed no significant reduction in mean scores for depression ([Table 1](#)).

Table 1. Participant questionnaire data showing mean scores for anxiety and depression before and after using heart rate variability biofeedback (N=15).

Participants (aged 13-24 years)	Before the intervention, mean (SD)	After the intervention, mean (SD)	Mean difference (SD)	Coefficient, <i>r</i>	<i>t</i> test (<i>df</i>)	<i>P</i> value (2-tailed)	Cohen <i>d</i> (adjusted)

^eAn adult participant did not complete the depression questionnaire.

Carer Reports on Behavior

Carers were asked to rate the frequency of participant behavioral outbursts or meltdowns at the initial and debriefing interviews. Carer ratings indicated a significant reduction (Wilcoxon signed-rank test) in the frequency of behavioral outbursts comparing initial interview data with debriefing interview data ($Z_{14}=-3.33$; $P=.001$; $r=0.6$).

ECG Assessment

Attempts were made to record wireless ECG data to detect changes in HRV over time using a psychophysiological stress test [24] before and after the intervention, but it was not possible to standardize this procedure because of the wide variations in the timing of assessments, differing home environments, and

the use of HRV data from both children and adults. However, baseline ECG recordings did enable within-subject comparisons. Pearson bivariate correlations compared heart rate and HRV variables with age and level of ASD symptoms (Table 2). Before the intervention, age was significantly negatively correlated with all HRV variables at baseline, namely high-frequency heart rate variability ($P=.02$), the root mean square of successive differences in normal heartbeat contractions ($P=.02$) and the variability of normal-to-normal interbeat intervals ($P=.04$). ASD symptoms were positively correlated with heart rate both before ($r=0.54$; $P=.04$) and after the intervention ($r=0.74$; $P=.001$), and negatively correlated with HF HRV recorded at the final assessment ($r=-0.56$; $P=.03$). In addition, HRV indices were negatively correlated with heart rate both before and after the intervention.

Table 2. Pearson bivariate correlation statistics before and after the intervention between physiological measures of heart rate and heart rate variability recorded with participant age and level of ASD (autism spectrum disorder) symptoms as measured by the Social Communication Questionnaire [59].

^aHF-HRV: high-frequency heart rate variability (a frequency domain index that can indicate parasympathetic nervous system activity).

^bRMSSD: root mean square of successive differences in normal heartbeat contractions or interbeat intervals measured in milliseconds (a time domain heart rate variability index that can be associated with parasympathetic nervous system activity).

^cSDNN: SD of the normal heartbeat contractions; that is, normal-to-normal interbeat intervals measured in milliseconds.

^dHR: heart rate measured in beats per minute.

^e $P < .05$ (2-tailed).

^fNot applicable.

^gAutism spectrum disorder symptomatology measured using the Social Communication Questionnaire [59].

^h $P < .01$ (2-tailed).

Adoption of Biofeedback Device During Intervention

Across the study, 474 web-based surveys were collected providing data on sources of stress and use of biofeedback devices throughout the intervention period. Participants who had difficulties using their biofeedback device or ECG recorder had their monitoring data included, provided they had consented.

Participants were asked during the intervention period whether the device had helped them when used. The majority (311/474, 65.6%) of the reports provided indicated that the biofeedback

device had been used and that “it helped” when used. Only 4% (19/474) of the reports indicated that the device “didn’t help” when used. Regarding use, 88% (417/474) of the reports indicated that the device had been used for between 0 and 10 minutes, with 12% (57/474) of the reports indicating that the device had been used for >10 minutes.

Participants were also asked to report the reasons for not using the device. A summary of 144 reports provided by participants detailing a range of reasons is presented in Table 3.

Table 3. Participant reported effect of biofeedback device when used (n=144).

Reported reason for not using device	Responses, n (%)
“Not stressed” today	65 (45.1)
No clear reason given	24 (16.7)
“Busy” or “away”	20 (13.9)
“Device not with me”	17 (11.8)
“Forgot to use”	9 (6.2)
“Practicing later”	6 (4.2)
“Error on device”	3 (2.1)

The most frequent reason reported for not using the device was simply that the participant did not feel stressed. Other reasons reported were “too busy” (20/144, 13.9%), “device not with me” (17/144, 11.8%), “forgot to use it” (9/144, 6.3%), “practicing the device later” (6/144, 4.2%), and “error on device” (3/144, 2.1%). Of all reports submitted, 16.7% (24/144) offered no clear reason for not using the device.

Equipment Usability

Usability ratings were captured on the 2 biofeedback devices, an ECG recorder, and a web-based survey (Table 4). The benchmark for the SUS is 68, with scores above this value considered to be acceptable [83]. Average ratings for the equipment used in this study indicated good usability.

Table 4. Participant ratings of 2 types of biofeedback devices, an electrocardiogram (ECG) recorder, and SMS text monitoring using the System Usability Scale (SUS) [68].

Type of equipment used ^a	SUS score, mean (SD; range)	Benchmark SUS score ^b , mean (SD)
StressEraser (n=9)	76.60 (16.25; 47.5-92.5)	68 (12.5)
Inner Balance (n=9)	83.61 (8.94; 70.0-92.5)	68 (12.5)
Actiwave ECG recorder (n=9)	70.00 (7.80; 60.0-77.5)	68 (12.5)
SMS text message survey (n=15)	78.50 (9.05; 65.0-100.0)	68 (12.5)

^aA total of 18 ratings of biofeedback devices were completed: 9 for StressEraser and 9 for Inner Balance; 9 ratings were completed regarding the electrocardiogram recorder; and 15 ratings were completed regarding the SMS text message report.

^bBenchmark calculation of average SUS scores [83].

Risks and Benefits

During the debriefing at the end of the study, participants and carers reported perceived benefits and any problems. Unexpectedly, many of the participants reported cold fingers during initial training, with 70% (7/10) of those initially allocated to the StressEraser reporting difficulty using this device at some point during the study.

Clinical disclosures included previously unrecognized cardiac irregularities (3/20, 15%) and severe mental health difficulties

(1/20, 5%). These were identified *after enrollment* after initial screening.

A range of positive benefits were reported by both participants and their carers, with the most frequent benefit reported being feeling *calm* or *relaxed*. A smaller number of problems were reported overall, mainly relating to difficulties with the fingertip sensor device. The results presented in Tables 5 and 6 show the frequency counts of key phrases reported in debriefing reports from participants.

Table 5. Participant reported problems of using biofeedback device (n=24).

Reported problems	Responses, n (%)
Finger sensor errors	5 (21)
Difficulty using while stressed	5 (21)
Lack of practice	4 (16)
Device functions difficult	3 (13)
Needed reminders	3 (13)
Didn't find it helped	2 (8)
Ear sensor difficulty	2 (8)

Table 6. Participant reported benefits of using biofeedback device (n=43).

Reported benefits	Responses, n (%)
Felt calm or helped	11 (25)
Ease of use	9 (21)
Helped breathing	5 (11)
Helped sleep	4 (9)
Good video tutorials provided	3 (7)
Visual or can “see” results	3 (7)
Helped when not using	2 (5)
Helped focus	2 (5)
Portable	2 (5)
Efficient	2 (5)

Discussion

Principal Findings

This pilot study highlights potential positive effects of HRV biofeedback in people with ASD, with fewer symptoms of anxiety being reported after using HRV biofeedback devices at home. Carers also reported fewer behavioral *meltdowns*. Remote monitoring indicated that although most (417/474, 88%) of the participants only used the device for short periods of time (0-10 minutes), the majority (311/474, 65.6%) indicated that the device helped when it was used. Notably, only 4% (19/474) of the reports highlighted instances where the device did not help. However, difficulties surrounding the usability of the finger-type sensor device were reported.

A perceived strength of this study was the experimentation of a new intervention in a population where there is high need and where little research exists on issues that affect the lives of people with ASD [84]. A further strength was the assessment of people with ASD by embedding self-reporting in place of traditionally used carer reports. Indeed, self-reports from young people with ASD can be reliable over time [85], and the use of remote monitoring, self-report questionnaires, and debriefing reports from participants combined with carer reports adds strength to the validity of the study findings. Overall, the findings confirmed that *young people with ASD can independently use portable HRV biofeedback devices, and such devices seem to help them manage anxiety*.

We note the discovery of previously undetected cardiac irregularities and deteriorating mental health. This highlights the mental and physical health vulnerabilities in this population [86,87] and the importance of providing them with both assessment and ongoing support. Pre- and postintervention data also indicated that a child participant and an adult participant showed increases in anxiety after the intervention. The debriefing reports indicated that usability issues with the device may have increased anxiety. The unforeseen instances of participants presenting with cold fingers, which affected the quality of the signal acquisition using the PPG finger sensor integrated into the StressEraser, was an unexpected finding. Cold fingers in some individuals have previously been correlated

with a shutdown in peripheral circulation as a result of stress [88]. Equipment checks did not indicate any fault with the equipment, and this device has previously been used successfully in several other populations [89,90]. These difficulties highlight the importance of personalizing digital health solutions to promote use and adoption alongside the need for ongoing clinical support when problems occur. Although the StressEraser is no longer being marketed, other devices using finger sensors may need to be used with caution in people with ASD.

Limitations

Several limitations are acknowledged in this pilot study. A necessary limitation was the small sample size and the inherent risk of error and bias when using self-report measures. It was not possible to determine the exact reasons for nonparticipation in the study because of the ethical constraints regarding contacting those who declined to participate. All participants contacted had already attended services for anxiety. It may be that those who did not participate were not now experiencing problems with anxiety or that they were concerned about participating in research into an untested intervention. Future studies should address this issue to further assess whom this treatment might be beneficial for.

It is possible that reductions in self-reported anxiety may have been related to other outside factors or to nonspecific therapeutic variables. However, it is of note that no time was spent with participants talking about their anxiety or providing any other type of intervention—the training given only involved a review of existing instruction guidelines in the use of each biofeedback device. It is also possible that unconscious bias may have occurred within carer interviews and participant reports because of a wish for the treatment to succeed; however, the debriefing reports indicated that several participants and their carers did report at the end of the intervention that the device did not help despite their initial hopes that it would be beneficial, and participant reports and carer reports were in concordance regarding the changes noted.

This study attempted to carry out before-and-after HRV assessment analysis by means of a single-lead ECG recorder using a psychophysiological stress test within participants' homes. This type of test paradigm assessment proved

unsuccessful because of the lack of standardized test conditions inherent within multiple home environments. This type of stress assessment is one which is unlikely to be useful outside of clinical settings. Before embarking on home intervention programs, future interventions using physiological monitoring such as ECG assessments may require an initial clinic appointment to carry out full mental and physical health checks [75].

In addition, individuals with ASD have also been found to exhibit both hyperarousal and hypoarousal responses to stress tasks, suggesting that the classic paradigm of a stress profile assessment designed for non-ASD populations is unlikely to provide a clear picture when used in people with ASD [56,91]. Recent research has suggested that it is preferable to carry out a longer assessment to obtain more accurate information on HRV, particularly in relation to psychological stress [92]. Because of the mental health difficulties and physiological differences observed in many people with ASD, this type of longer-term monitoring could be particularly valuable.

Usability assessment indicated that both ECG monitoring and remote smartphone monitoring of stress levels were found to be acceptable in people with ASD. Small wireless ECG monitors can now be used for 24-hour recordings, and the approach of remote stress monitoring combined with longer ECG recordings could be used in future studies to provide much needed data on anxiety and the physiological profile of people with ASD.

Comparison With Prior Work

A review of HRV biofeedback studies [93] concluded that, although positive outcomes are reported in many studies, there is not always concordance between questionnaire reports and physiological measurements, and the exact mechanisms of the effect underlying HRV biofeedback have been debated [46]. Our findings suggest that there may be anxiety reduction through use of smaller portable HRV biofeedback devices, but further research using standardized physiological assessments is needed to establish whether this has any long-term effect on underlying participant HRV.

Importantly, some participants in this pilot may not have been able to develop the specific type of resonant frequency breathing using home trainer biofeedback devices, which is argued to increase HRV [94]. The use of multichannel biofeedback equipment may be important for initial training sessions to increase HRV levels; however, for the large numbers of people now requiring intervention, this would require significant outlays in terms of time, training, and resources. Future studies could carry out initial psychophysiological monitoring in a controlled clinic setting and then provide participants with wearable technologies for home use.

This preliminary work has provided vital information for further studies, which could now test effectiveness of HRV biofeedback for home-based remote management of anxiety in an adequately powered randomized trial using a comparator intervention with matched intervention time. This approach was used with non-ASD populations in 2 recent studies that reported positive effects from biofeedback in comparison with control interventions, such as mindfulness and walking [90,95].

Studies investigating comparative interventions could use a breathing pacer app for smartphone use, which could assess paced breathing alone in comparison with HRV biofeedback. Future investigations should capture device data, enabling information to be gathered regarding length and type of breathing practice, which may help to address questions relating to any dose-response relationship for HRV biofeedback. Finally, this initial study only targeted young people aged 13 to 24 years with no known learning disability. A key step in further work will be to assess this methodology and intervention in other groups of people with ASD, such as older adults and people with intellectual disability.

Conclusions

ASD is now a common condition. Reports suggest high costs of supporting people with ASD; yet, little research has been undertaken into new types of interventions specifically designed to meet their needs [51].

Conditions such as ASD pose a significant cost to individuals, health care providers, and society as a whole [96]. Since the data were collected, limited access to interventions for mental health conditions such as anxiety has been exacerbated by health service imperatives to address the COVID-19 pandemic. It has been argued that the current health crisis demands a “digital mental health revolution” [97]. Digital health can provide important tools to help reduce the burden of mental illness and intervene with increasing numbers of people whom traditional models of *face-to-face* therapy cannot support [98].

Digital technology may represent a useful method of engaging people with ASD by using some of their characteristic strengths and interests, without the complex social and communication demands of traditional cognitive and behavior therapies [54] and without the potential risks of medication.

The application of home-based solutions to difficulties experienced by people with ASD also represents what has been termed a “naturalistic developmental behavioral intervention” that can help with the generalization of skills because of their use in real-world interactions [99]. Methods of remote monitoring to assess the symptoms as well as the effectiveness of interventions such as biofeedback may be useful for people with ASD, which should be trialed. These techniques may also assist practitioners striving to provide personalized *connected health* ASD intervention support at a distance.

Systematic reviews have outlined developments in biofeedback across a range of modalities as well as some of the challenges to be addressed in future investigations [28]. HRV biofeedback may be an important adjunct to existing interventions for non-ASD populations with mental health conditions [100,101], and people with ASD should not be excluded from developments in this area. Despite the limitations, this study provides preliminary information on the use, risks, and perceived benefits of HRV biofeedback for anxiety in people with ASD. Importantly, the direct reports from both participants and their carers provide a unique insight into the risks and difficulties as well as the potential benefits of this intervention. Although the exact mechanism of the effect remains unclear, our findings

suggest that further research is warranted to clarify its effectiveness.

Acknowledgments

HC was supported by a Health & Social Care Doctoral Fellowship (2013-2018) from the R&D Division of the Public Health Agency, Northern Ireland, United Kingdom. The authors wish to offer thanks to Professor Richard Gevirtz, Alliant University, for his help and guidance; Assistant Professor Keri Heilman, University of North Carolina, for her advice on assessment; and Dr Cathal Breen, Ulster University, for his help with electrocardiogram recording. This study would not have been possible without the direct and forthright contributions of people with autism spectrum disorder and the support of South Eastern Health and Social Care Trust.

Authors' Contributions

HC was responsible for the conception of this study. HC, MD, and WGK were responsible for the study design. HC and MD drafted the article, which was critically revised by all the other authors. HC was responsible for data collection and for clinical evaluations. HC, MD, and JM were responsible for data analysis.

Abstract

Background: Diabetes mellitus is a severe disease characterized by high blood glucose levels resulting from dysregulation of the hormone insulin. Diabetes is managed through physical activity and dietary modification and requires careful monitoring of blood glucose concentration. Blood glucose concentration is typically monitored throughout the day by analyzing a sample of blood drawn from a finger prick using a commercially available glucometer. However, this process is invasive and painful, and leads to a risk of infection. Therefore, there is an urgent need for noninvasive, inexpensive, novel platforms for continuous blood sugar monitoring.

Objective: Our study aimed to describe a pilot test to test the accuracy of a noninvasive glucose monitoring prototype that uses laser technology based on near-infrared spectroscopy.

Methods: Our system is based on Raspberry Pi, a portable camera (Raspberry Pi camera), and a visible light laser. The Raspberry Pi camera captures a set of images when a visible light laser passes through skin tissue. The glucose concentration is estimated by an artificial neural network model using the absorption and scattering of light in the skin tissue. This prototype was developed using TensorFlow, Keras, and Python code. A pilot study was run with 8 volunteers that used the prototype on their fingers and ears. Blood glucose values obtained by the prototype were compared with commercially available glucometers to estimate accuracy.

Results: When using images from the finger, the accuracy of the prototype is 79%. Taken from the ear, the accuracy is attenuated to 62%. Though the current data set is limited, these results are encouraging. However, three main limitations need to be addressed in future studies of the prototype: (1) increase the size of the database to improve the robustness of the artificial neural network model; (2) analyze the impact of external factors such as skin color, skin thickness, and ambient temperature in the current prototype; and (3) improve the prototype enclosure to make it suitable for easy finger and ear placement.

Conclusions: Our pilot study demonstrates that blood glucose concentration can be estimated using a small hardware prototype that uses infrared images of human tissue. Although more studies need to be conducted to overcome limitations, this pilot study shows that an affordable device can be used to avoid the use of blood and multiple finger pricks for blood glucose monitoring in the diabetic population.

KEYWORDS

diabetes; deep learning; machine learning; glucose concentration; noninvasive monitoring; optical sensors; glucose monitoring

Introduction

Background

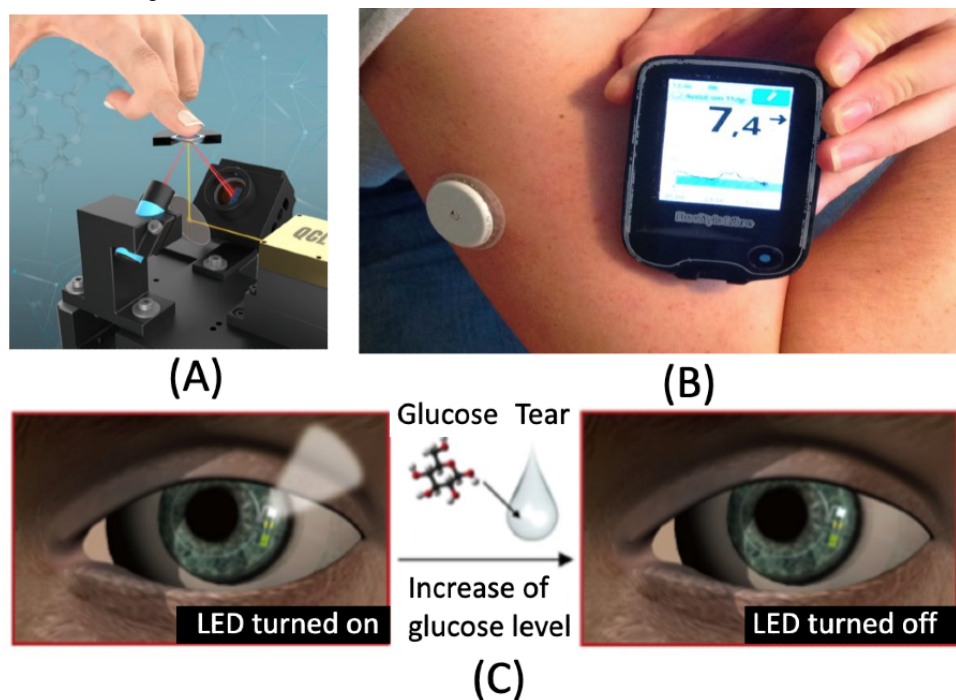

Diabetes affects approximately one out of every 10 people in the United States [1]. Its prevalence has increased from 23.4 million Americans in 2015 to 30.3 million in 2021 and continues to rise at an alarming rate [2].

Successful management of diabetes involves monitoring blood glucose levels multiple times per day. The standard method for monitoring blood glucose concentration is through the use of a glucometer [3]. This device determines glucose concentration from a droplet of blood obtained from a finger prick or a

laboratory blood draw. Taking repeated finger pricks over the course of a day is painful and creates a risk of infection at the collection site [4]. Therefore, noninvasive methods are an attractive alternative, however, those that are available today have several limitations.

Three main types of noninvasive glucose monitoring devices are currently available: (1) noninvasive optical glucose monitoring (NIO-GM), based on optical glucose monitoring, (2) noninvasive fluid sampling (NIFS-GM), based on fluid sample glucose estimation, and (3) minimally invasive devices (MI-GM), which use a sensor inserted into the subcutaneous tissue [5]. Figure 1 illustrates an example of each type of noninvasive and minimally invasive blood glucose monitoring.

Figure 1. Examples of (A) NIO-GM (adapted from Lubinski et al [6]), (B) MI-GM (adapted from Sjö [7], published under Creative Commons Attribution-Share Alike 4.0 International License [8] and (C) NIFS-GM (adapted from Park et al [9] published under Creative Commons Attribution NonCommercial License 4.0 International License [10]). MI-GM: minimally invasive device; NIFS-GM: noninvasive fluid sampling; NIO-GM: noninvasive optical glucose monitoring.

NIO-GM estimates glucose concentration from energy absorption, reflection, or scattering of a light beam directed through the tissue [11]. These devices have the advantage of being both portable and inexpensive. NIO-GM technology includes fluorescence spectroscopy, which may lead to toxicity from fluorophores [12,13]; Raman spectroscopy, criticized for its lengthy spectral acquisition time and poor signal-to-noise ratio [14,15]; photoacoustic spectroscopy, which introduces noise from its sensitivity to environmental factors [15,16]; optical coherence tomography, which is overly sensitive to skin temperature [17]; and occlusion spectroscopy, known to result in signal drift [18]. In contrast, we have developed a NIO-GM device using near-infrared absorption spectroscopy, which is more practical and cost-efficient than those described above [19-23].

Objectives

Here, we describe the development of a novel noninvasive glucose monitoring system that uses the computing power of sensors and Internet of Things devices to continuously analyze blood glucose from a microcomputer and a sensor embedded within a clip positioned on the finger or ear. The prototype uses infrared spectroscopy to create images of the rotational and vibrational transitions of chemical bonds within the glucose molecule, and incident light reflection to measure their corresponding fluctuation. The images are converted into an array list, which is used to provide entries for an artificial neural network (ANN) to create an estimate of blood glucose concentration. The prototype is easy to use and is paired with a mobile app for free-living environments. Figure 2 shows an overview of the proposed system.

Figure 2. Overview of the proposed noninvasive blood glucose monitoring system.

Methods

Physical Theory

Our prototype detects blood glucose concentration using noninvasive absorption spectroscopy optical glucose monitoring [24]. It is based on the Beer-Lambert law of absorption that is shown in equation 1 [24].

$$I = I_0 e^{-\mu_a l}$$

where I_0 is the initial light intensity (W/cm^2), I is the intensity of the i^{th} at any depth within the absorption medium in W/cm^2 , l is the absorption depth within the medium in centimeters, e is the molar extinction coefficient in $L/(mmol\ cm)$, and c is the concentration of absorbing molecules in $mmol/L$. The product of e and c is proportional to the absorption coefficient (μ_a).

The concentration of absorbing molecules is based on the above equation. However, the effect of other blood components and absorbing tissue components affects the amount of light absorbed. As a result, the total absorption coefficient is the summation of the absorption coefficients of all the absorbing components [25]. Then, to minimize the absorption due to all the other components, the wavelength of the light source should

be chosen so that the light source is highly absorbed by glucose and is mostly transparent to blood and tissue components.

Hardware Configuration

We used Internet of Things technologies to leverage power computing and low energy consumption of sensor devices and a Raspberry Pi camera for building the glucose-monitoring prototype [26]. Although the Raspberry Pi camera captures images, a laser light captures absorption. The specifications of the laser light can be found in Table 1.

A small clip that can be positioned on a finger or earlobe holds the laser on the top half and the camera on the bottom. Figure 3 depicts the elements of the prototype (Raspberry Pi, camera, and laser light). The prototype has been named GlucoCheck.

The Raspberry Pi camera captures one image every 8 seconds over 2 minutes, for a total of 15 images. Brightness and contrast levels are set to 70 cycles/degree, camera ISO sensitivity is set to 800, and resolution is set to 640×480 . Figures 4 and 5 show the prototype attached to the finger and ear, respectively.

The materials for the GlucoCheck prototype cost approximately US \$79-\$154 in 2022, depending on the availability of chips, which has been an ongoing issue in recent months. Typically, computer boards are abundant, but 2022 saw a shortage of chips, leading to inflated prices compared to previous years.

ANN Model

Due to the large number of images used by our prototype, we use a convolutional neural network (CNN/ConvNet) approach. The convolutional layer is the first layer of a CNN network and is the main building block that handles most of the computational work. We imported necessary libraries including

Tensor Flow, Keras, MobileNetV2, Matplotlib, and Numpy. The image data set was converted into arrays with preprocessing, then stored in a list format with assigned labels. Finally, the images were appended to a single data array with a corresponding label array and data augmentation techniques were used to train our model, including cropping, zooming, height and width shift, and horizontal flipping.

Our base model, MobileNet-v2, is a lightweight, 53-layer deep CNN method used to improve the classification of images with a limited data set. The next step was to build the head model, which sits on top of the base model. The next layer is the activation layer, which uses the rectified linear unit (ReLU) activation function [27]. The ReLU is a piecewise linear function that will output the input directly if it is positive; otherwise, it will output zero. It has become the default activation function for many types of neural networks because a model that uses it is easier to train and often achieves better performance [28]. The next layer is the pooling layer, which incorporates feature-down sampling. It is applied to each layer in the 3D volume. The fully connected layer, which involves flattening,

is the final step. The entire pooling feature map matrix is transformed into a single column, which is then supplied to the neural network for processing. We put these attributes together to make a model using the fully linked layers. Finally, we classified the output using a “Softmax” activation function. The ANN model was trained using the Adam technique, which included a total of 20 epochs, a batch size of 1, and an initial learning rate of $1e-4$, and a 0.5 dropout was considered. The next step was to train and test the model; 80% of the data was used for training the model, and 20% was used for testing the model. Figure 6 shows the ANN used for our glucose estimation process.

Figure 6. Artificial neural network model used for glucose estimation. ReLu: rectified linear unit.

Cloud Integration for Real-time Measures

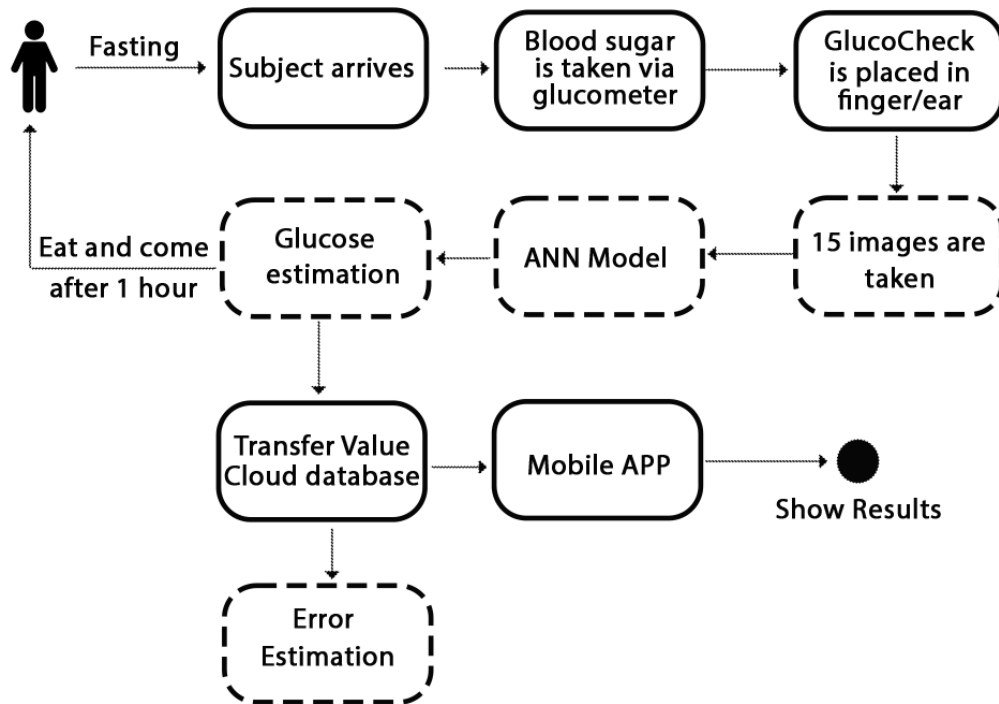

The glucose concentration obtained from the ANN model is sent to the cloud using HTTPS. Next, we configure an InfluxDB [29] database in the cloud to store the data. InfluxDB is an open-source time-series database developed by the company InfluxData. It is written in the Go programming language for storing and retrieving time series data in fields such as operations monitoring, application metrics, Internet of Things sensor data, and real-time analytics. InfluxDB is flexible enough to store data from each subject separately using tags. The integration with the cloud uses the Raspberry Pi, which is connected in real time, and the computed values are displayed on a mobile app for the user.

Model Testing

Glucose data from 8 individuals were used to train and test the model. Each participant was asked to fast for one hour following

an unstructured meal prior to the testing visit. Blood glucose concentration was estimated using a commercially available glucometer (FORA 6 Connect BG50 Blood Glucose Starter Testing [17]), according to manufacturer instructions. The GlucoCheck prototype was used to capture images from each participant at two positions: the index finger and the earlobe. As mentioned previously, 80% of the data was used for training the model and 20% of the data was used for testing. The LabelBinarizer module of the Python library sklearn was used to convert the image data to a binary format and store it in an array associated with its corresponding labels/categories (85-95 mg/dL, 96-110 mg/dL, 111-125 mg/dL). Data augmentation (cropping, zooming, height and width shift, horizontal flipping) was used to enlarge our data set for training and testing the model. The data were then passed to our model for glucose estimation. Separate models were developed for images from the finger and images from the earlobe. Figure 7 illustrates the workflow of the protocol.

Figure 7. Method workflow.

Ethical Considerations

For this pilot study, the following ethical considerations were in place. First, the Institutional Review Board of Kennesaw State University approved the study (IRB-FY22-318). In addition, participation in the study was voluntary. Participants were free to opt in or out of the study at any time. Informed consent was required to inform the participant about the study's purpose, risks, and funding before they agreed or declined to join. Finally, any personally identifiable data were anonymized and kept confidential for the research group.

Results

Experimental Data

Figure 8 shows images collected from a finger. The images were taken after the finger prick at seconds 8 (top left), 16 (top right), 24 (bottom left), and 32 (bottom right). Figure 9 shows images collected from an earlobe at seconds 8, 16, 24, and 32 after the finger prick.

All the images were then appended to a single data array with a corresponding label array. Then, we performed data augmentation (cropping, zooming, height and width shift, horizontal flipping), which allowed us to expand the variety of data available for training the model as we had a minimal amount of data. The data were then passed to our model for glucose estimation.

Figure 8. Fingertip images collected from volunteers.

Figure 9. Ear/earlobe images collected from volunteers.

Accuracy Evaluation

The accuracy of the model was assessed with a confusion matrix, which illustrates the proportion of images that were correctly classified. Blood glucose values were grouped as 111-125 mg/dL, 85-95 mg/dL, and 96-110 mg/dL, shown along the x and y axes.

Figure 10 shows the confusion matrix for the glucose estimates when worn on the finger, and indicates a 79% accuracy of the ANN model. The ANN model classified 8 images correctly and 4 images incorrectly in the 111-125 mg/dL category. For the 85-95 mg/dL category, 18 images were correctly classified and

0 images were classified incorrectly. All 3 images in the 96-110 mg/dL category were incorrectly classified. This poor level of accuracy is due to the limited data set for these values.

Figure 11 shows the results of the ANN model for the ear image data set, which achieved around 62% accuracy. The model classified 5 images correctly and 4 images incorrectly in the 111-125 mg/dL category. In addition, 6 images were correctly classified and 0 images were classified incorrectly in the 85-95 mg/dL category. Finally, 2 images were correctly classified and 4 images were incorrectly classified in the 96-110 mg/dL category.

Figure 10. Confusion matrix of finger artificial neural network model. The x-axis refers to the correct estimates, while the y-axis shows incorrect estimates. The unit for all x and y values is mg/dL.

Figure 11. Confusion matrix for ear artificial neural network model. The unit for all x and y values is mg/dL.

Mobile App

Our mobile app “GlucoCheck” is connected to our cloud InfluxDB database and provides continuous glucose monitoring and history data for users. Users can review their current glucose measurement and also view a chart of their previous measurements, allowing them to track glucose variation over a

specific period of time. Figure 12 shows the initial screen on the app (left) and the display of glucose readings from the prototype (right).

Users may also enter readings from a glucometer into the app to track and compare measurements from other devices, as illustrated in Figure 13.

Figure 12. Mobile app interface showing blood glucose level.

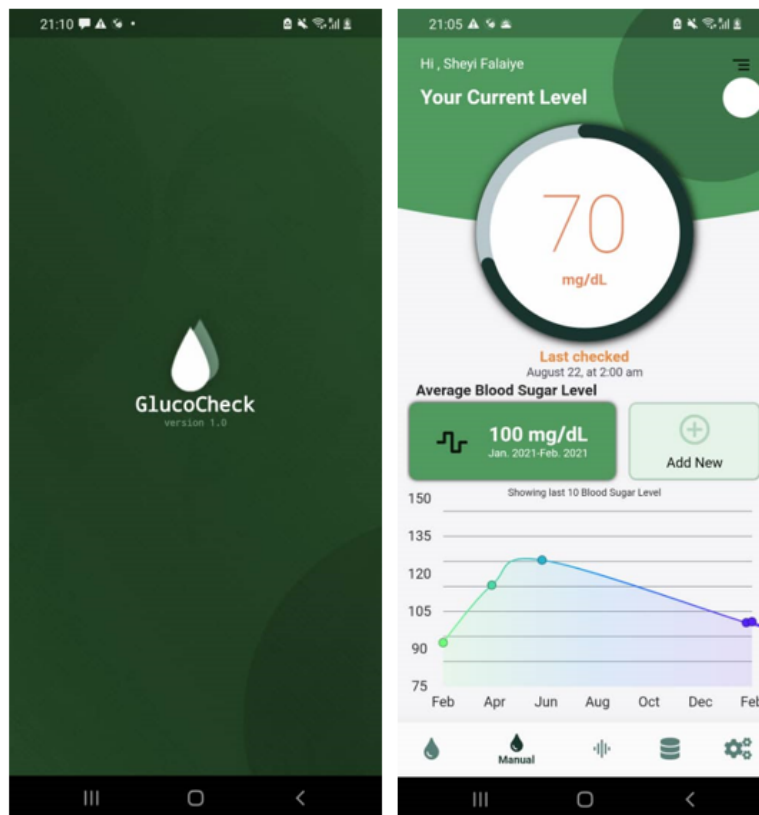

Figure 13. Option to enter glucose level manually. GlucoCheck readings (left) can be compared with other glucometer measures, entered by the user manually (right).

Discussion

Principal Findings

Here we detail and test a novel NIO-GM prototype that relies on an ANN and camera-based technology and is associated with an app that is user-friendly. Results indicate that these optical techniques and machine learning methodologies can effectively measure blood glucose when the light is transmitted and absorptive through the skin tissue. GlucoCheck had an acceptable 79% accuracy when images from fingers were

analyzed and 62% accuracy for images from the earlobe position.

Table 2 compares GlucoCheck with previously tested techniques. The potential of GlucoCheck is comparable with other studies, but it has advantages over other technologies. The use of an integrated computer board (Raspberry Pi) and integration with the cloud gives GlucoCheck the unique ability to display values in real time via a mobile app. Additionally, the optional earlobe position of GlucoCheck is unique and allows for the device to be developed as an earring.

Table 2. Comparison of this study with previous work.

Study	Body part	Technique	Number of subjects	Accuracy	Real-time	Mobile app	Year
This study (GlucoCheck)	Finger/earlobe	Binary format of image and convolutional neural network	8	79%	Yes	Yes	2022

Limitations

Future research is needed to address several limitations in the development of a more reliable noninvasive blood glucose prototype based on light. First, a large amount of data is needed for training a machine learning and deep learning model for complicated tasks. Collecting data from people with diabetes is often time-consuming and expensive compared with other tasks. Consequently, many studies face a shortage of data during their research cycles [30-35]. In this preliminary work, we used data augmentation techniques to compute additional data points from our preliminary data set. Additional data will be needed for the ANN model to detect the exact glucose value instead of a range.

Second, depending on the type of radiation used, a viable NIO-GM must account for differences in skin pigmentation, surface roughness, skin thickness, breathing artifacts, blood flow, body movements, and ambient temperature [36]. Accurate measures of the absorption (scattering) properties within human skin remains challenging in biomedical optics and biomedical engineering [37]. Similarly, skin roughness and pigmentation can affect light distribution when propagating through the skin [38]. These factors must be addressed in future technology.

Finally, the prototype enclosure design must be comfortable and usable to be effective.

Conclusion

In this paper, we have presented a noninvasive glucose monitoring system that leverages the computational power of Internet of Things devices and can be used for diabetes management. The prototype is based on images taken from the finger or ear, and does not require blood samples. An ANN model was used to classify and estimate blood glucose concentrations from the images. When using images from the finger, the accuracy of GlucoCheck was 79%. For images taken from the ear, the accuracy was attenuated to 62%. Though the current data set is limited, these results are encouraging. Future studies are needed to address three main limitations: (1) the size of the database (by expanding the data collection process); (2) the prototype enclosure design (by working with biomedical and hardware engineers); and (3) the external factors (by analyzing the impact of skin color, skin thickness, and ambient temperature, among others). If successful, this prototype will be an attractive, life-changing technology for people with diabetes.

Acknowledgments

The authors greatly appreciate the reviewers that contributed to improving the manuscript. They also would like to acknowledge the College of Computing and Software Engineering and the Office of Research at Kennesaw State University for funding this project.

Abstract

Background: Prior research has linked social media usage to poorer mental health. To address these concerns, social media platforms have introduced digital well-being tools to help users monitor their engagement. Nonetheless, little is known about the effectiveness of these tools.

Objective: In this study, we focused on Facebook to assess users' awareness and usage of the following six Facebook well-being tools: the *Unfollow*, *Snooze*, *Off-Facebook Activity*, *Your Time on Facebook*, *Set Daily Reminders*, and *Notification Settings* features. Additionally, we examined whether the use of these tools was associated with better mental health outcomes.

Methods: We conducted a cross-sectional survey of 598 Facebook users. The survey comprised questions about (1) baseline Facebook use, (2) the adoption of Facebook's digital well-being tools, and (3) participant demographics. These were used to predict the primary outcome measure—scores on the 21-item Depression, Anxiety, and Stress Scale.

Results: Most participants (580/598, 97%) knew about Facebook's digital well-being tools, but each tool was used by only 17.4% (104/598) to 55.5% (332/598) of participants. In turn, the use of two tools was associated with better well-being; although participants who spent more time on Facebook reported higher levels of depression, anxiety, and stress, those who managed their feed content or notifications by using the *Unfollow* or *Notification Settings* features had lower scores on each of these measures. However, the use of the *Snooze*, *Off-Facebook Activity*, *Your Time on Facebook*, or *Set Time Reminder* features was not associated with lower depression, anxiety, or stress scores.

Conclusions: Of the 6 Facebook digital well-being tools, only 2 were associated with better mental health among users. This underscores the complexity of designing social media platforms to promote user welfare. Consequently, we urge further research into understanding the efficacy of various digital well-being tools.

Introduction

Background

Over the past decade, social media platforms have been scrutinized for their potential impact on mental health. Among the general public, claims about social media harms have been widely publicized in both television documentaries [1] and whistleblower accounts [2]. Within the academic literature, multiple studies have also linked social media usage to symptoms of depression [3,4], psychological distress [5], poorer well-being [5,6], and lower self-esteem [7].

Two theories have been proposed to explain why social media platforms may compromise mental health [1,2]. First, such platforms allow users to compare themselves with celebrities or peers whose web-based posts portray more ideal lives than those of typical users [8,9]. This form of upward social comparison may result in users feeling worse about themselves, placing them at risk for poorer mental health [8,9]. Second, social media platforms are designed to draw users' attention for as long as possible [10,11]. In turn, this allure may result in excessive social media consumption, again impairing well-being [10,11].

To address public concerns about these social media harms, app developers have introduced digital well-being features to help users manage their engagement [12,13]. Nonetheless, it remains unclear (1) whether users know or use these features and (2) whether the use of these features predicts better psychological well-being. Consequently, this study examines these questions by focusing on Facebook as a case study.

Facebook's Digital Well-being Features

With 2.9 billion users worldwide, Facebook is the most widely used social networking platform in the world [14]. Given its popularity, it has also been the focus of most research studies that document the link between social media usage and poorer mental health [7,9,15]. As a result, Facebook developers consulted mental health experts and launched a series of digital well-being features, with the high-level goal of making subsequent Facebook usage "intentional, positive and inspiring" [16].

Facebook's digital well-being features broadly address the two proposed theories for social media harms. First, to minimize the amount of social comparisons, several features allow users to curate the content that they see. For example, the *Unfollow* option allows users to hide posts from selected friends, pages, or groups, while the *Snooze* option hides these posts for a 30-day duration [17]. Further, the *Off-Facebook Activity* feature allows users to customize how the platform integrates information from external apps to customize their feeds [17].

Based on prior surveys, content curation features seem to be adopted when users want to avoid friends' boastings, inappropriate posts (eg, racist content), content that they disagree with (eg, on account of political ideology), or excessive and irrelevant posts [18-21]. In turn, deploying these features can cause users to feel unburdened [22]. Consequently, we sought to examine whether the adoption of these features predicts better mental health.

In the second category, a separate set of digital well-being features enables users to monitor their usage patterns and curb excessive use. For example, the *Your Time on Facebook* feature displays the amount of time that a user has spent on Facebook over the past week, while the *Set Daily Reminders* feature notifies users when a predetermined cutoff has been reached (eg, 45 minutes of Facebook use) [17]. Additionally, the *Notification Settings* feature allows users to manage the in-app notifications that they receive, minimizing the amount of content that draws the users' attention.

As we are not aware of any study linking Facebook's digital well-being tools to mental health, we conducted a cross-sectional survey to address our two primary aims. First, we sought to document the extent to which Facebook users know and use the six outlined features—the (1) *Unfollow*, (2) *Snooze*, (3) *Off-Facebook Activity*, (4) *Your Time on Facebook*, (5) *Set Daily Reminders*, and (6) *Notification Settings* features. Second, we sought to replicate previous findings that linked Facebook usage with poorer mental health and examine whether participants' use of the well-being features was associated with better outcomes.

Methods

Study Design and Population

The participants were 608 Facebook users who were recruited from Amazon's web-based panel (Mechanical Turk) in June 2021. All participants met the following eligibility criteria: (1) individuals aged 21 years or older, (2) individuals who were proficient in English, (3) individuals based in the United States, and (4) individuals with a positive track record on the platform (human intelligence task approval rate: >95%; number approved: >500).

Ethics Approval

Participants gave their written consent in accordance with the Declaration of Helsinki, and were given a nominal sum of US \$0.50 upon study completion. This study was approved by the Yale-NUS College Ethics Review Committee (approval number: 2021-CERC-001) and was preregistered on ClinicalTrials.gov (trial number: NCT04967846).

Predictor Variables

Predictor and outcome variables were measured through a 10-minute survey that was hosted on the Qualtrics website (Qualtrics International Inc) [23]. The questions were written for a seventh-grade reading level and were pilot-tested before this study.

Baseline Facebook Usage

The first set of questions captured participants' baseline Facebook usage. Following studies that linked Facebook use to mental health, participants estimated the daily number of hours that they spent on Facebook over the past week [24].

To provide a context for these metrics, participants also reported how frequently they engaged in the following nine Facebook activities: reading their news feed, posting status updates, posting photos, posting original content, browsing friends'

timelines, viewing friends' photos, commenting on friends' posts, sharing friends' content, and using Facebook Messenger [24]. These were rated by using 7-point scales anchored with "never" and "more than once a day."

Awareness and Adoption of Facebook Well-being Features

Central to this study, participants also reported their awareness and adoption of the following six Facebook digital well-being tools: the *Unfollow*, *Snooze*, *Off-Facebook Activity*, *Your Time on Facebook*, *Set Daily Reminders*, and *Notification Settings* features.

First, participants were shown screenshots of each feature and reported whether they had heard of the features ("yes" or "no"). If participants responded "yes," they were then asked if they had used the features ("yes" or "no"). For features that were designed for repeated use (*Unfollow*, *Snooze*, *Off-Facebook Activity*, and *Your Time on Facebook*), participants reported how frequently they used each feature (using a 5-point scale anchored with "never" and "daily").

Demographics

As the final category of predictors, participants reported their age, gender, race, religion, marital status, education level, employment status, family income, household size, and living setting.

Outcome Measures

As an assay of mental health, participants completed the 21-item Depression, Anxiety, and Stress Scale (DASS-21) [25]. The DASS-21 has been well validated and widely used, consisting of 7 items for each of the following subscales: depression (eg, "I couldn't seem to experience any positive feelings at all" and "I found it difficult to work up the initiative to do things"; Cronbach $\alpha=.87$), anxiety (eg, "I was aware of dryness of my mouth" and "I felt I was close to panic"; Cronbach $\alpha=.89$), and stress (eg, "I found it hard to wind down" and "I tended to over-react to situations"; Cronbach $\alpha=.89$). Each item was rated on a 4-point scale (ranging from "0: did not apply to me at all" to "3: applied to me very much or most of the time"), and scores were summed and multiplied by 2.

Statistical Analysis

As part of data cleaning, we first verified that participants had read the questions through two verification items that asked participants to check boxes as instructed (modeled after the widely used CAPTCHA technique on the internet) [26]. Of the 608 participants, 10 (1.6%) failed the verification and were removed from the data set, resulting in a final sample of 598

participants. We then summarized participants' baseline characteristics by using medians (with IQRs) and counts (with percentages). For count data, error margins for the 95% CIs of proportions were computed by using the *prop.test* function in R (R Foundation for Statistical Computing).

As the primary analyses, we ran a series of linear regression models, using each DASS-21 subscale score (depression, anxiety, and stress) as an outcome measure. In the first model, we sought to replicate the oft-reported link between one's duration of Facebook use and poorer mental health [8]. To this end, we entered the number of hours that participants spent using Facebook as a predictor. As the visual inspection of the data revealed a right-skewed distribution, this variable was log-transformed to achieve linearity (model 1).

In the second model, we addressed this study's primary aim—examining whether the adoption of Facebook's well-being features predicted better mental health (having controlled for the duration of Facebook use). Correspondingly, model 1 was repeated with 6 additional predictors that coded for the use of each feature (*Unfollow*, *Snooze*, *Off-Facebook Activity*, *Your Time on Facebook*, *Set Daily Reminders*, and *Notification Settings*; model 2). For each predictor, nonusage was coded as "0" and usage was coded as "1."

Finally, we assessed the robustness of our findings by repeating model 2 with the inclusion of demographic variables (age, gender, race, religion, marital status, education, employment, family income, household size, and living setting; model 3).

Across the models, the type 1 decision-wise error rate was controlled at an level of .05, with adequate statistical power (0.80) for detecting small effect sizes ($f^2=.05$). All statistical analyses were carried out on SPSS 27 (IBM Corporation) and R version 4.0.3 (R Foundation for Statistical Computing).

Results

Participant Characteristics and Baseline Facebook Usage

Of the 598 participants, 309 (51.6%) were aged <35 years, and slightly over half of the participants (360/598, 60.2%) self-identified as men (Table 1). In terms of baseline Facebook usage, participants reported using the platform for a median of 3 (IQR 1-7) hours each day in the preceding week. Further, 289 (48.3%, 95% CI 44.3%-52.3%) participants accessed Facebook multiple times a day, while 130 (21.7%, 95% CI 18.4%-25%) logged in once a day (Table 1). On Facebook, participants were most likely to view a friend's photos or to read the news feed (Figure 1).

Figure 1. For each of the nine Facebook activities, participants rated whether they used it (1) multiple times a day, (2) once a day, (3) 4 to 6 times a week, (4) once a week, (5) every 2 weeks, (6) once a month, or (7) never. Each horizontal bar indicates the percentage of participants who chose each option.

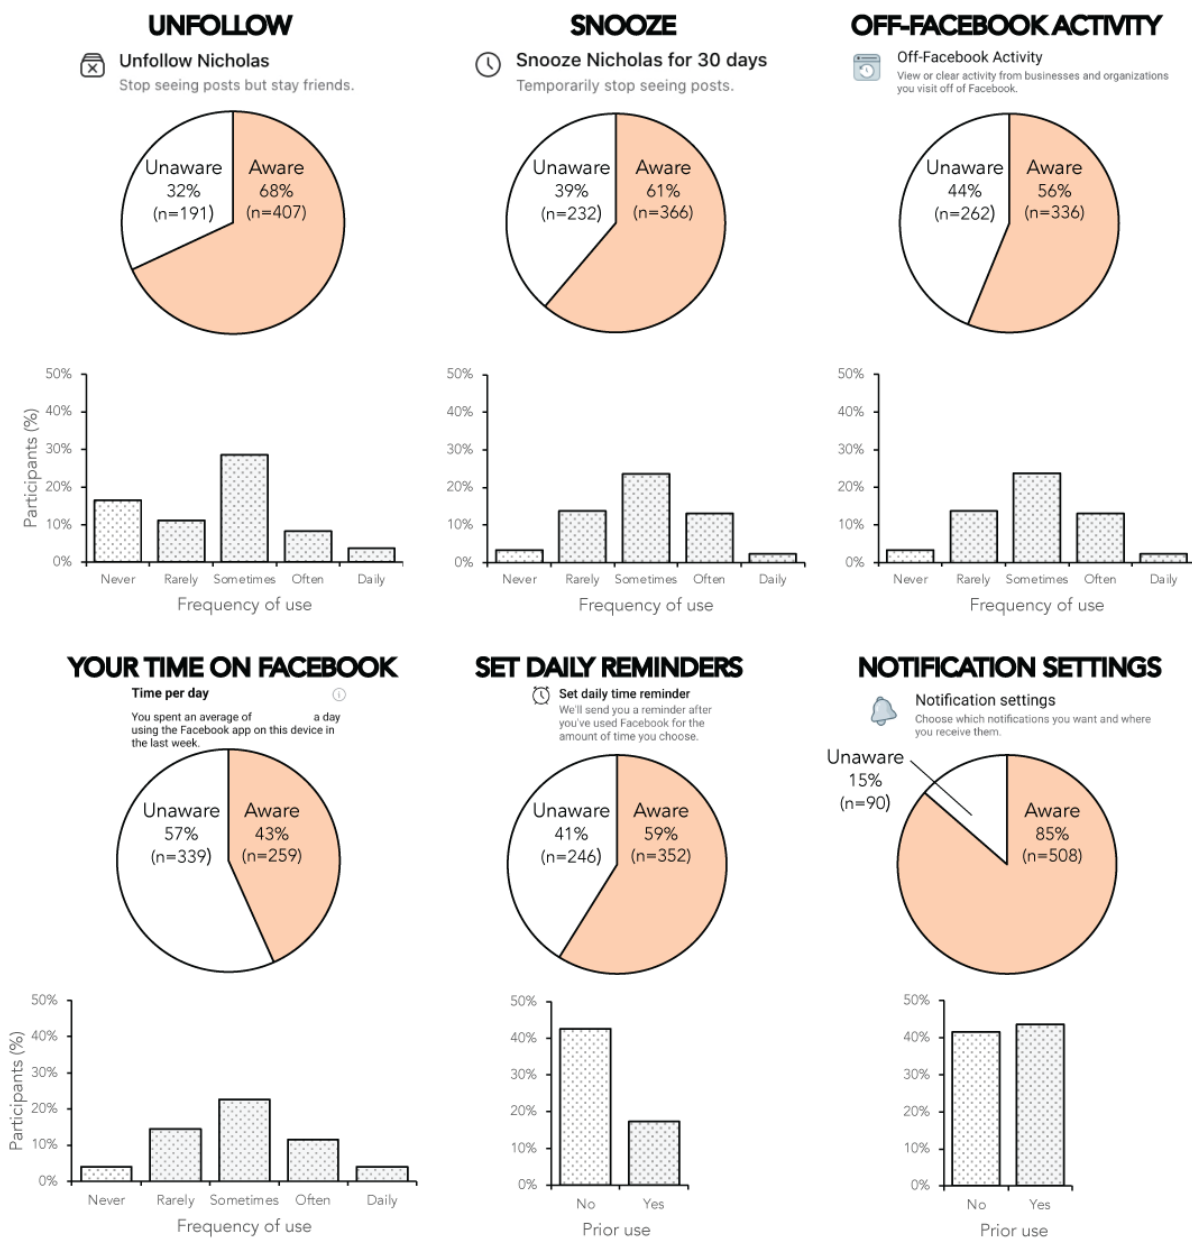

Awareness and Use of Facebook Well-being Features

Of the 598 participants, 580 (97%, 95% CI 95.6%-98.4%) were aware of at least one of Facebook's well-being features (Figure 2). However, awareness levels differed across features. For example, while 508 (85%, 95% CI 82.1%-87.9%) had heard of the *Notification Settings* feature, only 259 (43.3%, 95% CI 39.7%-47.3%) of participants knew about the *Your Time on Facebook* feature.

In terms of usage, of the 598 participants, 332 (55.5%, 95% CI 51.5%-59.5%) had used the *Snooze* feature, 316 (52.8%, 95%

CI 48.7%-56.7%) had used the *Off-Facebook Activity Tracker* feature, 315 (52.7%, 95% CI 48.6%-56.6%) had used the *Your Time on Facebook* feature, and 309 (51.7%, 95% CI 47.7%-55.7%) had used the *Unfollow* feature. Less than half had adjusted *Notification Settings* (n=260, 43.5%, 95% CI 39.5%-47.5%), and fewer still had used the *Set Time Reminder* feature (n=104, 17.4%, 95% CI 14.4%-20.4%). Where the repeated use of features was possible, participants were most likely to report using them "sometimes" on an ad hoc basis rather than on a routine basis (based on the median ratings for *Snooze*, *Off-Facebook Activity*, *Your Time on Facebook*, and *Unfollow*; Figure 2).

Figure 2. Participants indicated their awareness and usage of Facebook’s in-app digital well-being tools (*Unfollow*, *Snooze*, *Off-Facebook Activity*, *Your Time on Facebook*, *Set Daily Reminders*, and *Notification Settings*).

Use of Facebook Well-being Features and Psychological Symptoms

For the primary research question, we sought to predict participants’ depression, anxiety, and stress scores as a function of whether they used Facebook’s well-being features.

Depression

In terms of depression, we first replicated the well-documented association between Facebook usage and depression symptoms; namely, the more time that participants spent using Facebook, the higher their depression scores (model 1: $\beta=2.754$; $P<.001$; model 2: $\beta=1.357$; $P<.001$; model 3: $\beta=1.586$; $P<.001$; Table 2).

Factoring whether participants used Facebook’s well-being features increased the amount of variance in depression scores accounted for, from 8.7% (model 1) to 29.1% (model 2). Although the use of the *Notification Settings* feature ($\beta=-1.579$; $P=.003$) and the *Unfollow* button ($\beta=-1.319$; $P=.02$) was associated with lower depression scores, the use of the *Off-Facebook Activity* feature ($\beta=4.905$; $P<.001$) and the *Snooze* function ($\beta=2.337$; $P<.001$) was associated with higher depression scores. There was no significant association between depression scores and participants’ use of either the *Your Time on Facebook* feature or the *Set Time Reminder* feature (smallest $P=.48$).

Each of these findings was robust, and they persisted even when demographic variables were controlled for in model 3.

Table 2. Predicting depression symptoms as a function of Facebook usage patterns.

^eSignificant at the $P<.01$ level.

^fSignificant at the $P<.05$ level.

Anxiety

As with depression symptoms, the duration of Facebook use predicted increased anxiety scores (model 1: $\beta=4.331$; $P<.001$;

model 2: $\beta=2.270$; $P<.001$; model 3: $\beta=2.1846$; $P<.001$; [Table 3](#)).

Again, the inclusion of variables that coded for participants' use of Facebook's well-being features increased the amount of variance accounted for, from 13.8% in model 1 to 40.3% in

model 2. Namely, while the use of the *Notification Shortcut Bar* ($\beta=-2.387$; $P<.001$) and *Unfollow* functions ($\beta=-1.603$; $P=.02$) emerged as protective factors, the use of the *Off-Facebook Activity* ($\beta=6.760$, $P<.001$) and *Snooze* functions ($\beta=3.134$; $P<.001$) predicted higher anxiety. We found no

evidence that anxiety scores were linked to the use of either the *Your Time on Facebook* feature or the *Set Time Reminder* feature (smallest $P=.07$). Each of these findings persisted when we controlled for demographic variables in model 3.

Table 3. Predicting anxiety symptoms as a function of Facebook usage patterns.

When we added participants' use of Facebook features as predictors, the amount of variance accounted for increased from

8.3% (model 1) to 29.9% (model 2). Once again, we found that participants who used the *Notification Shortcut Bar* function

($\beta=-2.980$; $P<.001$) and *Unfollow* button ($\beta=-1.731$; $P=.03$) had lower stress scores, but those who used the *Off-Facebook Activity* feature ($\beta=7.124$; $P<.001$) and the *Snooze* button ($\beta=2.845$; $P=.002$) had higher stress scores. These associations remained significant in model 3, for which demographic variables were controlled. Across both models 2 and 3, there were no significant associations between stress scores and the use of either the *Your Time on Facebook* feature or the *Set Time Reminder* feature (smallest $P=.13$).

Sensitivity Analyses

For our sensitivity analyses, we (1) repeated models 2 and 3 without factoring participants' duration of Facebook use and (2) reran model 3, with *age group* entered as an ordinal variable (using the following age categories: 21-25, 26-35, 36-45, 46-55, ≥ 56 years). As shown in Tables S1-S3 in [Multimedia Appendix 1](#) and Tables S1-S3 in [Multimedia Appendix 2](#), the key findings pertaining to Facebook's digital well-being tools did not change.

Discussion

Principal Findings

In this paper, we present the first empirical study to evaluate Facebook's digital well-being tools. First, echoing prior studies [8], we found that participants who spent more time on Facebook had more symptoms of depression, anxiety, and stress. Accounting for Facebook consumption alone explained one-tenth of the variance (range 8%-13%) in participants' well-being. Consequently, we examined (1) whether participants used the platform's digital well-being tools and (2) whether usage was associated with better mental health.

Although most participants (580/598, 97%) knew about Facebook's well-being tools, each tool was used by only 17.4% (104/598) to 55.5% (332/598) of participants largely on an ad hoc basis. These adoption rates are lower than those of mainstream Facebook features that were introduced much earlier to the platform. For example, an estimated 4 in 5 Facebook users have deployed the *Unfriend* feature to remove contacts [27], while 3 in 4 have used the *Untag* feature to remove their name from a photograph [28].

Participants who used either the *Notification Settings* feature or the *Unfollow* tools reported fewer symptoms of depression, anxiety, and stress. Conversely, those who used either the *Snooze* feature or the *Off-Facebook Activity* feature had higher scores on each of these measures. Finally, there was no evidence that the *Your Time on Facebook* feature or the *Set Daily Reminders* feature was associated with well-being. This set of findings was robust and was observed regardless of whether we controlled for participants' duration of Facebook use or their sociodemographic factors.

Taken together, our findings underscore the complexity of designing social media platforms to optimize user welfare. Of the 6 digital well-being tools we examined, only 2 were associated with a decreased risk for mental health symptoms—(1) a feature for toning down the amount of content that is brought to a user's attention (*Notification Shortcut Bar* function) and (2) a feature that allows users to customize their news feeds (*Unfollow* feature), which, in theory, minimizes the

amount of social comparisons made on the platform. Nonetheless, it remains unclear why two other features that supported the customization of news feeds (*Snooze* and *Off-Facebook Activity*) predicted a higher risk for mental health symptoms. Further research is thus needed to understand these patterns.

It is noteworthy that we found no significant associations between the use of time-monitoring features (*Your Time on Facebook* and *Set Daily Reminders*) and well-being. This finding is counterintuitive because the time spent on Facebook has been linked repeatedly to poorer mental health outcomes (including in this study) [8]. Consequently, most social media developers have incorporated time-monitoring features into their digital well-being programs, allowing users to track how much time they have spent on a platform or set limits on usage (eg, on YouTube, Instagram, Facebook, and TikTok) [13,16,29]. Nonetheless, we found no empirical support for this widely used strategy, consistent with "digital detox" studies reporting that interventions for curbing social media use have a limited impact on mood and well-being [30].

Implications

Moving forward, our study has several implications for research and practice. First, it appears that the current well-being measures taken by social media platforms may be insufficient. This begs the question of how digital well-being tools should be designed to maximize users' benefits. Despite widespread calls for app developers to prioritize their users, there remains limited empirical data for guiding platforms in carrying out this mandate. We thus urge researchers to address this gap, thereby allowing for an evidence-based toolkit of in-app well-being features to be developed.

Limitations

In reporting our findings, we noted several limitations of our study. First, we chose the design of an epidemiological survey [31,32]. In a new area of research, this allowed us to (1) document baseline adoption rates for digital well-being tools and (2) examine multiple tools at the same time. Nonetheless, correlation does not equate to causation, and our findings need to be followed up with randomized controlled trials. Second, we recruited participants within the general population of internet users; the participant demographics were comparable to that of US Facebook users [33]. Nonetheless, it is possible that stronger effects would be observed in vulnerable groups, such as among individuals with problematic forms of Facebook usage [34] or among adolescents. Further research should thus explore this possibility. Finally, we focused on Facebook because of its widespread popularity. It is currently unclear whether our findings would generalize to other social networking services (eg, Instagram).

Conclusion

In the 2022 State of the Union Address, President Joe Biden called for social media platforms to be held accountable and for companies to pursue users' benefits over profits [35]. Amid these petitions, there is a need to understand how social media platforms can be designed to optimize users' well-being. Accordingly, our study provides the first line of evidence that

two digital well-being features may be linked to improved mental health. At the same time, we also caution app developers that (1) not all well-being features are alike and (2) certain features could backfire. Moving forward, we urge further research to develop and carefully investigate the impact of digital well-being tools on social media.

Abstract

Background: Black college-aged men are less likely than their peers to use formal, therapeutic in-person services for mental health concerns. As the use of mobile technologies and social media platforms is steadily increasing, it is important to conduct work that examines the future utility of digital tools and technologies to improve access to and uptake of mental health services for Black men and Black men in college.

Objective: The aim of this study was to identify and understand college-attending Black men's needs and preferences for using digital health technologies and social media for stress and mental health symptom management.

Methods: Interviews were conducted with Black male students (N=11) from 2 racially diverse universities in the Midwestern United States. Participants were asked questions related to their current mental health needs and interest in using social media platforms and mobile-based apps for their mental health concerns. A thematic analysis was conducted.

Results: Four themes emerged from the data: current stress relief strategies, technology-based support needs and preferences (subthemes: mobile-based support and social media-based support), resource information dissemination considerations (subthemes: information-learning expectations and preferences and information-sharing preferences and behaviors), and technology-based mental health support design considerations (subtheme: relatability and representation). Participants were interested in using social media and digital technologies for their mental health concerns and needs, for example, phone notifications and visual-based mental health advertisements that promote awareness. Relatability in the context of representation was emphasized as a key factor for participants interested in using digital mental health tools. Examples of methods for increasing relatability included having tools disseminated by minority-serving organizations and including components explicitly portraying Black men engaging in mental health support strategies. The men also discussed wanting to receive recommendations for stress relief that have been proven successful, particularly for Black men.

Conclusions: The findings from this study provide insights into design and dissemination considerations for future work geared toward developing mental health messaging and digital interventions for young Black men.

Introduction

Background

Mental health has become an increasingly prevalent issue on college campuses. In 2019, the American College Health Association released a survey with data from 67,972 college students from 98 institutions, including public, private, and 2- and 4-year institutions, within the United States [1]. In this survey, 60% of the students reported “overwhelming anxiety,” and 40% had difficulty functioning because of their depressive symptoms [1]. The mental health needs of college students have only increased during the COVID-19 pandemic [2,3]. During the pandemic, anxiety among college students increased by a factor of almost 7 [4], and there have been significant increases in clinically reported depression and anxiety symptoms among young individuals [5]. These increasing trends and risks of poor mental health have put growing strain on current systems of intervention such as face-to-face campus counseling centers [6,7].

Research shows that minorities and, more specifically, Black students bear a larger psychological burden because of extraneous stressors [8,9]. Specifically, among Black male students, the risk of experiencing poor mental health is increasing, resulting from overexposure to social and economic disparities rooted in race and racism [10-12] and compounded by stressors associated with college life [13,14]. However, Black male students seek and use mental health services at lower rates compared with their peers [15] and have been less likely to seek face-to-face therapy or counseling [15-17] for mental health concerns. From the current mental health literature, we see that this underuse of services is often due to discomfort and lack of trust as well as other attitudinal factors influenced by racial discrimination [17], medical mistrust [18], and stigma [19]. Despite efforts to attenuate such factors and improve mental health outcomes among minority populations [20], existing mental health resources such as campus counseling centers and services are chronically underused by minority students [21-25].

The current burden on health care systems and the continued underuse of formal services among minority students necessitate creative intervention strategies in digital mental health that are practical and user-oriented [26]. It is imperative that we find other avenues to address the unique mental health challenges currently facing college-aged Black men and to improve uptake and access to mental health support services [27,28]. Digital mental health programs may be an optimal way to engage Black men as they can be informal in nature and widely accessible [29]. Digital health equity research demonstrates that digital tools and mental health programs are effective in decreasing mental health issues and increasing access to services among minority populations [30]. However, many digital tools and health programs lack relevance to Black men and do not attenuate the social and attitudinal factors affecting young Black men’s engagement, use, and uptake of digital mental health resources [31] or their barriers to help seeking [24,32,33]. An approach to attenuating these factors and improving relevancy is to focus on understanding Black men’s current mental health

needs and examine their use of digital tools such as social media and mobile technologies.

Social media and mobile technology use has increased significantly in the last few years [34], especially among young adults with mental illnesses [35]. Among young adults aged 18 to 25 years, 96% own a smartphone [36], and an overwhelming majority of those aged 18 to 29 years (84%) consistently use social media platforms [29]. More than 65% of Black American adults use social media platforms on a daily basis [29]. Social media provides a potential platform to address the increasing mental health needs of students in higher education in a way that is user-friendly, accessible, and convenient [35]. Social media is increasingly used as a stress-coping or mood management tool [37], indicating its potential as a support structure to reduce the effects of stress, provide social support, and encourage well-being among users [38-40]. Despite the high use of social media platforms and their increasing popularity among Black young adults [34,41,42], there is little research assessing the acceptability and effectiveness of social media in mental health promotion and prevention among young Black men. This is a missed opportunity as social media tools may be especially effective for disseminating novel health resources [43,44] and have been the leading medium for communication and dissemination of information during the pandemic [45].

Digital mental health programs should aim to use tools that are relevant to Black men and are already being used by Black men and to understand the feasibility and acceptability of such tools in mental health promotion. Recent studies have found that most (85%) social media users expressed interest in using social media to access programs for well-being to cope with their mental health symptoms [46]. This body of evidence suggests a high potential for digital and social media-based interventions to begin to bridge the gaps in mental health care. Moreover, our lack of understanding of the factors that affect Black men’s uptake and engagement with current digital health interventions and tools is a critical barrier to expanding mental health services and achieving mental health equity. Digital mental health programs would also need to include culturally sensitive components, center the experiences of men, and use components that are created with Black men’s needs and interests in mind [47-49]. The relevance of such programs and the development of culturally appropriate components can be learned from Black men if researchers create opportunities for Black men to engage with them in the research and design processes [48,50].

This Study

This qualitative study was exploratory and aimed to identify college-aged Black men’s needs and preferences for using social media and mobile-based technologies to manage their stress and mental health symptoms. The specific aims were 3-fold: (1) to determine Black male college students’ current mental health challenges and strategies for stress relief, (2) to identify ways in which social media and mobile-based technologies can support their mental health needs and stress relief strategies, and (3) to identify digital health app features and social media platform features that are suitable for Black male college students who wish to manage their symptoms and seek help via

nontraditional methods. The results will point to considerations for designing and developing social media–based mental health interventions that are tailored to Black male college students' needs.

Methods

Overview of IntelliCare for College Students

This study was designed as a supplement to a larger study [51] focused on the dissemination and implementation of the mental health app IntelliCare for College Students. This app was adapted for college students from the IntelliCare platform, a self-guided mental health app [52] providing users with interactive apps, cognitive skills, behavioral strategies, and knowledge focused on depression and anxiety. Recent studies have shown significant improvements in anxiety and depression outcomes among IntelliCare users from various settings [51-53]. IntelliCare for College Students was implemented on the campuses of 2 racially diverse Midwestern universities. Preliminary findings from the larger study showed that Black male students were neither enrolling nor downloading this app despite it being free and accessible. Thus, this study was designed to investigate the potential reasons for low enrollment, identify mental health needs, and determine preferences for technology-based mental health and wellness resources among Black male students.

Recruitment

Participants were recruited from 2 universities. The first author (KDAW) sent direct emails and flyers to relevant student organizations serving the general students, organizations serving Black and diverse students (eg, Black student associations and Greek organizations), and counseling centers on these campuses. Word of mouth and web-based advertisements via social media were also used to recruit participants. Eligible participants could not have engaged with the app that is a part of the larger study and had to self-identify as Black or African American men, be between the ages of 18 and 35 years, be enrolled as undergraduate or graduate students at one of the participating universities, and have access to a computer or mobile device with a Wi-Fi connection. Emails and recruitment materials included information about the study and contact information for research staff whom students could contact if interested in participating. For students who responded and were interested, a link was provided in a follow-up email to gather their consent and conduct eligibility screening through REDCap (Research Electronic Data Capture; Vanderbilt University), a secure web-based survey instrument. After a student was screened as eligible for the study and completed a web-based consent form, an interview session was scheduled.

Study Procedure

Sessions were conducted by KDAW on a university-secured Zoom (Zoom Video Communications) account, and participants were given the option to have their video on or off for the interview. Participants were interviewed for 30 to 60 minutes using a semistructured interview guide to prompt an open-ended discussion related to the study goals and objectives. The

interview guide was developed by KDAW in consultation with the senior author (EGL) combined with feedback received from research team members. The interviews focused on understanding the men's mental health needs and ways in which social media and mobile-based apps could support their stress management strategies. Discussions also centered on the perceived acceptability of using social media and mobile-based platforms for mental health support and concerns. Sample interview questions included "Are you interested in using social media/mobile apps for stress management or for self-care?" and "What would make you interested or disinterested in using social media or mobile apps for stress management for self-care?" Prompt questions were asked for clarification purposes and as an aid to help students reflect on their own lived experiences as Black male students. The interviews were audio-recorded. After the interviews, participants were compensated for their time with a US \$20 Amazon gift card.

Data Analysis

Qualitative data were transcribed verbatim from the audio recordings by a professional transcription service. The transcripts were analyzed by 2 coders, who were both research assistants with training in qualitative analysis and worked under the supervision of KDAW. The coders used an inductive thematic analysis approach aligned with the methods described by Braun and Clarke [54]. First, an initial reading and open coding of each transcript was conducted for the coders to become familiar with the transcripts and data. The initial codes were grouped according to the study aims. KDAW and the 2 coders then developed a detailed codebook, which included the code name, the definition of each code, and illustrative examples such as quotations. The 2 coders independently analyzed the data using a web-based research app (Dedoose; SocioCultural Research Consultants) and met to compare, critique, and refine the coding process and discuss and resolve any disagreements. Finally, the coders, along with KDAW, derived salient themes from the data related to the study aims.

Ethical Considerations

Before the interviews, all participants were informed of the study and the study's purpose through recruitment emails during the screening for eligibility process and at the start of the interview sessions. Consent was gathered from all participants before their interview session. Participants were informed that the data collected for these interviews would only be used for research purposes and manuscript preparation. Importantly, all study procedures were approved (STU00205589) by the appropriate Institutional Review Board offices at the relevant institutions in which the study was conducted and from which the participants were recruited.

Results

Sample

A total of 11 men (n=4, 36% undergraduate and n=7, 64% graduate students) consented and completed the interview sessions. Their ages ranged from 18 to 35 (mean 26.90, SD 7.11) years. Table 1 shows the sample characteristics.

Themes

Overview

Four major themes emerged from the data: (1) current stress relief strategies, (2) technology-based support needs and

preferences, (3) resource information dissemination considerations, and (4) technology-based mental health support design considerations. [Table 2](#) presents a summary of the primary themes and subthemes, which are described in detail in the following sections.

Table 2. Brief summary of the themes.

Number	Primary theme	Subthemes
1	Current stress relief strategies	<ul style="list-style-type: none"> • ___^a
2	Technology-based support needs and preferences	<ul style="list-style-type: none"> • Mobile-based support • Social media-based support
3	Resource information dissemination considerations	<ul style="list-style-type: none"> • Information-learning expectations and preferences • Information-sharing preferences and behaviors
4	Technology-based mental health support design considerations	<ul style="list-style-type: none"> • Relatability and representation

^aThere was no subtheme for the primary theme listed.

Theme 1: Current Stress Relief Strategies

The men reflected on their established stress management activities. In general, participants cited the importance of creating dedicated time for self-care. A participant described this as “disconnecting from work, or school, and just taking time to take care of my mental health” as a strategy for dealing with their stress. In terms of specific activities for stress management, common ways of managing stress were either technology-enabled, such as watching YouTube videos, or nontechnology-enabled, such as going for a walk. Several men talked about how listening to music or watching funny videos on their computers or on television helped them relieve stress. For example, a participant described watching videos to boost his mood:

I believe part of the strategy to actually boost your mental wellness is to be happy from inside, to have this kind of joy. That’s why I kept on mentioning funny

videos because when you laugh, of course, you know that it’s part of mental wellness as well. You laugh, you just forget about some worries and some stress that might be holding you down.

Another student went into detail about specific television shows that provide stress relief:

I mean, TV does that in general, but Insecure specifically just takes me out of my problems of the day and the stress of the day, and I can just focus in on what’s happening. Just how engaging it is.

Multiple men discussed how they would go for walks, work out, and go to the gym to relieve their stress and see friends. A participant strongly emphasized the social component of seeing friends as a means of stress relief:

For me, I normally go to friends. Even if you’re required to drive, I go and then have some nice times with them and feel good before coming back.

Multiple men mentioned Calm, a meditation app, as a way in which they were currently relieving their stress. The men used Calm to meditate and as a resource to get their mind off stressors, such as schoolwork, or right before engaging in something stressful, such as work responsibilities. Some students mentioned appreciating having the time to sit, relax, and be still:

[It] just allows me to recalibrate myself and not get so stressed out and focus on sitting and thinking really deeply about how you're feeling and what you're going through.

Some men discussed already engaging with social media to disconnect from their current environments or seek positive interactions. For example, a participant reported using social media platforms to look for motivational quotes and wanting to obtain encouragement from positive words on social media platforms.

Theme 2: Technology-Based Support Needs and Preferences

There was discussion about how mobile-based apps and social media could support the men's current stress relief and management practices. The men were primarily interested in using social media and mobile-based apps for mental health support and stress management if social media and apps could connect them with resources, provide words of affirmation and encouragement, and provide stress relief recommendations.

Mobile App-Based Support

Students mentioned several areas in which mobile-based apps could support their mental health, including promoting physical activity or exercise, providing them with a space to watch television and movies (and offering suggestions), providing reminders to engage in activities that relieve stress, and helping them maintain a routine. Help with maintaining a routine, particularly through notifications, was a commonly discussed support preference. Regarding notifications, the men wanted to be reminded or encouraged to engage in stress relief activities or activities that allowed them to take care of themselves. A participant described how he could envision notifications being useful:

Maybe have the app say, "What do you wanna do to help you feel better? What do you think you can do to mitigate your problems?" and say, "Well, hey, I like to ride bikes." So, maybe have it set to say, "Hey, it's Saturday," or whatever. "Don't forget that you wanted to ride your bike," or do whatever you wanna do. For me, it's really I need an app that has a feature to remind me. I know you have life going on, but don't forget about this that you put time and effort into thinking about. So, honestly, notifications to help keep you on track is kind of the best way for an app to get you back on track.

Another participant mentioned that notifications could be important and help with their goal setting:

Not only ask you how you're doing—I think with a freeform answer, that would be hard, but preset things so that it could use that information to act upon it or

give you some kind of notification, but also to set up a goals, like what do you wanna accomplish this week or this month. And let's say somebody like me who's busy but on the weekends.

The men also discussed wanting mobile apps to be synced with their calendar and notify them of time and space to take to mediate or debrief from their day. Students described wanting apps to notify them with inspirational quotes, videos, or something funny that encouraged them to do something positive and have positive thoughts. A participant was particularly interested in being sent messages about positivity and "stress relieving quotes."

Another topic that emerged was how apps could provide some of the benefits of social media without the known detriments of existing social media tools to mental health. A student explained their views on how a mental health app could be a form of "healthy social media":

I think an app can work as a piece for healthy social media because social media, in general, can be very draining. So, whether it's just sharing ideas with people, or having a platform to where it's kinda like, the resource for different activities, like mindfulness activities, and self-reflect activities, or actualization activities, or introspection. So, I think stuff like that, and just have little activities and a way to where you can communicate with people outside of just the craziness that's going on. That way you can have a platform where you can like, ah, feel good today. Then I go to this, and I might just do a cool crossword puzzle or something, and then I feel better. You know?

Social Media-Based Support

The men were asked about the types of mental health support they would want or expect to see on social media. Participants discussed wanting to see visual examples of people dealing with stress as a means for them to learn to deal with their own stress. A man discussed a desire to see the following:

...other people's experiences on how they manage their stress, examples, more tutorial on the different kinds of stress and how to manage them. If there's daily tweets or daily comments one could register for that would help one to manage stress each day, I think that would go a long way.

Furthermore, several participants described how social media platforms could provide knowledge about symptoms and offer helpful strategies for dealing with symptoms while helping reduce stigma around mental health among Black men. A participant stated the following:

Honestly, I think just talking about it because even as you say symptoms, I really don't know all of the symptoms. So, a platform actually talking about mental health within the Black community. And even—well, mental health within the Black male community is too because that could definitely be separated. I feel like that would be important to—just to start a discussion.

The latter sentiment speaks to mental health stigma and the common perceived notion that mental health is not discussed among Black men or within the Black community. A student went further to talk about the importance of addressing mental health stigma by increasing awareness:

A big part is awareness because a big part of social media is bringing awareness to a lot of the issues going on in today's society. So, well, there's like, "Hey, have you been struggling with mental health? Here's who to contact." Mental health is real; making sure like eliminating the stigma around it because a lot of people just don't talk about mental health, which isn't healthy.

As with mobile-based app support, the men reported wanting social media to provide positive affirmations as a support method. A participant mentioned how receiving positive affirmations helped them "feel better" and "feel more confident." Positive affirmations were also mentioned to create a supportive environment in which people could be vulnerable with each other. The men also discussed ways to promote mental health on social media, including partnering with established communities, organizations, or influencers. Specifically, a participant mentioned an Instagram feature, Instagram Live, that would be useful for promoting mental health via established entities. The student suggested having someone who could relate to Black men or a person who was knowledgeable of mental health and its etiology use Instagram Live to talk about mental health issues:

I've seen big or maybe it doesn't have to be a big psychologist or whatever but having someone talk about mental health. Everybody tunes in and have an honest conversation. And again, with my previous point where I mentioned not it just being a one-way street where you tell us all the statistics about stress within Black men, stress within Black women, stress within the Black [community]

This student continued to talk about how this may help with increasing awareness and starting conversations about mental health. The men also thought it would be helpful to partner with and use already established outlets on social media, for example, tapping into Instagram influencers who may be already focused on mental health needs and promoting mental health in communities or among students.

Theme 3: Resource Information Dissemination Considerations

Another major theme related to how the men might expect or want to hear about mental health resources and how they personally might share information related to mental health support or resources with peers.

Information-Learning Expectations and Preferences

One of the ways in which the men would expect to hear about mental health resources included their interest in attending conferences and seminars organized by their institutions and that aimed to inform students such as them about mental health support or programs. For example, a student mentioned interest in learning about mental health resources via new student

orientations or student orientations specifically related to them. Specifically, if they were a premedical or international student, then they would prefer to hear about such support via that specific orientation or organization. Similarly, other ways the men discussed of hearing about resources for mental health were through admissions offices. A student went further to suggest what these programs and offices could do to disseminate information about mental health resources:

Those are good places where if you had a little card deck or something like that or a flyer, because as people are registering or getting admitted into school, the stressors of life come into play there a lot, so I think those would be good places for outreach.

Other suggestions included the men wanting and expecting to hear about resources through the mental health offices or "self-care parts of campus" and from campus-oriented wellness teams. The men would also expect to learn about resources from organizations and email listservs specific to people of color and from programs related to "ethnicity or religion or gender." A participant recalled a particular outlet through which they typically received campus information to explain how they might expect and would like to receive mental health information:

...newsletters from our BGSA [Black Graduate Student Association]; they send out emails probably once a week regarding how to cope with schoolwork, like outside of class, and just things relating to people of color.

Another student mentioned a preference toward receiving mental health information from "niche little mailing lists like the BGSA; I pay attention to those as opposed to the student-wide ones."

Information-Sharing Preferences and Behaviors

Through the interviews, participants shared potential ways in which they would be interested in sharing information about the mental health resources they were using or knew of through word-of-mouth discussion (ie, in-person, casual conversations with their friends). Word of mouth involved students having "casual" conversations with their friends and mentioning the resources. If sharing information about resources by phone, students would text words such as "This is a great app. Everybody should go check it out" and send the associated mental health resource website or app link along with that SMS text message. Participants mentioned that they might feel compelled to share and suggest a useful resource with the intention of helping another friend who might be dealing with issues or "feeling down." They imagined that, if they were talking with their friends and realized that their friends felt down, they could take it as an opportunity to share the resource:

And also, just reaching out to friends, seeing how they're doing and if they feel that they need a resource, I feel like bringing this up with them and sharing with others the resources that I use could be helpful.

As an example of how one might share a resource with a friend, a participant indicated that they might say something to the effect of the following:

“Hey, I’ve been using this app that’s pretty cool. It manages stress.” So, I mean, a lot of people have been feeling stressed out lately, so I could recommend it to my friends just casually.

A few men mentioned that their willingness to share a resource depended on whether they themselves used it and were able to benefit from it. A participant stated that “there is a common saying that if you have used, and it has worked for you, then you’ll be ready to recommend it.” Another participant suggested that, if they used it and it worked, they’d be willing to share it through the following avenues:

...ads and also sharing [with] groups everywhere on Facebook, on Twitter, sharing those types of information; shar[ing] it with friends.

Although word of mouth was popular for sharing information, the men discussed preferences using social media to share information about mental health resources. Using platforms such as Instagram and Twitter was frequently mentioned. The men would “tweet about it.” Hypothetically, a student discussed how, if they were using a resource, they would post comments and image-based posts showing personal “experiences concerning [mental health]; that way people who see it in such similar conditions would be interested in it.” The men also talked about the popularity of social media in addressing social issues, explaining this notion as a reason they might expect to hear and share information pertaining to mental health resources on social media:

Instagram, Snapchat, more Instagram, just because I know a lot of my friends on Instagram post a lot about social issues, whether it’s mental health or other parts of our society that are important. But even Snapchat too, just because I know that’s a lot of platforms that people might use.

A participant explained that social media is useful for promotion and would expect the following:

...a lot of events and apps or anything like [mental health-related] is really through social media. Social media, everybody uses that to post whatever is going on.

A participant went further to offer the sentiment that “any type of media promotion is usually how people at school learn about anything that’s going on at this point.”

Theme 4: Technology-Based Mental Health Support Design Considerations

Overview

The final theme focused on the men’s visual- and text-based preferences regarding features for social media-based or mobile app-based mental health resources. A common preference was for visuals that were primarily image-based or had minimal wording:

Pictorial representation of the message you are passing across gets people’s attention [better] than the words...If I see a picture of someone laughing or something so fascinating, I might be tempted to just click on it.

The men also mentioned wanting to see a social media platform that included testimonials, voice notes, or podcasts portraying individuals who looked like them and who had dealt with mental health issues. In these images or testimonials, they also would want men to describe the strategies they had used to deal with stress. The men also cited the use of clear and concise language as another factor to consider when designing platforms or resources for mental health support. Students explained this preference in relation to Instagram captions. The men would like Instagram captions to be simple in nature and less wordy, making them more attractive and easier to digest. The men noted that simple language would also be useful in suggesting a resource or stress relief activity.

The men noted that they would be drawn to platforms that provided resources for broad mental health concerns rather than specific disorders. A participant described how, as not everyone would resonate with having a specific mental illness, being broader with mental health messaging should be a consideration:

Mental health as opposed to specific terms for mental disorders...might not relate to everyone: “Well, that doesn’t really pertain to me right now,” so it doesn’t grab my attention. But yeah, I think something that’s more open to the entire umbrella.

Relatability and Representation

Emerging from this theme were discussions of the men wanting advertisements of resources to be portrayed in a way that resonated with their lived experiences. Probing questions were asked to gain more insight. Some men were able to provide examples, suggesting that platforms should include components or images that “portray men who look like them and are using resources or an app/platform for their issues” or “relate to their everyday lives as students or iPhone/droid users.” The men also described a preference for seeing resources or advertisements that showed Black men and used specific wording:

[I’m] drawn to someone who looks like me. And the words “Black men”...so I feel like I would personally be drawn to that once I—if I saw it somewhere.

The men were interested in seeing platforms that used words and phrases that focused on mental health and the stigma surrounding mental health challenges. The men discussed the lack of existing resources focused on helping and supporting Black men’s needs as well as the dearth of resources focused on dismantling the stigma associated with Black men and mental health:

And I’m a Black man, and back home in my culture we consider stress as a form of weakness, and people who go through a lot of stress. So, if more effort can go into putting the word out that going through stress is a normal thing and there are ways one could manage it. At this age now, I want to just have an idea of what this stuff is all about, like managing stress.

Another participant discussed wanting resources to use specific words to address stigma and provide help without judgment:

And then, the “doesn’t judge” part I think is really important. A lot of people don’t reach out because they’re scared of what people might think, so making that clear that we’re not going to judge, we’re here to help. That is comforting.

For digital mental health resources to be used by Black men and to increase men’s engagement with such tools, the resources, programming, and prevention efforts need to include visual- or text-based components that are visually appealing to men’s lives and lived experiences. Importantly, mental health efforts for Black men’s needs should be relatable and include evidence-based components that have been successful in addressing Black men’s mental health needs.

Discussion

Principal Findings

Overview

This study examined Black male college students’ needs and preferences for using social media and mobile-based apps for their mental health symptoms, stress management, and self-care. This qualitative study stemmed from a larger study [51] aimed at examining the uptake of a mental health app on 2 university campuses. In line with previous research indicating that minority students underuse existing mental health resources [24,55], early data indicated that Black male students were not enrolling in the parent study or downloading the stress management app despite its wide availability. To help address this limitation of the parent study, our qualitative study tackled a critical topic in digital health equity research—specifically, understanding and identifying digital mental health support needs and preferences among Black male students [31].

Primary existing methods of stress reduction included engagement with physical activity (ie, working out), watching television or YouTube videos, and spending time with friends. In terms of support needs and preferences, major themes included a desire for stress relief recommendations and positive messages, the helpfulness of notification-based support, and support via social media. Regarding dissemination considerations, overall, we found that the underuse of mental health services by Black male students does not reflect a lack of interest, nor does it reflect their lack of interest in learning about or sharing resources. Design considerations highlighted a need for visual-based content delivery and greater representation in how resources are advertised.

Stress Relief

Our findings regarding physical activity as an existing means of stress relief align with established literature on stress relief and mental health coping among young Black men in college; for example, Goodwill et al [56] similarly found that Black male students relieved stress through exercise, sports, or hobbies. Extending previous literature, our interviews revealed that physical activity provided stress relief for Black men. Specifically, within this study, physical activity included taking walks as a key form of stress relief [56]. Various men discussed taking walks as a form of self-care, which is a sentiment not often highlighted in the current literature.

A form of self-care and stress relief was mentioned in relation to social support which, in mental health research, is a common social-ecological factor that protects against mental health risk [57]. The men discussed spending time with friends and engaging in activities that promoted social support as a form of self-care and relief that helped them cope with stress. This sentiment aligns with recent broader mental health research examining the need for social components in apps. In recent work, we see that social support and social connectedness via social networking sites are preferred, associated with lower levels of depression and anxiety [58], and associated with higher engagement with apps [59]. We also see that, in other areas broadly related to mental health research, app users are more motivated to use the app and change their behavior if there is a social support component [60,61]. For example, Gowarty et al [61] found that participants with serious mental illnesses would be more motivated to quit if a smoking cessation app included a social support component. Notably, there is ambiguity in the mental health literature regarding which types of social support serve as a buffer for mental health among Black men and which do not. For the men in our study, engagement with friends was the primary source of social support that relieved their stress, which aligns with certain studies [57,62,63] but contrasts with others that suggest that social support via significant others or romantic partners is a stronger protective factor [64,65]. The stronger emphasis on social support from friends than from romantic partners in our study may be due to our college-aged sample; however, more research is needed examining the preferred social support among Black male college students.

Another important insight from this study involved the ways in which Black male students were already harnessing technology to cope with stress, which still points to design considerations for future digital health interventions. Multiple men reported watching YouTube videos and using social media platforms to seek encouragement from motivational quotes. This finding aligns with existing knowledge about preferred social media platforms from publicly available reports. Entities such as the Pew Research Center indicate that YouTube is the most popular of the social media platforms [29,42], and our results suggest that this preference also holds true among Black men.

Support Needs and Preferences

The men provided valuable insights into factors that make mental health services more relevant and effective for them. A common theme was a desire for notifications and reminders. Persuasive system design suggests that the personalization of digital tools (eg, through notifications) can promote engagement [66], leading to greater symptom improvement [53]. In line with this, the men in our study suggested that personalized notifications would help them maintain a routine and that calendar integration would be especially effective in promoting the carving out of space to practice stress relief methods. At the same time, this type of personalization is likely useful for the broader population and not necessarily specific to Black men. Black male students also discussed ideas on how to support self-guided digital mental health tools. Although there is a rich literature on using human support (in the form of a coach or clinician) to increase engagement with digital mental health tools [67], participants in this study were not asked about the

potential role of a human supporter, nor did they independently identify human support alongside a digital mental health tool as a valued strategy [67,68].

Dissemination Considerations

The results of this study offer insights into Black male students' preferences and needs in relation to learning about mental health resources. A finding from this study is the potential role of minority-focused or Black-focused campus-based organizations in disseminating mental health information to increase access to care for college-aged Black men. The men consistently mentioned wanting to learn about mental health support from campus-based organizations, particularly those specifically geared toward students such as them and that matched to their race or gender. This finding is consistent with literature suggesting that people from underserved populations are more receptive to information or resources delivered by people of a similar background, which promotes confidence and trust [69]. Notably, the results present a connection between dissemination preferences and potential ways to increase men's engagement with mental health support. Overall, the men in this study were interested in mental health services but, without evidence of the services being effective, they were less likely to engage. The men expanded on this further, stating how they would be more likely to share information about a mental health resource if it *works* and, importantly, if it *works* for Black men. This finding speaks to the role of evidence-based mental health services and peer dissemination practices in promoting engagement with mental health support among Black male students and further promoting receptivity and believability. This consideration would be important to incorporate, aiding in the likelihood of mitigating factors related to stigma and medical mistrust [18,19] and improving young Black men's access to and uptake of digital mental health support [27,28] down the road.

Previous research also underscores the importance of social media in disseminating political information for Black Americans [42] as well as for mental health promotion. The men discussed how they might be more open to specific social media platforms that promote mental health specific to college-aged Black men who are dealing with the same issues and concerns. Watkins et al [70] tested a Facebook-based intervention with content related to mental health education and support specifically for Black men. Qualitative analysis indicated that the men who engaged with this intervention had increased awareness not only of their own mental health and needs but also of the mental health needs of other Black men [70]. Our results similarly suggest that social media can be an acceptable tool for health promotion. The men in our study also discussed that they would willingly use social media to share mental health-related information with friends and peers, stating that social media would be an effective way of reaching them and their friends. The men indicated that they were already accustomed to receiving information about other health and social issues via social media, as were their friends. However, it is important to note that social media comes with limitations, namely, potentially misleading and inaccurate mental health resources and information, lack of mental health literacy, and the triggering of negative behavior [71]. Given the prevalence of social media use as a part of informal help seeking, future

investigations should examine how to consider the quality and accuracy of mental health information and resources on social media and other web-based platforms for this population.

Nonetheless, future work should examine how best to promote mental health via social media outlets such as Instagram, Snapchat, YouTube, and Twitter. Previous qualitative research suggests that the dissemination of health information via social media can be achieved using various strategies, including contests, interactive campaigns (eg, with educational polls), and community building [72]. At the same time, it will be important for future studies to address the challenge of using social media as a platform for health promotion while reducing the risk of misinformation.

Design Considerations

Overview

A key finding regarding design considerations involved the role of social modeling in health promotion. Behavior change research suggests that the modeling of a behavior leads to optimal behavior change outcomes [73,74]. In this study, Black male students indicated that they would be more likely to engage with a resource on a mobile-based app or social media platform if it offered testimonials portraying positive mental health. This sentiment, indeed, speaks to the need for relatable and representative content in mental health app research.

Relatability and Representation

Although it was difficult for the men to explain what they meant by relatability, they primarily related this concept to representation. The men wanted to see themselves, see advertisements and resources made for them and that include images or message components related to their lives—as students, as Black men, and as emerging adults in college. The men discussed that seeing themselves in advertisements or components would make the resources more relatable. This design consideration aligns with the need for targeted design efforts in mental health research, which can diverge from research focused on inclusive design among other minority populations [75]. In our study, this preference for representative components and relatable content aligns more with targeted design in which these men prefer visual representations that are made for them and reflect Black men's mental health needs. Importantly, the men also discussed that this preference stems from the observations that they do not see their lives, experiences, or needs reflected in current available resources and prevention efforts; therefore, their desire and comfort level to engage is limited. There is little research targeted to men from Black populations [76], which perpetuates disparities that further increase the risk of poor mental health and low treatment use among Black male students [77]. This gap also makes it difficult for researchers to develop mental health support that is effective in drawing Black male students in and engaging them in prevention efforts.

With targeted and tailored design approaches, specifically those that are culturally sensitive and appropriate, Black male students would be more likely to engage and resources would be better able to meet their needs [27]. This study focuses specifically on Black male students' needs, creating a space for them to

share those desires and needs, which will provide insights for designing targeted efforts that are visual, text-based, and reflective of the mental health experiences of Black men generally and in college settings. Thus, it will be important for campus-based practitioners and researchers to examine ways to tailor advertisements and intervention components specifically to Black men's lived experiences. The current lack of representation in mental health research may prevent researchers and clinicians from accurately recognizing mental health difficulties at initial onset among Black men and understanding how mental health difficulties may present within the context of a college campus [78].

Stigma

This study provides insight into appropriate visual- and text-based components to include in design efforts and more representative digital tools focused on addressing stigma, a factor that remains a significant barrier to treatment use among minority populations [19,76,79]. In particular, in a study conducted by Lipson et al [76] with a sample size of 40,000 students (13,000 students of color), male students had higher levels of perceived stigma. In our study, Black male students discussed their desire for mental health apps and social media mental health support that included visual- and text-based components that indicated a need to normalize the discussion of mental health in the Black male community. The men discussed how, today, mental health remains a public health concern that is not discussed and almost ignored, a finding that aligns with previous research on mental health as a "taboo" subject among this population [80,81]. Social media is widely accessible, reaching individuals who are typically underserved and providing an outlet for these individuals to engage with mental health promotion materials and resources to increase mental health awareness [29]. Given the stigma surrounding traditional avenues of mental health discussion and treatment in the Black male community, social media-based mental health support may represent an initial, more accessible form of treatment to reach college-aged Black men as well as a means of normalizing conversations around mental health [80,81].

Audio and Visual Components

The findings also offer insights into specific preferences for mental health support on social media. The men reported a preference for audio and visual content delivery, such as experiencing mental health support through podcasts and listening to voice notes. There is little research focused on the role of podcasts and voice notes as methods for mental health promotion among Black men and, specifically, among Black men in college; however, there has been work focused on the role of podcasts in mental health education [82]. Willis [82] showed how podcasts create an opportunity for psychiatry residents not only to better understand course material related to mental health promotion but also to provide them with skills that can better prepare them to treat patients and aid in attenuating risk factors that influence mental health disparities. A similar approach may be effective in providing mental health psychoeducation for the purposes of increasing awareness and promoting mental health among Black male college students. Further work should be conducted to determine the role of podcasts in mental health promotion among Black male students

and explore the feasibility of podcasting or audio in intervention work as a means of promoting desired behavioral health outcomes.

Our findings regarding design considerations suggest that text-based images are preferred avenues for health promotion. The men in our study preferred mental health support and resources that were image-based or had pictorial representations of mental health issues and safety. This is consistent with literature that suggests that methodologies related to photo elicitation are useful in promoting mental well-being [83,84] and should be further considered when designing mental health programs and interventions.

Strengths, Limitations, and Future Directions

The strengths and limitations of this study point to directions for future research. Our study was exploratory and targeted a small Midwestern sample, potentially limiting the transferability of the findings to college-aged Black men from this region. Importantly, in relation to the study aim, there is research to suggest that saturation can be met with small sample sizes in qualitative research [85]. We do not know how focal characteristics from this study, such as digital mental health treatment preferences or openness to social media use for mental health treatment, vary across subgroups (eg, in rural vs urban areas and across regions). In addition, our sample included a range of ages and more graduate than undergraduate students, including exclusively graduate students from university 2. However, there was no qualitative difference in how needs varied between undergraduate and graduate students or between younger and older men. In future work, it would be worthwhile to examine the potential differences in how young Black men's needs and preferences vary at different ages.

Selection bias may be a concern as well. The men in this sample may have been more motivated to participate in the study, especially if they heard about the study through a friend. However, we consider this a strength as well. These men's thoughts and experiences are important within the mental health space and will provide unique insight into appropriate dissemination strategies and design ideas that can also be adapted for recruitment efforts that are better able to engage Black male students in future research [86,87]. The study findings should also be interpreted in consideration of the COVID-19 situation at the time. Given that the study was conducted during the peak of the COVID-19 pandemic, when college students were overwhelmed by a sudden transition to digital and computer-enabled classes and communications, the findings may potentially be influenced by their digital fatigue [51]. Participants' perception of using web-based resources and digital tools may also be altered because of this.

Conclusions

Our qualitative investigation to understand Black male students' needs and preferences surrounding nontraditional methods of mental health promotion provides key insights into addressing current mental health access barriers. Our findings provide evidence for leveraging social media and digital tools to introduce mental health services in an informal way, making tools more widely accessible and more appropriate to meet their

needs [88]. Digital tools and social media platforms are already being used to discuss mental health concerns [89] and have the potential to reach large numbers of individuals who are less likely to use traditional mental health services [29,42,90], such as Black men. As the pandemic continues to disrupt the ways in which mental health support is provided and increase the demand for services, it is critical to understand how minoritized groups are seeking mental health support and address key factors affecting adequate mental health care and overall access. The insights from this study can serve as a stepping-stone for

researchers to develop work that is contextually and culturally relevant to Black male students, ultimately improving access and use rates of mental health services among Black men throughout their life span. Researchers, campus-based practitioners, and policy makers should aim to conduct work that promotes the role of social media and mobile-based technologies in mental health promotion and in supporting the unique mental health needs of Black male students and their communities.

Acknowledgments

The authors would like to thank all the Black male students who participated in this study and openly shared their thoughts and experiences, as well as the many university faculty, students, and staff who contributed to the design and implementation of this study. This work was supported by the National Institute of Mental Health (K08 MH112878), and KDAW and CAS were supported by a grant from the National Institute of Mental Health (T32 MH115882).

Abstract

Background: Social media is widely accessible and increasingly utilized. Social media users develop hashtags and visual, text-based imagery to challenge misrepresentations, garner social support, and discuss a variety of mental health issues. Understanding how Black men are represented on social media and are using social media may be an avenue for promoting their engagement with and uptake of digital mental health interventions.

Objective: The aim of this study was to conduct a content analysis of posts containing visual and text-based components related to representations of Black men's race, gender, and behaviors.

Methods: An exploratory, descriptive content analysis was conducted for 500 Instagram posts to examine characteristics, content, and public engagement of posts containing the hashtags #theblackmancan and #blackboyjoy. Posts were selected randomly and extracted from Instagram using a social network mining tool during Fall 2018 and Spring 2019. A codebook was developed, and all posts were analyzed by 2 independent coders. Analyses included frequency counts and descriptive analysis to determine content and characteristics of posts. Mann-Whitney U tests and Kruskal-Wallis H tests were conducted to assess engagement associated with posts via likes, comments, and video views.

Results: Of the 500 posts extracted, most were image based (368/500, 73.6%), 272/500 (54.4%) were posted by an individual and 135/500 (27.0%) by a community organization, 269/500 (53.8%) were posted by individuals from Black populations, and 177/500 (35.4%) posts contained images of only males. Posts depicted images of Black men as fathers (100/500, 20.0%), Black men being celebrated (101/500, 20.2%), and Black men expressing joy (217/500, 43.4%). Posts (127/500, 25.4%) also depicted Black men in relation to gender atypical behavior, such as caring for children or styling their children's hair. Variables related to education and restrictive affection did not show up often in posts. Engagement via likes (median 1671, $P<.001$), comments ($P<.001$), and views ($P<.001$) for posts containing #theblackmancan was significantly higher compared with posts containing #blackboyjoy (median 140). Posts containing elements of celebrating Black men ($P=.02$) and gender atypical behavior ($P<.001$) also had significantly higher engagement.

Conclusions: This is one of the first studies to look at hashtag use of #blackboyjoy and #theblackmancan. Posts containing #blackboyjoy and #theblackmancan promoted positive user-generated visual and text-based content on Instagram and promoted positive interactions among Black and diverse communities. With the popularity of social media and hashtag use increasing, researchers and future interventional research should investigate the potential for such imagery to serve as culturally relevant

design components for digital mental health prevention efforts geared towards Black men and the communities they exist and engage with.

Introduction

Background

Social media is extremely popular and widely accessible [1,2]. More than 80% of young adults use social media platforms extensively [1], with typical activity exceeding 6 hours per week [2,3]. Social media networking sites are also now dominant sources of health information and health promotion [4,5]. According to the Pew Research Center, 72% of adult users search for news and health information online [6,7] and 26% of adults in the United States learn about health experiences from others on social media platforms [6]. Despite the increasing popularity of social media and its use, user statistics about Black men on these platforms is extremely limited. However, more than 65% of Black adults in the United States are using social media platforms on a daily basis [1]. Understanding how Black men are represented on and use social media may be an avenue for promoting their engagement with and uptake of digital mental health interventions [8]. The conversations on social media include discussions about sensitive mental health topics and the sharing of individuals' personal experiences with mental health issues [9], as well as interactions where people are connecting with one another and seeking social support [8]. Content analyses on photo-based platforms, such as Instagram, could provide a unique approach for researchers to examine how social media platforms can promote mental well-being among underserved groups.

Instagram and #theblackmancan #blackboyjoy

Instagram, launched in 2010, is a free, widely accessible, photo- and video-sharing social networking site [10]. In the United States, Instagram is one of the more popular social networking platforms, more widely used than Twitter [11], with a national user base of over 170 million and a global user base of over 1.3 billion people [12,13]. In particular, Instagram is very popular among young Black adults [14,15].

The popularity of hashtags, which are phrases or words strung together with a hashtag (#) placed in front of it, has grown exponentially and gained traction on platforms such as Instagram. Hashtags are widely used and can be started by anyone, defying the limits typically associated with traditional media and news outlets, and can lead to significant political and social movements [15,16]. In 2017, the hashtag #MeToo sparked a social movement in global support of sexual assault and harassment survivors. Within the Black community, the hashtag #BlackLivesMatter, coined in 2013, continues to be an important campaign, set against violence and systemic racism toward Black people. Similarly, celebrities, such as Kid Cudi, and athletes, such as Dak Prescott, used social media and relevant hashtags to discuss their personal issues with bipolar disorder

and depression. The practical effects of these hashtags and movements are overwhelming, resulting in structural changes in both the entertainment industry and society at large. Despite this increased popularity and galvanizing nature of hashtags, there is little research focusing on the use of hashtags among diverse communities and the potential role they can play in mental health promotion.

The hashtags #theblackmancan and #blackboyjoy are popular among the Black male and Black community. The hashtag #theblackmancan was created by a nonprofit organization, TheBlackManCan, Inc., founded by Brandon Frame, to share stories aimed at empowering Black boys and men [17]. TheBlackManCan, Inc. started as a blog in April 2010, with the aim to empower Black men and has since become a "social community that reflects positive images of Black boys and men of color" [17]. The organization's Instagram now has over 898,000 followers [18]. The #blackboyjoy is another hashtag created specifically to promote positive imagery and images about Black boys and men to counter the negative stereotypes that are placed on Black men in today's society [19,20]. This hashtag was popularized in 2016 by Danielle Young [20], writer for *The Root*, an African American-oriented online magazine, after watching Black male musician and producer Chance the Rapper displaying happiness at an award show. This hashtag, used over 1,832,953 times on Instagram [21], has evolved, and is widely used to create and highlight online spaces for Black men to express and display sentiments of joy, happiness, and laughter. To date, there are no published analyses looking at these hashtags. Importantly, there is little research examining social media hashtag use as a possible avenue for mental health promotion, creating a gap in our understanding of the efficacy of utilizing these, and other hashtags, in promoting culturally relevant design elements for interventional efforts geared toward minority men's mental health.

Related Work

Much of our knowledge of social media platforms and related user-generated content excludes social representations of Black men [22], focuses heavily on understanding data dissemination [23], and is often focused on Twitter [24,25]. For example, one study examined characteristics of #fitspiration content on multiple social media platforms, finding that the majority of the posts depicted women, and presented imagery of women reinforcing the "thin" ideal, which is negatively associated with unhealthy behaviors [26]. This analysis, among others [27], provides direction for researchers investigating which ideals are most pervasive in reinforcing unhealthy social norms. Researchers, then, can develop messages that appropriately counter such norms and, instead, encourage healthy behaviors [26]. Few studies have taken this approach in relation to Black men's health behaviors and mental health, making this a critical

focus area. Content analyses have also examined the formation of social representations via images, which are important in health-promotion efforts [22]; examining health behaviors; understanding risk for health issues among underserved populations; and learning about the lived experiences of marginalized individuals [28]. However, there remains a paucity of content analyses focused on Black men, their interests, and their lived experiences. This lack of understanding and knowledge likely reinforces stigmatized beliefs related to Black men, their mental health, and their overall lived experiences.

Guiding Framework

There is a growing literature base in social media content analyses, providing insight into the role post content and hashtags can play in understanding the lived experiences of traditionally excluded populations. Such insight creates opportunities for researchers to design mental health-promotion efforts that are culturally and contextually relevant to those they wish to serve. Because there were no existing codebooks on the topic, this study utilized a framework informed by formative literature and relevant theoretical concepts, including Tyree et al [29] and Gray's [30] framework for Black masculinity, the Gender Role Conflict Scale, and aspects from The Black Man Can Institute's mission statement and Black Boy Joy's website.

Masculinity and Black Masculinity

Ideals associated with masculine norms are important to assess as social constructions of masculinity are significant barriers to the uptake of mental health-promotion efforts and often negatively impact mental well-being among Black men [31-33]. According to gender role conflict constructs [34], due to masculine norms and expectations, men have difficulty balancing workplace and family demands and are socialized to be competitive, emotionally restrictive, and refrain from showing affection for other men [34]. The extent to which men adhere and conform to these ideals can cause high levels of stress for men, as well as for their interpersonal relationships [35]. Studies report direct links between measures of masculine adherence and lack of adherence to medical and mental health-related help and treatment [35]. Black men are not only socially expected to conform to masculine norms but are also presented with unique societal expectations, resulting from negative stereotypes associated with Black masculinity and Black masculine positionality [29,30]. These stereotypes often stem from misrepresentations in the media [36]. Jackson [37] and Tyree and colleagues [29] provide a framework of Black masculinity and positionality, proposing that there needs to be a redefining in which Black men are defined by ideals more closely associated with their experiences as Black men in society [29,30]. Black men often relate to certain ideals of masculinity—struggle, recognition, independence, achievement, and community—that define their manhood, masculinity, and position in society [29,30]. Other characteristics of Black men that are positive and ascribed to include presenting a “cool pose” or exhibiting a comedic nature [29,30]. This study aims to analyze posts related to Black men's masculine identity. Findings may be translated to other work, serving as targets for conducting mental health work within the realm of social media.

Current Study

This exploratory, descriptive study employed content analysis to identify characteristics of Instagram post content containing the hashtags #blackboyjoy and #theblackmancan. This content analysis examines how diverse users, including Black men, are generating content and social media messages that present positive images and lived experiences of Black men. We also aimed to examine public engagement with posts to see how visual and text-based social media messages and user-generated content promoted engagement or interactions. The overarching research questions were:

- How are posts containing #blackboyjoy and #theblackmancan portrayed on Instagram and what are the characteristics of these posts?
- To what extent do these posts challenge stereotypes associated with Black men's race and gender?
- Do these posts garner interactions or support?

Methods

Study Design

A social media content analysis [38,39] was conducted to examine the content of posts related to Black men on a social media platform, Instagram. A random sample of public Instagram posts was collected using Netlytic [40], a web-based social network mining tool, during the Fall of 2018 and Spring of 2019. Posts containing the hashtags of interest, #theblackmancan and #blackboyjoy, were extracted. Posts were assessed visually for inclusion in analysis if they (1) contained either or both hashtags and (2) were in English or could be translated into English using Instagram's translation feature. Posts were excluded if they did not contain either hashtag or if the link for access was no longer active at the time of coding. The poster source, caption, post, and post components were examined for this study. Posts were coded for a variety of variables related to the study's aims and objectives and were coded by 2 independent coders (KDAW and SAD). Two coders received extensive training on the utilization of the codebook. An iterative process was conducted in which weekly meetings were established to discuss discrepancies, determine consensus, and reach agreement between coders; 10.0% (n=50) of the Instagram posts were independently analyzed by the coders to reach an agreement as assessed by Cohen κ [41]. Guidelines for reliability analyses in content analyses suggest that there must be agreement on at least 10% of the study's sample with a κ statistic near the recommended cut-off value of 0.70 [41]. For this study, intercoder reliability for coding and analysis showed a coefficient of agreement (κ) between coders no lower than 0.69.

Codebook Development

Given the dearth of evidence on content analyses related to Black men and relevant hashtags, there is no established codebook to use or adapt for this analysis; therefore, a codebook was developed specifically for this content analysis (codebook is available in [Multimedia Appendix 1](#)). The first author (KDAW) first developed and operationalized codes based on current literature, study objectives, and variables of interest.

The codebook went through multiple phases of revisions based on feedback from 2 university faculties with expertise in conducting quantitative content analyses on social media. These revisions focused mostly on the development and iteration of codes related to visual components of the posts. After revisions were made, the codebook was reviewed by 2 Black, male graduate students. These men's perspectives in choosing and developing codes were important to ensure appropriate interpretation of Instagram posts including variables related to Black culture and Black men. This technique mirrors member checking, providing feedback on study methods, and approaches by members of the intended target population, which promoted validity of the research methods and findings [42].

Variables of Interest

Post Characteristics

The initial set of codes focused on visual and face-value content and included codes related to the visual components. Variables included focused on poster source (ie, who is posting), the kind of visual (eg, text or image based), and people present in post (eg, number of people), among other aspects.

Post Content

Variables were then added to assess context and content. Such variables assessed aspects related to masculinity and gender roles and were informed by items from the Gender Role Conflict Scale, Gray [30] and Tyree et al's [29] framework for Black masculinity, as well as components of The Black Man Can Institute's mission statement [17] and Black Boy Joy's website. For example, posts were coded for whether (1=Yes) or not (0=No) they indicated aspects related to a creation of a safe space, displays of community service, the celebration of Black boys and men, protection, and if men could be seen displaying joy (ie, a boy or man smiling). Posts were also coded for whether (1=Yes) or not (0=No) they focused on aspects related to Black boys or men in educational contexts, receiving or giving mentorship, and men's attire.

Post Engagement

Codebook variables also included codes for assessing public engagement. The included variables were informed by engagement features typically used by Instagram users, analyzing how many likes, comments, and video views (all Instagram application features) were attached to each post.

Data Analysis

All statistical analyses were conducted using SPSS, version 26 (IBM, Inc.). Upon completion of data collection and coding,

frequency counts and descriptive statistical analysis of the coded variables were conducted. Three different types of engagement, namely, likes, comments, and views for videos, were evaluated using nonparametric tests, as Instagram engagement frequencies were not normally distributed. Specifically, Mann-Whitney *U* tests were used to investigate differences in the level of public engagement for variables containing a range of dichotomous variables; and Kruskal-Wallis *H* tests were used to investigate differences in engagement for nominal variables with 3 or more levels.

Ethical Considerations

This study did not directly involve human subjects and did not meet the regulatory definition of human subjects' research; therefore, this study was excluded from institutional review board review at the institution in which this study took place.

Results

Characteristics of Posts

The first research question focused on how posts containing #blackboyjoy and #theblackmancan are being portrayed on Instagram and the characteristics of these posts (see Table 1 for descriptive analyses). Approximately half of the sample either included the hashtag #theblackmancan (248/500, 49.6%) or #blackboyjoy (225/500, 45.0%). Only 27/500 (5.4%) of the posts included both hashtags. All posts contained a poster source, that is, the person or entity who posted the actual post with the hashtag. Of 500 posts, 272 (54.4%) were posted by an individual person, whereas 135 (27.0%) were posted by a community organization. It is important to note that the community organization code captured posts that were also posted by The Black Man Can Institute; however, the software that extracted the posts did so randomly and only extracted posts based on the hashtag itself.

Among posts that had a poster source, only 17/500 (3.4%) were posted by commercial sites. As many as 194/500 (38.8%) of the posts were posted by men and 81/500 (16.2%) were posted by women. Of these posters, 269/500 (53.8%) were posted by individuals from the Black populations. The types of visuals (ie, image or video) included were still images (368/500, 73.6%) and videos (106/500, 21.2%). Among these visuals, 177/500 (35.4%) contained only males, and 179/500 (35.8%) posts contained individuals who were Black. Of the 500 posts, 272 (54.4%) posts containing multiple people were Black. Furthermore, of these posts containing multiple people, 184/500 (36.8%) were of mixed gender and 122/500 (24.4%) posts contained multiple males.

Table 1. Characteristics, descriptions, and post content among posts tagged with #theblackmancan and #blackboyjoy (N=500).

Variable and category/item	Value, n (%)
Characteristics	
Hashtag

Cool pose	154 (30.8)

^aThese variables were visually assessed along with the captions associated with posts.

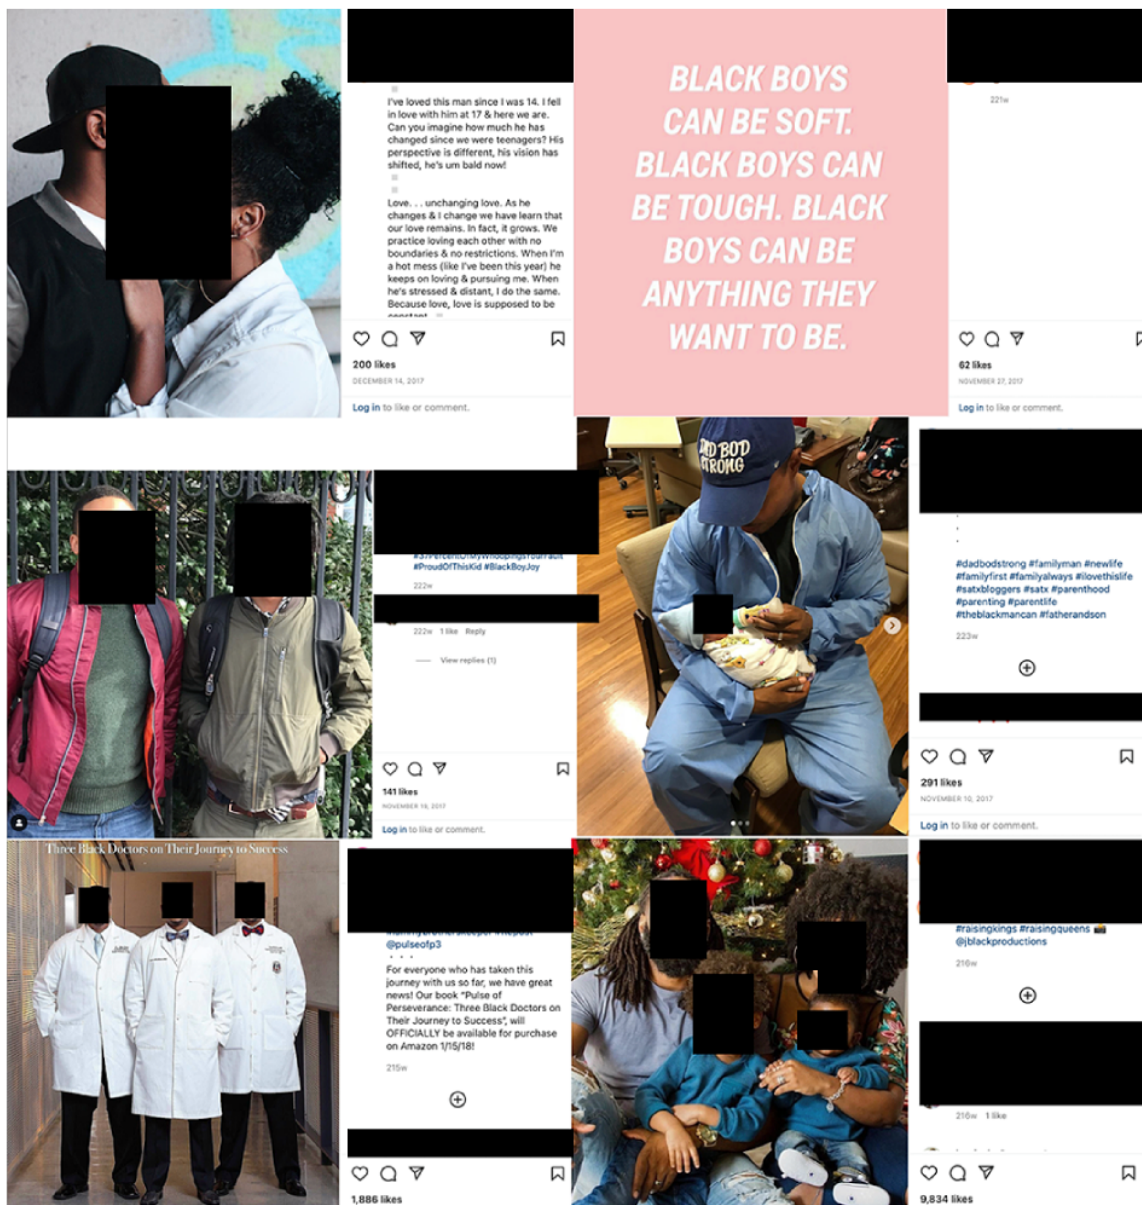

Post Content

The second research question focused on how these posts challenge stereotypes associated with Black men's race or gender and to what extent the public engages with these posts. For the variable assessing the type of imagery depicted in the visual (Table 1), descriptive analyses show that 32/500 (6.4%) posts solely depicted children, 48/500 (9.6%) posts portrayed praise for significant others, and 55/500 (11.0%) posts showed portraits of families (father, mother, and a child or children); 100/500 (20.0%) posts presented images or videos of Black men portrayed as fathers (see Figure 1 for examples of posts).

Among the codes assessing values associated with the mission statement of The Black Man Can Institute, analyses revealed posts celebrating or showing praise for Black men/boys

(101/500, 20.2%) and Black men/boys smiling and expressing joy (217/500, 43.4%). Attire of individuals in these posts were also of interest, as negative stereotypes often show Black men dressed in a manner that is indicative of being criminals and thugs. As many as 254/500 (50.8%) posts included persons who were dressed casually. Other posts showed persons who were dressed formally (50/500, 10.0%), business casually (36/500, 7.2%), and professionally (36/500, 7.2%); 1.2% (6/500) of the posts showed Black men dressed negatively or similar to that of a gang member or thug. Specific to gender roles, posts (127/500, 25.4%) showed men engaging in gender atypical behavior, such as caring for children, doing a child's hair, or engaging in a form of dance other than hip-hop (eg, ballet). However, not necessarily surprising, only 29/500 (5.8%) posts showed men who challenged the norm of restricted affection toward or among men.

Figure 1. Examples of posts portraying aspects related to finding joy, fatherhood, and celebration of Black boys or men.

User Engagement

Analyses revealed statistically significant differences, showing that engagement by likes was higher for posts using #theblackmancan (median 1671) compared with engagement scores of posts only using #blackboyjoy (median 140, $P<.001$). Similarly, for comments, there were significantly higher levels of engagement for posts using #theblackmancan compared with those using #blackboyjoy ($P<.001$). For engagement via views, there were significant differences in engagement between posts using #blackboyjoy and posts using both ($P<.001$) such that #theblackmancan showed higher levels. Mann-Whitney *U* tests were conducted for the variables in Table 2. For celebration of boys, there were significant levels of engagement across all types of engagement (likes, $P=.02$; comments, $P<.001$; views, $P<.001$). Similarly, for posts including men engaging in gender

atypical behaviors (eg, taking care of children, braiding child’s hair), there were higher levels of engagement displayed by likes ($P<.001$), comments ($P<.001$), and views ($P=.001$). Engagement by likes, comments, and views varied for several variables examined, and there were no significant differences for any types of engagement among multiple variables. Specifically, there were no significant differences in types of engagement for posts containing the mentorship (likes, $P=.83$; comments, $P=.47$; views, $P=.39$), community service (likes, $P=.95$; comments, $P=.64$; views, $P=.30$), safe space (likes, $P=.13$; comments, $P=.16$; views, $P=.71$), education (likes, $P=.57$; comments, $P=.47$; views, $P=.65$), conflicts between work and family (likes, $P=.89$; comments, $P=.28$; views, $P=.87$), or competition/power variables (likes, $P=.05$; comments, $P=.22$; views, $P=.22$).

Table 2. Median engagement scores for posts containing race and gender variables in this analysis (N=500 unless otherwise noted).

^aSignificant at $P < .05$.

^bSignificant at $P < .05$, but not significant in practice as both medians are 0.

Kruskal-Wallis H tests showed significant differences in engagement via comments ($\chi^2_7=15.961$, $P=.002$) for the attire type variable and via views ($\chi^2_9=19.490$, $P=.02$) for the group type variable. There were differences in engagement scores for the group type variable and attire type variable. The group type variable included categories such as children, friends, colleagues, family, brotherhood (see the “Multiple persons in visual can be” variable in Table 1). According to analyses, there were significant differences between posts containing the family variable (median 0) and those containing the “other” variable (median 54.00, $P=.006$). The attire type variable included categories such as an individual wearing casual clothes, business casual, professional, formal, or stereotypically dressed clothing (ie, thug garb; Table 1). There were significant differences

between posts containing the casual (median 0) and other variable (median 29.00, $P=.03$) and between the casual variable and formal variable (median 43.50, $P=.05$), but not among other groups.

Discussion

Principal Findings

This study analyzed Instagram posts containing the hashtags #blackboyjoy and #theblackmancan. The findings offer direction for researchers who wish to use visual and text-based content in mental health-promotion efforts geared toward Black men.

Overall, most posts were primarily image based with only a small number including videos or video-based images. Analyses

showed that there were few posts that portrayed depictions related to education and restricted affection, and posts depicting ideals particular to #blackboyjoy included imagery where men were shown celebrating Black boys and men and finding joy. When analyzing whether posts were posted by an actual person, group, or community organization, we see that Black men and communities are, in fact, using these hashtags. Community organizations, in particular, used the #theblackmancan hashtag more often compared with #blackboyjoy. We also see that the images analyzed in this study foster positive interactions from viewers and users on Instagram.

According to analyses of engagement, public engagement was positive for posts containing variables related to celebrating men and boys, men engaging in gender atypical behavior, and posts displaying sentiments of protection. In addition, engagement via viewership was high for the following variables: cool pose, finding joy, restrictive affection and restrictive emotion, and comedic presence. The #theblackmancan hashtag showed more public engagement, eliciting more likes and comments from the public, suggesting that ideals and expressions related to the #theblackmancan were more popular and relatable at the time of analysis and produced more aesthetically appealing content than #blackboyjoy. It is difficult to ascertain why this is the case; however, it may be due to social media users' access or the fact that this hashtag is influenced by the organizational reach of The Black Man Can Institute. It could be that the #blackboyjoy movement, though popular, did not have the same reach. However, this is unclear and difficult to establish for certain as the #blackboyjoy movement received a lot of national attention by a large group of people, including celebrities who have either endorsed or not endorsed the hashtag's use.

Comparison With Prior Work

The finding that most posts were image based was expected as Instagram is primarily a photo-sharing platform and indicates that, despite the social media having a feature for the posting of videos, the posting of still images and pictures remain the primary behavior on this social media platform [43]. Consistent with emerging research, many of the images expressed personal beliefs and values, which has relevance for recent research examining the impact of photo sharing and photo elicitation and its role in mental health prevention and promotion [44]. In community-based participatory work, researchers utilize similar methods to understand the experiences of marginalized populations in an effort to promote health and understand lived experiences of minority populations [45].

Notably in this study are posts including images of mothers or wives offering support for their significant others and showing appreciation for the Black men and boys in their lives. Although these images showed up in less than 50% (101/500, 20.2) of the posts, this representation of "celebrating Black men" is important and suggests how community, and even researchers, can utilize outlets such as Instagram to empower Black men and men of color and their accomplishments, which is atypical according to traditional images put forth by traditional media [46]. Images with Black men being celebrated also included sentiments of men with their families. The posts in this study

depicted Black men as family men who engaged in "gender atypical behavior" (127/500, 25.4%) such as men taking their children to work or doing their daughter's hair. This positive representation of Black men engaging in fatherhood is often underrepresented or inaccurately represented in the media, such that men are portrayed as absent in the household or intentionally disengaging from family responsibilities [47,48], leading to reinforcement of negative stereotypes [49] that inevitably impact Black men [50,51].

Increased depictions of Black men in a positive light will promote positive representation of Black men within digital mental health spaces that are visual based. This representation can then lead to men's increased interest, engagement, and acceptability of current and future mental health visual-based interventions [22]. This study's findings, related to Black men displaying joy and positive engagement, highlight a potential visual or text-based characteristic that can be incorporated into a social media, mental health message geared toward Black men. There is already work being done in the mental health message space such that Robinson and colleagues [52] found that social media-based, suicide prevention messages are acceptable and safe among young adults. A recent paper by Seidler and colleagues [53] set forth a call for action for developing "gender-sensitive" and appropriate mental health care and how such approaches should emphasize a redefining of men's masculinities. This redefining can include positive imagery as that seen in this study and will aid in our ability to increase representation of Black males and their engagement with mental health prevention efforts, specifically help-seeking and mental health prevention campaigns [53].

There were few posts that included depictions of men related to education and restricted affection. This finding can be related to the fact that misrepresentations and stereotypes associated with Black men being uneducated [54] and Black men being unable to show affection are not as easy to counter in this medium. These ideals, combined with social norms criminalizing Black men and stigmatizing mental health within this community, (1) reinforce unrealistic expectations related to unhealthy masculine ideals, such as restrictive emotion [31]; and (2) make it particularly challenging and uncomfortable for Black men to engage with health-related efforts and programming [28]. Few depictions of men related to education may also be reflective of educational disparities that continue to exist for Black men as there are higher dropout rates and lower retention among this group [55]. Such disparities and representations may be harder to challenge in this medium; however, future research would be appropriate to investigate this further.

Future Work

With social media constantly evolving, further research should be conducted to examine how prevalent hashtags can counter and reshape narratives that promote ideal health behaviors and mental health outcomes among Black men [56]. There are various approaches and avenues that researchers can utilize as we move forward in the field of digital mental health. One approach is further examination of user-generated, asset-based content that gives insight into the various images and imagery

Black men choose to express themselves on a digital-based platform and using digital tools most relevant to them, such as hashtag use. From this study, we see that Black men are portraying themselves in a different light but also show which factors or norms may be more pervasive and relevant to Black men and their communities. This “flipping of the narrative” can hold much promise for the future of mental health prevention geared toward minority men and other populations such that programming can take a visual-based approach, utilizing positive imagery that is relevant to minority populations.

Researchers can further examine study variables as potential mutable factors for intervention work and include intervention design elements that are culturally appropriate, contextually relevant to Black men and, eventually, once translated and adapted, other minority men and their communities. For example, in the posts, there were a high number of images containing visuals of Black men being celebrated. Figuring out how to incorporate this positive aspect into programming and visual-based campaigns will draw Black men in to participate in research as well as empower them, increasing their self-efficacy and promoting adherence of therapeutic treatments in which the campaigns are advertising.

Findings from this study also begin to highlight how a social media platform, such as Instagram, can be manipulated to promote sentiments, such as celebrating men or destigmatizing restricted affection and emotion. Researchers, clinicians, and mental health professionals can expand on the study findings, engaging in intervention work that focuses on Instagram and other relevant platforms, and consider how this generated content promotes health and mental health support messages. For example, within this study, there is some indication of the potential role of peer support via family and loved ones, who are using these hashtags and posting appropriate and relatable content. Future research should investigate how to combine the use of visual-based and text-based images with human support to create and implement future mental health and suicide prevention efforts [9] that are useful and sustainable within Black male communities. Similar to photo elicitation work [57], further exploration into image-based messaging will allow researchers to examine and begin to understand how images promote ideals related to mental health, their lived experiences, and even, their mental and emotional safety [28,44,57]. In addition, as we see community organizations may be engaging with this hashtag, and others like it, it would be important to conduct work with and partner with community organizations to foster men’s engagement on a broader level and with wider impact.

Limitations

As with any study, there are limitations to acknowledge. Although efforts were made to address the concern for human error in this study, there may have been posts falsely excluded due to misjudgment by coders. There are variables included in this analysis that only allowed for “other” or “unsure” or “uncertain” or “cannot tell” and, due to the subjective nature of content analyses, this may have led coders to miss variables, limit codes, or include irrelevant variables. There may have been posts unable to be included in the analysis because an Instagram user’s profile was private or the link to a profile at time of analysis was deemed “no longer existing.” Mentions (an Instagram feature where the poster uses an “@” symbol followed by an individual’s Instagram handle) were not coded in this study. Coders, then, did not code for this under the category Public Engagement. At the time of analysis, the hashtags, #blackboyjoy and #theblackmancan, though still used, were popular and used often; however, in posts, these hashtags were not the only ones used. Our analyses only aimed to extract posts that contained these hashtags and posts included in this analysis could contain other hashtags. Despite these limitations, the codebook was thoroughly developed and updated continuously for a period of over 5 months in collaboration with members who matched the study’s sample by gender and race to ensure there were codes appropriate in capturing variables associated with study goals and objectives.

Conclusions

Digital mental health interventions can reduce health disparities and improve access to service; however, there is a paucity of digital mental health work geared toward Black men. When members from underserved and underrepresented populations see themselves in prevention efforts, they are more likely to engage [22]. By examining social media content celebrating Black men, this study can inform the design of digital tools that are visual based and relevant. Developing technology and digital programming effective in promoting mental health among minority populations and improving related health behaviors are of vital importance. This study is one of the first to explore the use of the hashtags #blackboyjoy and #theblackmancan on Instagram, illustrating the potential for hashtags, as digital tools, that express Black men’s values and beliefs, allowing these men to illustrate their lived experiences as Black men in society. As social media users continue to access the platforms to share experiences and communicate, there is a need to further examine how members from underserved populations interact with social media and how this technology can be harnessed to promote their well-being.

Acknowledgments

KW and EGL are supported by grants from the National Institute of Mental Health (T32 MH115882; K08 MH112878). We would like to acknowledge and thank Sultan A. Hubbard and another Black male graduate student (will remain unnamed) who took time to provide extensive feedback on the codebook developed for this study.

Conflicts of Interest

None declared.

Abstract

Background: Trust in government is seen to facilitate crisis management and policy instrument adoption across numerous studies. However, in Japan, public support for government handling of the COVID-19 pandemic and trust in the government is low, yet the adoption of voluntary nondigital nonpharmaceutical interventions (NPIs) is high. This is an important tension this study seeks to unravel.

Objective: The aim of this study is to understand the antecedents of nondigital NPI and tracking app adoption in the COVID-19 pandemic in Japan.

Methods: A commercial company was contracted to deliver an online survey of 1248 Japanese citizens in December 2020. A quota technique was used to deliver a sample representative in terms of gender, age, residence, income, and education.

Results: The adoption of voluntary nondigital NPIs is predicted by confidence in public health scientists and a favoring of infection control over reducing economic and social costs. A novel and unexpected finding is that trust in government does not predict nondigital NPI use. Perceived risk and knowledge of infection did not increase the use of nondigital NPIs. Education and income were not significant factors, although female and older respondents demonstrated greater compliance. For the adoption of a phone tracking app, trust in government is important, as is urban residence, albeit with a lower use of the app compared to nondigital NPIs.

Conclusions: Voluntary compliance in the adoption of nondigital NPIs—if skillfully led by trusted scientific experts and in accord with societal norms—can be effectively achieved. We provide evidence that trust in government is effective in encouraging the use of the Japanese tracking app. Moreover, the technical efficacy of digital initiatives and perceptions of such will unsurprisingly affect citizen support and use of digital tools.

KEYWORDS

COVID-19; nonpharmaceutical interventions; social distancing; phone tracing; trust in government; confidence in scientists

Introduction

Background

A body of literature suggests that trust in government facilitates crisis management and citizen compliance with government directives and suasion during the COVID-19 pandemic [1]. Moreover, trust in government initially increased in several countries, partly due to perceptions of effective pandemic management [2]. Trust in government remains low in Japan, however [3]. Moreover, despite the relatively low death toll, surveys show low levels of support for the Japanese government's handling of the pandemic. Indeed, according to the Pew Research Center [4], only 55% of Japanese respondents believed that the government had dealt properly with the COVID-19 pandemic, a portion lower than that of Italy (74%) and Sweden (71%), both of which recorded more COVID-19 deaths as a proportion of the population. However, compliance with voluntary nondigital nonpharmaceutical interventions (NPIs) has been high, as this study will show. Hence, the role of trust in government in Japan in the adoption of NPIs is likely to be more complex than other studies suggest.

Apart from vaccination, the Japanese government recommended a range of NPIs, including hand washing, face mask wearing, social distancing, staying at home, and the use of ventilation. Citizens were encouraged to avoid the so-called 3Cs: closed spaces, crowded places, and close-contact settings. A contact-tracing app, the COVID-19 Contact-Confirming Application (COCOA), was developed and launched by the government on June 16, 2020. In most cases, there was no penalty for flouting government directives due in part to constitutional constraints prioritizing individual privacy and freedom. Instead, the adoption of NPIs depended on voluntary citizen compliance with government guidelines, which was largely achieved, albeit with lower contract-tracing app use compared to other NPIs. This is in marked contrast to some other countries' use of coercive and legal means to enforce lockdowns and other NPI adoption [5,6].

This study seeks to clarify the factors associated with NPI and tracing app adoption. Drawing on an online representative survey of 1248 Japanese citizens and testing 3 groups of hypotheses, we show that the adoption of nondigital NPIs is predicted by confidence in public health scientists and support for infection control over economic and social costs. Trust in government does not predict nondigital NPI use—an unexpected and counterintuitive finding. Perceived risk or knowledge of infection does not increase nondigital NPI use. Education and income are not significant factors although females and older respondents demonstrate greater compliance. Regarding the adoption of a phone-tracking app, trust in government is important, as is urban residence, but confidence in public health scientists is not.

Hypotheses

A variety of NPIs have been used worldwide to control the pandemic including social distancing, mask wearing, lockdowns, staying at home, hand washing, ventilation, and the adoption of digital tracing. Border closures, curfews, and other measures could also be classified as NPIs. There are historical precedents

for NPI use, including in the Spanish flu and SARS (severe acute respiratory syndrome) epidemics, and quarantining and social distancing have long histories in previous pandemics. There is also recent empirical support for their efficacy. For example, Bo et al [7] examined the effectiveness of mandatory mask use, isolation or quarantine, social distancing, and traffic restrictions; they confirmed significant reduction in morbidity across the 190 countries studied. Haug et al [8] analyzed the impact of various NPIs and found support for their effectiveness. China, the United States, the United Kingdom, and the European nations have used contact tracing through digital means, which are claimed to be effective [9-12].

Trust in government may predict NPI adoption during a pandemic [13]. A large body of research suggests trust in government is associated with policy instrument adoption [1,2]. For example, Goldfinch et al [2] found that trust in government and confidence in public health scientists predicted phone-tracking app use in Australia and New Zealand. Studies in the United States found that trust in government and government sources was associated with adoption of social distancing [14]. Moreover, with citizens relying on experts' guidance, confidence in scientific expertise is likely to be related to the adoption of NPIs. A multinational survey company, Ipsos, reported that doctors and scientists are trusted more than are governments by citizens worldwide [15]. In the case of Japan, (medical) doctors are rated "the first most trustworthy" (52%) and scientists are rated "the second most trustworthy" (43%) [15]. Kazemian et al [16] found in the United States that scientific trust raised support (although adoption was not measured) for COVID-19 social-distancing policies [16]. Given the Japanese context, we focus on the 6 NPIs recommended by the government: wearing facemasks, washing hands, social distancing, refraining from going out, avoiding the 3Cs, and maintaining ventilation. This wide range of measures adds to the novelty of this study.

This discussion leads us to our first set of hypotheses: hypothesis 1a—trust in government is associated with compliance with preventive behavior directives; hypothesis 1b—confidence in public health scientists is associated with compliance with preventive behavior directives.

Perceived risk, fear, and knowledge of the disease might be a factor in NPI adoption [6]. For example, Pedersen and Favero's [5] online survey of US residents found willingness to maintain social distance was predicted by perceived risk of the pandemic. Harper et al's [17] UK study found that a leading antecedent for adopting NPIs was the fear of COVID-19. Webster et al's [18] review found factors affecting adherence to protective health behaviors included levels of knowledge about the disease outbreak and risk of disease. Moreover, NPIs can have marked economic effects, and aspects of social isolation involved with staying at home and social distancing have profound psychological impacts, which are yet to be fully determined [19,20]. The decision to adopt NPIs then may also be an act of balancing one perceived risk—that is, the disease—against the risk of economic and social disruptions. Moreover, individuals may be more likely to accept new and unorthodox measures if the perceived loss from not doing so is greater, so how relative risks are framed by them and others will likely affect behavior

[21,22]. Hence, an individual's attitude toward the trade-offs of pandemic control may affect NPI compliance and contact-tracing app use. From this discussion, we develop the following hypotheses: hypothesis 2a—compliance with NPI requirements is higher when risk perception (knowledge) is higher; hypothesis 2b—compliance with NPI requirements is higher when infection control is prioritized over economic and social effects; hypothesis 2c—contact-tracing app use is higher when infection control is prioritized over economic and social effects; hypothesis 2d—contact-tracing app use is higher when risk perception (knowledge) is higher.

In the case of digital tracing, there are added concerns about privacy of information that is shared with and gathered by the government although the Japanese contact-tracing app does not collect personal information. Hence, it deserves dedicated study. Chan and Saqib's [23] experiments suggest that the reluctance to download contact-tracing apps can be explained by privacy concerns. Horvath et al's [24] experimental study suggests that trust in the UK National Health Service mitigates respondents' concerns about privacy in tracing apps, with the benefit of using tracing apps perceived to be larger than the risks of privacy and security breaches. Oldeweme et al [25] found that transparency and trust in government foster tracking app adoption. Goldfinch et al [2] found that in Australia and New Zealand, trust in government and confidence in public health scientists predict the use of contact-tracing apps [2]. Trust in government then provides a proxy for addressing privacy and security concerns that might arise with digital engagement. Accordingly, we propose the following hypotheses: hypothesis 3a—contact-tracing app use is higher when trust in the government is higher; hypothesis 3b—contact-tracing app use is higher when confidence in public health scientists is higher.

Methods

Survey

A commercial company was contracted to deliver an online survey of 1248 Japanese citizens in December 2020. A quota technique was used to deliver a sample representative in terms of gender, age, residence, income, and education. Respondents included both men and women in the age groups of 18-24, 25-34, 35-44, 45-54, 55-64, and 65 years and above. Quota methods are widely used in public health, medical, and epidemiological research and are considered state of the art [26,27].

Variables

The dependent variables are compliance with preventative behavior (CPB) and use of the contact-tracing app (COCOA).

CPB was measured via the following question: "To what extent do you comply with the government recommended behaviors for protection from COVID-19?" The 6 nondigital NPIs recommended by the Japanese government are the following: (1) wearing face masks, (2) hand washing, (3) social distancing, (4) refraining from going out, (5) avoiding the 3Cs, and (6) ventilation.

Responses were given on a 4-point Likert scale ranging from 4 = "always" to 1 = "not at all." As the responses might have

had different weights, we performed principal component analysis and used a single principal component score. Although there are several methods for determining the number of factors, we adopted the most representative and easily understood eigenvalue-1 criterion [28].

Use of the contact-tracing app (COCOA) was measured by the response to the following question: "To what extent do you use COCOA?" Responses were on a 4-point Likert scale ranging from 4 = "always" to 1 = "not at all."

The independent variables were operationalized as follows. Trust in government (Trust government) was measured based on the response to the statement, "(level of government) is generally trustworthy." The response was marked on a 4-point Likert scale ranging from 4 = "strongly agree" to 1 = "strongly disagree." This was derived from Goldfinch et al [2]. The answers for the national and local governments were summed. Confidence in scientific expertise (Confidence expertise) was determined by asking, "How much do you believe that public health scientists act in the best interests of the public?", which was also derived from Goldfinch et al [2]. Responses were marked on a 4-point Likert scale ranging from 4 = "a great deal" to 1 = "not at all."

We measured the perceived risk of infection (knowledge) by loosely adapting questions from Wise et al [29]. The perceived risk of COVID-19 (Perception risk) was measured via responses to the following 3 questions: "Have you ever received any information that your families are infected?", "Have you ever received any information that your coworkers are infected?", and "Have you ever received any information that other related persons such as clients are infected?" The answers were 1 = yes and 0 = no. The answers were summed. Previous studies have inquired about hypothetical "average" people (eg, the average person in the neighborhood, state, and country). As the Japanese media's focus was on the number of cases in the country, we focused on the extent to which family members, coworkers, and others had information about the infected rather than specifying the geographic area.

Respondents' perceptions of the appropriate balance between infection control and society and economy (Economics) were derived from the following question: "To which element do you attach more importance: infection control or maintenance of economic and social activities?" Responses were on a 4-point Likert scale ranging from 1 = "emphasize infection control more than economic and social activities" to 4 = "emphasize economic and social activities more than infection control." This question was derived by the authors based on concerns about balancing economic performance with infection risk, which is often discussed in Japan.

Sociodemographic factors may also influence NPI compliance. Riou et al [30] found adoption of protective behaviors to be correlated with age and comorbidity risk in China. Females are more likely to comply with government directives in general [31]. Older people might feel less at ease using contact-tracing apps that demand some digital competence but may be more compliant with government directives [32]. Accordingly, our other independent variables were the following: gender (male = 1 or female = 0), age (1 = 18-24, 2 = 25-34, 3 = 35-44, 4 =

45-54, 5 = 55-64, and 6 = 65 years and above), education (from 1 = secondary school graduate to 5 = postgraduate), residence (urban = 1, rural = 0), and household income (1 = up to ¥2 million, 2 = ¥2-3 million, 3 = ¥3-4 million, 4 = ¥4-6 million, 5 = ¥6-8 million, 6 = ¥8-10 million, 7 = ¥10-12 million, 8 = ¥12-15 million, and 9 = ¥15 million and above; a currency exchange rate of ¥1=US \$0.007 is applicable).

Statistical Analysis

Adoption of NPIs (CPB) was analyzed using the ordinary least squares multiple regression model, as shown in equation 1. Use of the contact-tracing app (COCOA) was analyzed via an ordered logistic regression model by maximum likelihood estimation, as seen in equation 2. The estimated coefficients explain the change in log odds of using COCOA. Analysis was performed using Stata/IC 16.1 (StataCorp).

$$\text{CPB} = \alpha_1 + \alpha_2 \text{Trust government} + \alpha_3 \text{Confidence expertise} + \alpha_4 \text{Perceptionrisk} + \alpha_5 \text{Economics} + \alpha_6 \text{Gender} + \alpha_7 \text{Age} + \alpha_8 \text{Income} + \alpha_9 \text{Education} + \alpha_{10} \text{Urban} + \varepsilon_1 \text{(1)}$$

$$\text{COCOA} = \beta_1 + \beta_2 \text{Trust government} + \beta_3 \text{Confidence expertise} + \beta_4 \text{Perceptionrisk} + \beta_5 \text{Economics} + \beta_6 \text{Gender} + \beta_7 \text{Age} + \beta_8 \text{Income} + \beta_9 \text{Education} + \beta_{10} \text{Urban} + \varepsilon_2 \text{(2)}$$

Here, the dependent and independent variables *CPB*, *COCOA*, *Trust government*, *Confidence expertise*, *Perceptionrisk*, and *Economics* are calculated as shown in the previous subsection. *Gender* is a dummy variable which is 1 if a respondent is a man, 0 otherwise. The variables *Age*, *Income*, and *Education* are continuous variables from responses. *Urban* is a dummy variable which is 1 if a respondent answers as living in an urban area, 0 otherwise.

Ethical Considerations

Ethics approval was obtained from the chairman of the Committee for Assessing Ethics on Research at Kamakura Women's University. The survey company received full confirmation from the survey monitors to consent with its privacy policy and quality control. The final contract for the

survey was approved by the president of the university (application #110853).

Results

Descriptive Statistics

Reported adoption of (nondigital) NPIs was high. Approximately 80% of respondents said they “always” or “mostly” behave according to government guidelines, with 97.20% (1213/1248) wearing masks, 95.43% (1191/1248) washing hands, 85.98% (1073/1248) engaging in social distancing, 78.21% (976/1248) refraining from going out, 83.25% (1039/1248) avoiding the 3Cs, and 76.52% (955/1248) using ventilation (see [Table 1](#)). The use of COCOA was considerably lower, with 57.85% (722/1248) nonusage. Trust in government in Japan was alarmingly low, with strong agreement or “agreement that government are generally trustworthy” at 1.60% (20/1248) and 35.74% (446/1248), respectively—far lower than that of other OECD (Organization for Economic Co-operation and Development) countries [2]. This finding of low trust in government in Japan is supported by other studies [3]. Confidence in public health scientists was far greater: 42.15% (526/1248) of respondents had “a great deal” of confidence and 48.32% (603/1248) were “fairly” confident that they work in the public interest.

[Table 2](#) presents the respondents' demographic characteristics. Gender and age were manipulated to have the same percentages during the online survey phase. Annual household income was most frequently between ¥6 and ¥8 million yen, and approximately 46% of the respondents had a college degree or higher. This sample is broadly representative although respondents had a lower rate of higher education and slightly higher income than Japan has as a whole [33,34].

[Table 3](#) shows the Pearson correlation coefficients among the variables. The correlation coefficients between CPB and COCOA and the independent variables were consistent with the results of the regression analysis. All correlation coefficients were lower than 0.3; hence, the potential for multicollinearity was small.

Table 1. Compliance with nonpharmaceutical interventions and COCOA (N=1248).

	Always, n (%)	Mostly, n (%)	Little, n (%)	Not at all, n (%)
Wearing mask	962 (77.08)	251 (20.11)	28 (2.24)	7 (0.56)

Hypothesis Testing

Testing our hypotheses provided unexpected, counterintuitive, and novel results (Table 4). First, trust in government was not significantly associated with the adoption of NPIs. Hence, hypothesis 1a was not supported. Confidence in public health scientists had a positive and significant effect on NPI adoption. Therefore, hypothesis 1b was supported. However, risk perception or knowledge had a negative and significant relationship with preventative behavior. This was an unexpected and counterintuitive finding. Consequently, hypothesis 2a was rejected. As expected, a belief that greater attention should be paid to economic effects rather than to infection (Economics) had a negative and significant relation with NPI adoption, and thus hypothesis 2b was supported. This is consistent with other findings that framing COVID-19 as primarily a health issue promotes a preference for social distancing, whereas economic framing motivates the opposite [33]. Men (Gender) were less likely to comply with government recommendations, consistent with previous findings that women are more law abiding [31]. Older people (Age) were more likely to adopt recommended

NPIs, in line with studies finding a positive relationship between age and a law-abiding orientation [32]. Income (Income), education (Education), and residence (Urban) were not significantly associated with preventative behaviors.

To test hypotheses 2c-2d and 3a-b examining tracing app use (COCOA), an ordered logit analysis was implemented. The results, shown in Table 5, are not always as predicted. Trust in government (Trust government) had a positive and significant effect on the use of COCOA, supporting hypothesis 3a. However, in contrast to NPI adoption, confidence in scientific expertise (Confidence expertise) did not have a significant impact on using the contact-tracing app. As a result, hypothesis 3b was not supported. Attitudes toward the economic or infection trade-off (Economics) also did not have a significant effect on the use of the app. Hence, hypothesis 2c was not supported. Risk (Perception risk) was also nonsignificant, and hypothesis 2d was not supported. Additionally, no other independent variable, except residence (Urban), had a significant effect on using the app. However, people living in urban areas (Urban) were more likely to use the contact-tracing app compared to those living in rural areas.

Discussion

Principal Findings

The use of NPIs to control the COVID-19 spread will remain important as the global vaccination rollout progresses unevenly and new COVID-19 variants emerge. Moreover, the lessons from this pandemic will assist the management of the next one, if or when it arises. Japan provides a particularly useful field to examine NPI use and its antecedents, particularly because it relies on voluntary adoption rather than on the compulsory use and legal and other sanctions adopted by other OECD countries. Despite the voluntary nature of NPI adoption, respondents from our representative online quota sample reported high use of the 6 types of nondigital NPIs we measured in the 80% and above range. This is in remarkable contrast to the claimed 30%-40% noncompliance rates for use of NPIs in the United States and the European Union despite legal enforcement and significant penalties for noncompliance [5,6]. Moreover, trust in government—seen as a predictor of policy compliance in several studies—is low in Japan and does not predict the use of nondigital NPIs.

Comparison With Prior Work

How can these differences be explained? Drawing on the limited but growing literature on the adoption of NPIs, we tested hypotheses focused on trust in government, confidence in public health scientists, perceived trade-offs between infection control and socioeconomic effects, and perceptions of infection risk based on knowledge of infection among close contacts. Our results sometimes differ from those predicted or indicated by other studies, and, therefore, this study reports a few novel, unexpected, and counterintuitive findings. First, trust in government did not have a significant effect on NPI use. Attention to personal hygiene is often claimed to be an existing aspect of Japanese culture [35]. Moreover, readiness to adopt preventative behaviors in disease control, such as mask wearing, is commonly exhibited. Trust in government may have little or no relationship to this. The second and more perplexing finding is that respondents' risk perception inversely affected NPI adoption or was not significant in terms of phone app use. Our risk measure is a perception based on the reported knowledge of infection among those close to the respondents. Wise et al [29] also reported that risk perception or infection knowledge did not increase concerns about COVID-19 morbidity [29]. Perhaps perceived risk to oneself is not a key driver of NPI adoption or other COVID-19-related control behavior in Japan. Rather, prosocial motivation, social conformity, and cultural constraints may be more important [5,36-39].

Confidence in public health scientists predicts compliance with government NPI directives. Preventive behavior was recommended by a group of experts on COVID-19, and it was associated with scientific leadership rather than political. A generalizable point is that confidence in scientific expertise can encourage compliance with health policy even when trust in government is low. In the past, the Japanese public has demonstrated the capability to be guided by trusted experts in new control measures—particularly when information and responses are clearly articulated and communicated—and to

dramatically change behavior as a result [40]. This has been exhibited during the recent pandemic. In April 2020, Hayasaki [41] quoted a Japanese professor in political science, Koichi Nakano, noting “People remain largely ignorant of the basic principles of ‘social distancing’—a term that remains unknown and alien in Japan.” However, within a few months, social distancing became part of Japanese life. Moreover, this adaptation has been seen across educational, residential, and income categories. These new behaviors are locked in place, and compliance maintained perhaps more through cultural conformity and control than through government fiat, with Japanese culture categorized as collectivist and a premium being placed on compliance with societal norms and group solidarity [36-38]. Once the control measures are successfully signaled by trusted scientific authorities and adopted by a significant portion of society, there arises a social risk of not complying [42-45].

Trust in government and urban residence predicts tracking app use (COCOA). Confidence in public health scientific expertise, however, was not significantly associated with the use of the app. Moreover, reported use of the app was lower than that of other NPIs. This may reflect the troubled development of the app. There may be a disjunction between public scientific expertise related to disease control and an app developed by a contracted nongovernment commercial operation plagued by bugs and low reliability. In collectivist Japan, the less easily observable phone app use may lack the “virtue signaling” of other forms of NPI, such as mask wearing, and hence be less enforceable by societal norms and censure. Trust, privacy protection, and technical efficacy, as well as perceptions of such, are likely to be important in the citizen adoption of digital tools for public health in the future. People living in urban areas are more likely to adopt the contact app, which might be related to a more densely populated environment, with a higher number of contacts and a higher chance of infection. However, risk perception does not have a significant effect on the use of COCOA.

Limitations

Our study has a few limitations. First, the analysis was cross-sectional, and behavior, including adoption of NPIs, might change as fatigue and complacency sets in. To examine causal relations and behavioral changes over time, a longitudinal study would perhaps be useful. A better operationalization of the antecedents of NPI and COCOA adoption, such as personality and cultural factors, might improve the verisimilitude of our results. Our use of an online survey method might have excluded those marginalized by a “digital divide,” particularly important in COVID-19, which may produce unequal outcomes based on socioeconomic status. However, in a time of lockdowns, travel bans, and other controls, an online survey was likely the most pragmatic solution. Generalizability would be improved with further cross-national studies, including an investigation of institutional and cultural factors. Other studies using panel data, alternative methods of sample selection (including nondigital ones), experiments, new antecedents, qualitative interviews, and comparative studies might strengthen findings, by, for example, providing a better understanding of causal relationships.

Conclusions

What are the implications for the implementation and development of public health and health policies? First, we show that voluntary compliance in the adoption of nondigital NPIs—if skillfully led by trusted scientific experts and in accord with societal norms—can be effectively achieved. Despite the voluntary nature of NPI adoption, respondents reported high use of the NPI we measured in the 80% and above range. This contrasts with the 30%-40% noncompliance rates for use of NPIs in the United States and the European Union despite legal enforcement and significant penalties for noncompliance [5,6]. Second, digitalization in the public sector should balance trade-offs between perceived usefulness and privacy. This may

be resolved if trust in government can be developed and maintained, and we provide evidence that trust in government is effective in encouraging the use of digital government services at least in the case of the COCOA tracking app. Moreover, technical efficacy of digital initiatives and perceptions of such will unsurprisingly affect citizen support and use of digital tools. Perhaps this is generalizable to the adoption of other digital tools and e-government in policy and public health, in which Japan remains a laggard. Risk perception and how risk is framed and focused around social and health outcomes may improve NPI uptake, again underpinning the importance of clear and focused communication in developing support and citizen compliance in pandemic control found in other studies [46].

Abstract

Background: Childhood cancer survivors require lifelong risk-based follow-up care. It should be noted that less than one-third of adult survivors of childhood cancer report any survivor-focused care, and fewer than 1 in 5 obtain risk-based follow-up care. It is thought that this may be due to inadequate transition readiness, including low levels of knowledge, skills, motivation, and resources to make the transition to independent self-management of follow-up care. Interventions that focus specifically on improving the transition from parent-managed to self-managed care are needed. Theory and prior research suggest that targeting self-management skills and using peer mentoring may be innovative strategies to improve transition readiness.

Objective: This study aims to identify the content of a self-management intervention to improve transition readiness among adolescent and young adult (AYA) survivors.

Methods: Intervention development occurred in 3 stages: formative research with AYA survivors to identify barriers and facilitators to obtaining risk-based survivorship care, content development using feedback from multiple stakeholders (AYA survivors, parents, and providers), and content refinement (usability testing) of the initial proposed educational modules for the program. Content analysis, guided by the social-ecological model of AYA readiness for transition, was used to identify themes and develop and refine the content for the intervention.

Results: A total of 19 AYA survivors participated in the formative research stage, and 10 AYA survivors, parents, and health care providers participated in the content development and refinement stages. The major barrier and facilitator themes identified included knowledge of cancer history and risks; relationships with health care providers; relationships with family members involved in care; emotions about health, follow-up care, and transfer of care; and lifestyle behaviors and life transitions. These themes were translated into 5 self-management modules: understanding treatment history and the survivorship care plan, managing health care logistics and insurance, communicating with health care providers and family members involved in care, dealing with emotions, and staying healthy in the context of life transitions. Feedback from the key stakeholders indicated that the content was relevant but should include participative elements (videos and tailored feedback) to make the intervention more engaging. The AYA survivors were receptive to the idea of working with a peer mentor and expressed a preference for using SMS text messaging, telephone calls, or videoconference to communicate with their mentor.

Conclusions: Incorporating AYA survivors, parents, and providers in the design was essential to developing the content of a self-management and peer-mentoring intervention. AYA survivors confirmed the important targets for the intervention and

facilitated design decisions in line with our target users' preferences. The next step will be to conduct a single-arm trial to determine the feasibility and acceptability of the proposed intervention among AYA survivors of childhood cancer.

KEYWORDS

self-management; peer mentoring; cancer survivorship; long-term follow-up care

Introduction

Background

Childhood cancer survivors are a growing population, with >500,000 in the United States [1,2]. As many as 67% to 95% of these survivors are at risk for developing chronic health conditions [3-6] as a result of cancer treatment; therefore, survivors require lifelong risk-based follow-up care to identify and treat late health effects based on the cancer treatment they received [7]. It should be noted that less than one-third of adult survivors of childhood cancer report any survivor-focused care and fewer than 1 in 5 obtain risk-based follow-up care [8,9].

The transition from pediatric to adult follow-up care is a critical period when many survivors are lost to follow-up [10]. This transition involves moving from parent-guided management to self-management of long-term follow-up care as survivors assume primary responsibility for tasks such as managing health records, making appointments, filling and taking prescriptions, and understanding late effects and how to follow-up with recommended screenings or treatments. This transition occurs during a critical developmental period when adolescents and young adults (AYAs) may be unaware of, or fail to recognize, their health risks and the need for regular follow-up [11]. Barriers to successful transition include survivors' lack of knowledge of their diagnosis and treatment, cancer-related anxiety and other emotional concerns, other life stressors common among AYAs that are perceived as a greater priority (eg, education and career), and failure or inability to assume personal responsibility for their own health [3,5,7].

Transition readiness refers to the capacity of the AYAs and their support network to prepare for, and complete, the process of moving to adult-oriented care [12]. The social-ecological model of AYA readiness for transition (SMART) [12] identifies modifiable factors related to transition readiness, including knowledge of health history, risks, and needs; self-management skills and self-efficacy for managing care; beliefs and expectations regarding the transition process or adult-oriented care (such as the belief that the adult provider will not understand the patient's needs); goals related to health transition; relationships with parents and providers; and psychosocial functioning of patients, parents, and providers (such as anxiety about the transition process or future health) [12].

To date, interventions targeting AYA survivors of childhood cancer have focused on educational conferences [13,14], providing survivorship care plans through mail [15] or through a mobile app [16], or SMS text messaging and a healthy peer navigator intervention [17]. These interventions have used

technology to overcome common barriers faced by AYA survivors, such as geographic mobility, lack of time, competing priorities, and the relatively small numbers of survivors at single institutions [18]. However, there is a gap in interventions focusing specifically on the transition from parent-managed to self-managed care. Peer mentoring has been recommended as an innovative approach to facilitate health care transitions for AYA survivors [19]. Qualitative and quantitative studies suggest that AYA survivors want to discuss their medical care needs with other AYA survivors [20-22]. The Adolescent and Young Adult Oncology Progress Review Group has recommended the development of standardized peer-to-peer programs as a strategy for supporting the psychosocial needs of AYA patients with cancer and AYA cancer survivors [14].

Objectives

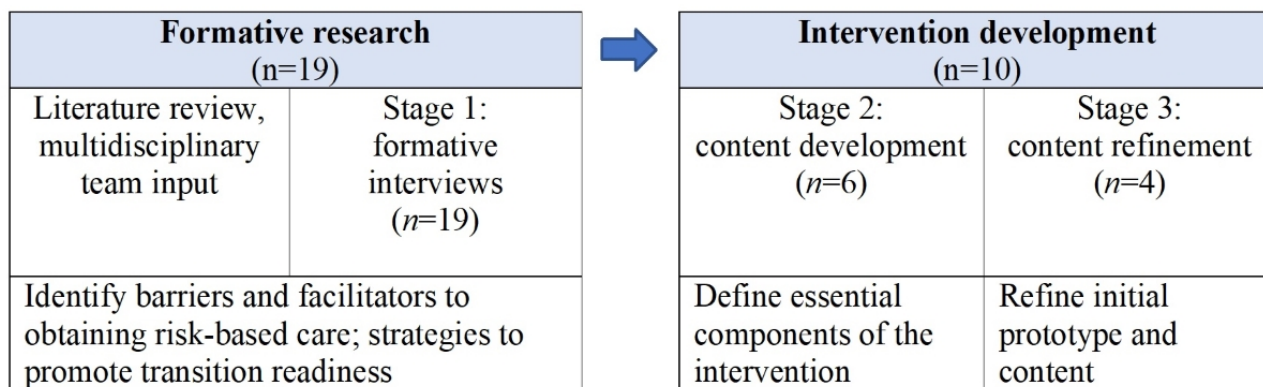

The goal of this work was to develop an intervention to improve transition readiness among AYA survivors of childhood cancer that would address their unique psychosocial and support needs. The development process involved identifying user needs (formative research), evaluating and applying relevant theory, and iteratively producing and refining the intervention product (ie, usability testing). We used principles of user-centered design, which propose an iterative process that identifies the needs and requirements of end users (ie, AYA survivors) and incorporates their feedback at multiple points in the intervention development [23]. The goal was to create an intervention that better meets the needs and expectations of the ultimate users of that intervention. In this paper we describe the user-centered design process used to develop a web-based self-management and peer-mentoring program to improve transition readiness of AYA cancer survivors.

Methods

Program Development

Similar to other intervention development studies [24-26], we used an iterative user-centered process in three stages: (1) *formative research* with AYA survivors to identify barriers and facilitators to obtaining risk-based survivorship care during the transition to adult health care; (2) *content development* using feedback from multiple stakeholders (AYA survivors, parents, and providers); and (3) *content refinement* of the initial proposed content and educational modules for the program with input from AYA survivors (Figure 1). Semistructured telephone interviews were conducted with survivors in stage 1; semistructured in-person or telephone interviews were conducted with survivors, parents, and providers in stage 2; and in-person usability testing was conducted in stage 3.

Figure 1. Managing Your Health intervention development stages.

Participant Eligibility

Eligibility criteria were consistent across the stages. Survivors were eligible if they (1) were aged 18 to 25 years at the time of informed consent, (2) had been diagnosed with any cancer between the ages of 0 and 21 years, (3) were at least 1.5 years after completion of cancer treatment (consistent with preparing to transfer to long-term follow-up), and (4) had no physician- or self-reported cognitive delay or impairment that would prevent self-management of health care. Parents were eligible if (1) they were a primary caregiver of a pediatric cancer survivor currently aged 18 to 25 years, (2) the survivor was at least 1.5 years after completion of cancer treatment, and (3) the survivor did not have physician- or caregiver-reported cognitive delay or impairment that would prevent self-management of health care. Health care providers (eg, physicians and psychologists) were eligible if they regularly provided clinical care to AYA pediatric cancer survivors.

Stage 1: Formative Research

The goal was to identify barriers and facilitators to obtaining risk-based survivorship care to understand the needs of AYA survivors transitioning from pediatric-oriented to adult-oriented care. AYA pediatric cancer survivors were recruited using advertisements posted on Twitter, web-based forums for cancer survivors, listservs of regional nonprofit organizations devoted to childhood cancer, and at the local clinic. This strategy was chosen to try to gain perspectives from survivors in various geographic locations who would represent a range of experiences with long-term follow-up care.

Individual semistructured interviews were conducted through telephone by the last author (KAD) and were audio recorded using digital recorders. Telephone interviews were chosen to allow participation from any geographic location and reduce respondent burden by not requiring an in-person visit. The semistructured interview guide was developed based on a model of factors associated with receipt of risk-based care [27] and the SMART model [12]. Questions elicited AYA survivors’ perspectives regarding survivor-related, provider-related, and health care system-related facilitators and barriers to receipt of care, including during the transfer from acute to long-term follow-up care and the transition from pediatric- to adult-oriented health care. Sample questions included the following: “What kind of follow-up care do you think is appropriate for cancer survivors? What care do you think you

need? Tell me about the transition from the end of your cancer treatment to long-term follow-up care. What barriers could or do prevent you from attending care visits? What could clinics or providers do to encourage childhood cancer survivors to attend? If you could change something about follow-up care, what would you change?” Participants also completed a brief demographic survey.

Each interview was transcribed using semiverbatim transcription. Interview transcripts were analyzed using content analysis, following the framework approach described by Pope et al [28]. An index of themes was created and applied systematically to the data by 2 coders. Themes were identified from the a priori models, and any new themes that emerged from participants’ data were added during the coding process. Data analysis continued until theme saturation occurred (ie, no new themes emerged from additional participants).

Stage 2: Content Development

The goal in this stage was to define the essential content components of the intervention. AYA survivors and caregivers were recruited from the local long-term survivorship clinic list. Health care providers (eg, physicians and psychologists) were recruited through email through the AYA and Survivorship Working Groups of the Children’s Oncology Group.

Semistructured individual interviews with AYA survivors, caregivers, and providers were conducted in person or through telephone and recorded for transcription and analysis. These interviews were guided by the SMART model and the results from the stage 1 formative research. The interview questions started by asking broadly about experiences with long-term follow-up care; for example, “What do you think is involved in the long-term follow-up care for your childhood cancer? What was challenging about beginning to take charge of your own health? What kinds of things were helpful to you in making the transition to taking charge of your health care?” Next, the themes from stage 1 were presented as the potential topics for a new intervention for survivors, and participants were asked to provide feedback on the proposed content. Questions included the following: “What seems useful to you? What does not seem useful? What are we missing?” The idea of matching survivors with a peer survivor who could serve as a mentor was proposed, and participants were asked about their receptivity to working with a mentor and preferred characteristics (eg, personality, cancer diagnosis, and gender). Participants were also asked to

provide feedback about the mode of delivery (eg, web based, videoconference, or SMS text messaging). Qualitative data were analyzed on a continuing basis following the same procedures as those followed in stage 1 and treating respondents as a group of key stakeholders rather than examining them separately by type (ie, survivor vs parent vs provider).

Stage 3: Content Refinement

AYA survivors were recruited from the local long-term survivorship clinic and completed the usability testing in person after their routine clinic visit. Participants were provided with the proposed structure of the program (ie, combination of web-based educational modules plus interaction with a peer mentor) and asked to review the prototype of web-based modules, which were accessible through Canvas, the Rutgers University web-based course management system, accessed through a computer or tablet provided by research staff. Survivors were asked to read through the program modules. Research staff asked questions about their overall impression of the program, the usability of the website, the content of each module, and suggestions for improvement. The staff asked survivors about their communication preferences (type of communication and frequency) and qualities they might prefer

in a mentor. This feedback was then used to modify and finalize the intervention content and format.

Ethics Approval

This study was approved by the institutional review boards at the University of Rochester Medical Center (RSRB00040459) and Rutgers Cancer Institute of New Jersey (Pro2013003819; Pro20150001955). All participants provided informed consent.

Results

Participants

In stage 1, a total of 19 AYA survivors from 12 different states in the United States participated. They were aged on average 22.8 (SD 1.6; range 20.0-25.0) years and were between 2.0 and 21.5 (mean 7.2, SD 6.2) years after completion of cancer treatment. In stage 2, a total of 6 key stakeholders participated: 2 (33%) AYA survivors, 1 (17%) parent of an AYA survivor, and 3 (50%) AYA oncology providers (of these providers, 1/3, 33% was an oncologist, and 2/3, 67% were psychologists). In stage 3, four new AYA survivors provided feedback on the initial prototype (Table 1).

Table 1. Adolescent and young adult survivor characteristics included in each stage of development.

	Stage 1: formative research (n=19)	Stage 2: content development (n=2) ^a	Stage 3: content refinement (n=4)
Age (years), mean (SD)	22.8 (1.6)	22 (1.4)	21.5 (1.5)
Sex, female, n (%)	17 (89)	2 (100)	1 (25)

Non-Hispanic	18 (95)	2 (100)	4 (100)
Diagnosis, n (%)			
Blood cancer	15 (78.9)	1 (50)	4 (100)
Solid tumor	3 (15.9)	1 (50)	0 (0)
Brain tumor	1 (5.2)	0 (0)	0 (0)
Currently receive follow-up care^b, n (%)			
Yes	15 (78.9)	1 (50)	4 (100)
No	4 (21.1)	1 (50)	0 (0)

^aIn stage 2, interviews were also conducted with 4 stakeholders (ie, n=1, 25%, parent of an adolescent and young adult survivor and n=3, 75%, adolescent and young adult oncology providers).

^bThis reflects whether participants reported receiving survivorship follow-up care but not the extent to which they have successfully transferred to adult-oriented care or managed their own care.

Stage 1: Formative Research

In total, five themes were identified from survivors' responses: (1) knowledge of cancer history and risks; (2) relationships with health care providers; (3) relationships with family involved in

care; (4) emotions about health, follow-up care, and transfer of care; and (5) lifestyle behaviors and life transitions. Table 2 defines each theme, lists illustrative quotes, and provides examples of how the theme informed content development.

Table 2. Themes from the stage 1 formative research (N=19).

Theme	Definition	Illustrative quote	Translating into content
Knowledge of cancer history and risks	Lack of knowledge is a barrier to obtaining care. Having a written survivorship care plan and education about required ongoing care facilitates care	<ul style="list-style-type: none"> “I think it’s important to be knowledgeable about what you’ve been through and what could potentially happen. So I feel really lucky that I have that book [of my treatment summary and potential late effects] and I was educated.” [Female Hodgkin lymphoma survivor aged 23 years; 007] “I just want to control and see that everything is correct to get peace for my mind. But I usually go if I am starting to notice any signs what I had before I got the cancer.” [Female ALL^a survivor aged 25 years; 014] 	Help survivors to understand their treatment history and details of their survivorship care plan
Relationships with health care providers	Concerned that adult providers will not understand their unique needs. Difficulty moving on from trusted relationships with pediatric providers. Adult health care system is complex and difficult to navigate	<ul style="list-style-type: none"> “I probably wouldn’t go through the hassle or the time to find a new radiologist in [current location]...the fact that they know me and they know my history does play a big role in it.” [Male Hodgkin lymphoma survivor aged 24 years; 004] “Ideally it would be nice if you could find someone that understands everything you’ve been through. Because I’ve had some effects already happen and they just look at me like oh, that shouldn’t happen to someone your age, but they don’t see what I’ve been through.” [Female ALL survivor aged 21 years; 008] “I don’t really know how to describe it but when I see them it’s like aww, it’s like meeting a family member again after a while and so much fun. I can just laugh with them and they become your friends. You know, they...they take care of you and...I’m grateful to them.” [Female ALL survivor aged 23 years; 003] 	Strategies for identifying and communicating with new adult health care providers
Relationships with family members involved in health care	Parents provide emotional and logistical support; they want to remain involved because of concerns about their child	<ul style="list-style-type: none"> “Oh, [my mom’s] totally on top of it. ’Cause when I got sick, I couldn’t handle all the medical stuff. So she did all of it...no matter how much time passes I think that she’s always gonna want to be there. And I don’t mind her being there.” [Female ALL survivor aged 22 years; 016] “I don’t even know what insurance is anymore because my parents just deal with all of that, which is really nice. If I didn’t have my parents dealing with it, I would probably be lost.” [Male ALL survivor aged 21 years; 001] 	Communication with parents about ongoing involvement in health care
Emotions about health, follow-up care, and transitions in care	Anxiety during transitions in care; worries about future health problems because of surveillance measures; feeling alone or different from healthy peers	<ul style="list-style-type: none"> “It was kind of like being thrown out there with nothing to float with. I guess it’s just kind of a shock because I went from almost every day to not seeing a doctor for 3 months. And it was...hard to do that.” [Female non-Hodgkin lymphoma survivor aged 24 years; 011] “I said I don’t want any more chest x-rays. I don’t want them every 4 months at least. Because then I’m just gonna get breast cancer and it’s gonna be a whole nother mess...It’s so awful how...the preventive measures also give you cancer.” [Female Hodgkin lymphoma survivor aged 22 years; 017] “You just feel...kind of alone sometimes. And even afterwards it’s a scary time because, you know, the treatment may have worked or it may not have worked. And kind of in a waiting period it really helps to have some people to talk to that know what you’re going through.” [Female non-Hodgkin lymphoma survivor aged 25 years; 018] 	Strategies to cope with emotions about health and follow-up care; peer support

Theme	Definition	Illustrative quote	Translating into content
Lifestyle behaviors and life transitions	Focusing on other preventive health behaviors (eg, diet and exercise); prioritizing other important life milestones (eg, pursuing college and career)	<ul style="list-style-type: none"> “It’s all just prevention at this point, trying to stop complications from happening again or anything like that. So it’s really important to make sure that you’re staying healthy, [to do] extra things that other people your age probably don’t have to do and you do.” [Female AML^b survivor aged 21 years; 002] “Sometimes, you know, in the busy lives and as we get older, college and everything, I think we kind of just kind of forget about it, just put it in the back of our minds and then we just kind of ignore it.” [Female ALL survivor aged 20 years; 010] 	Encourage healthy lifestyle behaviors and focusing on health in the context of other important life milestones

^aALL: acute lymphoblastic leukemia.

^bAML: acute myeloblastic leukemia.

In the first theme, a lack of knowledge about personal risk for late effects was commonly reported as a barrier to care. Participants who had received a written survivorship care plan found it to be an important tool to educate themselves about their cancer history and risks for late effects that require ongoing monitoring. Participants reported attending follow-up care to monitor for potential late effects.

The second theme centered on how survivors’ relationship with health care providers influenced their beliefs about follow-up care and the likelihood of attending it. Survivors who continued to see their original treatment team for long-term follow-up care cited their personal relationship with these medical providers as a major factor in their obtaining care. Participants commented that they had developed a strong personal bond because of the time spent with the health care providers during treatment and the seriousness of cancer treatment. They trusted their providers and found familiar providers supportive. The survivors also indicated that feeling *cared for* as a person (not just a disease) was important to them. Similarly, the survivors reported that they would be unlikely to continue care if they had to switch providers because of (1) the close relationship developed with the primary oncologist; (2) distrust of a new provider unfamiliar with their treatment history; (3) inconvenience of, and difficulty with, finding a new adult provider skilled in survivorship care; and (4) having to relay complex medical history to a new provider.

The third theme centered on the role of family members, particularly parents, in their medical care. Although emerging adulthood is typically characterized by greater independence from family, participants indicated that their parents were still involved in their follow-up care. Parents had been responsible for their cancer treatment and wanted to remain involved in follow-up care for their own emotional relief, hoping that their child’s cancer would remain in remission. Parents could help by asking questions, remembering what doctors tell them, and providing emotional support during the visit with the survivors. By contrast, attending clinic on their own was a sign of independence and responsibility.

The fourth theme focused on emotions about health, follow-up care, and transitions in care. Attending long-term follow-up care provided reassurance for survivors and their family that their cancer had not recurred. This reassurance could be sought

when they experienced symptoms that reminded them of the symptoms leading to their diagnosis, or it could be seen as part of routine follow-up care. Survivors could experience anxiety preceding or during their visits because of triggering of unpleasant treatment memories, but the relief about their health status outweighed their anxiety. Concerns about potential negative effects of screening procedures, including increased risk of developing a second malignancy, were barriers to care. There were also reports of feeling *alone* and *different* from healthy peers. Peer support from others *who know* what they were going through was seen as useful.

The fifth and final theme that emerged related to general preventive health behaviors and a focus on other developmentally appropriate life milestones such as going to college and starting a career. Lack of symptoms or late effects and the belief that one was *in the clear* after a certain amount of time after treatment could reduce motivation to seek care in the context of other life priorities.

Stage 2: Content and Program Development

In this stage, qualitative interviews with 6 key stakeholders confirmed that the modifiable variables from the SMART model were relevant and important targets for intervention. Specifically, the SMART constructs included knowledge, self-management skills, self-efficacy, relationships and communication, and goals and motivation.

Knowledge, specifically about treatment and potential late effects, was identified as essential for successful self-management by all (6/6, 100%) stakeholders. The AYA survivors noted that their parents were the ones who initially may have received the information about their follow-up plan and potential late effects and that this information needed to be repeated and provided again as they continue into young adulthood. The AYA participants called for a written guideline or map of what they needed to do and when. Similarly, the parent participant echoed this call for more guidance about what care was necessary moving forward. All (3/3, 100%) of the providers mentioned that their respective institutions provided a written survivorship care plan for guideline-concordant follow-up care. They also confirmed how important it was for patients to obtain a copy of this plan and to know where it is and how to access it as well as to bring it with them to future appointments with other providers.

All (6/6, 100%) participants acknowledged that a lack of skills in navigating the logistics of the health care system was a significant barrier to successful self-management. In particular, both the patient participant and 67% (2/3) of the providers specifically mentioned challenges in dealing with insurance. The providers noted the lack of support (including social work, school, and vocation support) for AYA survivors once they leave their pediatric provider. Both the providers and the parent participant acknowledged that AYA survivors may rely on parents for basic logistics of scheduling and keeping appointments, suggesting that they may lack confidence in handling these tasks themselves. When asked what topics would be a priority for a self-management program, the logistics of navigating the health care system was listed by 83% (5/6) of the participants.

Communication, both with providers and with parents and family members, was another barrier to successful self-management and follow-up care confirmed by participant responses. The AYA survivors described feeling fearful of meeting with new providers because they worried that not all providers would *understand them* and are *not insightful of specific symptoms or feelings* that may be unique to survivors. Of the 3 providers, 1 (33%) echoed sentiments about lack of effective communication and stated as follows:

I don't think survivors are always equipped especially at that age to advocate for themselves...that's maybe a skill that can be developed—how to better advocate for themselves in the health care system, particularly when you're talking with your doctor.

The AYA survivors also mentioned difficulty with talking with their parents about their disease or about taking over some of the tasks related to follow-up care.

Finally, all (6/6, 100%) stakeholders mentioned the importance of learning about other healthy behaviors (both for disease prevention and health maintenance). The AYA survivors described the difficulty of coping with other life events such as school or finding a job in conjunction with maintaining healthy behaviors. The providers echoed this sentiment, reporting that many times survivors will focus on cancer follow-up while excluding other important healthy behaviors, including tobacco

use, safe alcohol use, and sun protection behaviors. All (6/6, 100%) felt that it would be appropriate to provide education about maintaining *general health* within the context of a self-management intervention. When presented with the idea of providing educational content through technology along with a peer mentor, the stakeholders were receptive to the approach. All (6/6, 100%) stakeholders reported that the use of technology such as video calling and SMS text messaging would appeal to survivors. Several (4/6, 67%) stakeholders suggested that mentors should be outgoing advocates; they also suggested matching by diagnosis, if possible, but recognized that finding other things in common would be important for building a relationship. The stakeholders did not identify any new topics outside of the model and themes from stage 1; therefore, we determined that there was thematic saturation after these 6 key stakeholder interviews and moved to creating prototype content for usability testing.

Guided by these results and the SMART framework, we developed a prototype of the web-based self-management skills and peer-mentor intervention. We proposed that the intervention would consist of two components: (1) web-based educational modules to improve self-management skills (using Rutgers Canvas) and (2) a peer mentor to provide support and facilitate engagement with the modules. The web-based self-management modules encompass five key areas: (1) understanding treatment history and the survivorship care plan, (2) managing the logistics of health care, (3) negotiating family involvement in survivorship care, (4) dealing with emotions about survivorship health and follow-up care, and (5) staying healthy in the context of life transitions. Given the amount of self-management education, we decided that a website would be optimal for housing the information and delivering it consistently to all participants. [Table 3](#) presents the proposed content, the SMART constructs targeted by each module, and an illustrative quote from a key stakeholder affirming the relevance of the content. We proposed that the peer mentor would meet with the participant to review the content of the module, discuss how the participant could apply the content, and offer support. Mentors would also remind participants to complete the modules before their meeting.

Table 3. Proposed modules based on formative research and content development interviews.

Proposed module	Module content	SMART ^a constructs targeted	Supportive quote
1. Understanding treatment history and survivorship care plan	<ul style="list-style-type: none"> Name diagnosis, treatments received, and risks for late health effects Understand your treatment history Risk of late effects Obtain (if needed) and store survivorship care plan 	<ul style="list-style-type: none"> Knowledge Goals and motivation 	“I think just like knowing about what I could see in the future, what’s common, what’s not. What’s common with like the treatment I received? And things like that, I think that like mostly what I’m concerned about.” [AYA ^b -1]
2. Managing your health care	<ul style="list-style-type: none"> Review self-management tasks (eg, make appointments and obtain screenings) Establish and maintain relationship with primary care physician Logistics of insurance and health care tasks Identify barriers to obtaining care and problem solve Review motivation and confidence to assume responsibility for care 	<ul style="list-style-type: none"> Self-management skills Self-efficacy Relationships and communication Goals and motivation 	“I think most of the AYAs have a sense of how the health care system runs but I think even just the basic logistics of who do you call to schedule an appointment. You know who do you ask for, for what resource? Where do you get your medications? Things that their parents take care of at a very detailed level, but they sort of understand what the process is because their parents have been doing it for them all along.” [HP ^c -1]
3. Negotiating family involvement in your care	<ul style="list-style-type: none"> Discuss challenges of parents who do not relinquish control and issues related to communication skills Discuss supportive ways to include family 	<ul style="list-style-type: none"> Relationships and communication 	“It more or less started when I went to the doctors and I was talking to them, it was before I went to college. And I guess after that day my mom kind of realized you know she’s older. I’m able to sign my own forms. I was able to be at the office by myself. She didn’t necessarily have to go to the office so when the doctor started directing the questions and the suggestions to only me and not my mom as well it kind of clicked that hey you know I’m going to have to be an adult. I’m going to have to start taking charge of my own health.” [AYA-2]
4. Dealing with emotions about your health and follow-up care	<ul style="list-style-type: none"> Coping with uncertainty of future health Communicating with providers and families about adult-oriented health care 	<ul style="list-style-type: none"> Self-management skills Relationships and communication 	“Well, I think that one of the major things is just worrying about her health. You know and hoping that everything still goes forward in the right direction.” [P ^d -1]
5. Staying healthy in the context of life transitions	<ul style="list-style-type: none"> Recognize that health must be maintained in the context of other important life transitions (eg, education, career, and relationships) Skills and resources for healthy diet, exercise, sexual health, fertility, education, and career Identify value in prioritizing health 	<ul style="list-style-type: none"> Goals and motivation Self-management skills Self-efficacy 	“My goal is that if you take good care of your body and make wise choices your survivorship will be no different than your peers. By thinking about that you know smoking you know or doing drugs or not wearing your seat belt when you’re in the car, all of those things are potential factors that could end your life sooner than, per se, your peers so based on all of the therapy that you received you’re fortunate that you’re here today and what can we do to make sure that your lifelong health is protected?” [HP-2]

^aSMART: social-ecological model of adolescent and young adult readiness for transition.

^bAYA: adolescent and young adult (survivor).

^cHP: health care provider.

^dP: parent.

Stage 3: Content Refinement

All (4/4, 100%) participants found the content in the modules to be relevant and important for managing their own health. The AYA survivors found the website easy to use and reported that the instructions for progressing through the program were

clear. In general, there was a desire for more participative content, including animated videos and tailored quizzes. The survivors indicated a preference for information distribution through infographics and illustrations versus a written *e-book*-type format. Participants made specific recommendations for word changes to improve readability.

There were requests for links to additional resources, including support groups, scholarships, and career resources. Of the 4 survivors, 1 (25%) suggested adding a group discussion forum for all participants. Participants also indicated that they would be likely to access the website on both a computer as well as their mobile phones, and as such, the website should be tailored for mobile use. In response to these suggestions, we added an animated *how-to* video, quizzes for each module, and changed some text to improve readability. We also added a specific *resources* section covering the array of topics suggested. We decided not to add a group discussion forum at this time, given that it would require resources to moderate and add complexity to the intervention. However, we decided we would add a section where mentors could upload a picture and brief biography to share their stories. Our goal was to incorporate as many suggestions as possible with our limited resources so that we could move quickly to a feasibility trial. Sample screenshots of the revised prototype are presented in [Multimedia Appendix 1](#).

When asked specifically about their preference for mode of contact with the peer mentor (ie, videoconference, telephone, SMS text message, and social media), all (4/4, 100%) survivors expressed a preference for communicating with a peer mentor through videoconference or telephone and SMS text message rather than social media. They were receptive to the idea of working with a mentor. Of the 4 participants, 1 (25%) suggested that it would be helpful for the mentor to have received the same diagnosis as they, but another (1/4, 25%) suggested that shared interests or mentor training would be important to successfully initiate a relationship. Although SMS text messaging offers convenience, we felt that video calling would be optimal to build a relationship. With our participants' preferences in mind, we decided that we would introduce the peer mentor-participant pairs through secure SMS text message and then the peer mentor would be responsible for initiating 6 videocalls with their mentee. The first call would focus on rapport building, whereas the remaining calls (5/6, 83%) would focus on discussing and applying the content of the 5 web-based modules (ie, 1 module per call). We also plan to train and supervise mentors closely to facilitate positive relationships.

Discussion

Principal Findings

Childhood cancer survivors are a growing population with a demonstrated need for developmentally appropriate and evidence-based interventions to improve their transition readiness and self-management skills. The goal of this study was to develop a theory-based intervention to improve transition readiness of AYA survivors.

In the first stage of the study, the formative stage, we identified barriers and facilitators to AYA survivors receiving risk-based care, including lack of knowledge about personal risk for late effects, relationships with their medical care team and parents, emotional reassurance about health and remission status, and motivation to remain healthy and pursue normative developmental milestones. Participants reported that their parents remained involved in their follow-up care. The survivors

discussed the emotional challenge of being *different* from healthy peers, with the implication that getting support from peers who had successfully navigated the transition and understood what it is like to be a survivor could be helpful. These results align well with the broader literature on barriers to recommended survivorship care, particularly during and after the transition to young adulthood [29,30]. Combined with the existing literature, our results suggested that a skills-based self-management intervention that also incorporates social support from a peer could address the needs of this population.

In the second stage of the study, key stakeholders (ie, AYA survivors, parent, and providers) confirmed that our identified self-management topics (from stage 1 formative research and the SMART framework) were relevant and important components for an intervention. The stakeholders highlighted the need for increased knowledge about the risk of late effects, enhanced skills for self-management and health care system navigation, strategies for communicating with health care providers and family members involved in care, coping with the emotions of long-term survivorship care, and incorporating healthy behaviors into their everyday lives. These topics were incorporated into a series of web-based modules created to help improve self-management skills. The use of peer mentoring alongside the self-management skills modules is intended to provide support and advice regarding emotional and practical barriers to transition from someone with similar experience. In addition, a peer mentor may serve as a supportive accountability agent, facilitating participants' engagement with the web-based modules. The program was designed such that the mentee participant would complete 1 module per week and review it with their peer mentor.

The web-based modules were well received by the AYA survivors in stage 3 usability testing and were seen as helpful and informative for managing their care. Suggestions to improve the modules were primarily to make them more participative to increase usability and engagement. The AYA survivors were receptive to having a peer mentor. Mentoring has been found to be an acceptable method of intervention among other AYAs with chronic illnesses such as irritable bowel disease, juvenile arthritis, chronic pain, and juvenile diabetes [31-34]. The AYA survivors expressed a preference for using SMS text messaging, telephone calls, or videoconference to communicate with their mentor. Of the 4 AYA survivors, 1 (25%) expressed a preference for being *matched* with their mentor based on cancer type. This preference aligns with the theory of social networks, which proposes that social network ties with those who have direct personal experience with a life event or *experiential similarity* are more likely to offer specialized health-related informational support. Peer survivors, particularly those who have had similar diagnoses and treatments, can offer informational and emotional support through empathic understanding of the concerns of AYA survivors regarding health care self-management, serve as role models, and provide advice and encouragement as AYA survivors take greater responsibility for managing their health care [35,36]. Using a peer survivor mentor is novel compared with existing interventions [17]. However, there may be challenges in recruiting mentors with the same diagnosis, given the relative rarity of some diagnoses.

Limitations

The limitations of this study include reliance on a small sample to move quickly through the stages of development. Although we believed that it was important to recruit beyond our own local clinic catchment area, advertisements through social media and web-based platforms yielded a sample that was primarily female and lacked racial and ethnic diversity, which could limit whether our proposed intervention meets the needs of unrepresented groups. The use of telephone interviews allowed recruitment of individuals from different geographic locations where survivorship care may be different. Telephone interviews (vs in-person interviews) have advantages and disadvantages; telephone interviews may increase disclosure of information by respondents but prohibit observation of nonverbal cues [37]. The SMART model and existing literature were used to form the interview guides and develop the intervention. This gives the content strong theoretical underpinnings but may have limited creativity because our questions were aligned with the framework rather than more open-ended creative design exercises. We also limited our inclusion criteria to AYA survivors currently aged 18 to 25 years because they are legally responsible for their health care and this period is a common

time of transfer from pediatric-centered to adult-centered health care. However, transition is a process that should start earlier in adolescence, and our design process did not capture the input of those who were in the earlier stages of the process.

Conclusions

In conclusion, AYA survivors of childhood cancer are interested in a self-management and peer-mentoring intervention that may improve their confidence and skills to manage their own care. Incorporating AYA survivors into this formative work helped us to confirm theoretically important targets for the intervention and make design decisions in line with our target users' preferences. Although our focus was on AYA survivors of childhood cancer, the barriers and essential intervention topics we identified may be relevant for AYAs with other chronic health conditions because a recent systematic review found that relationship, access to care, insurance, knowledge, and self-management skill barriers transcend illness conditions [38]. Future research is needed to understand the feasibility and acceptability of the proposed intervention. The next step is to conduct a single-arm trial to determine the feasibility and acceptability of the proposed intervention among AYA survivors of childhood cancer.

Acknowledgments

The authors would like to acknowledge Susan Stephens, MSW, and Dawn Carey, RN, for their work in facilitating the study. This study was supported in part by the National Cancer Institute of the National Institutes of Health (R21CA222936) and the Rutgers Cancer Institute of New Jersey Cancer Prevention and Control Pilot Award (P30CA072720). Abstract

Background: Neck surface accelerometer (NSA) wearable devices have been developed for voice and upper airway health monitoring. As opposed to acoustic sounds, NSA senses mechanical vibrations propagated from the vocal tract to neck skin, which are indicative of a person's voice and airway conditions. NSA signals do not carry identifiable speech information and a speaker's privacy is thus protected, which is important and necessary for continuous wearable monitoring. Our device was already tested for its durable endurance and signal processing algorithms in controlled laboratory conditions.

Objective: This study aims to further evaluate both instrument and analysis validity in a group of occupational vocal users, namely, voice actors, who use their voices extensively at work in an ecologically valid setting.

Methods: A total of 16 professional voice actors (age range 21-50 years; 11 females and 5 males) participated in this study. All participants were mounted with an NSA on their sternal notches during the voice acting and voice assessment sessions. The voice acting session was 4-hour long, directed by a voice director in a professional sound studio. Voice assessment sessions were conducted before, during, and 48 hours after the acting session. The assessment included phonation tasks of passage reading, sustained vowels, maximum vowel phonation, and pitch glides. Clinical acoustic metrics (eg, fundamental frequency, cepstral measures) and a vocal dose measure (ie, accumulated distance dose from acting) were computed from NSA signals. A commonly used online questionnaire (Self-Administered Voice Rating questionnaire) was also implemented to track participants' perception of vocal fatigue.

Results: The NSA wearables stayed in place for all participants despite active body movements during the acting. The ensued body noise did not interfere with the NSA signal quality. All planned acoustic metrics were successfully derived from NSA signals and their numerical values were comparable with literature data. For a 4-hour long voice acting, the averaged distance dose was about 8354 m with no gender differences. Participants perceived vocal fatigue as early as 2 hours after the start of voice acting, with recovery 24-48 hours after the acting session. Among all acoustic metrics across phonation tasks, cepstral peak prominence and spectral tilt from the passage reading most closely mirrored trends in perceived fatigue.

Conclusions: The ecological validity of an in-house NSA wearable was vetted in a workplace setting. One key application of this wearable is to prompt occupational voice users when their vocal safety limits are reached for duly protection. Signal processing algorithms can thus be further developed for near real-time estimation of clinically relevant metrics, such as accumulated distance dose, cepstral peak prominence, and spectral tilt. This functionality will enable continuous self-awareness of vocal behavior and protection of vocal safety in occupational voice users.

KEYWORDS

mechano-acoustic sensing; voice monitoring; wearable device; neck surface accelerometer

Introduction

Background

Neck surface accelerometers (NSAs), a type of mechano-acoustic sensor, have been adopted as mobile health (mHealth) wearables for voice and upper airway health monitoring [1-5]. The vocal folds, which are housed in the larynx, oscillate at high frequencies (>100 Hz) when we speak or sing. The generated acoustic waves travel along the vocal tract, which acts as a resonator to shape the sound into audible speech. Concurrently, these acoustic waves propagate laterally to the tracheal wall and the neck skin surface. NSAs are used to convert these mechanical accelerations into electrical signals for digital devices, which can be applied to monitor a person's vocal activity and health.

Compared with other mHealth wearables embedded with acoustic microphones, NSA-based wearables have advantages of protecting speaker's privacy and increasing signal quality for remote, continuous voice monitoring. For instance, the neck tissue acts as a low-pass filter by nature and restricts the signal bandwidth to 1.5 kHz at maximum [4]. As most recognizable phonetic features (eg, vowel formants) are within the high-frequency range (around 6-8 kHz), identifiable speech information is already filtered by the neck tissue and barely captured by NSAs [6]. Furthermore, NSAs possess anti-interference ability against background noise because they are only sensitive to contact vibration but not to air-borne acoustic waves.

From the clinical perspective, an individual's voice condition is evaluated through an array of acoustic and aerodynamic metrics such as fundamental frequency (f_0), cepstral peak prominence (CPP), sound pressure level (SPL), subglottal pressure as well as the difference between the first and second harmonic magnitudes (H1 – H2). These clinical metrics are typically obtained from conventional clinical instruments such as Computerized Speech Lab, electroglottography, and Rothenberg mask systems. These instruments are, however, large and expensive, which are not suitable for mHealth apps. Several research groups, including our team, have thus developed compact and lightweight NSA wearables to collect voice-related metric data continuously without causing users' discomfort or interruptions to their daily activity [3,4,7-11].

Voice-related metrics obtained from NSA devices were not found to differ from those obtained with conventional instruments [12-14]. For instance, NSA-derived and microphone-derived jitter and CPP values were relatively

comparable across vowels in both normal and deviated voices (both $r > 0.78$) [12]. Estimation error of SPL from NSA signals of voiced speech was less than 2.8 dB [13]. To estimate aerodynamic features of voice sounds, an impedance-based inverse filtering model was applied to derive glottal volume velocity from NSA signals [15]. NSA-derived and airflow-derived H1 – H2 values were found fairly comparable ($r = 0.72$) [16]. Similarly, moderate correlation ($R^2 = 0.63$) was reported between the NSA root-mean-square amplitude and intraoral pressure in vocally healthy speakers across vowels [17].

Growing evidence further supports the robustness of NSA signals in discerning normal versus deviated vocal health conditions. For example, one study collected NSA-derived acoustic metrics from a group of female patients with hyperfunctional voice disorders and their matched controls for over a week [18]. The patient group displayed overall higher SPL values and less H1 – H2 variability than matched controls [18]. By applying machine learning techniques, our group showed that distinctive voice types (normal, breathy, and pressed voice) could be classified from NSA signals with more than 80% accuracy [4]. That said, in reviewing published studies using conventional air microphones, inconsistent calculated values of acoustic voice metrics were reported between sustained vowels and continuous speech [19]. Although sustained vowel tasks were more common in clinical voice assessment, continuous speech tasks are more ecologically valid to represent an individual's natural speaking voice. A thorough evaluation of NSA-derived acoustic metrics across phonation tasks is thus imperative as part of instrument validation.

One target clinical population for voice monitoring wearables includes those who use their voices heavily in the workplace. Voice actors, singers, and teachers are examples of occupational voice users who tend to develop vocal fatigue and disorders [20-23]. A key functionality of NSA wearables is to provide real-time alerts when a user's vocal safety limit is reached at workplace. That way, the user can take immediate action rather than unknowingly surpass the threshold for safe voice use, which would result in chronic vocal fatigue and irreversible vocal injury. Vocal dose metrics are available to estimate the amount of voice use by quantifying the distance that vocal fold travels during phonation. Several vocal dose metrics such as distance dose (Dd), cycle dose, and time dose were successfully derived from NSA signals by our group and others [11,24-27]. However, inconclusive literature suggested that these metrics could be gender dependent, which may implicate the need for creating gender-specific vocal safety limits [28]. An investigation on

the quantitative relationship between vocal doses and NSA-derived acoustic metrics in both females and males is thus pivotal to validate this critical question.

Research Objectives and Hypotheses

This study represents our ongoing work to develop and validate an in-house NSA wearable system for voice and upper airway health monitoring. Our device has already been tested in controlled laboratory settings [4,11]. As one major application of this device is to monitor voice use at workplace, the next logical step would be to test whether the device could endure one such ecologically valid condition. This study thus aimed to test the instrument validity of our NSA wearables in a group of occupational voice users, namely, voice actors, during their voice acting routines in a professional sound studio.

Briefly, all participants were subject to a voice acting session in an ecologically valid setting plus 2 follow-up sessions of voice assessments. Vocal doses and acoustic metrics were collected with our in-house NSA wearables and self-perceived vocal fatigue was assessed by an online questionnaire. NSA acoustic metrics were extracted from both sustained vowels and passage reading tasks. Furthermore, certain voice actors have a routine of practicing vocal warm-up exercise as part of their acting. Participants were thus randomized to either a warm-up group or no warm-up group before their acting session to protect the ecological validity while minimizing potential confounding effects from an individual's warm-up history.

We hypothesized that NSA-derived acoustic metrics and self-perceived vocal fatigue ratings would show similar trends

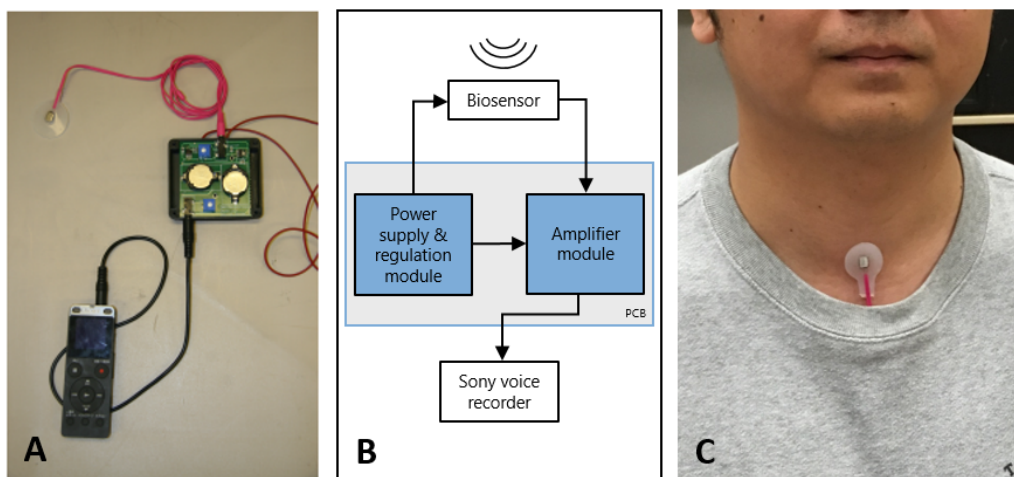

indicative of vocal fatigue and recovery. We also hypothesized that the acoustic metrics derived from passage readings would be comparable to those derived from sustained vowels. We further hypothesized that distance dose and NSA-derived acoustic metrics would be comparable between female and male participants in this study.

Methods

Hardware

Our in-house NSA system consisted of (1) an accelerometer (BU-27135; Knowles Inc.) set into a circular silicon pad with a diameter of 28 mm, thickness of 1.2 mm, and weight less than 20 g; and (2) a peripheral circuit containing 1 power supply module and 1 amplifier module on a printed circuit board (Figure 1). Four lithium coin batteries (CR2032; Panasonic Inc.) with a nominal voltage of 3 V and capacity of 225 mA hour were used as a power source. The peripheral circuit board was interfaced with the accelerometer using a 3.5-mm stereo audio cable. A Sony voice recorder (ICD-UX565F; Sony Inc.) was used as a data logger to save the NSA data in .wav audio format and transferred to a computer for signal processing and analysis. The total cost of each device was about CAD \$100 (US \$77). All NSA recordings were made using a linear pulse code modulation encoding mode with a 44.1-kHz sampling rate. A signal-to-noise ratio of 45 dB was achieved using the recorder's multiple modes for background noise suppression. Further details and verification tests of the NSA system were reported in our previous publications [4,5,11,29].

Participants

Participants were recruited via the Alliance of Canadian Cinema, Television and Radio Artists (ACTRA) (Montreal Chapter) network. A total of 16 professional voice actors aged 21-50 years consented to participate in the experiment. Participants were randomly assigned to either a *no warm-up* group (n=4 for both females and males) or a *warm-up* group (females: n=7;

males: n=1). All participants had basic voice acting experience defined as (1) having participated in at least one voice acting workshop organized by the ACTRA; or (2) having been contracted, on at least one occasion, to complete paid voice work on a project. All reported normal hearing bilaterally. Individuals with a smoking habit (>1 cigarette per day within the last year or any smoking habit within the last 2 months), current history of chronic (ie, lasting >2 weeks) voice problems,

or current use of medications that are considered to possibly affect an individual's voice (ie, diuretics, decongestants) were excluded from the study.

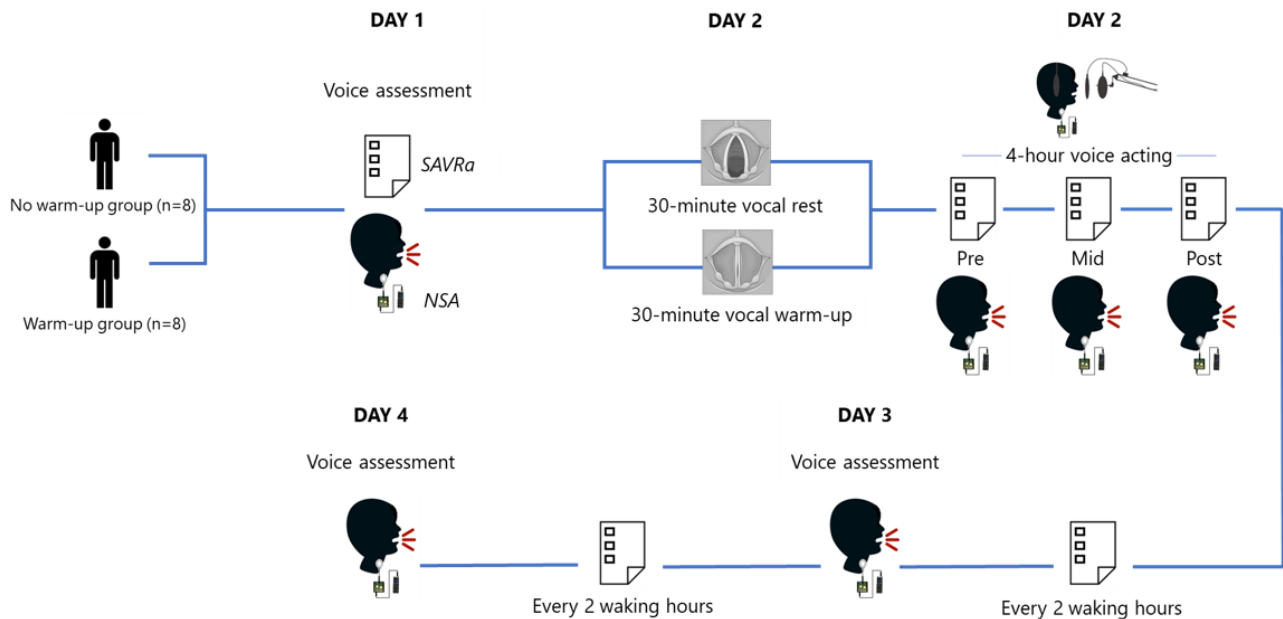

Experimental Design and Data Acquisition

Overview

The experimental protocol spanned across 4 consecutive days for various tasks (Figure 2). Voice assessments were conducted

on days 1, 3, and 4 at McGill University's Voice and Upper Airway Research Lab. Voice assessments and a professional voice acting session took place on day 2 at a professional recording studio. Upon arrival to the laboratory or the studio, an NSA was mounted onto a participant's neck surface around the glottal notch region. Two medical adhesives, (1) a conductive paste on the silicon pad to ensure adherence to the neck skin, and (2) a medical tape, were used to ensure the sensor did not shift during the study.

Figure 2. Human Protocol of Voice Assessments and Voice Acting. Voice assessments included Self-Administered Voice Rating questionnaire (SAVRa) and neck surface accelerometer (NSA)-derived acoustic voice evaluation.

Voice Acting Session

Participants were required to wear an NSA during the whole session. Before the voice acting, the warm-up group participants practiced a 30-minute vocal warm-up routine with a trained speech-language pathologist to ensure the warm-up exercise stayed consistent across participants. The no warm-up group participants were instructed to take vocal rest by refraining from using their voices completely during the 30 minutes preceding the acting session.

After that, all participants proceeded to perform a 4-hour-long voice acting session directed by a professional vocal director. The acting was based on a standardized script from the Assassin's Creed® video game. Participants were instructed to keep a mouth-to-microphone distance of 50 cm as much as possible without hindering their acting. The air microphone sound was purely used for on-site coaching purpose. Given the confidentiality in video game development, the air microphone data were prohibited for research use.

The acting session consisted of 2 parts: (1) part 1, consisting of low-intensity (eg, casual dialog) voice-over work; and (2) part 2, consisting of medium- (eg, barks, oh-noes) and high-intensity (eg, death cries) voice-over work. The voice director provided feedback to participants on their performance, in an effort to ensure that intensity levels and acting styles were consistent

across participants. As a common practice in voice acting, a 15-minute break was provided between parts 1 and 2. Further, participants had access to water and were encouraged to drink throughout sessions. The voice director would reinforce actors to take a drink during sessions when audible "mouth noises" were heard, as the resulting sounds could not be used in the game videos for technical reasons.

Voice Assessment Protocol

Time Points

The voice assessment protocol included self-perceptual ratings of vocal fatigue and acoustic voice evaluations derived from NSA measurements. The protocol was conducted at 6 study time points: (1) 24 hours before the voice acting session, as a baseline measure; (2) immediately prior to the voice acting session (pre-session); (3) halfway through the voice acting session (mid-session, ie, the 15-minute break between part 1 and part 2 of acting); (4) immediately after the voice acting session (post-session); (5) 24 hours after the voice acting session; and (6) 48 hours after the voice acting session. Participants were also asked to complete the self-perceptual rating questionnaire remotely every 2 waking hours following the voice acting session until the end of the study (Figure 2).

Self-Perceptual Ratings of Vocal Fatigue

The Self-Administered Voice Rating (SAVRa) questionnaire was administered to evaluate participants' perception of vocal fatigue [27]. Three SAVRa ratings were used in this study, namely, *current speaking effort level* (EFFT: 1=no effort, 10=extreme effort to speak), *laryngeal discomfort level* (DISC: 1=no discomfort, 10=extreme discomfort), and *inability to produce soft voice* (IPSV: 1=unproblematic soft voice,

10=extreme problems with producing the soft voice). An electronic version of the SAVRa was created on the SurveyMonkey website [30] for remote data collection.

Acoustic Voice Evaluation

To approximate a standard clinical protocol of acoustic voice evaluation, 4 phonation tasks were elicited from participants wearing an NSA (Table 1). A description of the 4 phonation tasks and related acoustic metrics is presented in Table 1.

Table 1. Phonation tasks.

Task number	Phonation task	Acoustic metrics
1	1-minute reading of the Rainbow Passage	<ul style="list-style-type: none"> • Cepstral peak prominence • Fundamental frequency • H1 – H2^a • Harmonic richness factor • Spectral entropy • Spectral tilt • Surface/skin acceleration level
2	Vowel phonation /a/ for 5 seconds	<ul style="list-style-type: none"> • Cepstral peak prominence • Fundamental frequency • H1 – H2 • Harmonic richness factor • Spectral entropy • Spectral tilt • Surface/skin acceleration level • Jitter • Shimmer
3	Deep breath and vowel phonation /a/	<ul style="list-style-type: none"> • Maximum phonation time
4	Glide on vowel /a/ from low to high pitch	<ul style="list-style-type: none"> • f_0 minimum • f_0 maximum

^aH1 – H2: difference between the first and second harmonic magnitudes.

Task 1 (Rainbow Passage task) was used to assess acoustic metrics during running speech. Participants were required to read the standard Rainbow Passage for a duration of 1 minute using a pitch, loudness, and pace similar to a natural conversational context. Seven metrics, namely, CPP, f_0 , H1 – H2, harmonic richness factor (HRF), spectral entropy (SE), spectral tilt (Tilt), and skin acceleration level (SAL), were extracted during this task.

Task 2 (sustained vowel task) was used to assess acoustic metrics in a more steady-state phonation style. Participants were asked to sustain the vowel sound /a/ for 5 seconds while maintaining a steady pitch and loudness. In addition to the aforesaid metrics, jitter and shimmer were quantified to measure pitch and loudness stability, respectively. Of note, the extraction of jitter and shimmer are only applicable for relatively stable and periodic signals, such as those of sustained vowels herein.

Task 3 (maximum phonation task) was used to measure the maximum time (in seconds) that a person can sustain phonation. Participants were instructed to take a deep breath and produce the vowel /a/ as long as possible, using a comfortable pitch and loudness.

Task 4 (pitch glide task) was used to evaluate an individual's pitch range. Participants were instructed to start saying /a/ at the lowest pitch possible and slowly glide their voice as high in pitch as possible. Minimum pitch (f_0 minimum) and maximum pitch (f_0 maximum) values were extracted for this task.

NSA Data Processing

All NSA-related data extraction and calculation were performed using the MATLAB (MathWorks) software. For the computation of acoustic metrics (see Table 2 for detailed algorithms), raw NSA data were first segmented into 45-ms long segments. The voice activity detection method, which was based on short-term energy and zero-crossing rate, was used to remove nonvoiced segments [31]. Only voiced segments were used to extract acoustic metrics and a Hamming window with fast Fourier transform was used to obtain NSA spectra [4]. For CPP, H1 – H2, HRF, Tilt, and SE computation, spectral amplitude normalization was further performed to normalize the amplitudes of all 45-ms spectral segments into the range [0,1]. Furthermore, peak-picking recognition function was applied to identify the harmonics location (ie, H1, H2, H3, ...) for the 4 harmonic-dependent metrics, namely, CPP, H1 – H2, HRF, and Tilt.

Table 2. Mathematical formulas and definitions of acoustic metrics.

Acoustic metrics	Mathematic formula	Units	Definition
CPP ^a	$Peak_max - (b_0 + b_1 * q)$ where Peak_max is the amplitude in decibels of the highest cepstral peak, b ₀ and b ₁ are the coefficients of the least-square linear regression model of the cepstrum, and q is the quefrency of the highest cepstral peak.	Decibels	The difference in amplitude between the cepstral peak and the corresponding value on the trend line through the overall spectrum, which represents how far the cepstral peak emerges from the cepstrum background.
f ₀ ^b	$1/T$ where T is the period.	Hertz	Frequency of vocal fold vibration that is the lowest of all the frequencies in the voice spectrum and is obtained by the reciprocal of the smallest period.
H1 – H2 ^c	$20\log(A1/A2)$ where A1 and A2 are the magnitudes of the first and second harmonics in the spectrum, respectively.	Decibels	The log-magnitude difference between the amplitudes of the first and second harmonics in the spectrum.
HRF ^d	 where H _r represents the magnitude of the rth harmonic.	Decibels	Ratio of the sum of the amplitudes at the harmonics above the fundamental frequency to the amplitude of the component at the fundamental frequency.
SE ^e	 where p _i is the normalized spectral density point (0-3000 Hz).	Relative value	Estimates the uniformity of signal energy distribution in the frequency domain.
Tilt ^f	 where H _n is the amplitude of spectral harmonics in decibels, b ₀ is the least-square linear regression intercept, and f is the spectral frequency.	Decibels/Hertz	Tilt of the trend line of the long-term average spectrum, which represents the degree to which intensity drops off as frequency increases.
SAL ^g	$20\log(\max[\text{data_frame}]/A_noise)$ where data_frame is voiced segment and A_noise is the system reference noise level and equal to 0.004 based on the nonvoice waveforms.	Decibels	The calculation is based on the maximum of each voiced segment amplitude for every 45-ms segment window.
Jitter _(relative)	 where T _i (i=1, 2, ..., N) is the period of each vocal cycle.	Percent	Average absolute difference between consecutive periods divided by average period, indicating the cycle-to-cycle variation of the fundamental frequency.
Shimmer _(relative)	 where A _i (i=1, 2, ..., N) is the peak magnitude in each vocal cycle.	Percent	Average absolute difference between the amplitudes of consecutive periods divided by average amplitude, indicating the cycle-to-cycle variation of vocal amplitude.
MPT ^h	T2 – T1 where T2 is the time at which the phonation of a vowel sound finishes and T1 is the time at which the phonation of a vowel sound begins.	Seconds	Measure of a maximally sustained vowel following a maximal inspiration, which provides an indication of the efficiency of the respiratory mechanism.

^aCPP: cepstral peak prominence.

^bf₀: fundamental frequency.

^cH1 – H2: difference between the first and second harmonic magnitudes.

^dHRF: harmonic richness factor.

^eSE: spectral entropy.

^fTilt: spectral tilt.

^gSAL: skin acceleration level.

^hMPT: maximum phonation time.

Conventionally, the computation of these acoustic metrics is based on glottal flow waveforms, which are derived from mouth-radiated acoustic pressure or airflow signals using inverse filtering estimation. However, as the NSA signals are based on

skin acceleration, no mouth-radiated pressure components are present for inverse filtering to obtain glottal flow pulses and thus the resulting waveforms. As such, algorithms of H1 – H2, SE, Tilt, and SAL were customized and parameterized in this

study [15]. For the calculation of H1 – H2, the first and second harmonics were derived from the NSA spectrum directly. For SE, this metric was computed to quantify the uniformity of signal energy distribution, that is, the degree of chaos, in the frequency domain of the NSA spectrum. From our previously published study [4], the SE was identified as a key acoustic metric in discriminating voice types, in which pressed voice showed higher SE value than those of normal and breathy voice. For the calculation of Tilt, the slope was equal to the amplitude of the spectral harmonics divided by the frequency. In this study, Tilt was computed as a least-square linear regression slope of the long-term average spectrum, which represents the degree to which intensity drops off as frequency increases. The first-order polynomial was used to calculate the slope of the spectral harmonics. For the calculation of SAL, the NSA background noise level was measured as an average value of A_{noise} , which is equal to 0.004. The SAL was calculated for every 45-ms voiced segments. The SAL was a logarithmic form of the NSA amplitude and showed positive correlation with SPL. Both our own and others work showed that SAL was a good estimate of the SPL outputs in phonation tasks [29,32].

Lastly, for distance dose, the algorithm was based on our previously published work [11]. In brief, equivalent SPL values were first estimated using a logarithmic curve-fitting model on SAL values. The location of each vocal cycle was then identified using the peak-picking recognition function. The equivalent SPL values were used to calculate the oscillating amplitude of vocal folds in each vocal cycle. The oscillating amplitude and the number of vocal cycles were finally used to calculate the total distance that the vocal folds traveled during the recorded time.

Statistical Analysis

Statistical Software

JMP Pro software (version 16.1.0; JMP Statistical Discovery LLC) was used for all statistical analyses. With the high number of contrasts carried out throughout this analysis, a more conservative α value of .01 was used to minimize the chances of a type 1 error.

SAVRa Scores

As SAVRa scores were obtained every 2 hours after the acting session, data were reduced by averaging the scores to the corresponding AM or PM of the day. For instance, day 3 scores obtained from 12:00 AM to 11:59 AM were averaged as day 3 AM, whereas those from 12:00 PM to 11:59 PM were averaged as day 3 PM. In addition, individual difference scores were computed for each participant by subtracting mean values at baseline (day 1) from means at each time point and then averaged as described above. Computing and analyzing

differences helped to normalize individual variation and allowed for analyses to highlight changes in vocal measurements and fatigue over time. Both means and difference scores were used for statistical analyses.

Mixed-effects ANOVA was performed on each SAVRa score (EFFT, DISC, and IPSV). Either study group (warm-up or no warm-up) or gender group (female or male) was treated as a between-subjects factor in separate mixed-effects ANOVAs. Full-factorial models were not conducted because of the uneven distribution of genders across study groups. *Time* was treated as a within-subjects factor (day 1, day 2 pre-session, day 2 mid-session, day 2 post-session, day 2 PM, day 3 AM, day 3 PM, day 4 AM, day 4 PM). Planned paired contrasts were performed for significant main effects ($P < .01$), for example, score on each day compared against day 1 (baseline). For analyses involving study group, individual difference scores were used instead of mean values to minimize the effects of the unequal distribution of males and females in each study group.

NSA-Derived Distance Dose

Accumulated distance doses for (1) the entire voice acting session (Total Dd), (2) the first part of the session (Dd part 1), and (3) the second part of the session (Dd part 2) were computed for each participant. No data normalization was performed for these data. Mixed-effects ANOVAs were conducted with session dose (Dd part 1 vs Dd part 2) as a within-subjects factor, and study group or gender group as a between-subjects factor. A separate *t* test was conducted for Total Dd.

NSA-Derived Acoustic Metrics

For NSA-derived acoustic metrics, mixed-effects ANOVAs were conducted using time as a within-subjects factor (day 1, day 2 pre-session, day 2 mid-session, day 2 post-session, day 3, day 4) and study group or gender group as a between-subjects factor. Planned paired contrasts were performed for significant main effects ($P < .01$). For analyses involving study group, individual difference scores (magnitude of change compared with baseline) were used instead of mean values.

Ethical Approval

This human protocol (A04-B21-17A) was approved by the Institutional Review Board at McGill University. The full purpose of the study was not communicated to participants until after completing the study to minimize participant bias on self-perceptual rating measures.

Results

Participant Demographics

The breakdown of participant demographics as functions of study group and gender group is shown in Table 3.

Table 3. Participant descriptive statistics.

Group	Age (years), mean (SD)	Voice acting experience (years), mean (SD)
Study group		
No warm-up	32 (5.1)	4 (2.9)
Warm-up	32 (5.5)	8 (5.7)
Gender group		
Female	32 (5.5)	7 (5.4)
Male	33 (4.7)	4 (3.2)

NSA Instrumentation and Analysis Validity

Participants performed their voice acting with NSA wearables for 4 hours in an ecologically valid setting. The wearables stayed in place for all participants regardless of active body movements during the acting session. All planned acoustic metrics were successfully extracted from NSA signals. To further validate

the NSA signal processing algorithm, numerical values of our acoustic metrics from the Rainbow Passage task were compared with those extracted from daily conversational speech by other research groups. Our data were found to be within a reasonable numerical range with others, supporting both the ecological and external validity of our instrument and analyses (Table 4).

Table 4. Acoustic metrics comparison.^a

^aMode and mean (SD) data for the acoustic metrics f_0 , CPP, H1 – H2, Tilt, and Tilt Abs are presented for our Rainbow Passage task as well as for conversational speech from related research studies.

^b f_0 : fundamental frequency.

^cCPP: cepstral peak prominence.

^dH1 – H2: difference between the first and second harmonic magnitudes.

^eTilt: spectral tilt.

^fTilt Abs: tilt absolute.

^gPVFL: phonotraumatic vocal fold lesions.

^h—: data not available.

ⁱPVH: phonotraumatic vocal hyperfunction.

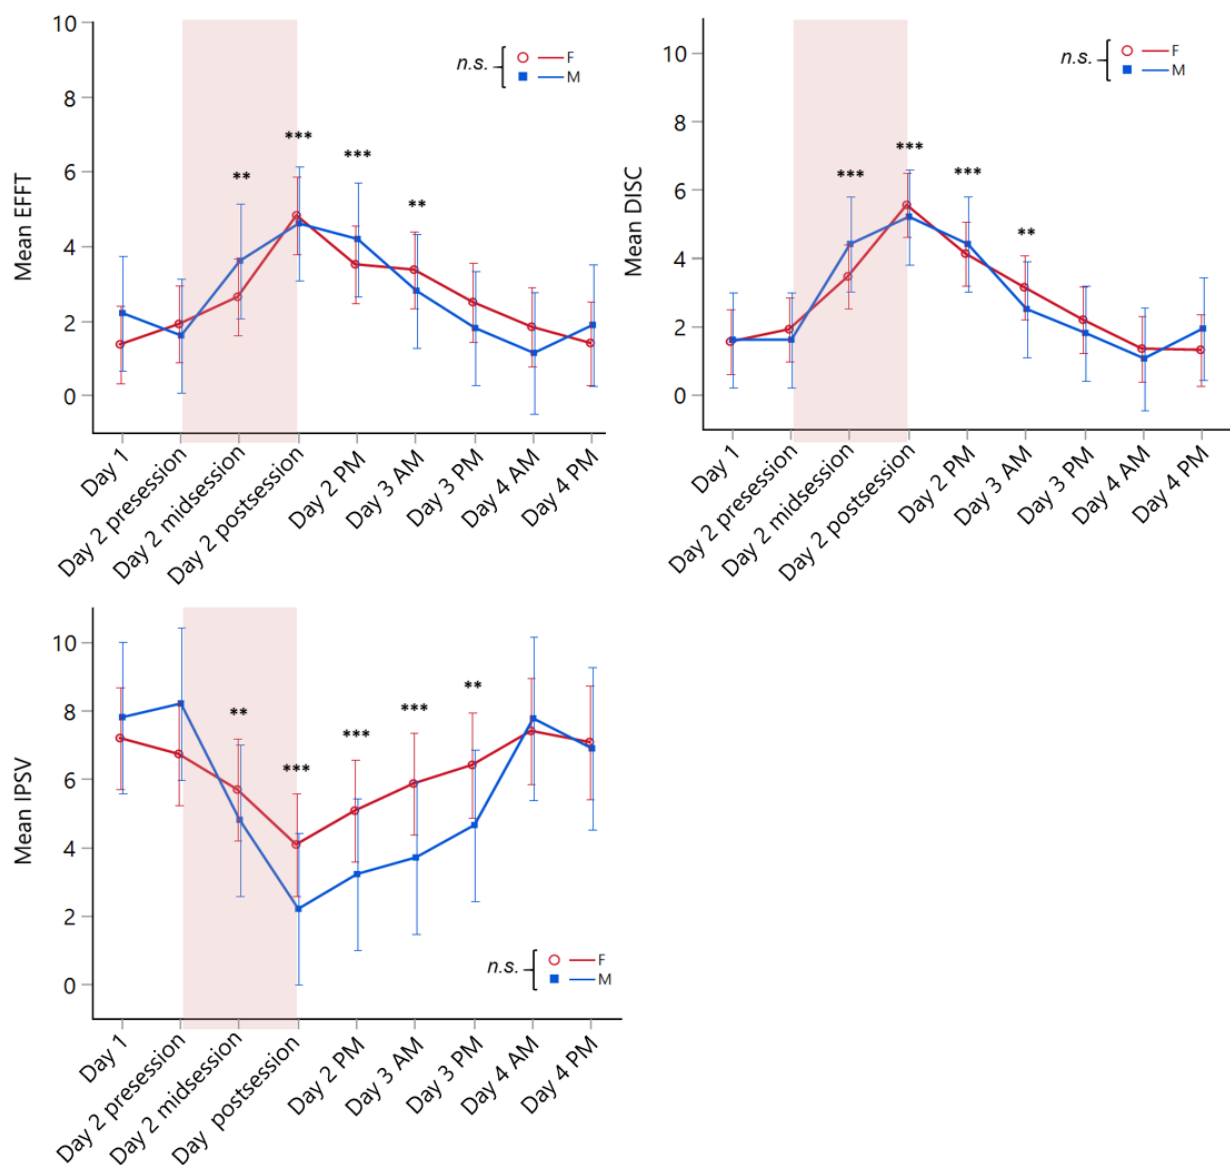

^jNPVH: nonphonotraumatic vocal hyperfunction.

SAVRa

No significant effects of study group or gender group were observed for SAVRa measures, but a main effect of time was found on all 3 SAVRa scores (all $P < .001$; Figure 3; see Multimedia Appendices 1 and 2 for detailed test statistics). Post hoc tests showed that EFFT and DISC scores were all

significantly higher than baseline from day 2 midsession to day 3 AM (all $P < .01$). IPSV scores were significantly lower than baseline starting from day 2 midsession to day 3 PM (all $P < .01$). These results suggest that professional voice acting could induce self-perceived vocal fatigue as early as 2 hours after the start of acting, with potential recovery occurring 24-48 hours after the completion of acting session.

Figure 3. Means and standard errors (error bars) of Self-Adminstrated Voice Rating questionnaire (SAVRa) as functions of Time and Gender Group. The voice acting session is highlighted in the pink region. Asterisks denote statistically significant differences between a specific time point and Day 1 (** $P \leq .01$, *** $P \leq .001$). DISC: laryngeal discomfort level; EFFT: current speaking effort level; IPSV: inability to produce soft voice; n.s.=no significant differences.

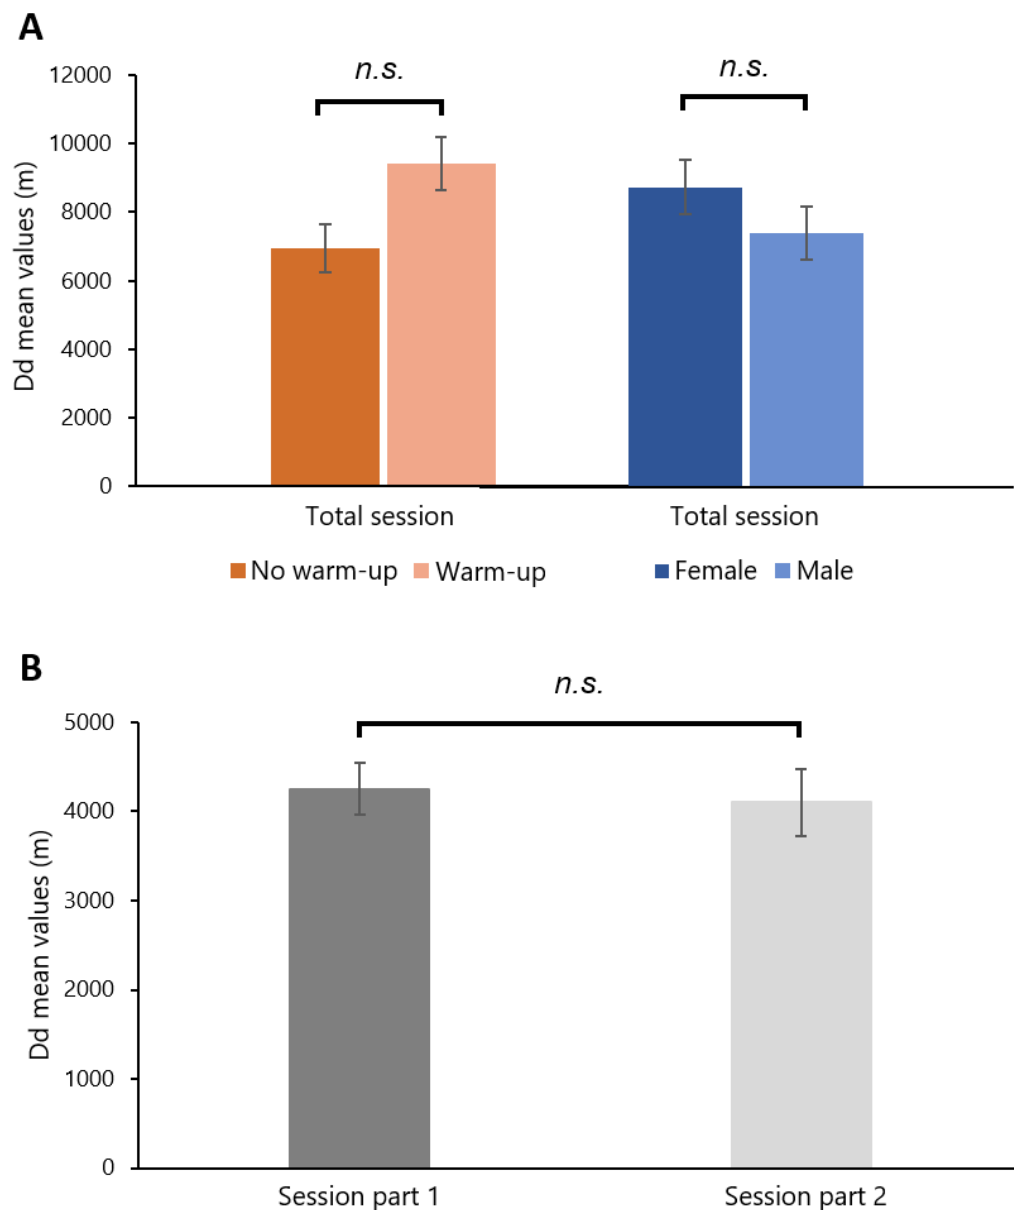

NSA-Derived Distance Dose

No significant main effects of study group, gender group, or session dose were found on independent tests of distance dose. The averaged Total Dd was approximately 8354.35 m (SD

2301.84 m) for a 4-hour voice acting across participants. The averaged Dd was approximately 4250.24 m (SD 1408.31 m) for part 1 and 4104.11 m (SD 1086.22 m) for part 2 of the acting

session (Figure 4; see Multimedia Appendix 3 for detailed test statistics).

Figure 4. Means and standard errors (error bars) of accumulated distance dose (Dd) as functions of Study Group and Gender Group. (A) Total 4-hour sessions. (B) First and second parts of session. n.s.=no significant differences, ie, $P>.01$.

NSA-Derived Acoustic Metrics

Overview of Tasks

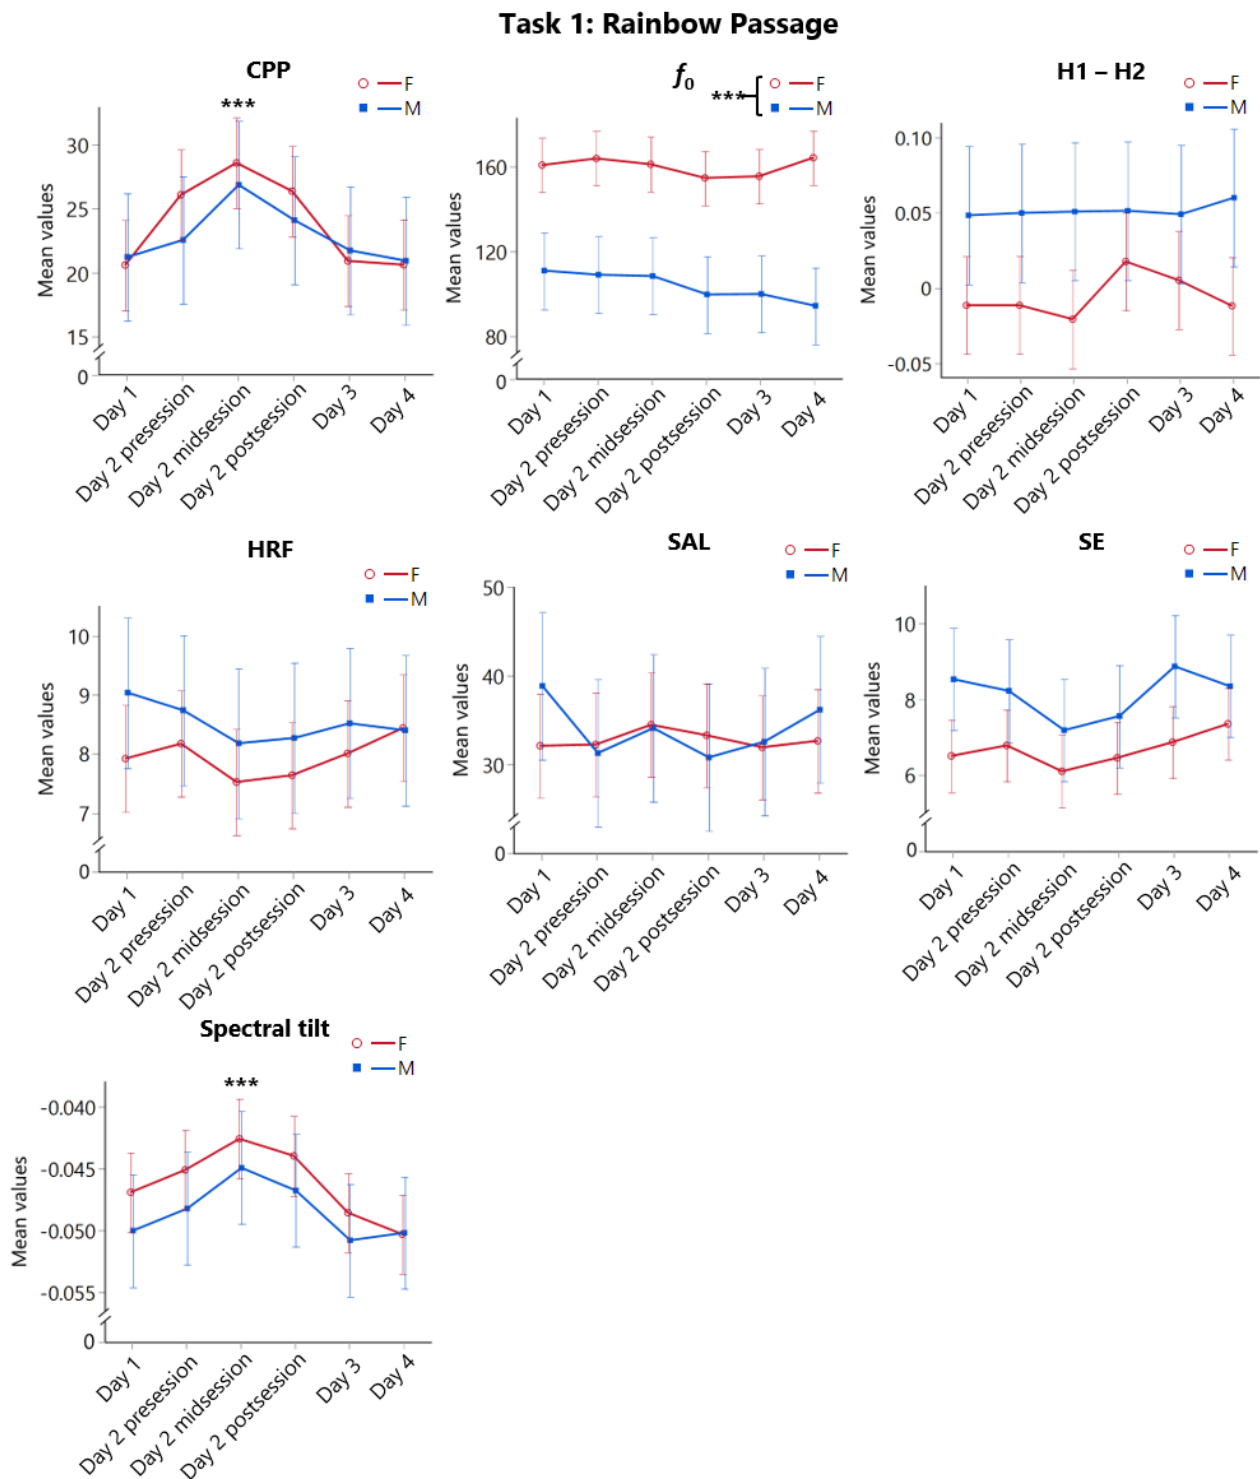

Across all phonation tasks, no study group effects (ie, main effect of study group or interaction of study group and time) were noted for acoustic metrics. By contrast, main and interaction effects of gender group and time were found in certain acoustic metrics depending on the phonation task.

Rainbow Passage Task

There was a main effect of time for CPP and Tilt (both $P<.001$) measures, but no significant gender group or interaction effects (Figure 5; see Multimedia Appendices 4 and 5 for detailed test

statistics). Both measures followed a similar trajectory as those observed in SAVRa, with values increasing from day 1 to day 2 midsession and then decreasing thereafter. Post hoc tests showed that values at day 2 midsession were significantly greater than baseline values (day 1) for both measures (CPP: $P<.001$; Tilt: $P=.001$). Testing also yielded a significant main effect of gender group for f_0 ($P<.001$), with females demonstrating higher f_0 values throughout. The gender difference on f_0 was expected because females generally have higher conversational pitches than males in vocally healthy populations. No significant gender group, time, or interaction effects were found in other acoustic metrics (see Multimedia Appendix 4 for detailed test statistics).

Figure 5. Means and standard errors (error bars) of neck surface accelerometer-derived acoustic metrics in the Rainbow Passage Task as functions of Time and Gender Group. Asterisks denote statistically significant differences (1) between the female (F) and the male (M) participant groups, as well as, (2) between a specific time point and Day 1 (*** P<.001). CPP: cepstral peak prominence; f_0 : fundamental frequency; H1 – H2: difference between the first and second harmonic magnitudes; HRF: harmonic richness factor; SAL: skin acceleration level; SE: spectral entropy.

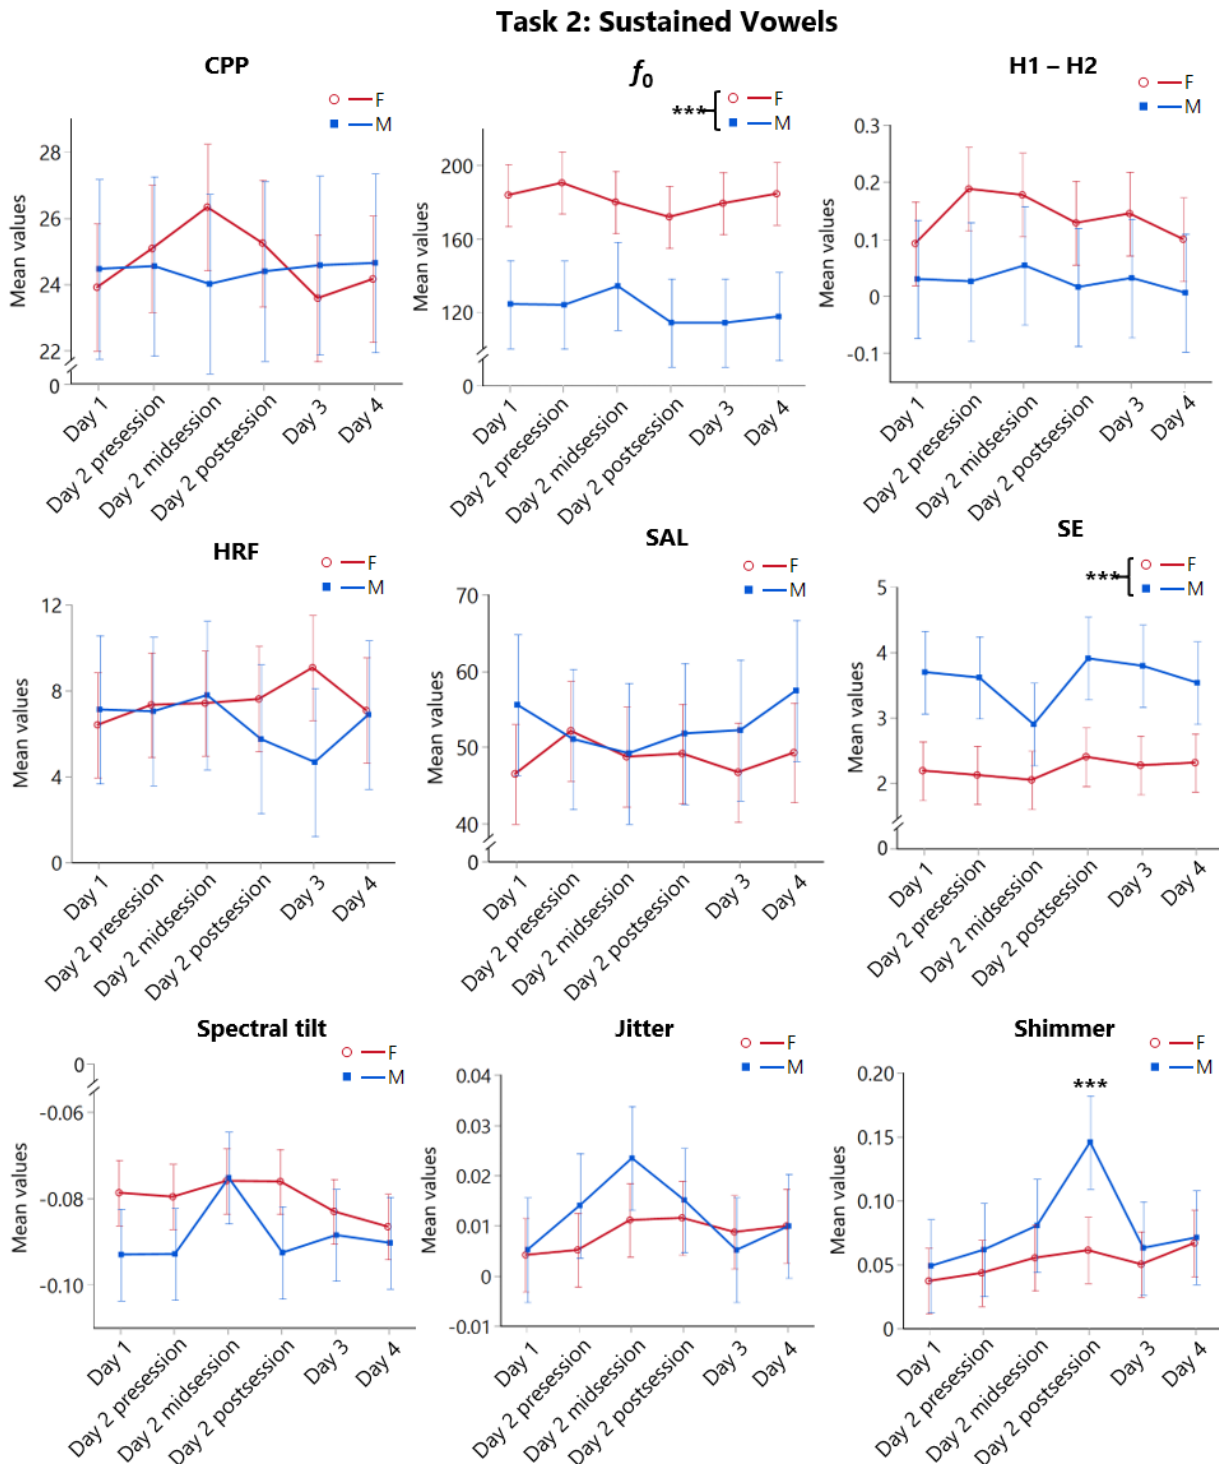

Sustained Vowel Task

There was a significant main effect of time for shimmer (P<.01), with values peaking at day 2 postsession and then dropping off afterward (Figure 6; see Multimedia Appendices 6 and 7 for detailed test statistics). Post hoc tests indicated that shimmer values at day 2 postsession were significantly higher than

baseline values (P=.001). This appeared to be driven by the male group, whose overall values at day 2 postsession were higher than the female group; however, effects of gender group did not reach significance (see Multimedia Appendix 6 for detailed test statistics). The main effects of gender group were also noted for SE and f_0 (both P<.001). For SE, males had higher values throughout, while females showed higher values

throughout for f_0 . No significant gender group, time, or interaction effects were found in other acoustic metrics (see [Multimedia Appendix 6](#) for detailed test statistics).

Figure 6. Means and standard errors (error bars) of neck surface accelerometer-derived acoustic metrics in the Sustained Vowel Task as functions of Time and Gender Group. Asterisks denote statistically significant differences (1) between the female (F) and the male (M) participant groups, as well as, (2) between a specific time point and Day 1 (***) $P \leq 0.001$. CPP: cepstral peak prominence; f_0 : fundamental frequency; H1 – H2: difference between the first and second harmonic magnitudes; HRF: harmonic richness factor; SAL: skin acceleration level; SE: spectral entropy.

Maximum Phonation Time and Pitch Glide Tasks

No effects of gender group, time, or their interaction were noted for maximum phonation time (MPT), f_0 minimum, and f_0 maximum (Table 5).

Table 5. Group-based means (SD) for the maximum phonation time and pitch glide tasks.^a

Acoustic metrics and gender groups	Experimental time points, mean (SD)						ANOVA		
	Day 1	Day 2 pre-session	Day 2 mid-session	Day 2 post-session	Day 3	Day 4	Time	Gender	Time × gender
MPT^b							$F_{5,65}=1.38$; P=.25	$F_{1,13}=2.37$; P=.24	$F_{5,65}=0.81$; P=.54

Male	694.61 (259.44)	689.70 (281.84)	661.19 (188.34)	626.75 (191.97)	823.09 (614.29)	574.22 (249.39)			

^aThere are no statistically significant effects ($P < .01$).

^bMPT: maximum phonation time.

^c f_0 min: f_0 minimum.

^d f_0 max: f_0 maximum.

Discussion

Principal Findings and Comparison With Prior Work

Accumulated distance doses are used to estimate a person's voice use [24,25]. Individuals with healthy voices were reported to have accumulated distance doses of around 18,000 m/week and 228 m/hour [10]. For individuals with disordered voices, the numbers were found to be notably higher with around 27,000 m/week and 345 m/hour [10,14]. In this study, for a total of 4-hour typical voice acting, accumulated distance doses were 8354.35 m on average, with approximately 2089 m/hour. Compared with the literature data, voice actors who engaged in 4 hours of voice acting in this study accumulated almost 46% of a typical person's weekly voice use (8354/18,000, 46.41%). In real-world situations, professional voice actors are often booked with more than 1 acting session in a week, suggesting an exceptionally high vocal demand at the acting workplace. A recent study further investigated the vocal doses from singers with vocal injury in their regular weeks [33]. Results showed that most distance doses in these singers were associated with speaking voice (about 268 m/hour) rather than singing voice (about 103 m/hour) in their weekly summaries (about 370 m/hour). Taken together, these results suggest the need for continuous voice monitoring in voice actors and other occupational voice users, not only in the workplace but also in daily life, to support further self-awareness and management of safe voice use.

Based on the SAVRa data, participants started to perceive significant increases in vocal effort and discomfort after the first part of the acting. The scores increased during acting, reached their peak right after acting, and gradually returned to baseline within 48 hours after acting. This arc-shaped trajectory replicated the same SAVRa variations obtained from our previous vocal loading study, in which participants were required to reach a distance dose of 500 m in each of the 6 consecutive voice sessions [11]. Among all NSA-derived metrics across phonation tasks, only *CPP* and *Tilt* from the Rainbow Passage most closely mirrored the temporal trends of the SAVRa with significant changes over time in both genders. These results are encouraging as *CPP* is already regarded as a robust measure of vocal fatigue and voice deviation with air acoustic microphone signals [35,36]. Even though our NSAs have more restricted bandwidth (around 3 kHz), the clinical robustness of *CPP* seemed to be preserved. For *Tilt*, a decreased slope of *Tilt* is suggested to correlate with perceived creaky voice, whereas an increased slope can be associated with breathy voice [37,38]. Our results showed that the *Tilt* measure increased with the time of voice acting. Individuals may tend to deviate from their modal voice type to a breathier phonation with the vocal fatigue ensued from acting. Overall, results from our current and previous study [11] agreed that, among all NSA acoustic metrics, *CPP* and *Tilt* were most robust to reflect an individual's voice variations and vocal fatigue.

In sum, both female and male actors showed comparable accumulated distance doses from voice acting, suggesting a

gender-specific vocal safety limit may not be necessary. Similar to the observation from air microphone signals, NSA-derived acoustic metrics performed differently between sustained vowels and running speech, whereby the latter is more ecologically valid [19]. In particular, NSA-derived *CPP* and *Tilt* from running speech were equally robust for the detection of voice variations in both genders. These 2 NSA metrics can thus be used as universal surrogates of vocal health biomarkers. One key application of this NSA wearable is to prompt occupational voice users when their vocal safety limits are reached for duly protection. However, continuous, real-time monitoring of an individual's body sound signals requires substantial computing power. Algorithms can thus be focused on processing selected metrics that are the most clinically relevant, such as accumulated distance dose, *CPP*, and *Tilt*. Machine learning techniques can be further applied to learn the time history of an individual's voice features, capture their detrimental variations, and predict risk levels of vocal injury. This functionality will enable continuous self-awareness of vocal behavior and protection of vocal safety in occupational voice users.

Limitations and Future Directions

The NSA system used in this study was a wired version, which poses challenges for users to wear it for long periods. The data transfer was also through a physical recorder and then to a personal computer. No user-device interaction such as

biofeedback of voice use was built into the current NSA system. To address these issues critical to mHealth, a wireless version of NSA wearable is now under development in our group. The NSA data will be transmitted through Bluetooth low-energy technology to a smartphone device. An in-house mobile app is also in development with features of NSA data visualization and vocal health feedback. We have already developed machine learning algorithms that are lean and efficient enough to classify upper airway symptoms such as cough and throat clearing on the NSA board [5]. The aforesaid system upgrades will broaden the NSA functionality to be more interactive and suitable for all-day monitoring.

Conclusions

Laboratory NSA wearable devices were deployed to a group of professional voice actors who underwent a 4-hour voice acting session. The devices were able to tolerate the strenuous body movements and ensued body movement noise from voice acting. Vocal dose measures and a regular check of clinical evaluation metrics (SAVRa and NSA-derived acoustic metrics) were included in this investigation to validate the instrumentation of the device, the NSA-derived acoustic metrics, and NSA's algorithm for voice monitoring. Future field tests are warranted to evaluate aforesaid new instrument and algorithm functions in predicting voice and airway health for occupational voice users and those with chronic airway diseases.

Acknowledgments

We acknowledge Luc Mongeau, Nicholas Ogradnik, and Laura Fasanella for providing assistance on the initial study set up and data collection. We thank Maia Masuda for supervising vocal warm-up exercise. We also sincerely thank The Alliance of Canadian Cinema, Television and Radio Artists for allowing their voice actors to work in sessions without their usual Union rates as compensation. We acknowledge research grants from the Canadian Institutes of Health Research (PJT-156412), The Centre for Research on Brain, Language and Music Research (CRBLM) Incubator Awards (NYKL-J), Canada Research Chair research stipend (NYKL-J), and National Institutes of Health (R01 DC 005788; LM). The CRBLM is funded by the Government of Quebec via the Fonds de Recherche Nature et Technologies and Société et Culture. Abstract

Background: Increased preexposure prophylaxis (PrEP) initiation is needed to substantially decrease HIV incidence among Black sexual minority men (BSMM). However, BSMM perceive others as PrEP candidates instead of themselves and are less likely than other groups to use PrEP if prescribed. Peers and smartphone apps are popular HIV prevention intervention tools typically used independently. However, they could be useful together in a multicomponent strategy to improve perceived HIV risk and PrEP initiation for this group. Information regarding attitudes and preferences toward this multicomponent strategy is limited.

Objective: The goal of this study is to obtain attitudes and perspectives regarding the design of a multicomponent intervention that uses a smartphone app and a peer change agent (PCA) to increase perceived HIV risk and PrEP initiation. The intervention will be refined based on thematic findings for a culturally responsive approach.

Methods: Data were obtained guided by life course theory and the health belief model using 12 focus groups and 1 in-depth interview among HIV-negative BSMM from Baltimore, MD, between October 2019 and May 2020 (n=39). Groups were stratified by the following ages: 18 to 24 years, 25 to 34 years, and 35 years and older. Participants were provided details regarding an existing mobile app diary to self-monitor sexual behaviors and a hypothetical PCA with whom to review the app. Facilitators posed questions regarding perceived HIV risk, attitudes toward the app, working with a PCA, and preferences for PCA characteristics and approaches.

Results: Most participants identified as homosexual, gay, or same gender-loving (26/38, 68%), were employed (26/38, 69%), single (25/38, 66%), and interested in self-monitoring sexual behaviors (28/38, 68%). However, themes suggested that participants had low perceived HIV risk, that self-monitoring sexual behaviors using a mobile app diary was feasible but could trigger internalized stigma, and that an acceptable PCA should be a possible self for BSMM to aspire to but they still wanted clinicians to “do their job.”

Conclusions: HIV-negative BSMM have dissonant attitudes regarding perceived HIV risk and the utility of a mobile app and PCA to increase perceived HIV risk and PrEP initiation. Future research will explore the feasibility, acceptability, and preliminary impact of implementing the multicomponent intervention on perceived HIV risk and PrEP initiation among BSMM in a pilot study.

Introduction

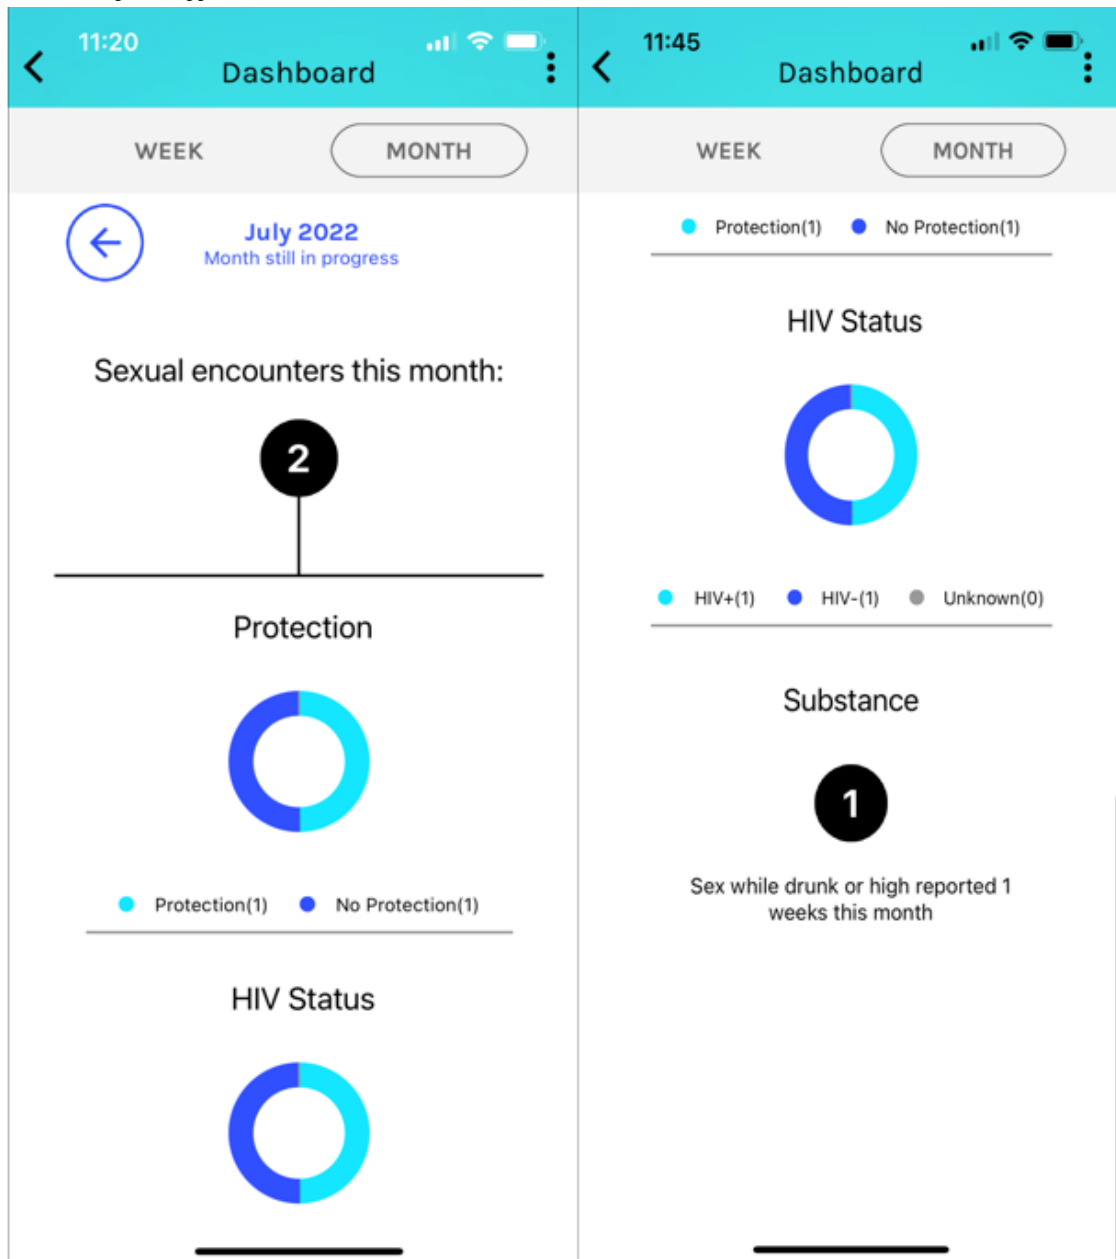

The United States will not reach its plan to end the HIV epidemic unless HIV incidence among Black sexual minority men (BSMM) substantially decreases [1,2]. Between 2015 and 2019, HIV incidence increased by 6% among BSMM aged 25 to 34 years; in 2019, BSMM accounted for 26% of HIV infections among US gay and bisexual men [1,3]. Approximately 75% of BSMM newly diagnosed with HIV are under the age of 35 years [1]. Preexposure prophylaxis (PrEP) use, however, remains substantially lower for BSMM than for other racial/ethnic groups of gay and bisexual men [4,5]. Increased PrEP initiation is urgently needed to substantially decrease HIV incidence for this group [2,6]. To achieve the US plan to end the HIV epidemic, incidence among BSMM must substantially decrease [1,2]. Between 2015 and 2019, HIV incidence increased by 6% among BSMM aged 25 to 34 years; in 2019, BSMM accounted for 26% of HIV infections among US gay and bisexual men [1,3]. Approximately 75% of BSMM newly diagnosed with HIV are under the age of 35 years [1]. Increased PrEP initiation is urgently needed to substantially decrease HIV incidence for this group [6].

Despite increased awareness, multilevel factors such as insufficient insurance coverage, medication costs, stigma, problems with patient-clinician communication, medical mistrust, concerns regarding side effects, and low perceived HIV risk are barriers to PrEP initiation for BSMM [7-11]. Some BSMM perceive others as at higher risk for HIV infection than themselves and do not view themselves as PrEP candidates because they view their current behaviors as relatively lower risk than their past or their peers [12,13]. Perceived HIV risk among BSMM is also influenced by decreased stigma regarding living with HIV due to data showing that individuals living with HIV can live healthy lives and that individuals with an undetectable viral load cannot transmit the virus [14,15]. However, in a high-prevalence subpopulation, low perceived HIV risk inadequately identifies their objective risk. BSMM with higher perceived HIV risk have greater PrEP interest and use than those with lower perceived HIV risk [16,17]. Since multilevel factors affect sexual behaviors, perceived HIV risk, and PrEP initiation among BSMM, interventions that address these barriers are needed.

Peers and smartphone apps are popular HIV prevention tools. Some interventions leverage in-group members as peer change agents (PCAs) who disseminate health-related information within the population for behavior change [18-21]. Other interventions use apps as electronic diaries because self-monitoring risk behaviors facilitates reflection and reactivity to reduce risks [22-26]. PCAs and apps as intervention tools can address multilevel barriers to PrEP by reducing stigma, circumventing discriminatory health care services, and improving access to care. However, these tools have typically been used independently. Few studies have incorporated PCAs and mobile app-based diaries in a multicomponent strategy, which could be useful to increase perceived HIV risk and PrEP initiation among BSMM.

We designed a multicomponent intervention that consists of an existing smartphone app called PrEPme [18] and a PCA to increase perceived HIV risk and willingness to initiate PrEP among BSMM. Briefly, PrEPme is a smartphone app designed for Maryland users to obtain statewide PrEP service information and navigation support from a community health worker [18]. PrEPme also allows users to self-monitor sexual risk behaviors, view a graph of sexual risk behaviors by week and month (Figure 1), and chat with the in-app community health worker to obtain PrEP service information [18]. In our intervention, we planned for a PCA to meet with HIV-negative BSMM during 2 sessions one month apart. In the baseline session, the PCA would conduct a motivational interview-consistent conversation with HIV-negative BSMM to assess their lifestyles, personal goals and values, HIV risk behaviors, perceived HIV risk, and relative PrEP interest [14,27]. At the end of the session, BSMM would be asked to download PrEPme to record their sexual risk behaviors during the month. In the second session, the PCA would review the diary with BSMM and conduct another motivational interview-consistent conversation to explore motivations for relative HIV risk behaviors, check alignment with goals and values, and assess their PrEP interest. A key utility of the PCA includes sharing health-related information regarding relative and acute risks for HIV, answering questions regarding PrEP efficacy and side effects, and tailoring prevention messaging to improve perceived HIV risk given the information in the PrEPme dashboard. At the end of each session, the PCA would collaborate with BSMM to help interested participants obtain PrEP services.

Figure 1. PrEPme smartphone app dashboard.

Guided by life course theory (LCT) [28-30] and the health belief model (HBM) [31,32], we hypothesize that this approach could prove feasible and acceptable, mitigate multilevel barriers, and improve perceived HIV risk and PrEP initiation among BSMM. LCT suggests that age-related differences in exposures to risk, timing of major life events, and accumulated risks impact health behaviors and outcomes [28-30,33]. The HBM posits that perceived disease susceptibility can lead to increased engagement in healthy behaviors [32,34]. Together, this framework informed the design of our multicomponent intervention. Perceived HIV risk and PrEP initiation could be improved by providing BSMM with PrEPme to self-monitor sexual risk and a PCA to change attitudes toward HIV acquisition and introduce PrEP. However, the success of an intervention among BSMM relies upon a culturally responsive strategy prior to its implementation and requires clarity regarding the components and potential barriers [14,35-37]. Therefore, the aim of this study is to explore attitudes toward

the intervention guided by our theoretical framework and identify ways to refine the strategy based on feedback from the target population. Findings from this formative research will be used to finalize the study protocol and implement the multicomponent intervention.

Methods

Ethics Approval

All study procedures were approved by Johns Hopkins School of Medicine institutional review board (IRB00211578).

Recruitment and Study Sample

Data were obtained from 12 focus groups and 1 in-depth interview among BSMM from Baltimore, MD, between October 2019 and May 2020 [38]. Participants were recruited using a combination of active (eg, contacting participants from previous studies who provided written consent to be called for future

research) and passive (eg, advertising on Craigslist, obtaining participant referrals) strategies [35,37]. Participants were eligible based upon the following criteria: self-identifying as Black or African American, self-identifying as a man, aged 18 years or older, self-reporting as HIV negative, having oral/anal sex with at least 1 male partner in the previous 6 months, and residing in Baltimore, MD.

Study Procedures

Most focus groups (n=9) were conducted in a private designated research space at Johns Hopkins School of Nursing. The protocol for the last 3 focus groups was updated to a virtual, synchronous format for safety due to COVID-19. Details regarding the protocol for virtual, synchronous focus group conduct have been published elsewhere [35]. The focus group guide was designed using LCT and HBM constructs, and groups were stratified by 3 age groups: 18 to 24 years, 25 to 34 years, and 35 years and older. Groups were limited to 5 or fewer for feasibility and to allow all participants to respond to each question [35,37]. An in-depth interview was conducted because only 1 participant attended a scheduled focus group and still wanted to be a part of the study and share thoughts regarding the intervention [14,38]. Two facilitators led the focus groups (and interview). One moderated discussions and recorded notes; the other recorded notes, observed group dynamics, and conducted administrative activities [35,37]. In-person participants provided written informed consent; virtual participants provided oral informed consent that was documented by the study team prior to beginning the focus group [35].

Data collection included reflexive debriefing among the facilitators before and after every focus group to review research intentions, identify potential biases, explore personal challenges of the investigative team, and explore preliminary themes [35,39,40]. Data collection began with a written or online survey via Qualtrics assessing demographic and behavioral characteristics along with perceived HIV risk, assessed using the 8-item Perceived Risk of HIV scale [41], the scores for which ranged from 10 to 40, indicating low-to-high perceived HIV risk. Focus groups were conducted after the survey and lasted 50 to 75 minutes. Facilitators began by asking participants for details regarding their current lifestyles and social activities and how their lives and self-image would change if they received a positive HIV test result to learn more about their perceived severity of disease. Facilitators also targeted domains regarding participants' thoughts about their behaviors and their risk relative to learning the high HIV prevalence within the city and likelihood of infection for BSMM nationally [6]. Facilitators then shared details regarding PrEPme using handouts and live demonstrations on a smartphone and asked questions regarding attitudes toward using the app to self-monitor sexual risk behaviors. After obtaining attitudes toward the app, facilitators

asked questions regarding the usefulness of a PCA in the intervention, attitudes toward sharing their PrEPme diary with the PCA, ideal PCA characteristics, and potential barriers to working with a PCA. All participants were compensated \$80 [35].

Data Analysis

All focus groups were audiorecorded and transcribed verbatim by an IRB-approved company. The first author reviewed all transcriptions for fidelity to audio files and revised text files as needed prior to coding in ATLAS.ti (version 8.4, ATLAS.ti Scientific Software Development GmbH). The facilitators reviewed all focus group recordings, transcripts, and notes and then designed a codebook for descriptive thematic analysis using the questions in the focus group guide ([Multimedia Appendix 1](#)). The first author coded transcripts and systematically identified themes using an adapted pile-sorting approach whereby quotes associated with specific codes in ATLAS.ti were into an Excel (Microsoft Corp) spreadsheet and organized [15,40,42]. The facilitators then reviewed the quotes associated with codes and sorted them into piles for similarity within Excel to represent themes. Facilitators identified themes as patterns or novel responses associated with specific codes or focus group questions. To identify a range of themes, novel responses that at least 1 person in the group mentioned were also considered [40,43]. Between-group analysis was conducted to identify potential thematic differences by age.

Results

Demographic Characteristics and Descriptive Data

Data resulted in 5 groups of BSMM aged 18 to 24 years, 4 groups aged 25 to 34 years, 3 groups aged 35 years and older, and 1 in-depth interview with a participant aged 18 to 24 years (n=39). All except 1 participant completed the survey ([Table 1](#)). Most who completed the survey identified as homosexual, gay, or same gender-loving (26/38, 68%), were employed (26/38, 69%), and single (25/38, 66%). A total of 34% (13/39) of participants had ever been diagnosed with an STI, of whom 38% (5/13) had repeated at least one STI. Perceived Risk of HIV scores ranged from 13 to 40 (\bar{x} =22.4, s =5.3), and HIV Incidence Risk Index for Men Who Have Sex With Men scores ranged from 5 to 28 (\bar{x} =16.2, s =5.7). Most (26/38, 68%) were interested in using a smartphone app to self-monitor their sexual behaviors. Half (19/39, 50%) of surveyed participants had ever used PrEP; 12 out of the 39 reported being current PrEP users.

Focus groups yielded important themes regarding perceived HIV risk and attitudes toward the proposed multicomponent intervention.

Table 1. Demographic and behavioral characteristics among Black sexual minority men (n=38).

Variable	Value

Low HIV Risk Perceptions While Perceiving Others as Risky

Across and within age groups, participants provided polarizing responses regarding perceived HIV risk. They mentioned that HIV infection would impact their mental health due to lifestyle changes and anticipated stigma from society and potential partners, but they expected to overcome those challenges since contemporary medications improved longevity and quality of life. Despite being presented with Centers for Disease Control and Prevention data regarding HIV prevalence and incidence among BSMM locally and nationally, participants across age groups still perceived their HIV risk as low—even if they disclosed drug use or condomless sex. Each group used positive terms such as goal-oriented and caring to describe themselves and reckless, impulsive, and drug addict to describe individuals they thought were likely to acquire HIV. However, they also mentioned they occasionally had the same characteristics as someone they perceived as high risk for HIV despite not equating their current sexual behaviors as high risk. BSMM in the 2 youngest groups specifically compared their current behaviors to their past and their friends who they believed had riskier behaviors or who had acquired HIV.

Textbox 1. Group aged 18 to 24 years (December 14, 2019).

S2: 42:29 “Some people will have sex to escape from their reality. Some people have sex because they’re sex addicts. Then you see it as offensive because it’s basically in your face like know what you’re doing. You’re constantly reminded that you,—“

S3: 42:42 “You’re being a ‘THOT’”

S2: 42:43 “—you’re being a sexually active person—it’s nothing wrong with having sex. Sex is a natural desire of man. Let’s say I’ve got the app ‘cause I’m trying to work on myself. And I see that I had 12 partners this week. I see that as offensive because now I’m like, ‘All right, I had 12 partners this week,’ and now I start attacking myself... This [gonna] make me feel insecure about myself because it’s right there in front of my face. I can’t deny. I can’t lie to the app.”

Concerns Regarding Privacy From App Developers and In-App Community Health Workers

The youngest 2 age groups mentioned concerns that their sexual diary could be hacked by app developers or seen by community

Self-monitoring Sexual Behaviors Triggers Internalized Stigma and Shame

Across groups, participants reported barriers regarding using PrEPme such as remembering to use it and providing honest responses. Those aged 18 to 34 years generally agreed that having a smartphone app diary could be useful for individuals with higher risk behaviors (eg, individuals who use drugs, practice condomless sex with multiple partners), but men age 35 years and older did not think it would be useful or used among BSMM. Participants across all age groups reported that seeing their sexual activities summarized on the dashboard could trigger feelings of internalized stigma regarding their risk behaviors (see [Textbox 1](#)).

Participants agreed that having an in-app dashboard of sexual risk behaviors would decrease BSMM’s willingness to provide honest responses and use PrEPme for long. Some added that seeing their condomless sex and receptive anal sex activities in the app could exacerbate internalized stigma and shame that would cause them to discontinue use because society, gay men, and clinicians stigmatize those behaviors.

health workers who were in-app support systems for PrEP linkage. These concerns could be related to anticipated stigma and shame regarding the sexual behaviors documented in the app. However, participants did not mention this explicitly or associate these directly.

The PCA as a Future Self

Overall, most participants across age groups affirmed that having another BSMM to discuss sexual health and PrEP before visiting a PrEP-prescribing clinician was acceptable if he was relatable and trustworthy. They specified that the PCA should be Black and a current PrEP user so they could share their experiences with side effects and maintaining adherence (see [Textbox 2](#)).

These and other characteristics such as aesthetics (eg, style of dress), language use, personal disclosures, and neighborhood familiarity served as indicators for BSMM to use to anticipate how stigmatizing, trustworthy, or relatable the PCA would be.

Despite agreeing that having another BSMM as a PCA was acceptable in a clinical intervention, there were age group

differences regarding additional PCA characteristics and the practical role of the PCA. Specifically, those aged 18 to 24 years shared preferences for having a PCA who was older or a Black woman, partly due to anticipated within-group stigma from another BSMM who might judge their sexual behaviors as risky. Older participants shared that they would prefer not to engage with a PCA in practice because they did not want to relieve clinicians of the responsibility of asking detailed and personal questions to know them as patients. They also mentioned concerns that working with a PCA prior to visiting a clinician could be another barrier to PrEP initiation for interested BSMM. Still, the older men agreed that the PCA should be a BSMM who was professional yet relatable to discuss specific cultural issues and PrEP-related concerns such as side effects, efficacy, and relative risks for HIV infection by sexual positioning.

Textbox 2. Group aged 35 years and older (February 1, 2020).

S3: 35:45 “I feel like some people will share with people that they see some of their self in that person. So, like, for you, for example, I feel more comfortable talking to you about this—”

S6: 35:59 “Yeah.”

S3: 36:00 “—because you are—I do see a lot of myself in you. I know we’re two completely different people but, rather than sitting here talking to like an older straight white lady. It would be a little uncomfortable ‘cause she don’t know this lifestyle like you do. She don’t know what we go through as a young Black gay male.”

S2: 36:24 “Yeah.”

S3: 36:25 “And to even see you have, like, your style—your hair, all that, that helps out... So when you have somebody like you in a room and just to know you a doctor and you still look like me. You’re still young. You groomed, you got the haircut. It just makes you more comfortable.”

S2: 37:19 “Yeah, you right because it took me a long time to open up to my doctor, she’s white.”

S2: 1:01:35 “He made a good example how he sees himself in you—sometimes that’s a good thing as well. You sitting there like, ‘That’s my past and I’m their future self, so I can give a little bit more insight on certain things, so they don’t have to worry about going through what they went through.’”

Sharing App Data With PCA to Avoid Negative Patient-Clinician Communications

Across groups, participants acknowledged that a benefit of a PCA in this intervention included being able to discuss sexuality freely and trusting the PCA’s cultural competency more than that of a clinician who was not a BSMM (see [Textbox 3](#)).

They mentioned that a PCA could help circumvent potentially stigmatizing or unsatisfactory conversations with clinicians regarding sexual risks but were not interested in the PCA discussing health concerns with the clinician on their behalf. Their interest in sharing their PrEPme dashboard with a PCA or clinician was contingent on their perception of how judgmental and trustworthy either would be.

Textbox 3. Group aged 25 to 34 years (May 5, 2020).

S2: 37:39 “I think that for the sake of like having a real conversation, if it’s somebody that I’m uncomfortable with, I would rather have the conversation in a real tone that’s a peer.”

S3: 37:57 “And someone who looks like me.”

S2: 37:59 “Yeah. And, and they got all the real information, you know what I mean? And they can turn that around and give that to the doctor, because the doctor doesn’t know how to talk to me. The doctor is saying to me, you know, *receptive*, you know what I mean? Versus the peer is saying to me, *bottom*, like, you know. And it’s like, I understand the two roles— like the two roles. But like I don’t think that that’s necessary to repeat myself, if the rapport with the doctor that I have is great. But if the rapport is trash, and that doctor is trash, and I don’t feel comfortable with that doctor, then I’m fine with talking to somebody else to make sure that the point is really internalized.”

Discussion

Principal Findings

We designed a multicomponent strategy to increase perceived HIV risk and PrEP initiation among BSMM and obtained in-group perspectives regarding the intervention components for refinement. Overall, BSMM had low-to-moderate perceived HIV risk. Using a PCA as an interventionist could be feasible

and acceptable among younger BSMM. However, findings are inconclusive regarding feasibility of using the diary in PrEPme to record and review sexual behaviors for this group. We found age-related differences in attitudes toward the intervention components, which could result from different exposures to HIV-related deaths by age group and changes in personal agency and perceived support needs due to older age [14,44]. Novel

insights regarding stigma and shame also emerged that informed considerations for intervention refinement.

BSMM held dissonant attitudes between their sexual behaviors and HIV risk, perceiving their risk as low. Other studies among BSMM have found similar results [17,45]. Having lower perceived HIV risk could be an attempt to combat stereotype threat, which is a perceived risk of conforming to negative stereotypes about a group [46,47] that exacerbates poor patient-clinician communication, refusal of clinical recommendations, and medication nonadherence among Black patients [47,48]. For BSMM, the threat of being stereotypically high risk or sexually deviant could be an important, understudied phenomenon impacting HIV and PrEP initiation. Anticipated and internalized stigma and shame regarding self-monitoring sexual behaviors, discussing sexuality with professionals, and receiving an HIV diagnosis were salient. Additionally, practicing receptive anal sex, or being a bottom, can also carry specific shame and stigma among BSMM due to masculinity stereotypes [49,50]. However, stereotype threat decreases with race-concordant clinicians [43,51]. Therefore, a PCA must be a trained professional with substantial sexual health literacy who understands the issues concerning internalized stigma, shame, and stereotype threat and can help BSMM navigate their perceived HIV risk to make decisions about PrEP. A culturally responsive PCA could circumvent some of the multilevel barriers to perceived HIV risk and PrEP initiation among young BSMM with cultural familiarity, acceptable language, explanation of privacy protocols, and personal disclosures to build trust [35,43].

Findings regarding perceived susceptibility and severity of HIV among BSMM expanded our perspectives regarding the intervention framework. Based upon findings that BSMM had low perceived HIV risk, internalized stigma and shame regarding sexual risk behaviors, and preferences for a culturally congruent PCA, we incorporated possible selves theory [52,53] along with LCT and HBM to refine the intervention strategy. Possible selves represent individuals' ideas of what they could and want to become in addition to what they are afraid of becoming and can incentivize future behavior [53,54]. Therefore, an intervention using a PCA should consider how congruent with and relatable the peer is with a future self for HIV-negative BSMM beyond race and sexuality concordance [14,35,43]. Factors such as cultural familiarity, professionalism, open-mindedness, sexual health literacy, and PrEP use could be key additional PCA characteristics that build trust, mitigate stereotype threat, and increase willingness to initiate PrEP among BSMM [35,37].

Future research should explore the relative impact of implementing this multicomponent strategy on perceived HIV risk and PrEP initiation among BSMM. Since a sexual health diary app could trigger internalized stigma and clinical research teams are not culturally congruent with BSMM, future research should implement interventions led by culturally congruent investigators familiar with these psychosocial barriers among this population. Future research could explore the potential impact of the dual role of an investigator or clinician as a PCA. Having PrEP clinical trials led by BSMM researchers and clinicians could be an important yet understudied structural, social, and psychological factor in HIV prevention among BSMM.

Limitations

Limitations should be considered. This study included a convenience sample and is not representative of HIV-negative BSMM. HIV status was self-reported. Groups were intentionally conducted with a small number of participants to increase rapport, trust, and privacy and to ensure that everyone could respond to every question if desired [35,37]. Information regarding implications of the intervention regarding on-demand and injectable PrEP was limited.

Conclusion

Qualitative studies are crucial to designing culturally relevant interventions for BSMM because they identify how socioecological factors such as stigma impact HIV risk for this group [55]. Despite the proliferation of smartphone apps for health promotion and HIV prevention [56], we found that using PrEPme to record and review sexual risk behaviors may not be as innocuous as anticipated. Therefore, we plan to train the PCA to anticipate stereotype threat and manage insider-outsider dynamics to demonstrate relatability, trustworthiness, care, and professionalism. In the refined intervention, we plan to encourage participants to use the diary in PrEPme and ensure that the PCA is a nonjudgmental possible self who can help BSMM navigate feelings of stigma, shame, low perceived HIV risk, and PrEP hesitancy as participants reflect on their behaviors. Since providing objective HIV risk scores alone does not increase PrEP uptake among BSMM [7], the PCA will be trained in motivational interviewing to partner with BSMM to explore their health goals, perceived HIV risk, and relative interest in PrEP given their responses to the diary in PrEPme. We named the refined intervention strategy *Possible* based upon findings from this study.

Abstract

Background: Study participants and patients often perceive (long) questionnaires as burdensome. In addition, paper-based questionnaires are prone to errors such as (unintentionally) skipping questions or filling in a wrong type of answer. Such errors can be prevented with the emergence of mobile questionnaire apps.

Objective: This study aimed to validate an innovative way to measure the quality of life using a mobile app based on the EQ-5D-5L questionnaire. This validation study compared the EQ-5D-5L questionnaire requested by a mobile app with the gold standard paper-based version of the EQ-5D-5L.

Methods: This was a randomized, crossover, and open study. The main criteria for participation were participants should be aged ≥ 18 years, healthy at their own discretion, in possession of a smartphone with at least Android version 4.1 or higher or iOS version 9 or higher, digitally skilled in downloading the mobile app, and able to read and answer questionnaires in Dutch. Participants were recruited by a market research company that divided them into 2 groups balanced for age, gender, and education. Each participant received a digital version of the EQ-5D-5L questionnaire via a mobile app and the EQ-5D-5L paper-based questionnaire by postal mail. In the mobile app, participants received, for 5 consecutive days, 1 question in the morning and 1 question in the afternoon; as such, all questions were asked twice (at time point 1 [App T1] and time point 2 [App T2]). The primary outcomes were the correlations between the answers (scores) of each EQ-5D-5L question answered via the mobile app compared with the paper-based questionnaire to assess convergent validity.

Results: A total of 255 participants (healthy at their own discretion), 117 (45.9%) men and 138 (54.1%) women in the age range of 18 to 64 years, completed the study. To ensure randomization, the measured demographics were checked and compared between groups. To compare the results of the electronic and paper-based questionnaires, polychoric correlation analysis was performed. All questions showed a high correlation (0.64-0.92; $P < .001$) between the paper-based and the mobile app-based questions at App T1 and App T2. The scores and their variance remained similar over the questionnaires, indicating no clear difference in the answer tendency. In addition, the correlation between the 2 app-based questionnaires was high (> 0.73 ; $P < .001$), illustrating a high test-retest reliability, indicating it to be a reliable replacement for the paper-based questionnaire.

Conclusions: This study indicates that the mobile app is a valid tool for measuring the quality of life and is as reliable as the paper-based version of the EQ-5D-5L, while reducing the response burden.

Introduction

Background

Questionnaires are increasingly used to determine the health-related quality of life and specifically the care needs of patients; for example, as part of patient-reported outcomes [1]. Although questionnaires are perceived as an easy and noninvasive tool by researchers, study participants and patients often perceive filling out long or repeated questionnaires as burdensome. Although quality of life is often used as an outcome measure in studies, not all questionnaires used are suitable for long-term monitoring of a patient to be able to measure the course of health status over time [2,3]. Long-term monitoring of a patient's quality of life is important for health care evaluation and may provide better insight into the actual value of interventions [4,5]. Therefore, there is a need to provide easy-to-use, patient-friendly, and valid health questionnaires. This study investigated the possibility of measuring health status in a simple and valid way using a mobile app developed by Q1.6 (Q1.6 mobile app). Using this mobile app, the response burden for participants was reduced by presenting 1 question at a time instead of requesting the complete questionnaire all at once.

Conducting paper-based questionnaires in studies is prone to errors, such as unintended skipping of questions or selecting multiple answers when 1 answer is expected [6]. In addition, data from paper-based questionnaires must be manually processed, which is time consuming, before analyses can be performed and manual entry can lead to data entry errors. With the emergence of apps for questionnaires that can be completed on smartphones, such inaccuracies can be prevented [7].

The use of smartphones and electronic devices has increased in our daily lives and in health care settings. Studies have shown that the use of smartphone app in intervention studies, for example, for self-monitoring, has become more accepted over time [8]. The use of eHealth services can lead to increased self-management of health complications [8,9]. Various patient-reported outcome measures can be queried using electronic devices [1]. The use of electronic devices is an advantage for both the individual patient and the researcher or physician: questionnaires can be answered at a convenient moment for the patient, which saves researchers' or physicians' and patients' time [10]. Flexible completion could increase the frequency with which a patient is willing to complete a smartphone-based questionnaire. In addition, because of the completion of the questionnaire on the web, the data are immediately available, are stored, and can easily be compared with previously completed questionnaires. Therefore, a patient can be monitored effortlessly by the physician or researcher, and the patient does not have to make separate appointments with the physician or researcher. From a data perspective, the benefits of completing questionnaires via a smartphone app include easy to retrieve data, reliable data, and prevention of data loss due to backup systems [11]. Before a mobile questionnaire app can be deployed in a clinical setting, it is essential that this new method is validated against the traditional method [12].

In this study, a validation of a new mobile method of the well-known EQ-5D-5L questionnaire, a short questionnaire in which the quality of life of a person was examined, was performed. A comparison of the gold standard, a traditional paper version of the EQ-5D-5L questionnaire, with a digitized, mobile measurement method of (subjective) health-related quality of life via a mobile app was examined. The EQ-5D-5L questionnaire is available in various modes of administration, including smartphones [13]. Several studies have used the electronic version of the EQ-5D-5L questionnaire and indicated the electronic version valid and reliable [10,14-16]. However, the Q1.6 mobile app of the EQ-5D-5L is designed to reduce the response burden of questionnaires by presenting a single question at a time and only querying 2 questions a day rather than the whole questionnaire at once. To validate the method, the EQ-5D-5L version of the EQ-5D Health Status Questionnaire was used. This is a standardized measure of the health-related quality of life questionnaire developed by the EuroQol group [17]. EQ-5D is the most widely used tool for obtaining health outcomes from a patient's perspective [18].

In this validation study, a comparison using correlation analysis was made between the mobile app version of the EQ-5D-5L questionnaire and the gold standard paper-based version of the EQ-5D-5L. To avoid possible bias due to time of the day (morning and afternoon), the questions in the mobile app were provided twice, referred to as time point 1 (App T1) and time point 2 (App T2), in a randomized order and differing in moment of the day (morning and afternoon).

Health-related quality of life measurement instruments must be both valid and reliable [19]. The validity of a questionnaire pertains to the degree to which the measurement reflects a construct of interest. Specifically, convergent validity is the degree to which a new scale is related to other pre-existing measures of the same construct [20]. Convergent validity between the paper, which is a pre-existing measure, and the mobile version of the EQ-5D-5L will be assessed through correlation analyses. Reliability is the consistency that the instrument measures, with test-retest reliability evaluating the consistency between 2 time points. Test-retest reliability assumes that no alterations emerge between measurements when the test is repeated and is the main aspect of reliability considered in this study [21].

Correlation analysis is the most commonly used method in validation and test-retest reliability studies and is the preferred method for this study [22]. Polychoric correlation was used for all EQ-5D-5L questions, except for the visual analog scale (VAS), because this construct uses a 5-point Likert scale [23]. Likert scales are ordinal scores, characterized by the assumption that the intervals between the scores are not equal (eg, the difference between categories 1 and 2 may not be as large as the difference between categories 2 and 3), with a limited number of possible scores. These polychoric correlations are the preferred correlational methods [24].

Owing to the longitudinal nature of the study, it was important to ensure that the differences we found were owing to differences in assessment methods and not owing to differences over time. As such, the correlation was checked between the

average mobile app score (mean of both time points) and the paper score, between App T1 and the paper score, between App T2 and the paper score, and also between the 2 time points in the mobile app to study the longitudinal correlation or the test-retest validity.

Objectives

The main objective of this study was to validate an innovative way to measure perceived health using the EQ-5D-5L questionnaire requested via the mobile app. In the validation study, a comparison using correlation analysis was made between the mobile app version of the EQ-5D-5L questionnaire and the gold standard a paper-based version of the EQ-5D-5L, in a large group of people.

In the next section, we will discuss our methods, including our study design and the statistical analyses used, followed by the results obtained by these statistical analyses and a discussion of what these results mean for the validation of the digitized Q1.6 version of the EQ-5D-5L questionnaire.

Methods

Study Population

Participant recruitment and data collection (questionnaires) were conducted by the research bureau MSI Advanced Customer Insights (MSI-ACI Europe BV). The participants were provided with a participant information sheet. Participants willing to participate sent in their signed and completed informed consent form digitally. To obtain a representative sample of the Dutch population, participants were selected to approximate the population distribution of age, gender, education, and place of residence. Of the 661 interested participants, 350 (52.9%) were eligible, and 261 (39.5%) eventually participated in the study. Participants were declared eligible when they met the following

inclusion criteria: aged ≥ 18 years, healthy at their own discretion, in possession of a smartphone with at least Android version 4.1 or higher or iOS version 9 or higher, digitally skilled enough to download the mobile app, and able to read and answer questionnaires in Dutch. Participants who completed the study received an incentive (digital bol.com store voucher) of €10 (US \$12).

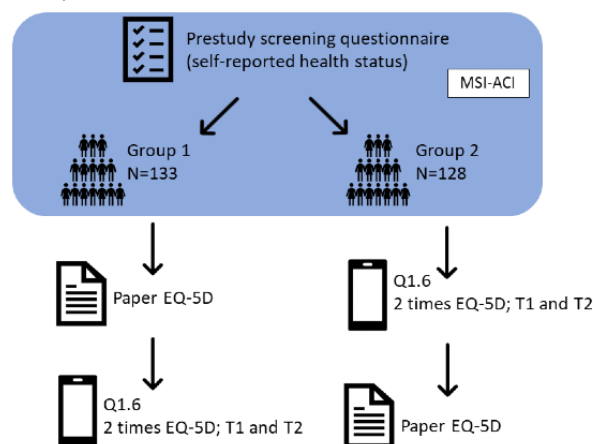

Ethics Approval

The study plan was approved by the Internal Review Board of TNO (Netherlands Organisation for Applied Scientific Research) on February 12, 2021 (number 2021-009). The study was conducted in accordance with the current assembly (64th) of the Declaration of Helsinki (Brazil, October 2008), which was updated by the WMA (World Medical Association) General Assembly in 2013. The study was conducted in March 2021 and completed in 4 weeks.

Study Design

This was a randomized, crossover, and open study. Eligible participants ($n=261$) were assigned to groups 1 or 2. A total of 50.9% (133/261) of participants were assigned to group 1. The participants in group 1 first received a paper-based questionnaire. They were given a maximum of 1 week to complete the questionnaire on paper and return it by postal mail. Thereafter, the participants were informed by email to start with the mobile app. A total of 49% (128/261) of participants were placed in group 2. Participants in group 2 first completed the mobile app questionnaire, followed by the paper-based questionnaire, which was sent by postal mail. Of the 261 participants, 255 (97.7%) participants completed both the paper-based version of the EQ-5D-5L and the mobile app version. A schematic overview of the study design is shown in Figure 1.

Figure 1. Study design. The figure shows the order of paper-based version and the mobile app questionnaires for groups 1 and 2. With exception of a visual analog scale score, questions of the EQ-5D-5L were asked twice via the mobile app. A single question was requested once in the morning and once in the afternoon on 5 consecutive days. MSI-ACI: MSI Advanced Customer Insights; T1: time point 1 (app question answered first time); T2: time point 2 (same app question answered second time).

The EQ-5D Paper-Based Questionnaire

The EQ-5D is a standardized measure of health-related quality of life questionnaire developed by EuroQol. The EQ-5D is the most widely used tool for obtaining quality of life from a patient's perspective [18]. The EQ-5D is a descriptive instrument

that focuses on five dimensions of health: mobility, self-care, usual activities, pain or discomfort, and anxiety or depression. Two versions of the EQ-5D are available: EQ-5D-5L (the 5-level version, each domain consisting of 5 levels; "1=no problems, 2=slight problems, 3=moderate problems, 4=severe problems, and 5=extreme problems") and EQ-5D-3L (the 3-level version,

each domain consisting of 3 levels; “1=no problems, 2=some problems, and 3=extreme problems”). Lower scores indicate better quality of life. The EQ-5D-5L questionnaire was used in this study. The second part of the paper-based questionnaire comprises a standard vertical 20-cm line representing a scale from 0 to 100, also known as the VAS. The respondents are asked to score their current health status on the scale and write the corresponding number in an adjacent box. A higher VAS score represents a better perceived health status.

The Q1.6 Mobile Phone App

The company Q1.6 developed a mobile app that prompts a participant to answer a short question about their health twice a day. For this study, the EQ-5D-5L was configured in the Q1.6 app ([Multimedia Appendix 1](#)). The participants were notified to download the mobile app to their personal mobile phones. For 5 consecutive days, the participants received notifications for 2 EQ-5D-5L questions per day. A single question was posed once in the morning and once in the afternoon. The EQ-5D-5L questions were randomized to be presented in the morning or afternoon to increase generalizability. On the fifth day, the participants also had to complete the VAS score. In total, all questions were asked twice spread over 5 consecutive days, with the exception of the VAS score, which was asked only once. Notifications prompting the participant to answer a question were sent to the participants' smartphones between 8 AM and 10:30 PM and closed automatically. Participants in possession of an iPhone received a notification every consecutive hour until the question was answered. On Android, questions were prompted when a user unlocked their phone until the question was answered.

Subjective evaluation of the mobile app was requested via an evaluation questionnaire in the mobile app to gain insight into the usability of the mobile app.

Sample Size

The number of participants needed in the study was based on a power calculation assuming a correlation of 0.7 with an α of .05 and a power of 0.90. To allow for the fact that any correlation is inherent in health measurements in general, no test against finding no correlation was performed, but the estimation of power was made to distinguish between the expected correlation of 0.7 and a more general correlation of 0.5, which may be found in any 2 health-related questionnaires. On the basis of G*power calculation [25], we required 200 participants to validate the mobile app questionnaire using these parameters.

Statistical Analyses

Descriptive variables were compared between the 2 experimental groups (ie, group 1: first paper-based EQ-5D-5L questionnaire or group 2: first mobile app questionnaire) to check whether randomization had achieved a good spread of baseline variables across the groups in the study. Participants missing >1 question in the mobile app (5, 1.9%) were removed from the analysis to have as many completed questionnaires as possible for

validation (approximately 200 completed on paper and via the mobile app).

To compare the paper- and app-based questionnaires, polychoric correlation analyses were used for all EQ-5D-5L questions, except for the VAS scale, as the questions were answered using a 5-point Likert scale [23]. For these calculations, the package Lavaan (version 0.6-9) in R (designed by Robert Gentleman and Ross Ihaka and developed by the R Core Team) was used [26]. Pearson correlation was estimated for the VAS. For the main outcome, that is, the correlation between paper and the mobile app, the average score over 2 days in the mobile app was correlated with the observed score from the paper version. The answers given the first time a question appeared in the mobile app were combined at time point 1 (App T1); the answers provided during the second time were combined at time point 2 (App T2). In addition, the correlations between the observed score on paper and App T1, and the observed score on paper and App T2 were calculated, as presented in [Multimedia Appendix 2](#).

To study the longitudinal correlation or test-retest reliability, we examined the test-retest correlation of the 2 time points using the mobile app (App T1 vs App T2) and the validity assessment (paper vs digital [the mobile app]) through the polychoric correlation. With similar correlation coefficients (eg, within a few points of each other), we can assume that both methods measure the same. Furthermore, paired *t* tests (2-tailed) were used to check whether participants consistently scored higher or lower on paper or on the mobile app ([Multimedia Appendix 3](#)).

Data are presented as mean (SD). A *P* value of <.05 was considered statistically significant. Correlation values of 0.0 to 0.3 indicate weak agreement, 0.3 to 0.5 indicate mediocre agreement, 0.5 to 0.7 indicate strong agreement, and >0.7 indicate very strong agreement [27]. Box plots are presented for descriptive analyses of the usability of the mobile app.

Results

Descriptive Results of Study Participants

A final data sample of 255 participants (117 males—group 1: 54, 43%; group 2: 63, 49% and 138 females—group 1: 73, 57%; group 2: 65, 51%), with an age of ≥ 18 years and no more than one observation missing, were included in the analysis. Although there was no maximum age set for inclusion of participants, the maximum age of respondents was 64 years. In total, 56.5% (144/255) of the participants were highly educated and had obtained at least a bachelor's degree. The demographic data of the participants are presented in [Table 1](#). Characteristics are listed in total and per condition (group 1: paper first; group 2: mobile app first). The distribution of the demographic characteristics between the groups was consistent. Group 2 appeared to have slightly more people aged >50 years (52/128, 40.6% vs 35/127, 27.6% in group 1) and people living in the eastern part of the Netherlands (39/128, 30.5% than in group 1 (24/127, 18.9%).

Table 1. Baseline characteristics of the participants (N=255) who completed the study in total and the representation in the group.

Parameter	Participants, n (%)	Group 1 (paper first), n (%)	Group 2 (mobile app first), n (%)
Gender			
Man	117 (45.9)	54 (42.5)	63 (49.2)
Woman	138 (54.1)	73 (57.4)	65 (50.7)
Age (years)			
18-34	88 (34.5)	48 (37.8)	40 (31.3)
35-49	80 (31.4)	44 (34.6)	36 (28.1)
50-64	87 (34.1)	35 (27.6)	52 (40.6)
Education^a			
Low	10 (3.9)	4 (3.1)	6 (4.7)
Middle	101 (39.6)	46 (36.2)	55 (43)
High	144 (56.5)	77 (60.6)	67 (52.3)
Region^b			
Cities	27 (10.6)	15 (11.8)	12 (9.4)
North	25 (9.8)	11 (8.7)	14 (10.9)
East	63 (24.7)	24 (18.9)	39 (30.5)
South	56 (22)	26 (20.5)	30 (23.4)
West	84 (32.9)	51 (40.2)	33 (25.8)

^aParticipants who only attended primary education, prevocational secondary education (VMBO or LBO) were defined as less educated. Participants with a secondary school (preparatory vocational secondary education [mavo], senior general secondary education [havo], or university preparatory education [vwo]) or senior secondary vocational education and training (MBO) degree were defined as middle educated. Participants with at least a bachelor's degree in higher professional or university education were categorized as having a higher education.

^bParticipants were recruited from all over the Netherlands. An overview of participants living near big cities and region of the Netherlands is presented.

Descriptive Results by Domain

The average scores of the different variables on paper, App T1 (first time question in the mobile app) and App T2 (second time question in the mobile app) are presented in [Table 2](#). With the exception of the VAS score (range 0-100), a lower score indicates a better quality of life (range 1-5). As can be seen, the group generally considers themselves healthy and scores between 1 and 2 on the five domains (mobility, self-care, usual activities, pain or discomfort, and anxiety or depression) across

the different media (paper vs the mobile app). The mean VAS score for paper administration was 77.7 (SD 14.3), and the mean VAS score for the mobile app was 78.7 (SD 15.8). The scores and their variability remained similar over the questionnaires, indicating no clear difference in the answer tendency. Within self-care, a very low variance and overall, a low score were observed (paper average 1.1, SD 0.4; mobile app average 1.1, SD 0.3). [Multimedia Appendix 3](#) presents 2-tailed *t* tests pertaining to the difference in responses on the paper and mobile app versions.

Table 2. Average score per EQ-5D-5L question.

Variable	Paper, mean (SD)	App, mean (SD)	App T1 ^a , mean (SD)	App T2 ^b , mean (SD)
Visual analog scale score	77.705 (14.324)	N/A ^c	N/A	78.697 (15.751)
Anxiety or depression	1.596 (0.845)	1.542 (0.782)	1.556 (0.798)	1.522 (0.832)
Pain or discomfort	1.659 (0.831)	1.587 (0.716)	1.616 (0.780)	1.578 (0.767)
Usual activities	1.467 (0.730)	1.437 (0.713)	1.410 (0.747)	1.451 (0.735)
Self-care	1.110 (0.439)	1.086 (0.332)	1.078 (0.335)	1.093 (0.354)
Mobility	1.247 (0.619)	1.247 (0.558)	1.235 (0.579)	1.240 (0.556)

^aApp time point 1 (App T1) was the first time the question was answered.

^bApp time point 2 (App T2) was the second time that the same question was answered.

^cN/A: not applicable (via the mobile app, each question of the EQ-5D-5L, with the exception of the visual analog scale score, was requested twice).

The Mobile App—Retest Results

The EQ-5D-5L questions in the mobile app were answered twice. Correlations between App T1 and App T2 were high (range 0.73-0.9; $P < .001$; Table 3), with the highest correlation observed for self-care and the lowest for anxiety or depression and mobility. This indicates high test-retest reliability across

all domains. Compared with the correlations between methods (Table 4), the differences were small (range 0.19-0.02). The CIs overlapped with a notable correlation with self-care. However, this may be because of the very low variance within self-care (Table 2), causing a small difference in answers and generating a disproportionately large influence.

Table 3. Polychoric correlations between app time point 1 (App T1) and time point 2 (App T2).

App T1 vs App T2	Correlation	SE	z score	P value	Range (lower-upper)
Anxiety or depression	0.729	0.029	24.838	<.001	0.671-0.786
Pain or discomfort	0.744	0.028	26.640	<.001	0.689-0.799
Usual activities	0.786	0.024	32.855	<.001	0.739-0.833
Self-care	0.897	0.012	73.058	<.001	0.873-0.921
Mobility	0.730	0.029	24.906	<.001	0.672-0.787

Table 4. Polychoric correlations between EQ-5D-5L paper and EQ-5D-5L mobile app (average App T1 and App T2) version.

Digital variable versus paper	Correlation	SE	z score	P value	Range (lower-upper)
VAS ^a _digital	0.636	0.030	20.876	<.001	0.576-0.696
Anxiety or depression	0.791	0.122	6.496	<.001	0.553-1.030
Pain or discomfort	0.824	0.121	6.783	<.001	0.586-1.062
Usual activities	0.812	0.122	6.657	<.001	0.573-1.052
Self-care	0.880	0.124	7.083	<.001	0.636-1.123
Mobility	0.915	0.121	7.545	<.001	0.677-1.152

^aVAS: visual analog scale.

Correlations Paper-Based EQ-5D-5L Questionnaire Versus the Mobile App

Table 4 displays the results of the polychoric correlations, showing high relations between the different scores on paper and in the mobile app (average App T1 and App T2) across the 5 domains (>0.79). It is difficult to set a cutoff value based on a variety of assumptions and indicators. However, as all correlations between the paper and digital questions are above 0.79, they indicate a very strong validity for repeated questions about anxiety or depression, pain or discomfort, usual activities, mobility, and self-care. Mobility showed the strongest correlation (0.92; $P < .001$). In addition, the correlations of the EQ-5D domains paper versus app were in the same range as the test-retest reliability results. The estimated correlation of the VAS scores was lower (0.64; $P < .001$) compared with the questions on the 5 domains (>0.79 ; $P < .001$).

The polychoric correlations between paper and App T1 and between paper and App T2 are presented in the Multimedia Appendix 2. Lower correlations were observed between paper and App T1 (>0.64) and paper and App T2 (>0.65), compared with the correlations between paper and the average score of the mobile app (>0.79) and compared with the correlations between App T1 and App T2. Using paired 2-tailed t tests, no

significant differences between the average mobile app score and the observed paper score were found (Multimedia Appendix 3) or between App T1 and App T2 (Multimedia Appendix 4). Consistently higher or lower scoring of paper compared with the mobile app was also not observed. A strong agreement between the paper and the mobile app was observed (>0.64), with no structurally higher scores on paper or the mobile app.

The slight difference in correlation strength between the correlations between App T1 and App T2 (Table 3) and the correlations found between paper and the mobile app (Table 4) may be because of the effect of time (between the 2 moments of answering in the mobile app) and not the difference in media (paper vs the mobile app). This is because the perceived quality of life changes slightly over the course of a day and between days, even in a healthy population [28].

Subjective Evaluation of the Mobile App

A short evaluation questionnaire was requested via the app to gain insight into its usability. Figure 2 shows the usability on three aspects: “the app provides a good representation of how I feel,” “it is no burden to answer this questionnaire quarterly,” and “the app is more user-friendly than the paper-based questionnaire.” The scores ranged from 1 to 7, with a higher score indicating that the participants strongly agreed with the statement.

Figure 2. Usability of the mobile app, where a higher score indicates higher agreement with the question posed, the questions being, “The app provides a good representation of how I feel;” “It is no burden to answer this questionnaire quarterly;” and “The app is more user-friendly than the paper-based questionnaire.”.

Most (197/261, 75.5%) participants indicated that the mobile app provided a good representation of how they felt. Furthermore, the participants perceived no burden to answer this questionnaire quarterly via the mobile app. In addition, the mobile app was perceived as more user-friendly than the paper-based questionnaire. However, some (42/261, 16.1%) participants mentioned in their free-text comments that user-friendliness could be improved in some ways. For example, a couple of participants mentioned that the notification or icon of the mobile app always remained at the top left on their phone screen, which was experienced as unpleasant.

Discussion

Principal Findings

This study aimed to validate an innovative way to measure health-related quality of life using a mobile app based on the EQ-5D-5L questionnaire that may replace the paper version of the questionnaire. The mobile app prompts a participant to answer a single question of the EQ-5D-5L questionnaire twice a day, once in the morning and once in the afternoon. In total, all questions were asked twice, spread over 5 consecutive days. This study was designed to compare the scoring in the mobile app to the gold standard paper-based version of the EQ-5D-5L.

This study showed high correlations, of over 0.79 ($P < .001$), for all 5 questions between the paper-based EQ-5D-5L questionnaire and the mobile app questionnaire (averaged App T1 and App T2). When comparing the paper-based version separately with the 2 time points App T1 and App T2 (Multimedia Appendix 2), the correlations were slightly lower. Depending on the domain (eg, mobility, self-care, usual activities, pain or discomfort, and anxiety or depression), the correlations between the paper-based version and App T1 or App T2 were higher. For all domains, the correlation of the mean of both entries was higher than that for one entry, regardless of whether it is App T1 or App T2. Averaging the 2 scores may have eliminated some variability, potentially increasing the correlation. Nevertheless, because of the high correlations for App T1 (>0.64) and App T2 (>0.65), completing the questionnaire once

via the mobile app seems to be sufficient, considering its high retest reliability. In addition, no significant differences between the paper score and the mobile app were observed, indicating that the scores were not structurally higher for either paper or the mobile app. Regarding test-retest reliability, high correlations were found between the App T1 and App T2 scores (>0.73). Both the high correlation between the paper version and the mobile app questionnaire, along with the high correlation of the in-between comparison of the mobile app time points (App T1 vs App T2), make the new mobile version of the EQ-5D-5L questionnaire a reliable replacement for the paper-based method.

A review [12] demonstrated the equivalence of electronic and paper-based patient-reported outcome measures. Equivalence was observed in 43 studies. However, 2 studies did not find equivalence, and 10 studies had no clear conclusions. Furthermore, Jiang et al [16] criticized the web-based method in comparison with the face-to-face method. Therefore, validation of the new smartphone method compared with the gold standard is important before using the new method in a health care setting.

Belisario et al [7] compared the responses to questionnaires using a mobile app with other methods (eg, paper, laptop, and web based). No major differences in using the app or “other methods” were observed. This study used a threshold correlation of >0.6 , which is in line with our results, and we found correlations of >0.64 .

Mulhern et al [10] executed a comparable study with the EQ-5D-5L questionnaire requested on paper and via a mobile phone app. In this study, a higher response rate was observed for mobile phone questionnaires. However, their study used a parallel design; the participants completed only one administration method. In comparison, in this study, participants completed both the paper-based and mobile app versions of the EQ-5D-5L. This study design is recommended to have confirmative evidence for equivalence [29], because the same participants undergo both methods. In a study by Lundy et al [30], the EQ-5D-5L paper version was examined using different devices (handheld, tablet, interactive voice response, and web).

They found substantial evidence supporting the measurement equivalence of the different modes of data collection (paper format and screen-based and phone-based formats of the EQ-5D-5L provided) [30]. Evidence that this is not the case for the current questionnaire was found in the study by Kim et al [31]. They showed high correlations for the International Prostate Symptom Score questionnaire requested via an app and on paper. Furthermore, Bellamy et al [32] found high correlations between a paper-based and mobile-based scores for osteoarthritis. Different studies [11,33,34] showed a similar response to a questionnaire requested via an app and a paper-based version. These results support the validity of the EQ-5D-5L mobile app questionnaire used in this study in healthy volunteers.

An attribute of the questionnaire itself in a healthy population, such as this, is the low variance. Most people answered that they did not have any daily issues on each of the Likert scale questions. Therefore, polychoric correlation was applied, because this method is more sensitive to ordinal data with low variance. The reliability and validity of the mobile app in unhealthy people should be tested in a follow-up study, because the variance in the domains may be higher, which could affect the correlations between the methods.

We found a lower correlation for the VAS score (0.62; $P < .001$) than for the 5 domain questions between the 2 methods. This may be because of the greater sensitivity to the daily differences in this score, as the scale runs from 0 to 100 instead of from 1 to 5 as the domain questions (continuous vs categorical data). However, most individuals (204/255, 80%) scored >70 , leaving an effective score range of 70 to 100. This means that an individual who scores 74 today and 75 tomorrow has an increase, whereas an individual who scores 74 today and 72 tomorrow has a decrease in score, although both deviations may be a nonnoticeable difference for the individual. When asked about categories, this would be the same category, and no deviations would be depicted.

Earlier studies showed a low yet positive correlation between consecutive measurement moments within persons for the EQ-5D VAS of 0.21 [35], indicating that a lagged correlation of 0.62 seems reasonable for a lagged relationship between individuals. In this study, there were several days between completing the questionnaire on paper and via the mobile app, which might have caused differences in the VAS scores.

Furthermore, the display length of the mobile device could affect the 0 to 100 scores differently compared with the paper length, resulting in more variation. However, other studies showed no effect of differences in device length on VAS scores; they were all similar even if the screen was half the size, meaning that the VAS itself may be a constant measure [36].

Strengths and Limitations

This study has some limitations. In this study, most (144/255, 56.5%) participants were highly educated, and only 4% (10/255) of the participants had a low education level. Therefore, it is not yet known whether this mobile app is usable for lower educated people and whether education level affects the validity of the paper-app comparison. Furthermore, the usability for

older people is not known, because the maximum age in the study was 64 years. In addition, although the app-based questionnaire is relatively simple, it does not test which minimal digital skills are needed for the use of the mobile app. The participants in the study were digitally skilled (as part of the inclusion criteria) and indicated that the questionnaire app was user-friendly (Figure 2). In addition, the mobile app was only tested with people who stated to be healthy at their own discretion, which may have caused low variance in scores.

Most eHealth app studies have nonrepresentative populations [37,38]. This indicates that there may have been a selection bias during the recruitment of people for this type of study. Nicholl et al [37] also reported that participants were predominantly female, White, well educated, and middle aged, and thus the wider applicability of digital self-management interventions remains uncertain. This is important for the usability of the at-home tests. However, this may not be applicable to the general population.

Despite these limitations, a good representation of the population with sufficient spread of age, gender, and people living in the Netherlands was obtained. Furthermore, the number of participants was sufficient for validation (calculated necessary: 200; completed the study: 255). Another strength of this study was the testing period of the mobile app before the start of the study. Before the study began, the mobile app was optimized using feedback from the testers.

Future Studies

Only healthy participants were included in this study. It is recommended to test the app in distinct groups of patients to gain insight into whether the perception of quality of life in diseased people can be measured with the mobile app as well.

An app should be attractive through pictures and should not be textual. Positive feedback and rewarding also play key roles in eHealth interventions [39]. The long-term use of and compliance with mobile apps require special attention. Recommendations for the app can be provided by using an extensive usability questionnaire. AB testing, which allows for the comparison of different variations of the mobile app, may be used to improve mobile app usability. Aesthetics (attractiveness), utility (relevance), and usability play vital roles in eHealth.

In addition, the study population consisted mainly of highly educated individuals. It is recommended that the mobile app be tested in a low socioeconomic group of people too. It is also worthwhile to validate the mobile app for use by older people. Older people are often less comfortable using mobile apps, and information about quality of life may be even more relevant for this group [40]. Another recommendation is to determine the use of the mobile app in long-term monitoring; for example, as a follow-up tool during or after treatment [11,31,34].

In addition, there is another instrument for scoring perceived health, the health monitor. The health monitor is inspired by the self-anchoring scale, also known as Cantril Ladder, which uses 10 steps to stress one's health [41], combined with a short questionnaire. The health monitor is used to measure a person's perceived acceptance and control of their illness or well-being. Future research should investigate whether the health monitor

is comparable with the EQ-5D and could be used as a future quality of life tool. Furthermore, the next level of nonobtrusive measurement of quality of life could be achieved by means of digital phenotyping. Digital phenotyping is the quantification of a particular human behavior using data from personal digital devices or wearables. In the near future, data such as proximity to other devices using Bluetooth, estimation of activity, or detection of voice could be applied as robust, continuous nonintrusive proxies of aspects of quality of life [42].

Conclusions

In this study, high correlations between the questionnaire requested via the mobile app and on paper were observed. This

indicates that the mobile app is valid for use and is as reliable as the paper-based version of the EQ-5D-5L. With the widespread use of mobile phones, the mobile app is potentially valuable for perceiving a patient's health in a simple and valid way, as an alternative to the paper-based EQ-5D-5L questionnaire. The mobile app could reduce the current burden and errors with the use of questionnaires, such as skipping questions, giving more answers than required, and data entry errors. In addition, mobile app data will be immediately available and stored and can easily be compared with previously completed questionnaires. However, more research is required to establish the use of mobile apps for consecutive monitoring of various user groups.

Acknowledgments

This study was funded by Janssen Pharmaceutical Companies and independently executed by TNO (Netherlands Organisation for Applied Scientific Research). The authors would like to thank Ton Peters for his excellent cooperation, Filip Vissers of Q1.6 for developing the mobile app, Jaap de Graaf of MSI-ACI for his collaboration and recruitment of participants, and the study participants for their time and effort.

Abstract

Background: Although behavioral interventions have been found to be efficacious and effective in randomized clinical trials for most mental illnesses, the quality and efficacy of mental health care delivery remains inadequate in real-world settings, partly owing to suboptimal treatment fidelity. This “therapist drift” is an ongoing issue that ultimately reduces the effectiveness of treatments; however, until recently, there have been limited opportunities to assess adherence beyond large randomized controlled trials.

Objective: This study explored therapists’ use of a standard component that is pertinent across most behavioral treatments—prompting clients to summarize their treatment session as a means for consolidating and augmenting their understanding of the session and the treatment plan.

Methods: The data set for this study comprised 17,607 behavioral treatment sessions administered by 322 therapists to 3519 patients in 37 behavioral health care programs across the United States. Sessions were captured by a therapy-specific artificial intelligence (AI) platform, and an automatic speech recognition system transcribed the treatment meeting and separated the data to the therapist and client utterances. A search for possible session summary prompts was then conducted, with 2 psychologists validating the text that emerged.

Results: We found that despite clinical recommendations, only 54 (0.30%) sessions included a summary. Exploratory analyses indicated that session summaries mostly addressed relationships (n=27), work (n=20), change (n=6), and alcohol (n=5). Sessions with meeting summaries were also characterized by greater therapist interventions and included greater use of validation, complex reflections, and proactive problem-solving techniques.

Conclusions: To the best of our knowledge, this is the first study to assess a large, diverse data set of real-world treatment practices. Our findings provide evidence that fidelity with the core components of empirically designed psychological interventions is a challenge in real-world settings. The results of this study can inform the development of machine learning and AI algorithms and offer nuanced, timely feedback to providers, thereby improving the delivery of evidence-based practices and quality of mental health care services and facilitating better clinical outcomes in real-world settings.

Introduction

Background

Mental health is a major global health concern. Mental illnesses will affect close to half of the world's population at some point in their lives [1]. In addition to the personal toll of these illnesses, they also cost the global economy US \$1 trillion per year in lost productivity alone [2]. Cognitive behavioral interventions have a robust evidence base for their efficacy and effectiveness in treating a variety of mental health issues. However, an ongoing challenge in the field has been how to "bridge the gap" between the laboratory or classroom and the clinic, with the data suggesting that the implementation of these methods in real-world settings is often much more challenging. One hypothesis for this is that therapists in real world settings may not be as adherent to the protocols on which these treatments have been tested and the evidence base established.

Cognitive behavioral treatments are designed to help individuals identify and alter maladaptive cognitions, emotions, interpersonal relationships, and problematic behaviors to reduce symptoms and lead more productive and satisfying lives. At this point, numerous versions of behavioral interventions have been manualized and studied in comparative trials with robust effects versus waitlist and placebo conditions, as well as medications and other forms of psychotherapy and disseminated worldwide. The need for focused behavioral treatments has become stronger following the COVID-19 pandemic, given the global increase in mental health disorders [2,3] and the resulting demand for mental health services, coupled with a dramatic shortage of clinicians [4]. Given this need-service gap, it is imperative that behavioral treatments be delivered in accordance with the empirically based guidelines based on which they were established in order to maximize the potential of replicating the outcomes of the clinical trials with individuals "in the real world" with mental health concerns.

Therapist Adherence to Treatments as Designed

"Therapist drift," or the tendency of clinicians to adhere only partially to established empirically supported practices, has been documented in the literature with respect to many treatment models [5,6]. Therapists' attitudes toward evidence-based practices (EBPs), their licensing status, and organization characteristics combinatorically affect their use of recommended strategies [7,8]. Further, clinical trainings or specialty workshops for EBPs are often not enough to facilitate change of practice and improved client outcomes unless some ongoing follow-up sessions are offered for supervision [9].

Complicating matters further, therapy is often like a "black box" in which little is done to monitor or encourage clinicians to adhere to core active ingredients of empirically supported treatments. As such, it has been proposed that clinical research should utilize observations that are less subject to bias [10,11]. In addition, data from real-world treatments indicate that few empirically based therapeutic techniques are in effect, even when clinicians report that they offered evidence-supported behavioral treatments [12].

Session Summary: An Example of Therapist Adherence

Empirically supported protocols are often built on a basic set of theoretical ideas. Although certain aspects may differ amongst protocols, certain essential concepts remain common to them all [13]. Dryden [14] argues that it is essential for the client to leave the session with what they view as important takeaways. As the session comes to a close, it is best practice for the therapist to invite the client to summarize the session rather than the therapist summarizing what transpired for the client during the session [14]. Indeed, one of the key elements in almost every manualized treatment is encouraging the client to compose a *summary* at the end of each therapy session [15-19]. This form of feedback is described as a means of helping clients review their own understanding of the session and the rationale for the interventions provided [20]. Further, a session summary provides clients an opportunity for feedback, which empowers clients to conceptualize their needs, assess their progress toward their goals, and make their own decisions. It also allows the therapist to ensure that key components of the sessions have been understood and highlighted. Therefore, a session summary could be viewed as a common, transdiagnostic evidence-based component that is one of the key ingredients related to the effectiveness of the session.

The importance of session summary has not been overlooked by researchers, and reports on treatment studies often mention this strategy [21,22]. Perlich and Meinel [23] even developed a tool for collaborative session summary, in which the client and the therapist review the session and their takeaways. However, when asked about their own adaptations of EBPs, 32% of therapists reported removing components of the intervention, with the session summary being the most frequently omitted part from the therapy process [24]. Similarly, one of the most common challenges of community mental health therapists learning cognitive behavioral therapy (CBT) was their limited attempts to solicit the client's feedback [20], and in text-based CBT, very few therapists summarized the session [25].

While the session summary is just one example of possible therapist drift [6], given its importance of reinforcing the therapeutic process and strengthening the learnings obtained during treatment, and that it is a technique that can be delivered quite briefly and has a high face validity across interventions, it may serve as a proxy for how much the clinician is adhering to the full range of tasks that are essential for evidence-based therapies (EBTs) to be effective. Therefore, this study explored how common are session summaries in real-world behavioral treatments.

Methods

Settings and Interventions

This study is based on the retrospective analysis of fully anonymized data from behavioral health treatments provided in 37 behavioral health care programs across the United States. All client participants received either individual, group, or couples therapy in either an outpatient or intensive outpatient

program. Clients sought treatment for a range of mental health concerns, and therapists were free to provide the intervention they believed was most suitable for the client's presenting problem and characteristics. Therapists were either psychologists, social workers, or licensed counselors. The sample comprised 17,607 treatment sessions administered by 322 therapists to 3519 clients.

The Eleos Health Platform

All sessions were processed via an artificial intelligence (AI) therapy-specific platform (Eleos Health). This platform captures the treatment conversations, provides a verbatim session transcript, and summarizes intervention insights to inform treatment-planning and clinical decision-making [26]. The platform collects key metrics from treatment sessions and integrates them with standardized evidence-based self-report measures, leveraging insights developed through machine learning (ML) and natural language processing (NLP) analysis of large treatment data sets [27]. Eleos also uses AI methods to increase adherence with clinical standards and drive operational efficiency.

Ethical Considerations

The platform is Health Insurance Portability and Accountability Act-compliant, and all participants consented to have their sessions processed through it. This study was approved by an external institutional research board, Sterling IRB (9545).

Data Processing

To fully capture and make sense of the speech data, we developed an algorithm to identify the specific interventions carried out in behavioral treatment sessions and consequently determine whether a session summary was recorded. First, the sessions were transcribed using an automatic speech recognition system (ASR) as well as a domain-based text-cleaning algorithm. Second, since the session transcripts are unstructured data, we developed a treatment-oriented, speaker diarization ML model in accordance with their utterances in the treatment session. A team of trained graduate-level clinicians tagged over 2500 therapy conversations and labeled the speakers as either "patient" or "therapist." These data were consequently used in

a model that analyzed the full transcribed session and assigned a speaker label for each participant. Third, we applied the term frequency-inverse document frequency, a commonly used feature generation method, to identify if the speaker is either the therapist or a client. As a classification algorithm, we used a logistic regression model with a binary cross-entropy loss and trained the model using stochastic gradient descent. On a session level, our in-house solution demonstrated 98% accuracy in differentiating between speakers in therapy sessions.

Data Analysis

Eleos's NLP-based engine extracted potential session summary from therapists' utterances, identifying the frequencies of lexical terms, which were said during the latter 20% of the session, and retrieving phrases such as the following: "[I] just want to review what we talked about"; "So what did you learn here today?"; "If it was something that you were going to take away from today's session, what would it be?"; "What's your take home message from today?"; "Alright, let's do our summary for the day"; "kind of [your] two main takeaways"; and so on. For quality assurance, 2 psychologists (SSS and TK) reviewed 682 sessions that included language associated with a session summary and indicated whether the algorithmically identified text did in fact reflect a meeting review prompt. Figure 1 outlines the data analysis approach used in this study. Finally, we compared sessions with and those without a summary on the following variables: most commonly discussed topics, therapist-to-client listening ratio, the most commonly used intervention techniques, and content of the progress note that the therapist had generated for this session in the program's electronic health record (EHR). Further, to assign the sentiment expressed during these specific sessions, we applied Valence Aware Dictionary and sEntiment Reasoner (VADER) [28] on the therapist's and patient's texts, independently. VADER is a lexicon and rule-based sentiment analysis tool that uses a sentiment lexicon and a list of lexical features (eg, words) that are labeled in accordance with their semantic orientation as either positive or negative [29]. VADER not only classifies the data to either positive or negative, but also provides a score to indicate the strength of the sentiment detected [28].

Figure 1. Overview of the classification and data analysis process for real-world session summaries. ASR: automatic speech recognition; ML: machine learning; VADER: Valence Aware Dictionary and sEntiment Reasoner.

Results

Provision of a Session Summary

Our analysis found that only 54 of the 17,607 (0.30%) behavioral treatment sessions included a session summary. Of these 54 treatment meetings, session summaries most commonly addressed interpersonal relationships with family and friends

(n=27), issues related with work (n=20), the word “change” (n=6), and alcohol (n=5).

Characteristics of Sessions Including Summaries

Data were further analyzed to review descriptive differences between therapy sessions with and those without a summary. Sessions that included a prompt to help the client summarize the meeting had a lower therapist listening ratio (33% vs 49%),

indicating that therapists were less verbally active throughout the meetings that included feedback. The number of therapeutic interventions detected was greater in sessions that included a session summary; on average, therapists used 17% more interventions in meetings with a summary. Sessions with meeting summaries also included greater therapist use of validation, complex reflections, and proactive problem-solving techniques. Moreover, therapists who prompted their client to summarize their session were 83.3% more likely to assign treatment homework and report it on their EHR progress note. Therapists who encouraged a summary also had a 12% greater likelihood of completing their progress note within 48 hours of the session's date: 69% of those who had asked for a summary

also completed their progress note within this time frame, compared to 61% of therapists who did prompt a summary. [Table 1](#) provides an overview of the differences between sessions including and not including summaries.

Applying the VADER algorithm in sessions that included summaries revealed that the clients expressed, on average, slightly more positive and negative emotions (0.6% and 4%, respectively) than those with no summary. However, the therapists tended to express less emotion in the sessions including a summary, expressing 9% less positive statements and 7% less negative statements. [Table 2](#) provides an overview of the differences between sessions including and those not including summaries around statements' sentiments.

Table 1. Differences in therapists' behaviors between sessions including and those not including a meeting summary.

Sessions	Listening ratio, %	Progress note completion rate, %	Type of interventions detected
Without a summary	33	61	1.04
With a summary	49	69	1.26

Table 2. Sentiment differences between sessions including and those not including a meeting summary.

Sessions	Patients' positive statements, %	Patients' negative statements, %	Therapists' positive statements, %	Therapists' negative statements, %
Without a summary	7.70	4.50	8.90	4.20
With a summary	7.40	4.50	8.20	3.90

Discussion

Principal Findings

While the evidence base is strong and robust for behavioral interventions, their efficacy is tied to maintaining a structure and including certain key components in each session. Therapist drift from the key active ingredients of validated treatment protocols could compromise the efficacy and effectiveness of the treatments, thus limiting the impact of treatment on the individual [30]. This study examined the practice guidelines versus practice in real-world behavioral health care settings as they pertain to a key component found in most behavioral interventions: encouraging clients to review and summarize their treatment session [20]. Session summaries are important because they allow the client an opportunity to reflect back on the treatment meeting, their developing understanding of the maladaptive processes underlying their symptoms, as well as some effective coping strategies they could employ. They also allow the therapist to ensure that key components of the sessions have been understood and highlighted. In controlled and case-series studies reported in the literature, the technique of requesting feedback is stated explicitly [31]. This study found that very few therapists provide feedback to their clients in the form of a session summary. Our findings suggest that providers who encouraged their clients to reflect on their treatment demonstrated a more active therapy style—their sessions were characterized with more back-and-forth exchanges between the therapist and the client, they provided more interventions during the meeting, and they even tended to complete their progress note faster. These results suggest that therapist adherence to at

least one of the key components of most empirically supported behavioral treatments was absent in most of the real-world sessions we reviewed.

Comparison With Prior Work

The findings of this study indicate that in contrast to guidance in treatment protocols, therapists delivering behavioral treatments in real-world settings rarely encourage their clients to reflect on the session during their meeting. To the best of our knowledge, this study is the first to evaluate a large and diverse data set of actual therapy sessions. These findings extend the results of previous studies that have exclusively relied on practitioner self-report and provide insight on how therapists practice in real-world treatment settings [32]. Therapists may overestimate their adherence to practice guidelines, as 32% reported not providing all parts of treatments [32], while this study suggests that adherence rates are much smaller. Session summary, or feedback, can be perceived as a method for prompting clients to form implementation intentions, thereby likely facilitating greater treatment impact; however, prior research has found that therapists do not often explicitly discuss with their clients to plan actions as a result of the treatment session [33]. Further, higher-caseload therapists reported feeling that learning about new EBTs would be time-consuming, which consequently could serve as a barrier to implementing these techniques [30]. In light of this research, it may not be surprising that therapists do not adhere to EBT recommendations despite realizing their potential benefits to service users. Of note, it has been proposed in the literature that treatment protocols are difficult to administer in the field as originally designed in controlled studies, and that "flexibility within fidelity" should

be practiced in order to maximize the effects of these programs [13]. Hence, a systematic understanding of the context affecting variations from prescribed practice and omissions of specific techniques is warranted.

Limitations

This study utilized data from 17,607 sessions taking place in behavioral health clinics across the United States. The data are likely more representative of the therapist behaviors occurring in real-world settings than are the findings of controlled studies. Nonetheless, this study has limitations. The anonymized database did not include demographic and clinical information of the clients and therapists, which could have enriched our analysis. Future studies should also collect explicit data on the treatment that was provided and how it maps on to the client's treatment plan. Further, the low number of sessions with summary statements limited our ability to utilize the sentiment and content analyses. Additionally, the analysis did not include outcome data such as symptom reduction or client satisfaction,

which are important to assess in the context of the treatment process. From a theoretical and practical standpoint, interviewing therapists about their considerations of using strategies will help better define underlying processes affecting behavioral treatment implementation.

Conclusions

Given the importance of following treatment protocols as initially intended, there is much potential in automating timely feedback for therapists. This study is the first to our knowledge that provides real-time, observational data on clinical practice in real-world settings. As such, it provides a new perspective to how clinicians provide therapy that can enrich that data captured by therapist self-reports. Empirically supported ML and AI algorithms can offer clinicians, trainers, supervisors, and stakeholders nuanced observations on treatment adherence, thereby improving the quality of implementation, dissemination, and ultimately, effectiveness of mental health treatments.

Data Sharing Statement

The data that support the findings of this study are not publicly available owing to privacy and ethical restrictions.

Conflicts of Interest

SSS, SJ, GP, and TK are employees of Eleos Health Inc, which created the platform providing the data for this study. SAR is an unpaid advisor to Eleos Health Inc.

Abstract

Background: A challenge facing researchers conducting mobile health (mHealth) research is the amount of resources required to develop mobile apps. This can be a barrier to generating relevant knowledge in a timely manner. The recent rise of “no-code” software development platforms may overcome this challenge and enable researchers to decrease the cost and time required to develop mHealth research apps.

Objective: We aimed to describe the development process and the lessons learned to build Pathverse, a no-code mHealth app design platform.

Methods: The study took place between November 2019 and December 2021. We used a participatory research framework to develop the mHealth app design platform. In phase 1, we worked with researchers to gather key platform feature requirements and conducted an exploratory literature search to determine needs related to this platform. In phase 2, we used an agile software framework (Scrum) to develop the platform. Each development sprint cycle was 4 weeks in length. We created a minimum viable product at the end of 7 sprint cycles. In phase 3, we used a convenience sample of adults (n=5) to gather user feedback through usability and acceptability testing. In phase 4, we further developed the platform based on user feedback, following the V-model software development process.

Results: Our team consulted end users (ie, researchers) and utilized behavior change technique taxonomy and behavior change models (ie, the multi-process action control framework) to guide the development of features. The first version of the Pathverse platform included features that allowed researchers to (1) design customized multimedia app content (eg, interactive lessons), (2) set content delivery logic (eg, only show new lessons when completing the previous lesson), (3) implement customized participant surveys, (4) provide self-monitoring tools, (5) set personalized goals, and (6) customize app notifications. Usability and acceptability testing revealed that researchers found the platform easy to navigate and that the features were intuitive to use. Potential improvements include the ability to deliver adaptive interventions and add features such as community group chat.

Conclusions: To our knowledge, Pathverse is the first no-code mHealth app design platform for developing mHealth interventions for behavior. We successfully used behavior change models and the behavior change technique taxonomy to inform the feature requirements of Pathverse. Overall, the use of a participatory framework, combined with the agile and hybrid-agile software development process, enabled our team to successfully develop the Pathverse platform.

Introduction

Advancements in internet-enabled digital devices (eg, smartphones and wearables) and improved access to these devices have led to the rapid growth of mobile health (mHealth) research [1]. Due to the flexibility and scalability of mHealth technology, there has been tremendous interest among researchers and public health agencies in leveraging mHealth for promoting a healthy lifestyle and preventing chronic diseases [1-4]. Previous studies have shown that mHealth interventions can be efficacious in improving physical activity and healthy eating behaviors and reducing sedentary behavior [1,2,5]. However, research on the optimal ways to design these mHealth interventions to maximize effectiveness for different health conditions and population groups is still in its infancy. A recent meta-analysis found that efficacious mHealth apps that aimed to improve diet and physical activity and reduce sedentary behavior used a variety of behavior change theories and behavior change techniques (BCTs). BCTs are strategies that help individuals change their behavior; thus, these strategies are critical to creating effective and replicable behavior interventions [6]. Some efficacious apps incorporated BCTs such as motivational messages, rewards, gamification in the form of exergames, social support through interaction with peers, and friendly team challenges [7]. Meanwhile, other effective interventions have shown that using tailored health advice, goal setting, self-monitoring, and performance feedback in an app's design can lead to greater intervention effects [7-10]. Overall, more research is needed to realize the full potential of mHealth technology.

One of the challenges facing researchers conducting mHealth intervention research is the cost and time required to develop and maintain mobile apps [11]. The cost to develop these customized mobile apps (eg, behavior health counselling interventions, daily diary survey studies, and self-monitoring apps) can range broadly. Even an app with few features can cost between US \$70,000 and \$100,000 and take 3 to 6 months to develop [12]. Furthermore, the app development cost often does not fit into the budget of government research grants (eg, those provided by the National Institute of Health Research or the Canadian Institute of Health Research). Existing mobile app development kits, such as Apple's ResearchKit and Android's ResearchStack, have attempted to improve the app development process for researchers [13,14]. However, these frameworks

still require significant software programming to develop apps and often require researchers to hire specialized software developers to develop iOS and Android apps. Due to the rapidly evolving digital technology space, these challenges can be a significant barrier to developing relevant mHealth knowledge in a timely manner [15]. The need for research tools to help generate rapid and relevant research knowledge has been a long-noted issue in health research and a solution is desperately needed [16].

An innovative solution to overcome these mHealth app development challenges facing researchers has recently arisen: "no-code" development platforms [17]. A no-code mHealth research app development platform could enable researchers with no previous software programming skills to create apps through a graphical user interface (UI). Similarly to using no-code tools such as Squarespace to create websites [18], researchers could use a no-code mHealth design platform to create multiple versions of an app to evaluate their effectiveness in various conditions. Researchers could use drag and drop tools to select the required BCTs (eg, self-monitoring and goal setting tools) needed for a behavior change framework. We believe a no-code app design platform could significantly expedite the mHealth app development process and reduce the time and cost required. Currently, there is a lack of a no-code app design platform explicitly designed for researchers to develop mHealth behavior interventions. Thus, the purpose of this paper is to describe the development process and the lessons learned in building a no-code mHealth app design platform, Pathverse.

Methods

We used a participatory research framework to develop a no-code mHealth app design platform called Pathverse [19]. A participatory framework is a method that involves active collaboration between end users (ie, researchers) and software developers at various stages of development to ensure that the final product is relevant and useful [20,21]. This study was divided into four phases: (1) determination of features required for a no-code mHealth design platform; (2) development of the platform; (3) gathering of user feedback; and (4) implementation of user feedback to further refine the platform. The entire development process took place between November 2019 and December 2021. A summary of the development timeline and activities is shown in [Table 1](#).

Table 1. Development phases of the web-based program.

Phases	Activities	Dates
(1) Determine feature requirements	Determine features required for the "no-code" mHealth design platform, Pathverse	Nov 2019-Mar 2020
(2) Develop the platform	Use the Scrum development framework to design the Pathverse platform	May 2020-Dec 2020
(3) Gather user feedback	Usability and acceptability testing	Feb 2021-May 2021
(4) Implement user feedback	Revise the Pathverse platform based on usability and acceptability testing	Sep 2021-Dec 2021

Phase 1: Determine Feature Requirements (November 2019-March 2020)

mHealth researchers (n=13) with various levels of research experience (eg, students, early career researchers, and senior

researchers) and software developers (n=4) were involved in identifying key software features for the no-code app design platform, Pathverse. The team members' demographics are presented in [Multimedia Appendix 1](#), Table S1. The mHealth research team's expertise included mHealth app development

and evaluation, behavior science, psychology, health promotion, and usability testing. The software development team expertise included Python, JavaScript, Dart, and the Scrum development process. We performed an exploratory web search using Google with the search term *no-code mHealth app builders* to determine whether such mHealth app builders existed. In addition, we performed a literature search to determine mHealth apps features that were associated with intervention effectiveness. Specifically, MEDLINE, PubMed, EMBASE, and PsycINFO were searched for articles published from January 2009 to December 2019 with the following key words: (*mobile health OR mHealth OR internet intervention OR web-based interventions*) AND (*effectiveness OR efficacy*) AND (*features OR characteristics OR behaviour change techniques OR theories*) AND (*systematic review OR literature review OR meta-analysis*). Our interdisciplinary team met regularly throughout this phase to brainstorm features (eg, self-monitoring tools and goal setting) required to build mHealth apps. In order to ensure that these features met the researchers' requirements for building mHealth apps, our team used the multi-process action control framework (M-PAC) as a theoretical template model and used physical activity change as the template outcome behavior. The M-PAC framework has been shown to be effective in promoting physical activity [22-24]. M-PAC emphasizes a social cognition approach to intention formation, the adoption of action control through self-regulation, and an action control maintenance phase once a behavior becomes habitual and self-identified [23]. One advantage of the M-PAC model is its ability to address the "intention to behavior" gap, which poses a particular challenge for individuals adopting a new lifestyle, because almost all individuals joining mHealth app interventions have already formed an intention to adopt a healthy lifestyle [23,25,26]. Finally, we matched the proposed BCTs to the M-PAC mechanisms of action [22], which guided the features for the Pathverse app development platform. A list of key features and a mock-up design of the Pathverse platform were developed by the end of this phase.

Phase 2: Develop the Platform (May-December 2020)

We used the Scrum framework to develop the Pathverse platform [27]. This agile software framework uses an iterative approach that allows for valuable input from end users throughout the software development cycle. Scrum uses predefined short-sprint cycles that usually last from 2 to 4 weeks. Each sprint cycle consists of design, implementation, evaluation, and planning for the next sprint. The Scrum framework enables the development team to create the first version of the software at the earliest stage of the development process. Furthermore, regular meetings throughout the development cycles enable end users to provide valuable feedback and make rapid adjustments throughout the development cycles.

We used a 4-week sprint cycle in this project. We aimed to produce a working version of the platform in about 7 months (ie, 7 sprint cycles). The key members in the Scrum team were an mHealth researcher (the product owner, SL), the Scrum master (HL), and the software development team. End users with various levels of mHealth research experience (researchers, research assistants, and students) were involved during each sprint. The Scrum team presented the completed platform

features and discussed goals for the next sprint with the team at the end of each sprint.

Phase 3: Gather User Feedback (February-May 2021)

Similarly to our previous studies [28,29], we gathered user feedback by assessing the usability and acceptability of the Pathverse platform. Usability and acceptability assessments are part of a technique in user-centered interaction design to evaluate how researchers interact with the platform; we used this approach to evaluate whether Pathverse met its intended requirements. We used a convenience sample of health researchers (n=5) who were interested in using or had used mHealth applications in their research. Participants were required to have not previously used the Pathverse platform. Due to the COVID-19 pandemic, the assessments were conducted using video calls. A week prior to the video call, participants were given access to the platform and were asked to use it to build a mobile app program aimed at promoting a healthy lifestyle. During the video call, we conducted a structured interview to gather feedback on what the user liked and disliked about the platform and to determine areas needing improvement. The qualitative interview data were summarized using thematic analysis to identify areas for improvement. Participants were also asked to complete a questionnaire evaluating the likeability and usefulness of the platform. The questionnaires were adapted from an mHealth app usability questionnaire that assesses the likability and usefulness of the platform [30]. The score had a scale ranging from 0 to 10, with 10 indicating "strongly agree," and 0 indicating "strongly disagree."

Phase 4: Implement User Feedback (September-December 2021)

Based on user feedback, our team planned for an additional phase of development. During this phase, we used the V-model software development process. This method combines traditional sequential development methodology (eg, the waterfall method) with feedback mechanisms in the agile development process (eg, Scrum) to ensure that the new features added work appropriately [31]. The V-model software development process was chosen instead of the Scrum method due to the well-defined project requirements and the smaller project size [31]. Our team used the following development stages: (1) requirement analysis (ie, gathering project requirements from researchers), (2) system and architectural design (ie, determining the critical software components required for the final product), (3) module design (ie, determining the critical modules for the software components identified), and (4) coding (ie, starting to program the modules). We also conducted validation testing for each development stage to ensure that the platform worked appropriately. The validation testing consisted of the following: (1) unit testing (performed by the software team to eliminate system bugs during the coding phase), (2) integration testing (performed by the software team to ensure the new features developed worked appropriately with the existing platform), (3) system testing (conducted by the researchers to ensure the development met the build requirement), (4) user acceptance testing (performed by the research team to ensure the platform was ready for use in the real world).

Ethical Considerations

Informed consent was obtained from participants completing the usability and acceptability testing. This study was approved (17361) by the Human Research Ethics Board at the University of Victoria.

Results

Phase 1: Determining Feature Requirements

Our multidisciplinary team of researchers and software developers met regularly to determine requirements and features for the Pathverse platform. A summary of the activities conducted at each meeting is shown in [Table 2](#). Our exploratory Google web search revealed that there was a lack of no-code mHealth app development tools designed for researchers. A literature review suggested that an mHealth app platform would need a variety of software features in order to deliver a wide range of BCTs [3,7,32-34]. For example, a review of BCTs in 40 exercise and dietary apps showed that the apps included an average of 8.1 (range 2-18) techniques [35]. Commonly included BCTs were “provide instruction” (33/40 of apps, 83%), “set graded tasks” (28/40, 70%), “prompt self-monitoring” (24/40, 60%), and “model/demonstrate the behavior” (24/40, 53%). At least one of the following 3 BCTs was also included in 55% (22/40) of the apps: “provide opportunities for social comparison,” “plan social support/social change,” and “prompt identification as a role model” [35]. A more recent systematic review suggested that prompts and cues, personalization, goal setting, and action planning were the most common BCTs used in effective mHealth trials to improve lifestyle behaviors and

chronic condition management [36]. However, the optimal number and combinations of BCTs needed for effective mHealth interventions would most likely depend on the underlying theoretical approach and the proposed mechanisms of action. Thus, this reinforces the need for the Pathverse platform to provide researchers with the flexibility of building mHealth apps with various BCTs for a chosen theoretical framework (eg, M-PAC, self-determination theory, or theory of planned behavior).

Our team generated a list of potential Pathverse features by building a mock-up app using the M-PAC framework as a template theoretical framework and physical activity as the behavior change outcome. Similarly to our previous study, our team then matched the BCTs required to implement the physical activity app using the M-PAC framework [28].

The final platform features included the ability to (1) design customized and interactive multimedia content in the app; (2) set flexible content delivery logic (eg, delay the time release or only show new lessons when completing the previous lesson); (3) deploy customized surveys to the participants; (4) provide personalized self-monitoring trackers (ie, daily steps); (5) enable participants to set goals; (6) implement customized app notifications to remind participants of any new mHealth intervention content; (7) provide gamified points and badges; and (8) enable participants to share progress made on their social media accounts (eg, Instagram and Facebook). [Table 3](#) shows how these Pathverse features could potentially be used to deliver the BCTs listed in the Coventry, Aberdeen & London—Refined (CALO-RE) taxonomy [37].

Table 2. A summary of the activities conducted during the meetings.

Date	Activities

Table 3. Behavior change techniques that can be implemented using the identified Pathverse features.

Pathverse features	Potential behavior change techniques that could be implemented using the proposed Pathverse features. The numbers in parentheses refer to behavior change techniques in the Coventry, Aberdeen & London—Refined taxonomy [37].
(1) Ability to design customized multimedia content (eg, text, pictures, video, and interactive quizzes) on various app pages; the content can be organized into “lessons” depending on the intervention curriculum (for example, lesson 1 might discuss the benefits of physical activity and lesson 2 might provide information on setting graded goals)	<ul style="list-style-type: none"> • Provide information on consequences of behaviour in general (1) • Provide information on the consequences of behaviour to the individual (2) • Provide information about others’ approval (3) • Provide normative information about others’ behaviour (4) • Barrier identification/problem solving (8) • Set graded tasks (9) • Prompt review of behavioural goals (10) • Prompt review of outcome goals (11) • Prompt rewards contingent on effort or progress towards behaviour (12) • Shaping (14) • Prompting focus on past success (18) • Prompting generalization of a target behaviour (15) • Prompt self-monitoring of behavioural outcome (16) • Provide information on where and when to perform the behaviour (20) • Provide instruction on how to perform the behaviour (21) • Model/demonstrate the behaviour (22) • Teach to use prompts/cues (23) • Environmental restructuring (24) • Fear arousal (32) • Prompt self talk (33) • Prompt use of imagery (34) • Relapse prevention/coping planning (35) • Stress management/emotional control training (36) • Motivational interviewing (37) • Time management (38) • General communication skills training (39) • Prompt identification as role model/position advocate (30) • Facilitate social comparison (28)
(2) Set program delivery logic for the content created (for example, a new program lesson can be delivered every week)	<ul style="list-style-type: none"> • Provide feedback on performance (19) • Use of follow-up prompts (27)
(3) Deploy customized surveys to the participants; the surveys can include multiple choice answers, Likert scales, and drop-down or open-ended questions	<ul style="list-style-type: none"> • Barrier identification/problem solving (8) • Prompt self-monitoring of behavioural outcome (16) • Facilitate social comparison (28)
(4) Track physical activity–related outcomes from participants’ fitness trackers; data will be automatically synchronized from trackers connected to Apple or Google Health	<ul style="list-style-type: none"> • Prompt self-monitoring of behaviour (16)
(5) Enable participants to set personal goals; participants can also receive reminders about the goal due date	<ul style="list-style-type: none"> • Goal setting (behaviour) (5) • Goal setting (outcome) (6) • Action planning (7) • Set graded tasks (9) • Prompt review of behavioural goals (10) • Prompt review of outcome goals (11)
(6) Implement customized app notifications to remind participants of any new mHealth intervention content	<ul style="list-style-type: none"> • Prompt review of behavioural goals (10) • Prompt review of outcome goals (11) • Prompt practice (26)
(7) Provide gamified points and badges ^a	<ul style="list-style-type: none"> • Prompt rewards contingent on effort or progress toward behaviour (12) • Provide rewards contingent on successful behaviour (13) • Shaping (14) • Stimulate anticipation of future rewards (40)
(8) Enable participants to share progress made on their social media accounts (eg, Instagram and Facebook) ^a	<ul style="list-style-type: none"> • Provide information about others’ approval (3) • Facilitate social comparison (28) • Plan social support/social change (29) • Prompt identification as role model/position advocate (30)

^aThese features were not developed in the Pathverse app (version 1.5).

Phase 2: Platform Development

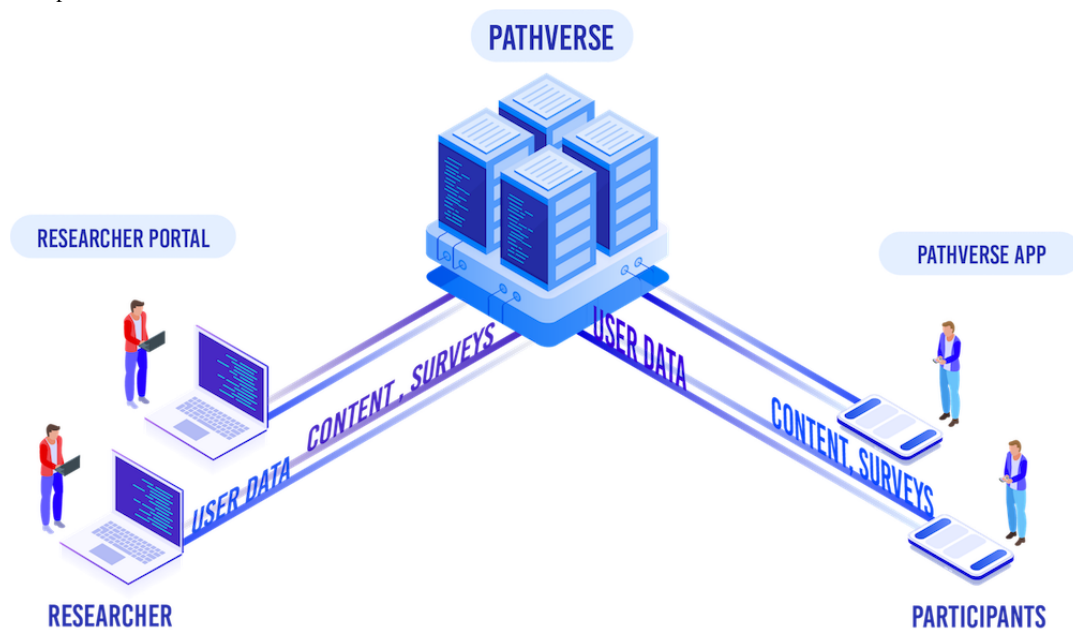

The Scrum team met with researchers throughout the sprint cycles to gather user feedback and plan the tasks to be completed by the end of the next phase. A summary of the activities completed in each Scrum phase is described below. The commit history of the software development process can be found in [Multimedia Appendix 2](#).

Sprint 1

The first sprint started with determining the Pathverse platform architecture required to implement the key features identified in phase 1. The platform consisted of 3 main components: the Pathverse researcher web portal, the Pathverse participant app (available in both the iOS and Android app stores), and the

backend application program interface (API) server and databases ([Figure 1](#)). The researcher portal enabled a researcher to create mHealth apps. The research participants could then download the Pathverse app to access the intervention. The API server acted as an intermediary between the database and the frontend interfaces by relaying information back and forth between storage and users. In this stage of the sprint, our team planned and designed the foundations of the 3 components. This started with determining all the types of data that were going to be used within these components. With the data structure decided, our team worked on user flow and UI for each of the components. Finally, our team finalized platform security. At the end of this phase, researchers and our programming team met to finalize the platform architecture to start development.

Figure 1. Pathverse platform architecture.

Sprint 2

The programming team simultaneously coded the components of the Pathverse platform. At the end of this sprint, the programming team developed a prototype version of the dashboard of the Pathverse researcher web portal using React.js, a JavaScript library licensed from the Massachusetts Institute of Technology [38]. The login and home screen of the participant app used Flutter [39], and the Pathverse API server used Django, an open-source Python web framework (Django Software Foundation). Along with the visuals, the team also completed designing the platform's database, optimized relationships within the database, and added data serializers and authentication functions. Researchers and the programming team met at the end of the phase to review the preliminary UI designs of the web portal and the participant app.

Sprint 3

The main priorities for this sprint were to finish developing the feature that enabled researchers to upload customized multimedia content for an mHealth intervention and set the delivery logic for the intervention. This was the first time the integrated platform was tested collectively. After sharing a

working prototype at the end of this phase, researchers tested the prototype and provided feedback on system bugs and design issues, and they also suggested other features that would improve their experience. The top-priority suggestions included the need to optimize multimedia content (eg, font size and color) for various screen sizes, organize the order of the intervention content delivery using drag and drop, and provide real-time visualization of the multimedia content added to the Pathverse participant app in the research portal.

Sprint 4

The programming team attempted to implement the suggestions made by the end users from the previous sprint. Additionally, the programming team completed the customized survey feature. This feature enabled the researchers to collect various types of survey responses (eg, multiple choice, ratings or Likert scales, drop-down questions, and open-ended questions). These features were tested, and various system bugs, UI design issues, and additional features were discussed. Specific main feature modification requests included providing options to enable participants to complete the survey multiple times and randomize the order of the questions. Due to the large quantity of feedback received (for UI and feature requests) and the slower

than expected feedback implementation, our team decided not to develop 2 features: gamified points and social sharing. This was to ensure that a working prototype of the Pathverse platform could be delivered on time.

Sprint 5

The programming team developed and implemented the self-monitoring tool for step tracking in the participant app. This allowed the Pathverse app to connect to Apple or Google Health wearable devices and display a user's daily step data. The end users worked with the development team to provide feedback on how the wearable data were displayed in the app. The end users provided the feedback that participants should also be able to display other health metrics, including blood pressure, weight, and daily active minutes.

Sprint 6

The programming team completed the development of goal setting and customized app notification features during this sprint. The goal-setting features enabled the participants to set customized personal goals and customized reminders for goal due dates. The customized app notification enabled researchers to set personalized app reminders whenever new app content

became available to the participants. At the end of this phase, the programming team presented the first beta version of the platform to the end users. Due to time constraints, the programming team could not implement the feature that allowed the participant app to display all the health metrics requested, such as blood pressure and weight. A prototype of the daily active minutes feature was added. Our team decided that the next sprint would focus on conducting quality assurance (QA) testing.

Sprint 7

The primary goal of this sprint was to conduct QA testing prior to launching the Pathverse platform and submitting the app to the Apple App Store and Google Play Store. The end users and programming team generated a list of system bugs while testing the various features that were developed (eg, multimedia tools, survey tools, and self-monitoring tools). The programming team and the end users met weekly during this sprint to discuss solutions to resolve known system bugs. The app (version 1.0) was officially submitted to the iOS and Android app stores at the end of this sprint. [Figure 2](#) shows screenshots of the Pathverse research portal for creating mHealth app interventions and [Figure 3](#) shows the Pathverse participant app.

Figure 2. Pathverse researcher portal for creating mHealth app content.

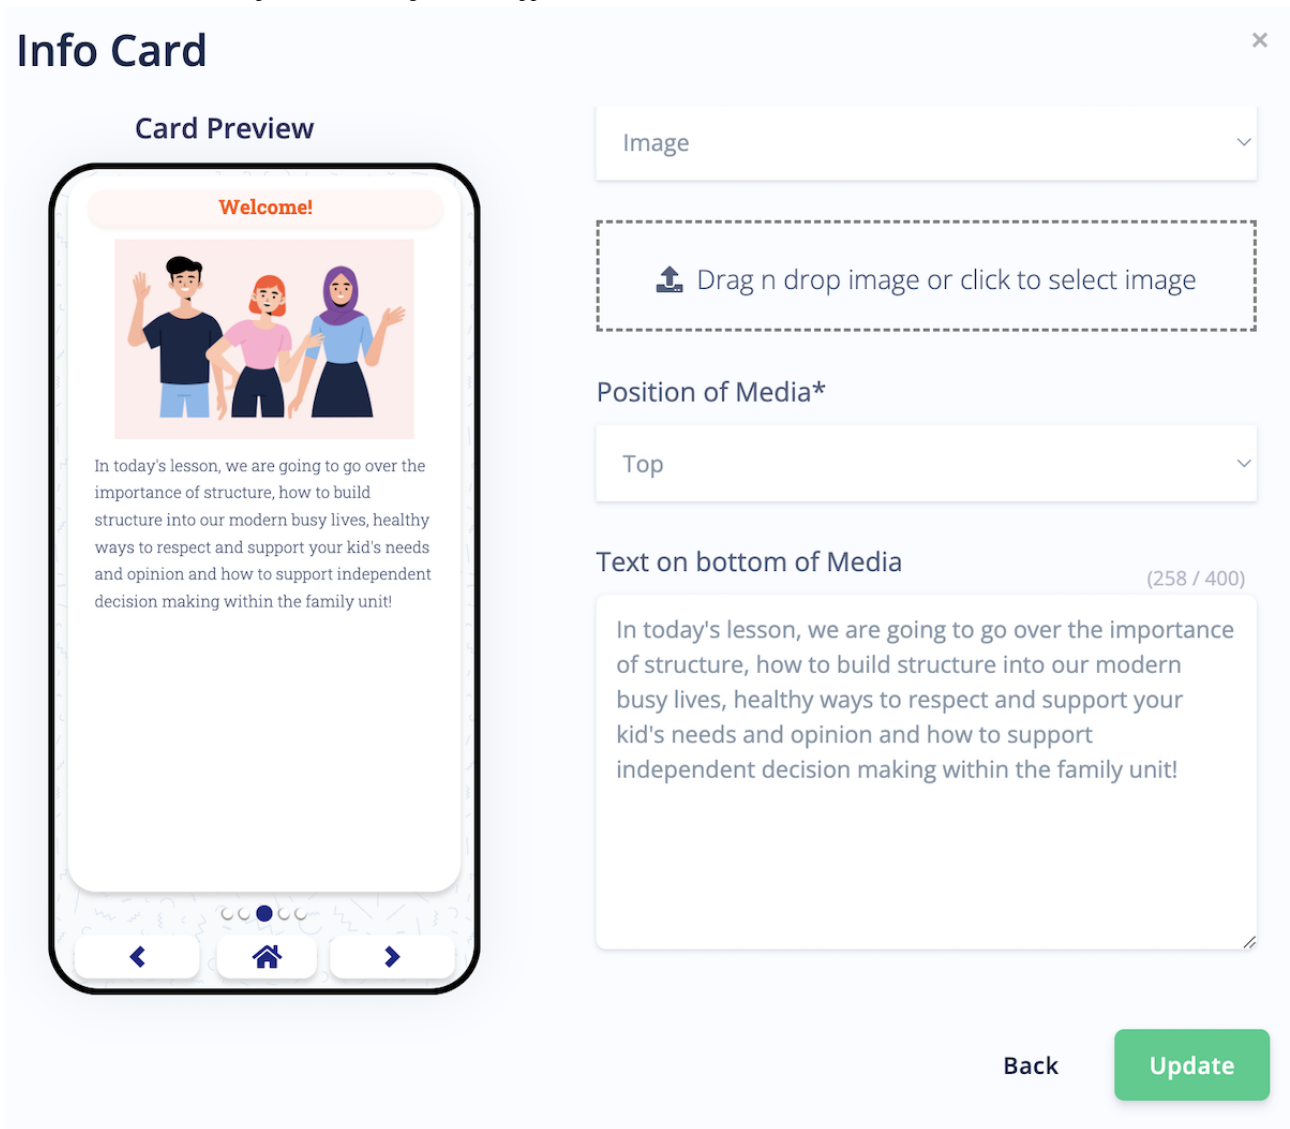

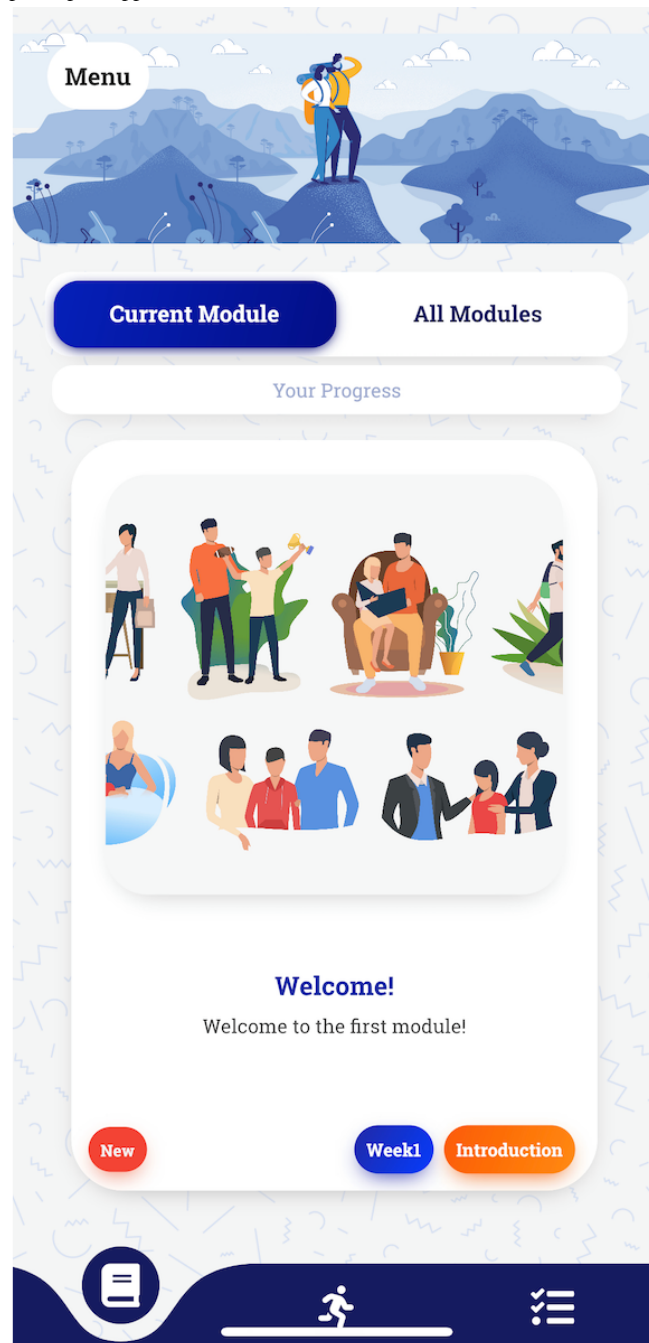

Figure 3. Screenshot of the Pathverse participant app.

Phase 3: Gathering User Feedback

We invited 5 participants to provide feedback on the Pathverse platform. The demographic characteristics of the researchers are shown in [Multimedia Appendix 1](#), Table S2. Overall, all participants had previous experience with mHealth research; 3 of 5 were from a different research institution from the platform development team. Overall, the platform received high scores for likeability (mean score 8.2, SD 2.2, range 4-10) and usefulness (mean score 8.3, SD 1.5, range 6-10). See [Multimedia](#)

[Appendix 1](#), Table S3 for a descriptive summary (with the mean, SD, range) of the questionnaire items used to evaluate platform likeability and usefulness.

The most helpful features identified by the users included easy navigation for both the research portal and participant app and the ability to download app usage and survey data. Potential improvements included the ability to deliver multiple surveys throughout the day, add the ability to deliver adaptive interventions, and add features such as community group chat. A summary of the feedback received is shown in [Table 4](#).

Table 4. Summary of feedback received in phase 3.

Questions	Summary of feedback (illustrative quotes)
What did you like about the app?	<ul style="list-style-type: none"> • <i>The participant's app layout was easy to navigate.</i> • <i>The self-monitoring tools for physical activity were useful and it was great that can be integrated with Apple and Google Health.</i> • <i>The user-interface design is clean and logical.</i> • <i>It is available on both IOS and Android.</i>
What did you dislike about the app?	<ul style="list-style-type: none"> • <i>Slow load time when multiple modules were added.</i> • <i>Text font size was too small on some pages.</i> • <i>There is limited character space per page. Some text/title are cut off in the app.</i> • <i>There are some spacing/formatting issues. Not sure if this can be fixed on the admin portal or a display issue.</i>
What changes do you think can help improve the app?	<ul style="list-style-type: none"> • <i>Greater ability to customize app layout, color, font.</i> • <i>Add community chat features, gamification.</i> • <i>Current goals can only be marked as complete. The ability to mark current goals as incomplete and need time to revisit can be helpful.</i> • <i>Zoom/video chat integration.</i> • <i>More self-monitoring tools can be helpful (e.g. weight training log, diet log).</i>
What did you like about the research web portal?	<ul style="list-style-type: none"> • <i>Good research portal navigation. It was easy to use the multimedia content, quizzes, surveys to the mHealth app.</i> • <i>Easy to use research portal console to enrol research participants</i> • <i>It was great to see the updates made to the app is reflected in real-time.</i> • <i>The ability to download app usage and survey data.</i>
What did you dislike about the research web portal?	<ul style="list-style-type: none"> • <i>The self-monitoring tools are pretty limited. It will be great to add more monitoring tools and integrate with other wearables.</i> • <i>Sometimes the web portal will not be able to save the order of the modules. Autosave will be helpful.</i> • <i>Finding the right image size for the app graphics is challenging.</i> • <i>Not knowing how long the title or text should be before it gets cut off in the app.</i> • <i>Can't change the font size or color.</i> • <i>Not sure the function of the "tags". Need better instructions.</i>
What changes do you think can help improve the research web portal?	<ul style="list-style-type: none"> • <i>The ability to deliver multiple surveys throughout the day. This can greatly expand the survey feature to be used for a daily diary or ecological momentary assessment study.</i> • <i>The ability to choose whether to display self-monitoring tools in the participant app. Not all mHealth studies (e.g., daily diary/EMA studies) need to show participants their daily steps.</i> • <i>The app usage data download can be formatted in a way that is easier for analysis (e.g. long vs wide format).</i> • <i>The ability to download third party wearable data from the platform.</i> • <i>Should consider adding adaptive intervention delivery logic.</i> • <i>Add rich text card will be helpful.</i> • <i>Change the app preview to look like a phone can enhance the preview experience.</i>

Phase 4: Implementing User Feedback

We applied the V-method of software development. The requirement analysis phase occurred in September 2021. Based on the user feedback from the previous phase, our team determined three main requirements that we would implement given the availability of resources: (1) expand survey functionalities so that multiple surveys could be delivered throughout the day, (2) improve the data download format (eg, allow a longer data structure format) for easier analysis and postprocessing, and (3) provide the ability to customize whether to use the self-monitoring features, as not all mHealth studies require this feature. The system and architecture design and the module design phase took place during the last week of September 2021. The programming team determined the main modules to be developed to meet the program requirements. These modules included customized survey release times in the researcher web portal, a display of the various surveys in the

participant Pathverse app, the ability to download survey data in .csv format, the ability for researchers to choose whether to collect wearable and survey data in the researcher web portal, and revision of the UI design for the participant app to not display self-monitoring tools. Based on these module designs, the software team initiated the coding phases from October to November 2021. The validation testing to resolve system bugs took place in December 2021. Pathverse (version 1.5) was released to the app stores at the end of this phase. Video demonstrations of the functionality of the platform were made available online [40].

Discussion

Principal Findings

This study describes the development process of a no-code mHealth app design platform for researchers. To our knowledge, this platform (Pathverse) is the first no-code mHealth app design

platform for developing mHealth behavior interventions. This platform has the potential to enable researchers with no previous software programming skills to design mHealth intervention apps. Consequently, this should help reduce the time and cost required to develop mHealth interventions. Our team used a behavior theory framework (M-PAC) and the BCT taxonomy to inform the design of the various software features in the first version of the Pathverse platform. These features can offer researchers the flexibility to design mHealth interventions with various BCTs, depending on the behavior theory or the mechanisms of action. The participatory development methods used in this project allowed our team to ensure that feedback from end users (researchers) was incorporated throughout the development phases. Despite receiving helpful feedback (eg, the social wall, gamification, and app color and font customization) from the researchers, our team could only address the most important issues given resource availability. However, we plan to address all the feedback received in future development.

Comparison With Prior Work

Similarly to previous mHealth software development studies [28,29], our team learned several lessons throughout the development process. First, the use of M-PAC and matching the proposed BCTs to the M-PAC mechanisms of action was effective in gathering feature requirements for the Pathverse platform. This process enabled our team to determine various BCT use cases and ways to implement them using the features developed (eg, multimedia content delivery, program logic, and self-monitoring tools). We believe that future platform development could use a similar process and could benefit from the use of other behavior theories as templates. This may help our team discover new use cases for the features developed.

The software development methods (eg, Scrum and the V-model) used in this study were effective in delivering the product on time. However, our team found that the Scrum method easily led to scope creep, resulting in a buildup of backlog tasks and feature cancellation. For example, after completing the customized survey feature, the research team requested additional survey functionality (eg, randomization of survey choices) in sprint 4. Similarly, they requested additional self-monitoring trackers (eg, for weight and blood sugar) in sprint 6. We also spent a significant amount of time optimizing and making changes to the app UI throughout the Scrum cycles. Future development should set a limit on the number of UI changes that can be made after the initial designs have been approved. Scope creep is a known challenge in agile development environments [16]. There are several contributing factors to scope creep, which include unclear communication,

project complexity, quality issues, time constraints, over-optimism, and unwillingness to say “no” to the client [41]. Several strategies have been proposed to prevent scope creep in software development [42]. For example, mapping the impact of a change as a percentage of the time, cost, and quality of the product could help an agile project manager decide whether to accept or reject the change. Future development may consider using similar techniques to control scope creep.

Finally, we learned the need to implement QA protocols throughout the software development phases. We did not designate a specific QA analyst role during the rapid sprint cycles. Thus, some QA issues were not discovered until the product was launched. Adopting QA testing early in the development cycle could help avoid users experiencing software bugs following deployment. An advantage of using the V-model was the systematic approach to QA testing throughout the development stages. Thus, future Scrum software development might consider incorporating a dedicated QA analyst as part of the team.

Strengths and Limitations

The end users identified several useful features (eg, the online community, adaptive intervention features, and gamification features) that could be implemented in the future to further expand the capabilities of the no-code mHealth app builder tool for researchers. A strength of the study was using the participatory framework throughout the development of the Pathverse platform. This process enabled our team to gather valuable insights into ways to improve the platform. A limitation of the study is that the end users who were involved in designing and testing the platform were mHealth researchers; this may limit the generalizability of our findings beyond this population. Furthermore, the end users provided feedback about platform feature development throughout the development phases. Due to our limited sample size during usability testing, it remains unclear how these features would be used in a larger group of users. Future studies are warranted.

Conclusion

In summary, this study describes the development process of Pathverse, a no-code mHealth app design platform. The process reinforced the importance of involving end users (eg, researchers) and demonstrated the use of agile and hybrid-agile software development methods to develop mHealth research tools. Our participatory research approach enabled our team to clarify the feature requirements of the Pathverse platform. Overall, we believe that our no-code mHealth app design platform will help researchers decrease the resources required to leverage mHealth technology.

Acknowledgments

SL is supported by the Michael Smith Foundation of Health Research. We also would like to acknowledge Utkarsh Patadia, Rafay Chaudhry, Kahvi Patel, and Parambeer Johal for helping design the platform.

Conflicts of Interest

After the development of the Pathverse platform, SL and HL cofounded Pathverse Inc to commercialize the platform described in this paper.

Abstract

Background: Introduction of new tobacco products in the United States, including those that may be lower on the risk continuum than traditional combustible cigarettes, requires premarket authorization by the US Food and Drug Administration and information on the potential impact of the products on consumer behaviors. Efficient recruitment and data capture processes are needed to collect relevant information in a near-to-real-world environment.

Objective: The aim of this pilot study was to develop and test a protocol for an actual use study of a new tobacco product. The product included in this study was a commercially available oral nicotine pouch. Through the process of study design and execution, learnings were garnered to inform the design, execution, analysis, and report writing of future full-scale actual use studies with tobacco products.

Methods: A small sample (n=100) of healthy adult daily smokers of 7 or more cigarettes per day were recruited to participate in an 8-week prospective observational study conducted at 4 geographically dispersed sites in the United States. A smartphone-based customized electronic diary (eDiary) was employed to capture daily tobacco product use, including 1 week of baseline smoking and 6 weeks during which participants were provided with oral nicotine pouches for use as desired.

Results: Online screening procedures with follow-up telephone interviews and on-site enrollment were successfully implemented. Of 100 participants, 97 completed the study, with more than half (59/99, 60%) identifying as dual- or poly-users of cigarettes and other types of tobacco products at baseline. There was more than 90% (91-93/99, 92%-94%) compliance with daily eDiary reporting, and the majority (92/99, 93%) of participants expressed satisfaction with the study processes. Product use data from the eDiary indicated that after an initial period of trial use, pouches per day increased among those continuing to use the products, while per day average cigarette consumption decreased for 82% (79/97) of all study participants. At the end of the week 6, 16% (15/97) of participants had reduced their cigarette consumption by more than half.

Conclusions: The design of this study, including recruiting, enrollment, eDiary use, and oversight, was successfully implemented through the application of a detailed protocol, a user-friendly eDiary, electronically administered questionnaires, and remote monitoring procedures. High-resolution information was obtained on prospective changes in tobacco product use patterns in the context of availability of a new tobacco product. Future, larger actual use studies will provide important evidence supporting the role that alternatives to combustible cigarettes may play in smoking reduction and/or cessation and lowering the population health burden of tobacco and nicotine-containing products.

harm reduction; pilot; nicotine pouch; actual use; electronic diary; smartphone; survey; combustible cigarette; smoking reduction; remote monitoring

Introduction

Combustion-related toxicants drive the adverse health effects associated with cigarette smoking, including cardiovascular disease, respiratory disease, and cancer, among others [1]. The American Cancer Society indicates that “smoking is by far the leading risk factor for lung cancer. About 80% of lung cancer deaths are thought to result from smoking” [2]. To reduce the harm associated with smoking, alternatives to combustible cigarettes that fall lower on the toxicant exposure and health risk continuum are increasingly available [3,4]. These can include heated tobacco products, electronic nicotine delivery systems, smokeless tobacco products, and oral nicotine pouches (ONPs). Similar to smokeless products, ONPs are placed in the mouth for use. ONPs contain nicotine and flavorants but no tobacco leaf, resulting in much lower toxicant levels compared to other combusted and noncombusted tobacco products. Thus, ONPs are anticipated to present fewer potential health risks to users [5,6].

Tobacco products such as ONPs are regulated by the US Food and Drug Administration (FDA) and require authorization from the Center for Tobacco Products before they can be sold in the United States [7]. Manufacturers must submit premarket tobacco applications with sufficient information for the FDA to determine whether their marketing is appropriate for the protection of public health [8]. The Center for Tobacco Products requires information to assess the potential impact of a new product on current tobacco user behaviors, including who uses the product, how the product is used, and the effects of its use on the use of other tobacco products. Various study designs can be employed to provide this information, including randomized clinical trials, longitudinal cohort studies, and actual use studies (AUS) [3,9-15].

Unlike in a randomized clinical trial with managed interventional arms, in the prevailing model of tobacco AUS, smokers (the intended user) are sufficiently supplied with study products and remain free to use or not use the product at their discretion. Research participants are followed over varying time periods to capture daily product use patterns, including use of the new product and any consequent changes from their baseline tobacco consumption patterns. An AUS can also provide

information on whether tobacco users revert to using their usual tobacco products after initiating use of the new product, subjective experiences to inform use transition patterns, and whether users engage in product misuse. To date, few AUS findings are in the published literature. Two industry-sponsored studies have been published that assess the use of novel tobacco products [10,11]. In the first, over 1000 US smokers were provided a nonmarketed heated tobacco product for use over a 6-week period and recorded their tobacco product use using a daily electronic diary (eDiary) [10]. A similarly sized AUS was conducted to assess the use of a marketed ONP among adult US smokers and smokeless tobacco product users [11]. End points included complete substitution of combustible cigarette by the new products and reductions in levels of combustible cigarette use.

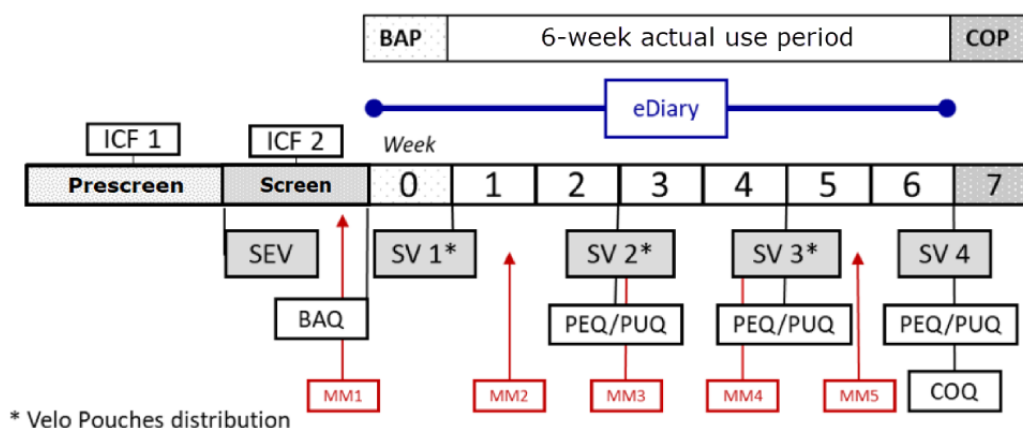

Collecting the required information on nonmarketed products is challenging due to the requirement of obtaining authorization for research use of new tobacco and nicotine-containing products (TNP), determining the appropriate sample population of who to include in studies (ie, current smokers or dual users of cigarettes and other tobacco products), and the cost of studies with large numbers of participants. In designing appropriate studies with large samples, it is beneficial to trial and test procedures to maximize efficiency around factors such as recruiting, optimizing the logistics around distributing study products (accommodating regulatory restrictions), and the establishing procedures to ensure capture of reliable use data on a frequent (at least daily) basis. Therefore, we conducted a pilot study with 100 adult smokers to inform the design, execution, analysis, and report writing of future full-scale AUSs.

Methods

Study Design

This was a pilot multisite, open-label, 8-week, prospective observational study (Figure 1), conducted between September 25 and December 31, 2020, at 4 sites geographically dispersed across the United States. The primary objective was to describe the patterns of use for the ONPs and combustible cigarette over a 6-week actual use period (AUP) using a self-reported daily eDiary.

Figure 1. Overall study design. BAP: baseline assessment period; COP: close out period; ICF: informed consent form; SEV: screening and enrollment visit; SV: site visit; BAQ: baseline assessment questionnaire; PEQ: product experience questionnaires; PUQ: product use questionnaires; MM: marketing material; COQ: close out questionnaire.

Study Products

The study products were 2 oral nicotine pouches: Velo Pouch Mint (4 mg nicotine) and Velo Pouch Citrus (4 mg nicotine, Modoral Brands Inc). Participants could select which flavors they received and could move between flavors as desired. Originally supplied at site visit 1, the product was resupplied at follow-up site visits. Detailed product accountability logs were kept by site staff.

Study Population

A total of 100 generally healthy US adults (aged 21 years or older) who were daily menthol and/or nonmenthol cigarette smokers of 7+ cigarettes per day (CPD) were recruited from nationally representative consumer databases of individuals agreeing to be contacted for market research studies.

The sample for this pilot study of 100 was considered adequate to develop and test procedures across multiple sites, with a reasonable number of participants per site ($n=25$) to allow for monitoring of the staff training, recruitment, and product distribution processes, across geographies. The sample size was not determined by any a priori formal sample size calculation.

Inclusion criteria included no intention of quitting tobacco use during the next 8 weeks, no participation in tobacco research studies in the past 3 months, and ability to complete all surveys in English. Anyone who used Velo Pouches currently or in the past; was pregnant, breastfeeding, or planning to become pregnant; or did not agree to restrict Velo Pouch use to only the products supplied in the study was excluded from participating.

Procedures

The overall study design and notable events are provided [Figure 1](#). Candidate participants were identified using a 2-stage screening and informed consent process. During the first stage (prescreening), a computer-assisted telephone interview identified interested and eligible candidate participants. These candidates gave verbal consent for further screening at the on-site screening and enrollment visit, where eligibility was reconfirmed and age was verified with a photo identification. Prior to signing the second informed consent form, eligible candidates reviewed product information and physical examples of the study products. Those who indicated an intention to use

the products at least once during the 6-week study underwent the second informed consent process before any protocol-specific procedures were carried out.

The second informed consent form explained the full nature of the study, including the optional use of study products, use of a daily eDiary, frequency of repeat visits to the sites for interviews and questionnaire completion, description of the study products, and expected experiences of their use. In addition to having the participants read the informed consent forms themselves, trained site staff explained the research study to the research participants and answered any questions that arose. A verbal explanation was provided in terms suited to their comprehension of the purposes, procedures, and potential risks of the study and of their rights as research participants. Restrictions and requirements of the study were also explained to the participants. Participants were informed that participation was voluntary and they could withdraw from the study at any time, without prejudice. Participants confirmed their willingness to be in the study using via electronic signature, were enrolled in the study, and completed the baseline assessment questionnaire ([Multimedia Appendix 1](#)) prior to leaving the site and beginning the baseline assessment period. The baseline assessment questionnaire captured additional demographic information (eg, education, occupational status, income), past 30-day TNP use, and supplemental questions related to cigarette dependence.

During the baseline assessment period (week 0), participants recorded their daily tobacco product use in the eDiary as described below. Following the baseline assessment period, participants participated in a 6-week AUP in which they were allowed to use the nicotine pouch study products and all TNP use was recorded daily. Participants were scheduled for in-person site visits 5 times during the study as noted in [Figure 1](#) (screening and enrollment visit and site visits 1 to 4). Participants received reminders prior to the day of each follow-up visit by email (1-3 days prior) and by telephone (1 day prior).

At site visits 1 through 3, study products were provided at no cost for use as desired. At site visits 2 through 4, participants were interviewed to review their prior period's eDiary compliance and share their experience with and use of the ONPs

via a product experience questionnaire ([Multimedia Appendix 2](#)) and product use questionnaire ([Multimedia Appendix 3](#)). Given the study was fielded during the COVID-19 pandemic, appropriate mitigation procedures were in place (temperature testing, social distancing, masking, etc) to ensure participant and staff safety. At the close of the AUP on site visit 4, participants returned all unused product and were asked about their satisfaction with study participation via a closeout questionnaire ([Multimedia Appendix 4](#)). The 1-week closeout period allowed participants to communicate any adverse events (AEs) or ask additional study questions.

eDiary

Due to the high frequency of daily use over an extended period of time, participants used an eDiary installed on their personal smart devices to record their daily combustible cigarette and other TNP use rather than a paper diary. This practice decreased the overall study burden on participants, reduced potential sources of error when transferring data from a paper diary to a study database, and allowed for familiarity and ease of use of the device by participants. Those who did not own smartphones or whose own devices were incompatible with the eDiary app were provided provisioned devices and limited data plans for the duration of the study. This ensured that barriers to enrollment were not created for those of limited means or lower socioeconomic status. The eDiary was an easy-to-use third-party app slightly modified by its developers for use in this study and previously used in other published health-related studies [16-18].

The app was programmed to capture daily TNP use during a set 6-hour time window every evening. Four unique electronic marketing executions were delivered via the eDiary app, one approximately every 7 to 9 days, to simulate advertising exposure as in the real world. Participants received daily notifications that their eDiary was open for completion and compliance was monitored by site staff through an online portal including sites sending additional reminders or phone calls for any data missing for the prior 2 days.

Electronic patient-reported outcome best practices were followed in its design [19]. All information collected via the app was held by the developer on a restricted access secure database in compliance with the appropriate data protection regulations in the United States. Any personal information such as email addresses and IP addresses were kept separately and securely and not linked to any other data. Participants were assigned a unique identification number to link the data with the questionnaire data in the EDC and only pseudoanonymized, individual-level data were processed for the purposes of the study.

Data Management and Analysis

All eDiary and questionnaire data were collected by an FDA 21 Code of Federal Regulations Part 11 compliant electronic data capture system [20].

Data sets were created and exported for analysis according to FDA standards. Although the small number of participants in this pilot study precluded detailed substantive analyses, a comprehensive statistical analysis plan and study report were prepared according to International Council for Harmonisation

of Technical Requirements for Pharmaceuticals for Human Use guidelines to prepare for and identify additional requirements that would be used for planning larger studies [21]. All analysis were descriptive by design, with no a priori statistical hypotheses and no statistical testing or multivariate modeling. The statistical evaluation was performed with the software package SAS (release 9.4, SAS Institute Inc).

Ethics Approval

Oversight

The final protocol, informed consent forms, and all pertinent study documents were reviewed and approved by the Sterling Institutional Review Board (reference number: 8229) prior to participant recruitment and any study procedures. The study was conducted using standard operating procedures adopted by Cerner Enviza, an Oracle company, and was conducted under the rubric of good epidemiological practice [22].

Monitoring and AEs

A telephone hotline was available throughout the study for participants to report any pregnancies, product complaints, or AEs associated with the study products. A separate monitoring team ensured adherence to the protocol and a detailed procedures manual which included interview and product accountability guidelines. In-person monitoring was intended to be conducted on-site but due to COVID-19 was converted to a remote monitoring process which used streaming technology to observe participant interviews and confirm site compliance. As an observational study with commercially available tobacco products and no clinical end points, this study was not submitted to any publicly available trial registry.

Compensation

Participants received industry-standard prorated compensation at each site visit for time spent on completing the daily eDiary and attending the site visits. The compensation schedule was designed to maximize return to sites for periodic visits and completion of the study, so honoraria were distributed at key milestones. The compensation did not depend upon the use of any tobacco or nicotine-containing products, including their own combustible cigarettes or study-provided nicotine pouches.

Results

Recruitment

This pilot study was successful in terms of designing and evaluating all the procedures and processes necessary for a full-scale AUS. A total of 3690 candidate participants were screened online, 223 were interviewed by telephone, and 137 met all criteria, including preliminary interest in the study product, and were scheduled for a screening and enrollment visit. There was a 20% no show rate for the screening and enrollment visit, and a screen fail rate of 7% at the screening and enrollment visit.

Once the target sample size of 100 was achieved, screening was discontinued. The predominant reasons for not qualifying for the study were not being a daily smoker of the minimum of 7 CPD, having previously used Velo Pouches, no interest in using

the study product, and currently quitting or planning to quit all TNP use in the next 8 weeks.

Participant Demographics

Participant demographic characteristics at enrollment are presented in [Table 1](#) (n=100). All participants in the final analysis set (n=99 after exclusion of 1 participant who did not fulfill criteria of using at least 1 pouch) started regular smoking more than 12 months prior to study entry. Participants' self-reported CPD mean was 14.6 (SD 5.72) during the 6 months prior to study entry, and just over half (59/99, 60%) of

participants reported also using other types of tobacco products (eg, electronic nicotine delivery systems, smokeless tobacco) within the past 30 days. Approximately half (49/99, 50%) were classified as having low nicotine dependence based on a total score of 4 or less on the Fagerström Test for Nicotine Dependence [23].

Over the study period there was very low attrition (3%: 1 withdrawal, 2 lost to follow-up). Attendance at each site visit was high, with only 3 participants missing a scheduled site visit 2 or 3.

Table 1. Participant demographic characteristics at enrollment (n=100).

Characteristic	Value
Age (years), mean (SD)	48.1 (11.03)
Age category (years), n (%)	
21-48	48 (48.0)
>49	52 (52.0)
Gender, n (%)	
Male	56 (56.0)
Female	44 (44.0)
Nonbinary	0 (0.00)
Race, n (%)	
White	61 (61.0)
Black or African American	35 (35.0)
All other	4 (4.0)
Ethnicity, n (%)	
Hispanic or Latino	6 (6.0)
Not Hispanic or Latino	94 (94.0)
Education, n (%)	
Some high school	2 (2.0)
High school degree or equivalent	58 (58.0)
College graduate	40 (40.0)
Income (\$), n (%)	
<39,999	31 (31.0)
40,000-79,999	50 (50.0)
>80,000	19 (19.0)
Employment, n (%)	
Working now	70 (70.0)
Not working	30 (30.0)

eDiary Experience and Compliance

The eDiary was well received with very high participant compliance. More than 90% (91-93/99, 92%-94%) of participants were fully compliant with daily eDiary entries, and 97% (95-98/99, 96%-99%) reported their product use at least 5 days during each week of the AUP.

Only a small number of participants (15/99, 15%) required reminder calls (a total of 19 calls) if they had not completed the diary at the end of the day.

In addition to the functional success of study procedures and processes, the study was viewed positively by participants with 93% (92/99) satisfied with the experience and 95% (94/99) were being likely to recommend the study to others (87/99, 88% very likely; 7/99, 7% likely).

Some participants suggested improvements for future studies such as providing more flexibility around time frames to complete the eDiary (9 mentions). Others indicated a preference for a broader range of product options (flavors/nicotine levels; 5 mentions), and for remote interviewing (3 mentions).

The product use questionnaire showed that the majority of use was as described on the product packaging and communicated to participants during the informed consent process. In total, only 4 participants reported using Velo Pouches in any way other than instructed and none were associated with any AE report. One participant sucked the pouch, one moistened the pouch with water, one moistened the pouch on the tongue, and one participant used two pouches at the same time. Further, 15 participants used the product at the same time as another TNP, two accidentally swallowed the pouch, and 38 reported spitting out saliva while using the product. No safety issues emerged during the study, and no AE reports required adjudication.

Product Use

In the first week of the AUS (following the baseline assessment period), all participants tried the study ONPs (Figure 2). Over time, the proportion of participants using ONPs decreased (from 0% reporting no use in week 1 to 15.5% [15/97] in week 6). Among those who continued using the ONPs, the average pouches per day increased (Figure 2, darker bars). Whereas the proportion of participants using between 1 and 6 pouches per day decreased between week 1 and week 6 (71/99, 72%, to 40/97, 41%), the proportion using 7 or more pouches per day increased from 27% (27/99) in week 1 to 42% (41/97) in week 6.

Of interest for potential tobacco harm reduction, combustible cigarette use decreased over the study period for 82% (79/97) of the study participants (see Figure 3). At week 6, approximately 16% (15/97) of participants reduced their cigarette consumption by more than 50%, 18% (17/97) reduced their CPD between 30% and 50%, and almost half (47/97, 49%) reduced their CPD between 1% and 30%.

Discussion

Principal Findings

The success of this pilot study in terms of methods and procedures relied on a detailed protocol, user friendly eDiary, and electronically administered questionnaires to capture study product and TNP use and other information about product use patterns. Experience during the pilot study execution highlighted some considerations to be incorporated in future AUS designs.

Selection Criteria

Because of the high level of dual use, particularly with electronic nicotine delivery systems, at baseline, future studies should consider maintaining a broad definition of eligible participants to encompass a real-world demography. Traditional studies on tobacco harm reduction have tended to use only daily combustible cigarette use as an entry criterion [24-26]. A definition of regular use may be more appropriate as product use behaviors are changing with increasing availability and acceptance of other forms of TNP [27,28].

Similarly, many daily smokers in the candidate pool did not meet the 7 CPD threshold. With the rise of combustible cigarette alternatives and an overall decline in combustible cigarette use, lower thresholds for study entry may be warranted to reflect the real-world behaviors of those likely to use the new products in the future, including for those looking to completely supplant combustible cigarette use [29]. Optimally, participants should have sufficient combustible cigarette daily use to detect a change in combustible cigarette use behaviors over the time of the study.

Candidate participants were excluded if they were quitting or intending to quit all TNP use. Future AUS may relax this criterion and allow the inclusion of those intending to quit

combustible cigarette but continue use of other TNP. This would allow for an investigation of differences in product use and changes in cigarette smoking among smokers who were not immediately interested in quitting all TNP [30].

Recruitment

Recruitment of the 100 planned pilot study participants via market research sites was successful. A larger AUS powered to achieve narrow confidence intervals around product adoption or CPD reductions may necessitate using additional recruitment strategies to boost or augment the number of combustible cigarette smokers in their databases and to increase diversity of enrollees. For example, a multimodal recruiting strategy may be needed to increase representation of younger adult smokers [31,32]. This pilot was conducted in only 4 sites and recruited a relatively large proportion of African American participants, while the number of those of other races and ethnicities was low. Identifying sites with higher populations of other important subgroups will also be helpful in expanding demographic diversity for future studies.

Product Use

Since there was no sampling of the product during the enrollment or baseline period, participants first opportunity to try the product was during week 1 of the AUP. Nearly all participants used pouches in the first 2 weeks. The majority rated their liking of the product as in between. By week 6, the number with strong positive reactions to the product increased, and the data suggest that those who did not like the product after trial discontinued use whereas those who liked the product increased their use. Furthermore, product use other than as directed was infrequent and did not suggest any significant modifications to procedures or participant instructions in future studies.

Although the number of enrolled participants was small and precludes a detailed statistical analysis and interpretation, the results of ONP uptake and CPD reduction provide a directional indication of potential product use in a real-world setting that can be tested in follow-up studies with larger sample sizes.

Comparison With Prior Work

The pilot results were in a positive direction for the potential of ONP to supplant combustible cigarette use, in line with preliminary trends seen in a recent ONP AUS with a larger sample size [11]. The study attrition was low, and eDiary compliance in our study was high as compared to other reported studies with shorter time frames [33]. Low attrition may be attributable to the compensation level and in-person payments being spread over the entire 8-week study. High eDiary compliance could have resulted from reinforced attention to the eDiary via intermittent marketing material delivery, regular reminders to complete the eDiary, and the close monitoring of the eDiary data by site staff. Once per day eDiary entries, rather than multiple entries throughout a given day, also helped to reduce the protocol burden on participants and improve compliance [34]. Given the eDiary success, one key learning from this study was to expand the technology used to manage the study. In this study, 2 systems were used for data capture—a central database for eDiary data and individual site spreadsheets for product dispensation and return. Integrating these data streams into a single portal-based system will improve efficiency in managing products, reconciling product use data, and requesting product-specific feedback so that item responses can be captured for only the products that have been distributed to a particular participant.

Consistent with moves toward more decentralized clinical trials [35,36], the pivot to remote monitoring due to COVID-19 was successful for this study and will be incorporated in future studies. Videoconferencing tools, electronic data capture, and electronic signatures allowed for more efficient and timely communication, expanded sponsor participation in on-site activities, and reduced travel-related costs and off-site supervision of participant interviews by monitoring staff.

Limitations

The main limitation of this actual use pilot study is its small size. However, the purpose of the study was to determine the logistic feasibility of conducting a full-scale study. Future studies with much larger sample sizes will have the power to test for explicit associations between combustible cigarette use and study product use and the variation by subgroups of interest (eg, by demographics or smoking history). As with all AUSs, general limitations exist. Participants were all incentivized to participate and received study product at no charge, both of which can limit generalizability.

All data collected were via participants' self-report in a real-world setting. Future AUSs could consider including measurement of change in any proximal biomarkers that could reflect more distal health outcomes. Collecting relevant biosamples (blood, urine, respiratory output) at the start and end of an AUP (especially if longer than a 6-week duration) could provide early indicators of improved health function

among those who reduce their cigarette consumption though use of study products. Since participants returned to each site for product fulfillment, a degree of social desirability bias is possible if participants believed the interviewers expected to see high levels of study product use. The informed consent form at enrollment explained the optional nature of using study product, which was reinforced in staff training and ongoing monitoring interviews. The eDiary data were consistently captured, regardless of the level of study product use.

All questionnaires and the eDiary relied on participants' recall of their TNP use, which can be affected by time since use, environmental considerations, and other factors outside the control of the investigators. With this in mind, participants were given a short, 2-day grace period to enter product use information. Including this small window around diary entries limited recall errors while improving participant compliance. Other research has demonstrated high degree of congruity between eDiary logs and actual combustible cigarette use [37]. Since all TNP uses were captured, the risk of differential recall for cigarettes versus pouches would be minimal and unlikely to be biasing. The small number of participants who required reminders to complete the diary the study would preclude meaningful analyses to gauge the potential impact of any delayed data entry bias, which could certainly be examined in a full larger AUS.

In the closeout questionnaire, a small number of participants made suggestions for future studies. These suggestions can be considered in the design of future studies, although there are limitations to their applicability. Participants suggested more product choices, which will be determined by future research needs and market changes. Some suggested expanding the time frame of eDiary completion, which would necessitate a trade-off between satisfying individual preference flexibility against the minimization of programming and analytic complexity. Finally, a few suggested the preference for being interviewed remotely. This practice is now much more common in accommodation of the COVID-19 pandemic and would be very helpful for several reasons. It could greatly expand the geographical and demographic diversity of participants, who could be interviewed at time convenient to them without needing transportation, childcare, or time away from work, and would allow for increased efficiency and consistency across all sites with the use of remote interviewers. The challenge remains that any AUS would still require close product accountability and means to get products into the hands of age-verified respondents (and return of unused products), in a regulatory environment where there can be significant legal and logistical restrictions to remote distribution of study products.

Conclusions

This pilot (and other research studies) provides an opportunity to assess the impact of product introduction on existing product use patterns. The initial trends from this work provide evidence that the availability and use of this alternative TNP may be associated with combustible cigarette reduction or smoking cessation use and thus has the potential to positively impact public health. The execution of this pilot study with very low participant attrition, successful daily eDiary data collection, and

strong participant satisfaction indicate a high likelihood of success for future fuller AUS with much larger samples and broader geographical distribution. If regulatory and legal challenges can be overcome and alternative study product distribution methods become available (eliminating attendance at sites in person), such studies will be able to attract a broader demographic mix, especially among groups of participants with

barriers to study participation because of logistical difficulties. Finally, as we look to the future and the ultimate public health goal of reducing the deleterious impact of cigarette smoking on the public health, incorporating biomarkers of exposure/biological effect and biomarkers of potential harm in AUSs could provide early indicators of ultimate improved health outcomes.

Acknowledgments

The authors would like to acknowledge Bill Bagwell, RPh, and Patti Ensor, MBA, for their expertise and reviewing and providing feedback on the study protocol and survey instruments, and Bobbette Jones, DrPH, for critical review of this manuscript.

Abstract

Background: Mass media campaigns for preventive health messaging have been shown to be effective through years of research. However, few studies have assessed the effectiveness of campaigns on digital media, which is currently how youths and young adults are primarily consuming media. In particular, a platform that can accurately assess exposure to digital messaging in a real-life setting has yet to be developed.

Objective: This study examines the feasibility of a unique survey platform, Virtual Lab, to conduct a study on exposure to a media campaign within Facebook using a chatbot-style survey administration technique.

Methods: Virtual Lab is a survey platform that was used to recruit and survey participants within Facebook and Facebook Messenger, respectively. We created a Facebook business account with 2 Facebook pages: one for recruitment and disseminating the survey and the other one for serving the target advertisements. Pre- and postexposure surveys were administered via Facebook Messenger using a chatbot-style questionnaire 1 week apart. During this time, the target advertisements were shown to participants who completed the pre-exposure survey. The total time from recruitment to completion of the postexposure survey was 13 days, and incentive costs were US \$10 per participant. Survey data were compared between those who completed both pre- and postexposure surveys and those who only completed the pre-exposure survey; that is, those who were lost to follow-up. The demographics of the complete cases were also compared to the US census data.

Results: A total of 375 Facebook users aged between 18 and 24 years met eligibility requirements and consented to the study, which consisted of complete cases (n=234) and participants lost to follow-up (n=141). A few differences between complete cases and participants lost to follow-up were observed. Regarding gender, complete cases comprised 40.2% males and 59.4% females, and among participants lost to follow-up, 44.0% were male and 50.4% were female ($P=.003$). Differences were also observed for e-cigarette use status, where a greater number of current users and fewer past and never users were lost to follow-up than complete cases ($P=.01$).

Conclusions: The use of Virtual Lab yielded a diverse sample quickly and cost-effectively. Demographic characteristics of participants who completed the study and those who were lost to follow-up were similar, indicating that no biases were caused by the platform during recruitment or testing. This study suggests the feasibility of the Virtual Lab survey platform for studies of media campaign exposure within Facebook. This platform can advance health campaign research by providing more accurate data to inform digital messaging.

KEYWORDS

campaign evaluation; outcome evaluation; young adults; social marketing; health communications; tobacco control and policy; health campaign; youth; Facebook; digital media

Introduction

Mass media campaigns have been shown to be effective in preventive public health efforts, such as tobacco countermarketing [1,2]. Media campaigns have adapted to using digital media to disseminate health messages, particularly among target audiences that include youth and young adults. Having sufficient exposure of media campaigns is important to measuring their effectiveness [3]. However, a feasible platform to accurately assess exposure, awareness, and outcomes of digital messaging in a real-life setting is yet to be developed, which would ultimately help health communication researchers execute more accurate methodology for campaign evaluation and inform audience segmentation.

In recent years, the transition from a traditional media landscape (TV, newspaper, etc) to consuming digital media via social platforms and streaming services has been largely driven by youths and young adults [4]. With 81% of teens now using social media and more than 33% using social media sites multiple times in an hour, digital media has undoubtedly become a large part of youths' and young adults' lives [5,6]. A majority of 18-29-year-olds use social media platforms such as TikTok, Instagram, and YouTube, and 70% of 18-29-year-olds use Facebook [7]. This transition has occurred at a faster pace than research on how to measure campaign exposure in a digital landscape.

While TV uses standardized gross rating points, the fragmentation of digital media and the way in which people experience digital media have made it complex to determine a standardized encompassing metric. In digital media, advertising is often skippable and perceived as more of a disturbance [8,9], and the obstacles of data privacy make it complicated to obtain or create metrics that are standardized across platforms and parsimonious. There is little research on exposure of media campaigns in a real-life digital setting, likely owing to limited options of viable platforms [10,11]. An increasing number of studies are being conducted within social media, specifically Facebook, to recruit participants [12-14], as well as to assess the feasibility of using Facebook to reach and survey youths and young adults about the use of tobacco and other substances [15,16].

Our pilot study utilized Virtual Lab, a platform that enables research studies to be conducted on Facebook. Recruitment of

participants and exposure to target advertisements occur on Facebook. The surveys are disseminated within Facebook Messenger using a chatbot questionnaire, which has been shown to increase user engagement, user satisfaction, and data quality over traditional web surveys [17-19]. The feasibility of Virtual Lab would allow for quick recruitment of participants and delivery of results, as well as easy navigation of a dashboard during data collection, while remaining cost-effective. The ability to conduct research within the same platform on which campaigns are actively being conducted is important to the progress of campaign evaluation research. The objective of this study was to determine the feasibility of the Virtual Lab platform to recruit participants and assess awareness of an anti-e-cigarette health campaign on Facebook.

Methods

Recruitment

Virtual Lab is a survey platform used to recruit and survey participants within a social media platform, and is owned and run independently of social media companies [20]. To utilize what Virtual Lab has to offer, specifically within Facebook, the first step was to create a Facebook business account. To prevent potential biases, the account was given a general name, "Digital Health Research." Under this account, we created a Facebook page, "Digital Media Experiment," to host advertisements for recruitment purposes. In order to demonstrate the credibility of the page, we posted relevant content and acquired likes. We used this Facebook Page to run recruitment advertisements during August 5-12, 2021. The recruitment advertisements were shown to our target population of people aged 18-24 years and located in the United States. The two recruitment advertisements used in this feasibility study (Figure 1) were designed using the 99designs website. The advertisements used the text "Take a 15 minute survey, get paid \$10." After participants clicked on the study's advertisement, they were sent a message via Facebook Messenger inviting them to participate in the study.

Under the same business account, we created another Facebook page named "Consumer Consciousness," which was solely used to run the target advertisements on the enrolled participants' Facebook Newsfeeds during August 20-26, 2021. We created this second Facebook Page with a different name to prevent biases.

Figure 1. Recruitment advertisements shown on potential participants' Facebook pages.

Ethical Considerations

Privacy measures include encryption of data that are stored and in transmission. Before beginning the pre-exposure survey, participants were sent messages regarding the topic of the survey, compensation, privacy measures, and contact information if they had any questions. Following those messages, the participants were sent a message asking for consent for their participation in the study and if they would like to continue. All studies were reviewed and approved by the institutional review board at George Washington University (NCR202837).

Survey Implementation

The pre- and postexposure surveys were completed using a survey platform called Typeform, which is supported by Virtual Lab. After designing the surveys in Typeform, they were linked to our Facebook business account and pages using the Virtual Lab interface. Typeform used our “Digital Media Experiment” page to send automated messages through Facebook Messenger, similar to a chatbot, to participants who clicked on the recruitment advertisements. Through Typeform, we were able to create logic jumps based off participants’ responses and confirm that they met the recruitment criteria. If participants did not meet the eligibility criteria, they were thanked for their participation and the survey ended. If the participants met the eligibility criteria, they were allowed to continue the survey.

After participating in the pre-exposure survey administered by the “Digital Media Experiment” page, respondents randomized to be exposed were shown the target advertisement via the “Consumer Consciousness” page in their Facebook Newsfeeds. All participants were invited to take the postexposure survey a

week after completion of the pre-exposure survey. The postexposure survey was also administered by the “Digital Media Experiment” page via Facebook Messenger.

Measures

The pre-exposure survey consisted of questions to determine demographic characteristics and e-cigarette status. Questions determining demographics included age, gender, sexual orientation, combined race and ethnicity, and perceived financial status. e-Cigarette use status was determined through 2 questions: an ever-use question, “Have you ever tried using any e-cigarette/vape (even 1 or 2 puffs)?” with response of “yes” or “no.” For those who responded with “yes,” there was a current-use question, “During the past 30 days, on how many days did you use an e-cigarette (even 1 or 2 puffs)?” where they could respond with 0-30 days. Respondents were classified as never users if they responded with “no” to the ever-use question, as past users if they responded with “yes” to the ever-use question and 0 to the current-use question, and as current users if they responded with “yes” to the ever-use question and >1 days to the current-use question.

Intentions to use e-cigarettes was determined by asking the question, “Do you think you will use an e-cigarette (even 1 or 2 puffs) in the next year?” Answer choices were “definitely not,” “probably not,” “probably yes,” and “definitely yes,” where “definitely not” was coded as no intentions to use and all other choices were coded as having intentions to use. Intentions to quit using e-cigarettes was only asked of current users: “Are you seriously thinking about quitting e-cigarettes/vapes for good?” The responses were dichotomized where “No, I am not thinking about quitting” was coded as no quitting intentions and the following were coded as having

intentions to quit: “Yes, but not within the year,” “Yes, within the year,” “Yes, within the next 6 months,” “Yes, within the next 30 days,” and “I’ve already quit.”

The post-survey included questions for e-cigarette use status and intentions to use and quit, as listed above, as well as questions about the target advertisement they were exposed to between taking the pre- and postexposure surveys. These questions were asked in the pilot study to ensure feasibility for the proceeding full study. Participants were first shown an advertisement they were exposed to and asked if they can see and hear the video. If they responded with “no,” they were directed to the end of the survey. Those who responded with “yes” were asked how many times they have seen the advertisement, receptivity questions on what they thought of the advertisement, and about actions they would take after seeing the advertisement. This series of questions on the target advertisement were then repeated for the second target advertisement.

Statistical Analysis

A series of descriptive analyses were conducted to examine the feasibility of recruitment methods and the diversity of samples. Survey data were compared between complete cases and participants lost to follow-up and among different e-cigarette use status groups. Complete cases were defined as participants who completed the survey through the last question in the postexposure survey. Loss to follow-up was defined as participants having been lost at any point before the last question in the postexposure survey.

In analysis 1, we compared sample demographics and use status between complete cases and participants lost to follow-up. For continuous measures, means and SDs were obtained and *t* tests were conducted to compare differences between groups. For categorical measures, frequencies and proportions were obtained and Pearson chi-square tests were conducted. The analysis included the number of missing participants to observe the difference between complete cases and participants lost to follow-up.

In analysis 2, we compared sample demographics with the US national survey data. Race and ethnicity were compared by sex between the US population and complete cases collected in this study. The US national demographics for the population aged 18-24 years were retrieved from the US Census Bureau as of 2019 (the most recently available year). We conducted chi-square tests to evaluate the difference of proportions of these demographics between the US population and the study sample. Analyses were conducted using Stata SE 15 (StataCorp) and Excel (Microsoft Inc).

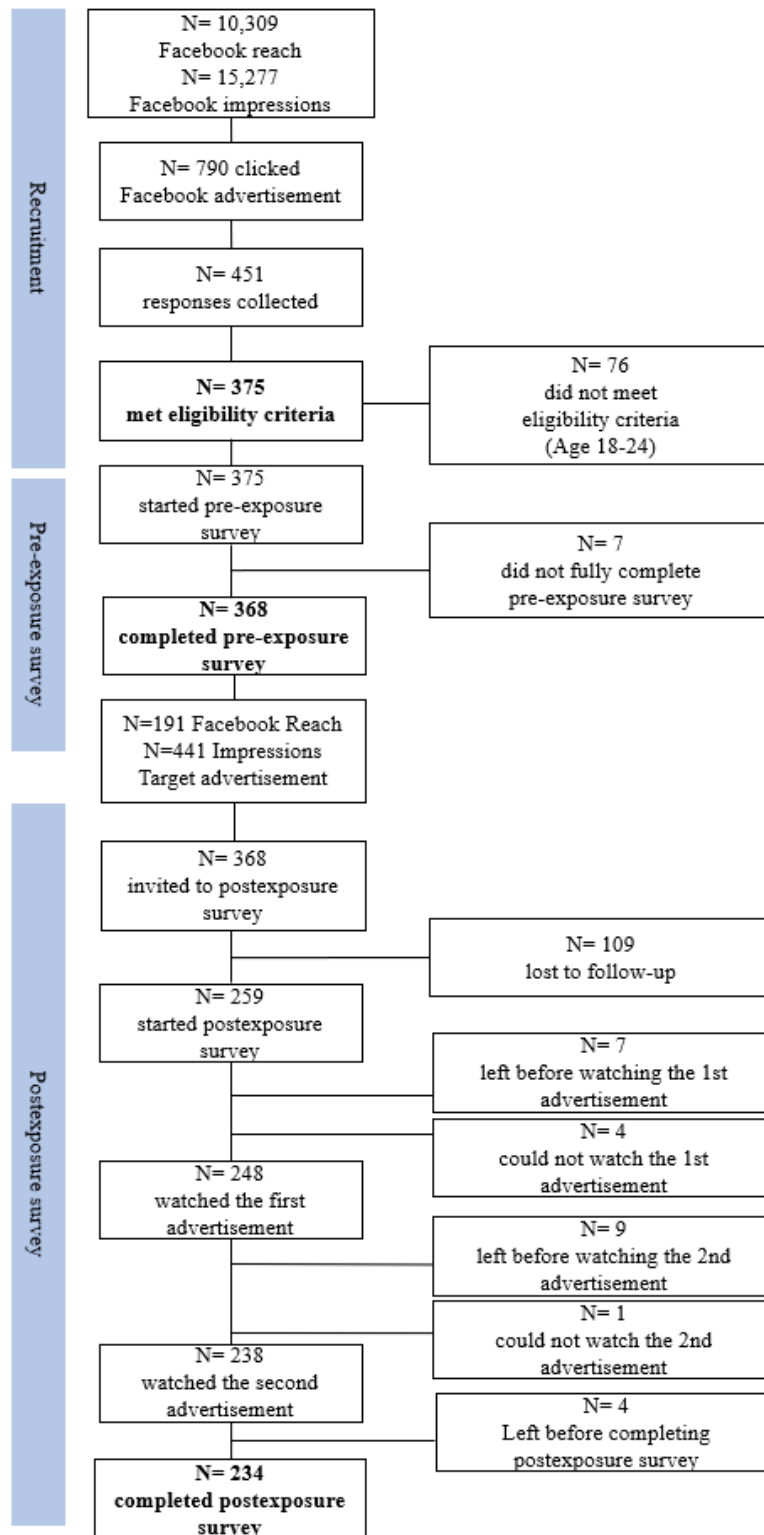

Results

Recruitment and Target Advertisements

The study’s Facebook recruitment advertisements had a reach of 10,309, which is defined as the number of unique individuals who saw the advertisement at least once. The recruitment advertisement generated 15,718 impressions—that is, the number of times the advertisement was displayed on a person’s screen—and was clicked a total of 790 times. The percentage of times a person saw the recruitment advertisement and clicked on it, or the Link-Click-Through Rate, was 4.77%. The study’s Facebook target advertisements had a reach of 191 unique individuals and generated 441 impressions. The target advertisements were played a total of 353 times and were played to 100% of their length only 11 times. The largest drop after any play time to 25% of the total advertisement length was from 25% to 50% of their length (70 and 29 times, respectively). The advertisements were played to 75% of their length 19 times. A visual representation of the in-platform recruitment data is shown in [Figure 2](#).

The subsample of participants lost to follow-up consisted of participants who began the pre-exposure survey but did not finish ($n=7$), completed the pre-exposure survey but did not begin the postexposure survey ($n=109$), started the postexposure survey but did not watch the first or second advertisement ($n=21$), and watched both advertisements but did not complete the postexposure survey ($n=4$). If they did not watch either advertisement in the postexposure survey, it could have been because they left the survey or responded that they could not see or hear the advertisement.

Figure 2. Flowchart of sample recruitment and retention.

Sample Characteristics

Sample demographics are summarized in Table 1 and organized by the total sample (n=375) and subsamples of those who completed both surveys (n=234) and those lost to follow up (n=141). Participants included 375 Facebook users aged 18 to

24 years. They were on average 21 (SD 2.0) years old, 56.0% female, and racially and ethnically diverse (45.6% non-Hispanic White, 12.0% Hispanic, 10.1% non-Hispanic Black or African American, or 23.7% non-Hispanic Asian). Of them, 45.6% were never users, 20.5% were past users, and 33.3% were current users.

Table 1. Demographics and e-cigarette use status between complete cases and participants lost to follow-up (N=375).

Variables	Total participants	Complete cases (n=234)	Participants lost to follow-up (n=141)	P value
Age (years), mean (SD)	21.0 (2.0)	21.1 (2.0)	20.8 (2.0)	.14
Gender, n (%)				.003

Non-Hispanic Black or African American	38 (10.1)	22 (9.4)	16 (11.3)	
Non-Hispanic Asian	89 (23.7)	63 (26.9)	26 (18.4)	
Other/missing	32 (8.5)	17 (7.3)	15 (10.6)	
Financial status, n (%)				.11
Live comfortably	119 (31.7)	75 (32.1)	44 (31.2)	
Meet needs with a little left over	135 (36.0)	94 (40.2)	41 (29.1)	
Just meet basic expenses	69 (18.4)	39 (16.7)	30 (21.3)	
Do not meet basic needs	21 (5.6)	11 (4.7)	10 (7.1)	
Decline to answer/missing	31 (8.3)	15 (6.4)	16 (11.3)	
e-Cigarette use status, n (%)				.01
Never user	171 (45.6)	112 (47.9)	59 (41.8)	
Past user	77 (20.5)	56 (23.9)	21 (14.9)	
Current user	125 (33.3)	66 (28.2)	59 (41.8)	
Missing	2 (0.5)	0 (0.0)	2 (1.4)	

Analysis 1

The proportions for gender and use status differed between complete cases and participants lost to follow-up. Complete cases comprised 40.2% males and 59.4% females, whereas participants lost to follow-up comprised 44.0% males and 50.4% females ($P=.003$). Based on chi-square analysis, the statistical difference found for gender was driven by the “other/missing” category. Complete cases comprised 47.9% never users, 23.9% past users, and 28.2% current users, whereas participants lost to follow-up comprised 41.8% never users, 14.9% past users, and 41.8% current users ($P=.01$); the largest difference was observed among current users. Age, sexual orientation, race and ethnicity, and financial status did not significantly differ between groups.

Analysis 2

The proportions of gender and race and ethnicity in complete cases in the study sample were significantly different from the US census data, as shown in Table 2. The sample comprised 40.3% males and 59.7% females, whereas the US census data set comprised 51.3% males and 48.7% females ($\chi^2_{1,233}=11.2$, $P<.001$). The sample included 43.4% Non-Hispanic White, 12.9% Hispanic, 9.4% Non-Hispanic Black or African American, and 27.0% Non-Hispanic Asian participants. This was significantly different from the US census data set that comprised 53.7% Non-Hispanic White, 22.1% Hispanic, 14.3% Non-Hispanic Black or African American, and 5.5% Non-Hispanic Asian participants ($\chi^2_{4,233}=218.4$, $P<.001$).

Table 2. Demographics between US national survey and complete cases among 18–24-year-olds.

Race and ethnicity	US national survey ^a			Complete cases		
	Total sample, %	Males, %	Females, %	Total sample, %	Males, %	Females, %
Non-Hispanic White	53.7	51.4	48.6	43.4	43.6	56.4
Hispanic ^b	22.1	51.5	48.5	12.9	43.3	56.7
Non-Hispanic Black or African American	14.3	50.7	49.3	9.4	9.1	90.9
Non-Hispanic Asian	5.5	50.8	49.2	27.0	49.2	50.8
Other/missing	4.4	50.5	49.5	7.3	23.5	76.5
Total	100	51.3	48.7	100	40.3	59.7

^bDerived as the difference between total and non-Hispanic counts from the US Census Bureau.

Discussion

Principal Findings

To our knowledge, this is the first study to examine the utility of Virtual Lab within the real-life setting of Facebook as a viable platform for media campaign awareness studies. The results of this pilot study provide support for continued use of the Virtual Lab platform to recruit participants and obtain data from a nationwide sample.

We found that recruitment yielded a diverse sample, consistent with other convenience samples [10,21], and it was carried out cost-effectively and quickly. Within 1 week of recruitment and 1 week of conducting the study, 375 respondents participated in the study with a total of 234 to complete the study. Including the US \$5 Amazon e-gift cards for each survey, the total cost for incentives per respondent was approximately US \$10 [22]. There were additional costs for executing the study and recruitment, which vary on the basis of project goals and sample size; expenses remained lower than those on other survey platforms. Overall, this is a low-cost data collection option with great potential for high reach and customized sampling by respondent characteristics via longitudinal panel research on a social media platform.

Most demographic characteristics were similar between those who completed the study and those who were lost to follow-up, indicating that the platform is not causing biases in recruitment or testing to result in certain groups dropping out of the study at greater rates than others. Chi-square analysis showed a difference in gender between complete cases and participants lost to follow-up. This was also observed when comparing the samples to the US census data. However, a resulting sample with a greater proportion of females than males is commonly seen in surveys using a convenience sample [10,21]. Although the sample lost to follow-up shows a higher rate of current use status than that of the complete cases sample, the latter consists of a significant amount of past and current e-cigarette users, comprising over 50% of the sample. e-Cigarette use status in the completion sample is also similar to nationwide prevalence numbers, deeming the sample to still be valuable and representative.

Limitations

Although the results support the feasibility of the Virtual Lab platform, there are some limitations to this study. First, a large proportion (37.6%) of the eligible starting sample of the pilot study was lost to follow-up. Efforts to bolster retention are being made for the proceeding study, including increasing compensation for participation and speed of distribution of compensation. Second, this study only examined the feasibility of Virtual Lab on Facebook. Thus, the feasibility of Virtual Lab on other social media platforms, such as Instagram, will require future research once it becomes available. Third, there were limitations in the ways to ask questions within Facebook Messenger using the Typeform platform. One of these limitations includes the inability to select more than one response for a question, such as identification of race and ethnicity. In order to address this limitation, we programmed the survey to repeat questions where multiple-choice responses would normally be available until the participant indicated that they had selected all relevant responses. Another limitation we encountered when converting the Typeform survey to Facebook Messenger was the inability to boldface words.

Digital health is a growing field, but there has been relatively little research using social media platforms to recruit participants, deliver interventions, and collect data. The ability to follow up with participants over time and collect data in a low-cost, rapid, and relatively low-burden manner offers tremendous potential for social media health research and interventions. It can lead to more effective campaign interventions that aim to improve youth and young adults' health behaviors, such as substance use prevention. This study suggests that such intervention studies are feasible and may be a valuable tool for researchers. Future studies should include randomized controlled trials in real-world settings on Facebook and other social media, provide social media stimuli aimed at health behavior change, and follow participants over time to evaluate outcomes.

Conclusions

The development and use of a platform that allows for experimentation within social media platforms is essential for the progress of mass media campaign evaluation research. Virtual Lab, a new cost-effective platform that allows for

customized recruitment and longitudinal follow-up of participants and execution of survey research on Facebook, has shown to be feasible for media campaign awareness studies.

Importantly, with the use of Virtual Lab, research can result in more accurate data to inform health campaigns and their dissemination.

Abstract

Background: Mood disorders and depression are pervasive and significant problems worldwide. These represent severe health and emotional impairments for individuals and a considerable economic and social burden. Therefore, fast and reliable diagnosis and appropriate treatment are of great importance. Verbal communication can clarify the speaker's mental state—regardless of the content, via speech melody, intonation, and so on. In both everyday life and clinical conditions, a listener with appropriate previous knowledge or a trained specialist can grasp helpful knowledge about the speaker's psychological state. Using automated speech analysis for the assessment and tracking of patients with mental health issues opens up the possibility of remote, automatic, and ongoing evaluation when used with patients' smartphones, as part of the current trends toward the increasing use of digital and mobile health tools.

Objective: The primary aim of this study is to evaluate the measurements of the presence or absence of depressive mood in participants by comparing the analysis of noncontentual speech parameters with the results of the Patient Health Questionnaire-9.

Methods: This proof-of-concept study included participants in different affective phases (with and without depression). The inclusion criteria included a neurological or psychiatric diagnosis made by a specialist and fluent use of the German language. The measuring instrument was the VoiceSense digital voice analysis tool, which enables the analysis of 200 specific speech parameters based on machine learning and the assessment of the findings using Patient Health Questionnaire-9.

Results: A total of 292 psychiatric and voice assessments were performed with 163 participants (males: $n=47$, 28.8%) aged 15 to 82 years. Of the 163 participants, 87 (53.3%) were not depressed at the time of assessment, and 88 (53.9%) participants had clinically mild to moderate depressive phases. Of the 163 participants, 98 (32.5%) showed subsyndromal symptoms, and 19 (11.7%) participants were severely depressed. In the speech analysis, a clear differentiation between the individual depressive levels, as seen in the Patient Health Questionnaire-9, was also shown, especially the clear differentiation between nondepressed and depressed participants. The study showed a Pearson correlation of 0.41 between clinical assessment and noncontentual speech analysis ($P<.001$).

Conclusions: The use of speech analysis shows a high level of accuracy, not only in terms of the general recognition of a clinically relevant depressive state in the participants. Instead, there is a high degree of agreement regarding the extent of depressive impairment with the assessment of experienced clinical practitioners. From our point of view, the application of the noncontentual analysis system in everyday clinical practice makes sense, especially with the idea of a quick and unproblematic assessment of the state of mind, which can even be carried out without personal contact.

Introduction

Background

Mental illnesses are highly important worldwide [1]. In particular, affective disorders such as depression or anxiety lead to considerable distress in individuals who are affected [2]. In addition, these disorders are an economic and social burden to society [3]. To recognize the need for care and the effects of ongoing treatment or treatment that may need to be adapted quickly, contact with mental health professionals (physicians, trained nursing staff, or psychologists) is essential [4]. Still, many of the patients were in primary care treatment without mental health specialization, only with short-time contact with a physician and did not reach complete remission [5]. In addition to the difficulty of getting an appointment with a professional, there is a problem of fluctuations in the symptoms [4], which makes it challenging to determine clinical symptoms. The calls to implement measurement-based treatment in psychiatry are increasing; however, clinician-rated assessments and patient-reported outcomes may be complex [6]. Therefore, the necessity for new assessment methods is undisputed, with which more frequent or even regular progress control is possible.

For several years, such assessments have been known as ecological momentary assessment (EMA) [7,8]. With the development of digital technologies, particularly smartphones, they have been extensively studied [9]. Conventional measurement methods are either digitized or mobilized. Diverse approaches have also been undertaken to develop and evaluate new measurement methods that were previously not feasible; for example, use of wearables measuring biological and behavioral indices such as temperature, movement, or heart rate [10]. Such procedures result in 2 advantages from the point of view of the practitioner: on the one hand, it is possible to collect findings from real life in a close-meshed manner [11]; on the other hand, the application of the technology enables the person concerned to do part of the recovery process himself and control what increases compliance [12]. The application of EMA allows a short assessment to be performed frequently and under conditions of everyday life [7].

The importance of language and voice in conveying feelings, emotions, and moods is undisputed, and impairments in speech production are well known in mood disorders [13-15]. The content of the spoken word (the "text") [16] and nonverbal aspects (speaking style, flow of language, speech melody, etc) are both relevant and relatively independent [17-19]. Even without social interaction, inner speech is essential for the development of self-worth and self-efficacy, as well as for reflecting on experience and relational framing [20]. Human language as a form of expression, with human listening on the other side, has been the basis of professional therapeutic support for mental disorders for more than 100 years [21]. Recent developments in linguistic and psychological research in

relational frame theory have been acceptance-based treatments, such as acceptance and commitment therapy [22,23].

In the last few decades, advances in digital technology to diagnose or treat mood disorders have been enormous and have enabled a wide range of applications [24]. The worldwide spread of smartphones is so pronounced that an overwhelming proportion of people have access to this technology [25]. This also allows a better acquisition of voice recordings over a distance than was possible a few years ago, and the development of calculation power to push forward machine learning in different ways allows more intensive and detailed analysis of speech and voice [26,27]. By developing and applying unique algorithms, attempts can now be made to map the performance of active human listening and the associated assignment of emotions and moods [26]. This technique using machine learning should then be applied in the sense of an EMA in everyday life to record depressive moods and, ideally, observe the therapeutic effect and course [28].

It is well known that human speech is not simply the process of opening and closing the mouth but a more complex process involving more than 100 muscles, powered by many different brain regions, especially the auditory cortex, somatosensory cortex, and other brain parts and networks working in language perception and speech production [29]. There are many different acoustic features, such as pitch, speed, sound intensity, jitter, tremor, and vowel space, which are different in depressed patients compared with nondepressed persons. Research has been conducted to improve the knowledge of single-person aspects [30]. Thus, we have learned in the past that experienced clinicians or close friends can realize altered acoustic features in the case of depression, but it should be an essential perspective to implement accurate algorithms to analyze these parameters correctly without human supervision.

This study uses a noncontent linguistic analysis algorithm developed by VoiceSense, a company specializing in prosodic speech analysis, which links speech patterns to behavioral tendencies. Using machine learning technology to analyze data obtained from the speech or voice of patients with mental health complaints could be helpful to (1) complement the assessments of experienced psychiatrists or not-so-experienced physicians in primary care and (2) monitor the symptomatology of patients between consultations. This technology could optimize treatment procedures by learning the success rates of different individual treatments [31]. However, it is essential to train and check the machine learning algorithms and prove the algorithms repeatedly using samples with English or non-English native speakers, different mental states, or defined mental disorders in a longitudinal study [32].

This study provides a structured setting for the differentiated evaluation of psychopathological factors (effects, personality aspects, psychomotor factors, etc) using speech pattern analysis.

Research Objectives

The primary objective of this study was to examine the depression severity state of patients with depression, as measured by the Patient Health Questionnaire-9 (PHQ-9), compared with their acoustic vocal patterns.

We hypothesized that the vocal analysis system could confirm depression severity classification performed by an experienced psychiatrist consultant.

Methods

Setup

Participants

Participants were recruited in an outpatient neuropsychiatric treatment center.

The inclusion criteria were neurological or psychiatric diagnosis made by a psychiatric consultant who was not part of the study team and fluent use of the German language. The diagnostics were based on the International Classification of Diseases, 10th Revision criteria because they are binding in the German public health care system and the psychiatric consultant's experience.

Exclusion criteria included psychosis, dementia, speech or language disorders in neurological diseases, terminal or life-threatening illnesses, addiction history, a suicide attempt recently or in the last 12 months, or insufficient language skills.

Data collection took place between November 2018 and September 2019.

After removing participants who did not complete either the psychiatric assessment or audio collection, a total of 163 participants were included in the study, 47 (28.8%) of whom were men. We established a G-power calculation before starting

the study and calculated the necessity of 152 participants to reach the required power.

Assessment Sessions

Each participant participated in at least one assessment session (psychiatric and voice). In contrast, a part of the participants (100/163, 61.3%) took part in 2 assessment sessions, and a part of the participants took part in 3 (29/163, 17.8%) assessment sessions. Because of our proof-of-concept study setting, we set a relatively open frame for the participants and assessments. The number of assessments carried out was determined by the follow-up appointments of the attending physicians; participants who had one or more outpatient appointments with the therapist within a short period were asked to participate in the next assessment more frequently.

The time intervals between the first, second, and third sessions for the same participant were at least one week, ranging up to 3 months, so that the psychiatric state and the voice patterns could be different in the session, even for the same patients. Therefore, each participant session was treated as a separate data point in the sample and included an independent psychiatric assessment and voice analysis.

Number of Assessments

Overall, there were 292 psychiatric assessments and 292 recorded audio sessions for the 163 participants. These 292 sessions (psychiatric and voice) consisted of the data set sample to compare the psychiatric state and vocal patterns.

Demographic Characteristics

The participants were aged between 15 to 82 years. The participants were categorized into 6 age groups to examine age-related differences. [Table 1](#) shows the distribution of the participants and sessions across the demographic scales.

Table 1. Participants' distribution across demographic scales (N=163) and sessions (n=292).

Demographic category	Participants, n (%)	Sessions, n (%)
Gender		
Male	47 (28.8)	73 (25.0)

Tools

Psychiatric and Behavioral Assessments

To differentiate and compare depressive states, we used PHQ-9 with 9 questions, developed and published in 1999 [33]. This assessment was initially created for the screening and measurement of severity. The PHQ-9 score ranges from 0 to 27, because each of the 9 items can be scored from 0 to 3. A score of 3 indicates severe symptoms, and 0 indicates an absence of symptoms. The authors of the PHQ-9 described a model that

shows a high correlation between the 5 states of depression and between clinicians' diagnosis and severity classification, whereas other authors replicated the quality of the tool [34]. Validation of the tool included 3890 patients. We used the PHQ-9 for both the diagnosis and the severity classification.

The PHQ-9 scale consists of 5 depression categories. [Textbox 1](#) lists these 5 categories.

We also performed other measurements to compare vocational state with other mental problems or disorders, but the results will be published elsewhere.

Textbox 1. Patient Health Questionnaire-9 (PHQ-9) depression categories.

PHQ-9 scale and depression category
<ul style="list-style-type: none"> • 0 to 4: absence of depressive disorder • 5 to 10: subsyndromal symptoms • 10 to 14: mild symptoms • 15 to 19: moderate symptoms • 20 to 27: severe symptoms

Audio Collection Software

The participants' voices were recorded using the VoiceSense mobile audio collection app. VoiceSense mobile apps collect patients' audio for health care monitoring. The app required a log-in based on the coded ID of the participant to prevent personal identification. After log-in, the participant was presented with general questions (eg, "Please say in a few sentences on your social life. How often do you meet with friends? Do you spend quality time with your family?"). There are 9 such general questions, and the appl displayed 1 out of the 9 questions every time. The participant was requested to press *record*, answer vocally to the presented question, and press *stop recording* when completed. If required, additional questions were raised until at least 2 minutes of the participant's voice were collected. Once completed, the audio was uploaded to VoiceSense's cloud server for analysis using a special algorithm. During audio collection, the participants were alone in one of our testing rooms.

Vocal Analysis

The VoiceSense behavioral vocal analysis software analyzed the recorded voices of the patients based on previous work to code and train a machine learning analyzer.

VoiceSense behavioral vocal analysis software applies acoustic analysis, focusing on the prosodic features of speech. The analysis was language independent. The analysis does not use speech recognition, so there is no understanding of what has been said; hence, it is entirely content-free. To help the participants speak freely and noncontentually, they were presented with a set of questions ([Multimedia Appendix 1](#)). They had the option of either answering these questions or expressing their ideas and opinions.

According to the rules of the European Union regulations or the Defense Advanced Research Projects Agency of the US-Military (DARPA), we describe the process of analytics a little bit more in the next sentences not as a *black box* but as a process with 3 steps:

1. VoiceSense vocal analysis first calculated over 200 raw voice parameters from the samples of each audio recording. These basic parameters consist of a wide range of acoustic feature segmentation, including lengths, ranges, slopes, frequencies, values, and shapes of pitch-extracted parameters, amplitude-extracted parameters, and silence-extracted parameters within the speech recording. Thousands of data points are calculated and averaged per recording to form a data set of over 200 parameters that

reflects the individual's speech patterns in the given recording.

2. The basic parameters were then calibrated and normalized to overcome possible biasing effects within the specific recording owing to amplitude differences, pitch differences, speech type differences (conversation or monologue), gender differences, and age differences. The calibration process was performed against large natural-speech vocal reference data sets with over 14,500 recordings collected by VoiceSense over the years, covering different speech types, genders, ages, and languages.
3. The calibrated and normalized parameters were then analyzed using machine learning techniques to select and weight the vocal parameters that best correlated with the searched phenomena. The process uses the standard repeated random subsampling cross-validation method, which randomly splits the data set into training and test subsamples and repeats the process for multiple iterations to obtain a stable and reliable predictive model equation. Therefore, this model provides a unified speech-based score with normalized continuous scores as well as categorized (1-10) scores, which are associated with the phenomena, in this case, with depression. The statistical fit of the model to the reference scale (in this case, depression) was evaluated using Pearson correlation, ANOVA, and positive and negative predictive values (confusion matrix).

Procedures

Participant Recruitment

Participants were recruited from August 2018 to August 2019 at the Neuropsychiatric Center of Hamburg, one of Germany's largest outpatient only treatment centers, focused on neurology and psychiatry.

All participants were patients treated at the Neuropsychiatric Center with a diagnosis of depression. During the recruitment period, the patients were informed of the possibility of their physicians' participation in the study.

In all, 2 study supervisors (PT and NS) recruited the participants. The supervisors did not have any contact with the participants.

Baseline Assessment

After participants recruitment, a baseline assessment was taken, which include the items listed in [Textbox 2](#).

The results of the Big-5 personality questionnaire and the attention deficit hyperactivity disorder-related diagnostics will be published later.

Textbox 2. List of items in baseline assessment.

Baseline assessment

- Demographics (gender, age, psychological treatment, educational level, and marital status)
- Big-5 personality questionnaire for assessment of behavioral tendencies. The Big-5 questionnaires were administered only once, as unlike the psychiatric state, it was not expected to change from one session to the other.
- Attention deficit hyperactivity disorder (ADHD): some of the participants had already undergone ADHD assessment in the past. The ADHD diagnosis (yes or no) was added to the data set of the participants.

Psychiatric Assessment Session

In each assessment session, the participants completed the following psychiatric evaluation tools as listed in [Textbox 3](#).

Textbox 3. Psychiatric evaluation tools.

Evaluation tools
<ul style="list-style-type: none"> • Patient Health Questionnaire-9 for depression • General Anxiety Disorder-7 scale • Patient Health Questionnaire-15 for somatic symptom severity, somatization, and somatoform disorders • Symptom Checklist-90-R

Audio Collection Session

VoiceSense audio collection apps were installed on the tablets of the mental health professionals who participated in the research.

During each assessment session, the research assistant activated the VoiceSense app installed on the tablet. The app was logged in with the participant's experiment ID in each session. However, the participant's ID was only a serial number given to each participant by the research administrator. In this way, the recording could be associated with a specific participant but could not be associated with the actual identification of the participant. The conversion table between the actual participant's ID and the ID of the experiment was kept secure by the research administrator.

After log-in, the app presented to the participant selected general questions (as described in the audio collections section). The participant was requested to answer the question, and the app recorded the participant's voice while responding to the questions. The mental health professionals ensured that the recording was performed in a quiet environment (the session room), and only the participant's voice was recorded. At least two minutes of audio was collected per participant in each session. If the recording length after the first question did not reach 2 minutes, the app presented another question or questions until at least two minutes of audio were collected.

Central Audio Analysis

Once the recording session was completed, the app sent the recorded audio to the VoiceSense cloud server. The VoiceSense cloud server is a highly secure server running under Microsoft Azure cloud facilities (in the United States) and is recognized by the German authorities as safe for keeping medical data.

VoiceSense software processes are certified by the ISO's (International Organization for Standardization) highest information security standards, ISO 27001 and ISO 27799.

The audio data for each session were analyzed as described in the *Vocal Analysis* section, and over 200 raw speech parameters were generated for each recorded session.

These raw data parameters were calibrated and normalized to overcome possible biasing effects. The calibrated parameters

The participants completed the questionnaires. The assessments were performed after the session. The results of the General Anxiety Disorder-7 scale, Patient Health Questionnaire-15, and Symptom Checklist-90-R will be published in a separate publication.

of the 292 sessions were used as the input data set for statistical analysis.

Calculating the Vocal Depression Score

As described in the *Vocal Analysis* section of the *Methods* section, more than 200 raw voice parameters were calculated per audio recording. The parameters were calibrated and normalized by audio analysis and then passed as input data to the machine learning models for the vocal depression score calculation.

As described, a *repeated random subsampling cross-validation method*, using training and test subsamples, was used to select and weight the vocal parameters that best correlated with the searched phenomena (in this case, depression) to generate the articulated predictive model for depression.

Given the relatively small sample size of the study (N=292) compared with typical machine learning data sets, 5-fold cross-validation was chosen. The method randomly split the sample into a training subsample of 192 scores and a test subsample of 100 scores, and the process repeated itself for 10 iterations.

The method generated a predictive model (equation) consisting of a selected feature set of 13 weighted vocal parameters (out of over 200 input parameters). The outcome scores were normalized to generate a continuous vocal depression score (mean 5, SD 1). The score was also calculated on a categorical 1 to 10 scale (10=high depression).

Ethics Approval

The study protocol was approved by the ethics committee of the Neuropsychiatric Center of Hamburg, Germany (No. 2017-002) under the Declaration of Helsinki. Written informed consent was obtained from all participants before inclusion in the study.

Results

Overall, 163 participants completed both psychiatric assessments and audio collection, and 292 sessions had both psychiatric and vocal analysis scores.

Psychiatric Scales Scores

The state of psychiatric severity could change between sessions and was, therefore, measured separately in every session. Hence, all 292 scores were used for psychiatric score comparisons, although there were only 163 participants in the study.

Vocal Analysis Scores

The vocal analysis patterns could change between sessions and were, therefore, measured separately in every session. Hence,

all 292 session scores were used for verbal and psychiatric score comparisons, although there were only 163 participants in the study.

Correlation Between the Vocal Depression Score and the Psychiatric Depression Score (PHQ-9)

The overall Pearson correlations between the vocal depression score and the PHQ-9 depression score were highly significant, as presented in [Textbox 4](#).

Textbox 4. Pearson correlations between the vocal depression score and Patient Health Questionnaire-9 for depression.

Pearson correlations

- Overall sample (N=292): $r=0.41$; $P<.001$
- Training sample (N=192): $r=0.46$; $P<.001$
- Test sample (N=100): $r=0.30$; $P=.001$

PHQ-9 (Depression)

Overview

[Table 2](#) shows the PHQ-9 depression scores distributed by the 5 depression severity categories and the vocal analysis scores.

As can be seen, the average vocal depression score increases by the PHQ-9 depression severity category.

A single-factor ANOVA test was performed on the vocal depression scores and different PHQ-9 categories to determine whether the differentiation between the categories was

significant. This result was highly significant ($F_{291}=14.5672$; $P<.001$).

Specific 2-tailed t test comparisons were performed to determine the significance of the differences in vocal depression scores between each PHQ-9 depression severity category.

[Table 3](#) shows the t test probability matrix of all the specific comparisons between the vocal depression scores of the different PHQ-9 severity categories. As can be seen, the vocal scores of all severity categories are significantly different from each other, except for the difference between categories 2 (subsyndromal symptoms) and 3 (mild symptoms) and between categories 4 (moderate symptoms) and 5 (severe symptoms).

Table 2. Depression (Patient Health Questionnaire-9 [PHQ-9]) scores by severity categories and vocal depression scores.

Overall sample (N=292)	Severity category				
	Absence of depressive disorder (1)	Subsyndromal symptoms (2)	Mild symptoms (3)	Moderate symptoms (4)	Severe symptoms (5)
Assessments, n	87	98	49	39	19
Vocal depression score, mean (SD)	4.521 (1.0929)	4.933 (0.841)	5.179 (0.829)	5.626 (0.913)	5.792 (0.963)

Table 3. *t* test probability matrix of vocal depression scores by Patient Health Questionnaire-9 (PHQ-9) severity category.

Current psychological treatment				
No	60 (36.8)	124 (42.5)	1.653 (0.817)	4.652 (0.865)
Yes	103 (63.2)	168 (57.5)	2.833 (1.222)	5.257 (1.017)

Gender Differences

No significant differences were found between men and women for either the PHQ-9 scores (ANOVA test: $F_{291}=1.173611$; $P=.28$) or vocal depression scores (ANOVA test: $F_{291}=3.175943$; $P=.08$).

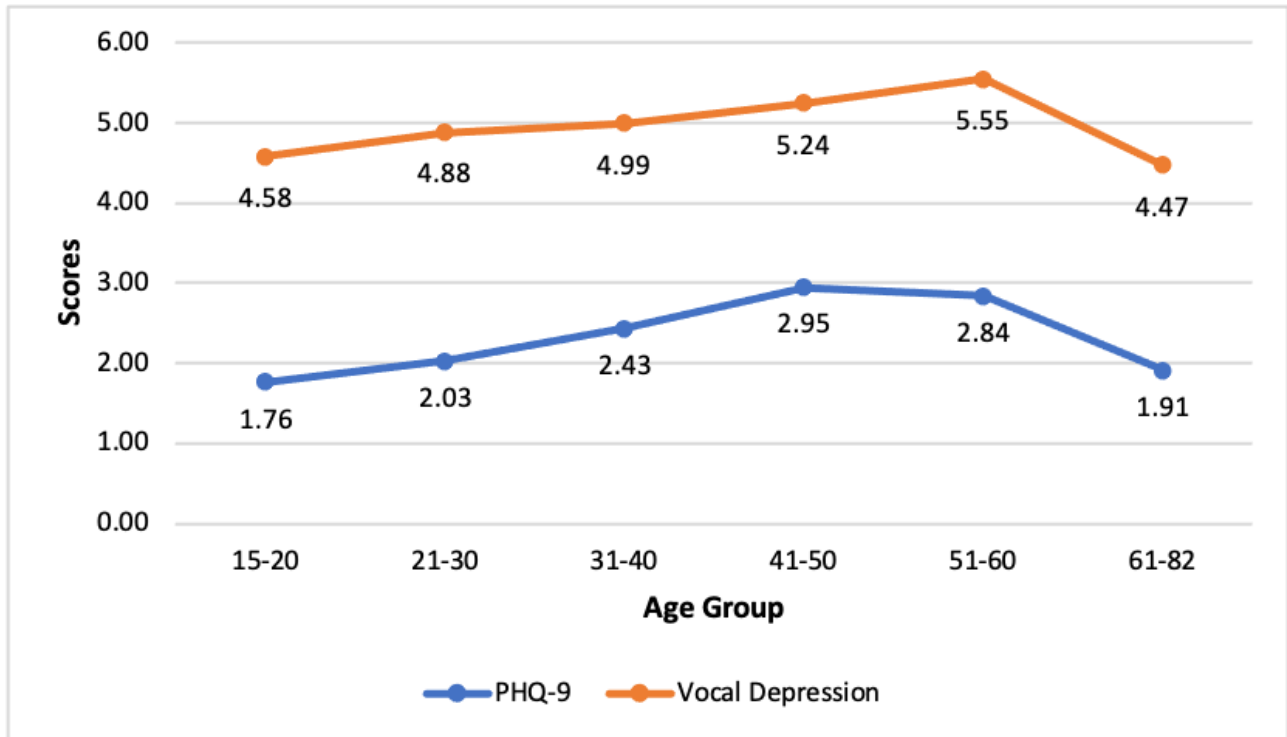

Age Group Differences

Significant differences in depression scores were found between age groups for both the PHQ-9 (ANOVA test:

$F_{291}=6.162602798$; $P<.001$) and vocal depression ($F_{291}=4.125516$; $P<.001$) Depression scores were generally higher in older age groups for both PHQ-9 and vocal depression, except for the oldest age group.

As seen in [Figure 1](#), the average score changes between age groups were very similar for PHQ-9 and vocal depression scores (the average scores are different owing to the different scales).

Figure 1. Patient Health Questionnaire-9 (PHQ-9) and vocal depression scores by age group.

Educational Level Differences

Significant differences in depression scores were found between educational level groups for both PHQ-9 (ANOVA test: $F_{291}=5.769297$; $P<.001$) and vocal depression ($F_{291}=3.593119$; $P=.007$).

As seen in Figure 2, the average score changes for education levels were very similar for the PHQ-9 and vocal depression scores (the average scores are different owing to the different scales).

Figure 2. Patient Health Questionnaire-9 (PHQ-9) and vocal depression scores by educational level.

Marital Status Differences

No significant differences were found in depression scores between the marital status groups, neither for the PHQ-9 (ANOVA test: $F_{291}=1.081893$; $P=.52$) nor for vocal depression scores (ANOVA test: $F_{291}=0.434517$; $P=.73$).

Psychological Treatment Differences

Overview

Significant differences in depression scores were found between psychological treatment status for both the PHQ-9 (ANOVA

test: $F_{291}=86.937647$; $P<.001$) and vocal depression (ANOVA test: $F_{291}=28.66407$; $P<.001$).

As seen in Figure 3, the average score changes for current psychological treatment status *no* in every sessions (0) and *yes* in every session (1) are similar for the PHQ-9 and the vocal depression scores (the average scores themselves are different due to the different scale), the average score changes are not clear similar in *no* in one session (2), but this group is too small with $N=5$ to allow a clear explanation.

Figure 3. Patient Health Questionnaire-9 (PHQ-9) and vocal depression scores by psychological treatment status.

Statistical Fit (Predictive Power) of the Vocal Depression Scores to the PHQ-9 Depression Scores

As shown by the aforementioned results, strong and significant relationships were found between the vocal depression scores and PHQ-9 depression scores.

However, what is the practical accuracy that can be expected from using vocal analysis for tracking and screening for depression? In statistical terms, this question relates to the predictive power of the vocal model or its statistical fit to PHQ-9 depression reference scores.

A common way to evaluate a model's strength is by labeling the model's scores as positive and negative predictive values and performing a confusion matrix analysis.

The PHQ-9 scores were labeled as follows: scores 1, 2, and 3 were labeled as *Low Depression* and scores 4 and 5 were labeled as *High Depression*. A total of 63.4% (185/292) of participants were labeled as *Low Depression*, and 36.6% (107/292) of participants were labeled as *High Depression*.

The vocal depression scores were labeled as follows: scores 1 to 6 (within the 1-10 scale) were labeled as *Low depression risk*

and scores 7 to 10 were labeled as *High depression risk*. A total of 59.9% (175/292) of participants were labeled *Low depression risk*, and 40.1% (117/292) of participants were labeled as *High depression risk*.

Table 5 shows the confusion matrix of the number of participants classified according to these 4 labels for the entire sample and training and test subgroups.

Of the 107 participants that were labeled as *High Depression* according to the PHQ-9, 68 (63.6%) were classified as *High depression risk* by the vocal depression analysis (true positive) and 39 (36.4%) were classified as *Low depression risk* (false negative).

Out of the 185 participants that were labeled *Low Depression* according to the PHQ-9, 136 (73.5%) were classified as *Low depression risk* by the vocal depression analysis (true negative) and 49 (26.5%) were classified as *High depression risk* by the vocal depression analysis (false positive).

Overall, out of the 292 participants, 204 (136+68) were classified as consistent with the PHQ-9 depression (accuracy=69.9%).

Table 6 provides the confusion matrix attributes for the entire sample and training and test subgroups.

As explained in the *Methods* section, the vocal depression model was developed using a training subsample (on which the model was trained) and a test subsample (on which the model was tested).

Hence, the model's predictive power is best evaluated using the confusion matrix results for the test subsample. It is also

interesting to observe the differences between the training and test subsamples to assess the expected stability of the model.

As can be seen, the confusion matrix results for the test subsample were similar to the results of the training subsample. The overall accuracy of the model was 70.8% in the training subsample and 68% in the test subsample. This means that the vocal depression model is relatively stable and is expected to provide an overall accuracy of close to 70% when used for depression screening and tracking.

Table 5. Patient Health Questionnaire-9 (PHQ-9) depression and vocal depression labeled matrixa.

Confusion matrix (vocal depression)	PHQ-9 depression (N=292)			Training subgroup (N=192)			Test subgroup (N=100)		
	Low	High	Total	Low	High	Total	Low	High	Total
Low risk	136	39	175	89.2	24.7	113.9	46.8	14.3	61.1
High risk	49	68	117	31.3	46.8	78.1	17.7	21.2	38.9
Total	185	107	292	120.5	71.5	192	64.5	35.5	100

^aThe values are participants and virtual parts of participants predicted and classified from the algorithm.

Table 6. Confusion matrix attributes.

	Entire sample (%)	Training subgroup (%)	Test subgroup (%)
Accuracy: correct classifications	69.9	70.8	68.0
Sensitivity (recall): true positive rate	63.6	65.5	59.7
Specificity: true negative rate	73.5	74.0	72.6
Precision: positive predictive value	58.1	59.9	54.5
False positive rate	26.5	26.0	27.4
False negative rate	36.4	34.5	40.3

Discussion

Principal Findings

In this study, consisting of 163 participants affected by different degrees of depressive states, it was shown that there is a high correlation between the depression severity classification as measured by the PHQ-9 self-filled questionnaires and between the depressive vocal scores as measured by the VoiceSense analysis system.

Compared with other studies that used biomarkers or wearables for detecting depressive states [35], we only used noncontent speech analysis. No participant had to buy or wear an additional digital tool or some hardware; no participant had to be aware of some unexpected action of an unusual wearable device. To start the analysis, it was only necessary to perform one short call with the VoiceSense system. The implementation of the VoiceSense speech analysis was unproblematic; the connection via Wireless Local Area Network showed adequate sending and receiving performance for the tablets used for recording. The sound quality was good and enabled a fair vocal analysis evaluation.

Each depressive vocal score was calculated based on only one voice recording in the evaluation. It is expected that the accuracy will increase with multiple recordings. Corresponding

calculations will be performed for participants who have made several sound recordings.

As the basis for speech analysis, we used a machine learning algorithm that had already been applied to various personality aspects and affective states in English-speaking participants. Here, we tested whether and to what extent it is possible to let this system *learn further* to change the language and to what time the recognition of affective states can succeed in comparison with clinical tests. We achieved a high level of agreement with at least 384 training minutes after running the algorithm 10 times. The results of the confusion matrix showed that fairly good accuracy was achievable. The accuracy of the test sample was maintained at 68%. Specificity and sensitivity also correspond to high values of 59% and 72%, respectively. Even in everyday clinical practice, no better agreements are achieved by different therapists in cursory examinations.

We were able to achieve stable results with the voice analysis system, which largely corresponded to the results of testing in the PHQ-9. The effects were long-lasting; after training on the first 192 data sets, the following data sets could be detected with high accuracy. No restrictions due to the course of time or abnormalities in the intervals between individual tests were recognizable. Thus, the use of the speech analysis system alone could accurately discriminate individuals with a high risk of depressive phases or could monitor the course of treatment and

recovery of patients without direct contact with an experienced psychiatrist.

Comparison With Previous Research

We compared our study to other studies that investigated the approach to analyzing speech in patients affected by depression. Some actual research studies noncontent aspects of speech compared with low or severe depressive symptoms [36]. The results confirm a relationship between acoustic parameters of speech not only in the case of severe depressive disorder but also in nonsevere cases. This study used humans' interpretation of audio recordings; we used digital techniques for a similar task. However, some research has been conducted to develop machine learning settings to identify if someone is depressed. In the various conferences of Audio Visual Emotion Challenge and Workshop in recent years, based on different data sets of depressed people, some researchers have shown that automatized techniques to identify this subgroup could reach a good recognition level [37,38].

In a group of older adults with depression, voice pattern and speech activity could be shown in an automated deep learning–based analysis as essential parameters to detect late-life depression [39].

The results that we were able to find here correspond to the descriptions of the specified studies. The main strength of our study is that data from an average outpatient group were available from an outpatient care center. None of the test participants were first made aware of the study or the problem of depressive disorders and how external stimuli could measure them. Therefore, the results can be regarded as reliable.

Nevertheless, the experimental results of the researchers cited are confirmed. With a training effort of only 192 candidates, we achieved almost congruent results for the remaining 100 measurements in the test run. Therefore, the use of the technical approach described here for easier and faster diagnosis of depressive disorders can be considered helpful in clinical practice, especially in detecting depressive disorders at an early stage or monitoring close-meshed treatment.

An interesting study showed that a measurement-driven therapy approach for patients with depression (as part of a telemedicine platform) can achieve far better treatment results than the previous approach, with occasional live contact with the treating physician. Suppose you transfer the core idea here—the regular

and low-threshold recording of treatment effects and progressions—to implementation in everyday therapy, independent of a telemedicine treatment platform. There should also be exciting improvements in the treatment quality if changes in findings can be applied promptly [40].

Such an automated analysis with a shallow threshold to commit will make it possible to provide a more intensive and individual, person-centered treatment if the measurement results show a highly negative mood or other problematic stages of depressive disorder. It can assist in regulating treatment and medication dosage more accurately according to the patient's state at the time of vocal assessment.

Conclusions

The PHQ-9 is a well-established and appropriate tool for screening and assessing depressive disorders and depressive phases. However, the PHQ-9, similar to other assessment tools, is problematic for some patients and time consuming for both physicians and patients.

Using a tool with machine learning algorithms, such as VoiceSense, to capture the affective phase of a patient can work not only much faster but also over distance because the patient and physician do not need to see and sit together. VoiceSense could be installed on the patient's smartphone so that only the scores are transmitted to the physician's database. Treatment flexibility is possible, and distance diagnostics can be used.

The importance of such an assessment is not a considerable question—both to improve individual therapy planning and to distinguish threatening phases of depression of an individual from harmless ones with significantly reduced effort. The value of such a remote monitoring approach has recently been emphasized during the COVID-19 pandemic.

In a further step, possible changes in the course of therapy must be recorded more precisely. The extent to which the result of the speech analysis changes if the condition of the test participant changes, and of course, it must ultimately be confirmed whether the good correlation is also confirmed if the recording of the test participant's condition is not only proved by a self-rating similar to the PHQ-9 but also through a suitable third-party rating. That is now reserved for future studies; we will conduct this in collaboration with one of the largest German public health insurance companies.

Conflicts of Interest

YD works in a company called VoiceSense. VoiceSense has developed the vocal analysis system used in this study and it also funded this study.

Multimedia Appendix 1

List of the general questions presented in the VoiceSense mobile audio collection app.

Abstract

Background: Depression and anxiety symptoms in early childhood have a major effect on children's mental health growth and cognitive development. The effect of mental health problems on cognitive development has been studied by researchers for the last 2 decades.

Objective: In this paper, we sought to use machine learning techniques to predict the risk factors associated with schoolchildren's depression and anxiety.

Methods: The study sample consisted of 3984 students in fifth to ninth grades, aged 10-15 years, studying at public and refugee schools in the West Bank. The data were collected using the health behaviors schoolchildren questionnaire in the 2013-2014 academic year and analyzed using machine learning to predict the risk factors associated with student mental health symptoms. We used 5 machine learning techniques (random forest [RF], neural network, decision tree, support vector machine [SVM], and naive Bayes) for prediction.

Results: The results indicated that the SVM and RF models had the highest accuracy levels for depression (SVM: 92.5%; RF: 76.4%) and anxiety (SVM: 92.4%; RF: 78.6%). Thus, the SVM and RF models had the best performance in classifying and predicting the students' depression and anxiety. The results showed that school violence and bullying, home violence, academic performance, and family income were the most important factors affecting the depression and anxiety scales.

Conclusions: Overall, machine learning proved to be an efficient tool for identifying and predicting the associated factors that influence student depression and anxiety. The machine learning techniques seem to be a good model for predicting abnormal depression and anxiety symptoms among schoolchildren, so the deployment of machine learning within the school information systems might facilitate the development of health prevention and intervention programs that will enhance students' mental health and cognitive development.

Introduction

Background

Mental health conditions are emerging as health priorities around the globe, with depression being the main cause of illness among adolescents [1], as all other aspects of life in the early adolescent years are greatly affected by poor mental health. The majority of mental health disorders appear by the age of 14 years, yet they may go untreated and thus present severe consequences for the child's mental, physical, and social health in the long term [2]. The early detection and treatment of mental health conditions in childhood and adolescence not only enhance the child's quality of life, academic performance, physical health, and social life but also helps them cope with external risk factors as adults [3,4].

With over 300 million official diagnoses worldwide, depression is the most prevalent mental health condition [5]. Although ordinarily and mistakenly interchanged, as well as with a major overlap within their symptoms and treatment, depression and anxiety are 2 distinct diagnoses with different consequences for the patient [6]. The main symptoms of depression include memory loss, lack of concentration, inability to make decisions, loss of interest in daily life activities, feelings of guilt, irritation, and in some cases, suicidal thoughts [6,7]. Anxiety, on the other hand, is an "aversive emotional and motivational state occurring in threatening circumstances" [5], whereby an individual is unable to make decisions or identify the best behavior to remove or instigate the threat. Furthermore, the overlapping depression and anxiety symptoms might affect several of the students' life areas, including school and family life, friendship, and academic performance. Studies found that depression and anxiety could lead to a lack of attention or motivation, which could influence schoolchildren's performance [8-11].

Although both anxiety and depression are conditions that severely affect schoolchildren and adolescents and have been shown to predict future mental health problems, interventions are focused on prevention or treatment instead of prediction and risk factors [12].

Prior Work

Schoolchildren's mental health problems including depression and anxiety have been studied by many researchers [12-16]. Research studies have reported that depression and anxiety lead to several negative consequences on children's health development, such as functional impairment and poor cognitive development, social development, and educational and academic performance. It has been found that depression and anxiety symptoms are associated with many risk factors, including poor lifestyle and eating habits, violent behavior, negative social and family support, and socioeconomic factors [13-16].

Data mining and machine learning (ML) techniques have previously been used for mental health prediction, yet most researchers have focused on target populations besides schoolchildren [4,6,17]. Several ML algorithms were used in predicting anxiety- and depression-associated risk factors, such as support vector machine (SVM), convolutional neural network, random forest (RF) tree, and naive Bayes (NB). For instance,

Seah and Shim [7] used data mining techniques on social media users, particularly the Reddit platform, to understand the risk factors associated with suicide. Wang et al [18] studied the change of anxiety severity and prevalence among undergraduate students undergoing web-based learning during the COVID-19 pandemic using the XGBoost ML model. Priya et al [4] aimed to predict anxiety, depression, and stress among employed and unemployed individuals through the use of 5 different ML algorithms. Richter et al [6] used ML for differentiating the symptoms of anxiety and depression among adult patients. In 2 studies [4,19], RF and NB algorithms reported an average accuracy rate of 71% and 73% for anxiety and depression symptoms, respectively. Rois et al [20] assessed the performance of different ML algorithms in predicting depression, anxiety, and stress among Bangladeshi university students and found that the RF model had the highest accuracy level of 89.7% and the logistic regression model had the lowest accuracy level of 74.5%. Furthermore, in Priya et al [4], decision tree (DT), NB, SVM, RF, and k-nearest neighbor algorithms were used in predicting anxiety and depression among adults aged 20-60 years, and the study found that the RF algorithm had the highest performance accuracies of 79.8%, 71.4%, and 72.3% for depression, anxiety, and stress, respectively.

Overall, ML techniques have been successfully used as predictors for childhood obesity [21,22], academic performance [23,24], children's personalities [25], and cognitive performance [1,5,26,27], among others. Thus, the literature has proven that ML is an effective methodology for the prediction of risk factors in several fields—one of which is mental health. The RF classifier and ensemble techniques have been shown to have the highest accuracy rates [4].

Aim

The role of ML in predicting mental health conditions among schoolchildren specifically has seldom been explored. Therefore, this study aimed to assess the accuracy of 5 ML techniques in predicting depression and anxiety and its associated risk factors (mental health, physical health, social support, and violence, among others) among schoolchildren in Palestine.

Methods

Data Collection

The data were collected from the multidisciplinary research project on the Determinates of Students' Health (physical, mental, and social) in the West Bank and East Jerusalem, conducted in collaboration between the Ministry of Education and Al-Quds University in the 2013-2014 academic year. The study sample included students in fifth to ninth grades (aged 10-15 years) in public schools (administered by the Palestinian Authority) and United Nations Relief and Works Agency schools. A representative sample of 3984 students selected from 100 schools was used in this study.

Ethics Approval

The study received ethical approval from the Ministry of Education and Al-Quds University Institutional Review Board (05-Aug-2013-12/10).

Variables

The data set included the associated risk factor variables related

to depression, anxiety, physical, and social health, in addition to the sociodemographic variables evidenced in [Table 1](#).

Table 1. Machine learning models' variables.

Variable name	Description	Value
Gender	Gender	Boy or girl
Age	Age	10-15 years
FAS ^a	Economic status	Low, medium, or high
ST	School type	Public or refugee
LP	Living place	Urban or nonurban
FatherEdu	Father's education	≤Secondary or >secondary
MotherEdu	Mother's education	≤Secondary or >secondary
HealthyIntake	Healthy food intake	Low or high
UnhealthyIntake	Unhealthy food intake	Low or high
BMI	Body mass index	Normal, overweight, or obese
Smoking	Tobacco risk	Yes or no
PAL	Physical activity	Low active or active
FAL	Free-time activity	Low active or active
FSL	Family support level	Low, moderate, or high
PSL	Peer support level	Low, moderate, or high
SSL	School support level	Low, moderate, or high
PTSD ^b	Posttraumatic stress symptoms level	Low, moderate, or severe
Depression	Depression symptoms	Normal or abnormal
Psychosomatic_SympL	Psychosomatic symptoms	Low, moderate, or severe
Health_Perception	Positive health perceptions	Low, medium, or high
LSL	Life satisfaction level	Low, medium, or high
Academic_Score	Average grades score	Excellent/very good, good, or weak/fail
Violence	Home violence	Never, sometimes, or often true
Bullying	Bullying behaviors	Never, bullied, or bully/victim
Anxiety	Anxiety symptoms level	Normal or abnormal

^aFAS: family affluence scale.

^bPTSD: posttraumatic stress disorder.

Sociodemographic Variables

The variables considered were gender, age, degree level, place of residence, household income, school category (public or United Nations Relief and Works Agency), and parents' education.

Depression

The depression data were collected using the 18-item Depression Self-Reported Scale (DSRS) [28] for children aged 8 to 14 years. The DSRS items were composed of 3 answer categories (never=0, sometimes=1, and always=2), with the highest score indicating higher depression. The item "I like to play outside my home" was excluded given that, in Palestinian culture, girls do not go outside for play. The total score was calculated through the addition of the scale items' answers. The DSRS total score was classified into the following groups:

- Normal: between 0 and 9 points.
- Mild or moderate depression: between 10 and 20 points.
- Severe depression: higher than 20 points.

To improve the performance of ML prediction, the mild or moderate and severe depression categories were grouped into 1 category (called the abnormal category). The final scale was classified into the normal and abnormal categories.

Anxiety

The 7-item General Anxiety Disorder [29] scale was used for measuring anxiety. The anxiety score was estimated by assigning the scores of 0, 1, 2, and 3 to the response categories of "not at all," "about every week," "more than once a week," and "every day," respectively. The scores of 5, 10, and 15 were taken as the cutoff points for mild, moderate, and severe anxiety, respectively. To improve the performance of ML prediction,

the mild, moderate, and severe anxiety categories were grouped into 1 category (called the abnormal category). The final scale was classified into the normal and abnormal categories.

Physical Activity

The students were asked 3 questions to collect the following data on the levels of physical activity: (1) the number of days the students were physically active for more than 1 hour in the last week, (2) the frequency of the number of hours of playing sports outside of school, and (3) the total number of hours of physical exercise per week.

Free-Time Activity

The following data on students' free-time activities were collected from the students through questions: (1) the daily number of television-watching hours, (2) the number of hours spent on using the internet per week, and (3) the daily number of hours spent on playing video games.

The physical and free-time questions considered the weekdays only (excluding weekends). The activities categorization used the quartiles analysis. For physical activity, the active level of students was identified by the upper quartiles range, whereas the inactive level was identified by the lower quartiles range. For free-time activities, the inactive students were identified by the upper quartiles range, whereas the active ones were identified by the lower quartiles range.

Food Intake

The students' food intake information used the 7-item food frequency scale. The scale items were classified into 7 categories based on intake profile similarity: (1) legumes and vegetables; (2) fruits; (3) milk, yogurt, cheese, and alternatives; (4) sugar; (5) soft drinks; (6) juices and beverages; and (7) energy drinks. The response categories were (1) never, (2) one to two times/week, (3) three to four times/week, and (4) five to seven times/week (almost daily). Students were categorized into 2 groups, healthy and unhealthy intake, based on the item scale sum. The healthy intake group included participants who reported that they did not consume unhealthy food groups (soft drinks, sugar, or energy drinks), and the unhealthy group included participants who did not report to consume healthy food items (vegetables, fruits, milk, and dairy products).

Social Support

The variable considered 3 aspects of support: (1) family, (2) schoolteachers, and (3) peers. Each survey section included 2 items related to the students' communication frequency with the above aspects of social support.

Health Perceptions

The perception of health and life was assessed using the 6-item perception scale. The scale items included questions about the students' self-perception of health and life quality.

Life Satisfaction

Students were asked to evaluate their life satisfaction by ranking it from 0 to 10, with 0 indicating the worst life satisfaction and 10 indicating highly satisfied.

Posttraumatic Stress Disorder

A 20-item posttraumatic stress symptoms measurement scale was used. The scale measured the anxiety disorder caused by an intensely stressful event. The items were ranked on a 5-point scale from 0, indicating "never," to 4, indicating "very much."

Academic Performance

This variable was obtained from the students' academic records. The average performance score was calculated for 6 school subjects: Arabic language, English language, Religion, Social Studies, Science, and Mathematics. The total score was identified by the following categories: excellent/very good, good, or weak/fail.

Home Violence

The home violence variable was assessed through 5 items rated on a 3-point scale; the answer options were (1) never, (2) sometimes, or (3) often true. Higher scores point to a higher occurrence of home violence.

School Violence and Bullying

These variables were assessed by asking questions related to the frequency of bullying either experienced or witnessed at school. There were 4 violence and bullying categories identified: 0 for not engaged in bullying behavior; 1 for bullying others only; 2 for bullied only; and 3 for bully-victim (those who were both bullies and victims).

Psychological Attributes

The parent version of the Strengths and Difficulties Questionnaire was used to assess students' psychological attributes [30]. The scale was composed of 25 items covering negative and positive attributes; each item was answered with either "not true=0," "somewhat true=1," and "certainly true=2." The scale included emotional symptoms, behavior problems, hyperactivity or inattention, peer relationship problems, and pro-social behavior. In all, 3 categories were identified from this scale: 0 for "normal" (0-13 points), 1 for "borderline" (14-16 points), and 2 for "abnormal difficulties" (≥ 17 points).

ML Algorithms

In this study, 5 ML predictive models (artificial neural network [ANN], RF, SVM, NB, and DT) were built and compared to each other to consider their predictive accuracy on the given data set. This predicted the depression and anxiety symptoms among schoolchildren according to the severity level. The data set was divided into the ratio of 70:20:10, representing training, testing, and validation, respectively. The cross-validation approach with grid search method was used for parameters optimizations. The parameters for different algorithms were set as follows:

- In the ANN model, the hidden layer had 500 neurons, with 500 as the maximum number of iterations based on logistic activation function.
- The RF model had 1000 trees and 5 maximum depth trees. The maximum number of samples for splitting the internal nodes was set to 2, and the leaf node minimum number was set to 1.

- The SVM regularization parameter was set to 20, the Radical Basis Function kernel was set to 0.001, and the bias error control factor was set to 1.
- Based on the optimization results, the algorithms were used in predicting the depression and anxiety symptoms. The ML algorithms used are described in [Table 2](#).

Table 2. Description of machine learning techniques.

Machine learning algorithm	Description
Artificial neural network	Neural networks are a series of algorithms that recognizes relationships between sets of data. The algorithm is built of many small, classified aggregators that feed-forward from the input data to the target prediction [31,32].
Random forest	Random forest is an ensemble learning technique that is used for classification along with regression through decision trees and outputs the plurality of votes from the trees [33]. Each tree is exposed to a data subset and independently evaluates the features available to arrive at a conclusion [34,35].
Support vector machine	The support vector machine is an algorithm used for classification in addition to regression analysis. Support vector machine creates a decision surface for the prediction of variables starting from a small number of similar cases across the support vector and then classifying the remaining cases based on how they fall on the side of the support vector [34,35].
Decision tree	A decision tree is an algorithm that builds a tree-like structure for classifying features with multiple levels of observations [32]. The substructures, “leaves,” represent the objects’ class, whereas the “branches” represent the features [34-36].
Naive Bayes classification	Naive Bayes is the easiest and most powerful algorithm to predict features within a data set. This machine learning algorithm analyzes the training sets across the variables to find how likely the variables’ ability is for predicting the target [34,35].

Data Analysis

The data variables were cleaned and normalized before analysis. The data set consisted of 3984 student records. The ML algorithms were applied to predict the students’ mental health depression and anxiety symptoms by using the Orange data mining software [37] for testing and validating the ML models.

Different performance measures were used to evaluate whether the ML models can predict schoolchildren’s depression and anxiety symptoms, such as accuracy, specificity, precision, recall, and F-measure. The calculating equations for performance measure are as follows:

$$\text{Specificity} = \text{True Negative} / (\text{False Positive} + \text{True Negative}) \text{ (1)}$$

$$\text{Precision} = \text{True Positive} / (\text{True Positive} + \text{False Positive}) \text{ (2)}$$

$$\text{Recall} = \text{True Positive} / (\text{True Positive} + \text{False Negative}) \text{ (3)}$$

$$\text{F-measure} = (2 \times \text{Precision} \times \text{Recall}) / (\text{Precision} + \text{Recall}) \text{ (4)}$$

$$\text{Accuracy} = (\text{True Positive} + \text{True Negative}) / (\text{True Positive} + \text{True Negative} + \text{False Positive} + \text{False Negative}) \text{ (5)}$$

Results

A brief descriptive analysis was performed to present the depression and anxiety levels among the Palestinian schoolchildren and understand the data distribution before the evaluation of ML techniques. The data set was composed of 3984 students with a mean age of 13 (SD 1.5) years, ranging from ages 10-15 years. Among these students, approximately 29.8% (n=1188) were boys and 70.2% (n=2796) were girls. Data in [Table 3](#) show the depression levels distributed by grade levels. The eighth and ninth grades students reported the highest moderate depression levels (eighth: 61%, 469/769; ninth: 61.5%, 494/803). The seventh and ninth grades students reported the highest severe depression levels (seventh: 6.6%, 54/824; ninth: 7.3%, 59/803). The results show that more than half (57.3%, 2283/3984) of the students reported a moderate level of depression in all ages.

Table 3. Students' depression and anxiety levels by grade.

Mental health condition, grade	Normal, n (%)	Moderate, n (%)	Severe, n (%)
Depression			
Fifth grade (N=797)	362 (45.4)	404 (50.7)	31 (3.9)
Sixth grade (N=791)	288 (36.4)	460 (58.2)	43 (5.4)
Seventh grade (N=824)	314 (38.1)	456 (55.3)	54 (6.6)
Eighth grade (N=769)	256 (33.3)	469 (61)	44 (5.7)
Ninth grade (N=803)	250 (31.1)	494 (61.5)	59 (7.3)
Anxiety			
Fifth grade (N=797)	452 (56.7)	147 (18.4)	198 (24.8)
Sixth grade (N=791)	426 (53.9)	164 (20.7)	201 (25.4)
Seventh grade (N=824)	432 (52.4)	203 (24.6)	189 (22.9)
Eighth grade (N=769)	438 (57)	172 (22.4)	159 (20.7)
Ninth grade (N=803)	479 (59.7)	192 (23.8)	133 (16.6)

The results in [Table 3](#) show the percentage distribution of anxiety levels by grade levels. The participants reported a decrease in anxiety severity levels as grade levels increased. Students in the fifth and sixth grades had the highest anxiety levels (24.8%, 198/797 and 25.4%, 201/791, respectively). Overall, more than half (55.9%, 2227/3984) of the students reported normal anxiety levels at all ages. However, the minimum anxiety level found in ninth graders (16.6%, 133/803) might still affect the students' growth and development. We observed significant differences between the depression and anxiety scores, grades, and genders. The results also indicated that girls reported higher depression (6.4%, 180/2796) and anxiety (22.9%, 640/2796) levels than boys (4.3%, 51/1188 and 20.2%, 240/1188, respectively). Furthermore, the results in [Table 4](#) show that the univariate analysis of depression symptoms indicated a high significant association with posttraumatic stress disorder (PTSD), life satisfaction, health

perception, gender, physical activity, family support, smoking, home violence, and grade; whereas for anxiety, the results show a significant association with PTSD, family support, school support, friend support, grade, home violence, gender, and bullying behaviors.

[Table 5](#) demonstrates the comparison between ML algorithms' accuracy rates for the models used in predicting students' depression and anxiety. Besides the SVM and RF models, which had the highest accuracy rates (depression: 92.6% and 92.4%, respectively; anxiety: 76.5% and 78.4%, respectively), the other ML algorithms had acceptable performance accuracies. The 2 classes of depression and anxiety resulted in the confusion matrix depicted in [Table 6](#); the columns show the predicted classes, whereas the rows show the actual classes. To further present prediction accuracy, the instances classification accuracy of the 5 models is shown in [Table 7](#).

Table 4. The univariate analysis of depression and anxiety symptoms by study variables.

Mental health condition, variable	<i>F</i> test (<i>df</i>)	<i>P</i> value
Depression		
PTSD ^a	643.5 (1,3983)	<.001
Life satisfaction	83.6 (1,3983)	<.001

^aAUC: area under curve.

^bCA: correspondence analysis.

^cF1-score: harmonic mean between precision and recall.

Table 7 shows the different performance measures (area under curve [AUC], accuracy, error rate, F1-score, precision, and recall) calculated for the 5 ML models. The results in Table 7 indicated that the highest accuracy rates for both variables, depression and anxiety, was achieved by the SVM and RF algorithms. Nevertheless, the results of the confusion matrix in

Table 6 show imbalanced classes of depression and anxiety classifications by the ML algorithms, which means that accuracy measure will not provide sufficient performance measure. Therefore, we used the harmonic mean of recall and precision (F1-score) as an additional performance measure for the selected ML algorithms. The F1-scores obtained by the SVM and RF

models were the highest for both depression and anxiety, whereas the NB model reported the lowest accuracy and F1-scores for both depression and anxiety. The classification results show that the RF, SVM, and ANN models presented the highest accuracy levels for predicting students' depression and anxiety. However, all algorithms used in this study produced an acceptable performance measure for depression and anxiety symptoms.

The RF receiver operating characteristics for the 2 depression and anxiety classes are presented in Figures 1 and 2 and Table 8. There were 2 numerical categories of student depression and anxiety used: normal and abnormal. The receiver operating characteristics resides in the upper left corner; thus, the RF algorithm has a better prediction of positive value than the other studied algorithms (AUC of 82% and 81% for depression and anxiety, respectively).

Figure 1. SVM and random forest receiver operating characteristics curve for abnormal depression (TP rate of sensitivity against FP rate of specificity). FP: false positive; SVM: support vector machine; TP: true positive.

Figure 2. SVM and random forest receiver operating characteristics curve for abnormal anxiety (TP rate of sensitivity against FP rate of specificity). FP: false positive; SVM: support vector machine; TP: true positive.

The features importance ranking for depression and anxiety symptoms were analyzed using the RF ranking method. The features importance was scaled from 0% to 100%. The features with importance greater than 60% were selected and presented in Table 8. The most important features that affected depression symptoms were age, bullying behaviors, PTSD, life satisfaction, anxiety symptoms, health perception, friend support, academic score, school support, home violence, and family income.

Psychosomatic symptoms, age, bullying behaviors, family support, PTSD, depression symptoms, friend support, school support, home violence, academic score, family income, and physical activity were the most important features that affected the schoolchildren's anxiety symptoms.

Other variables were found to be less important for depression and anxiety among schoolchildren and therefore were not presented in Table 8.

Table 8. Depression and anxiety symptoms predictors importance ranking.

Mental health condition, symptom	Importance, %
Depression	
Family income	60
Home violence	66
School support	71
Family support	75
Academic score	78
Friend support	80
Health perception	83
Anxiety symptoms	84
Life satisfaction	85

Depression symptoms	84
Family support	88
Bullying behaviors	90
Age	93
Psychosomatic symptoms	96

^aPTSD: posttraumatic stress disorder.

Discussion

Principal Findings and Comparisons With Previous Work

In this study, we used ML models in predicting depression and anxiety symptoms among schoolchildren. The study found that two-thirds of students reported moderate depression symptoms and about 7% had severe depression, whereas around 22% of students reported moderate and severe anxiety symptoms. The

data showed that students in the sixth, eighth, and ninth grades had higher depression symptoms, whereas students in the fifth and sixth grades reported higher anxiety symptoms. These results are consistent with similar studies that found high depression and anxiety rates among adolescents [4,15,38-40]. The severe depression level of our study was close to those reported among schoolchildren in Germany, Canada, and Jordan [14,39,41]. The severe anxiety level was consistent with the results reported among adolescents living in Jordan, Spain, Canada, and Saudi Arabia [38,39,41,42].

The performance of the ML algorithms in predicting schoolchildren's depression and anxiety was assessed using the AUC, accuracy, precision, recall, and F1-score performance measures. In total, 23 relevant features were used after performing feature selection using ML algorithms. The features were used as input variables, whereas the average depression and anxiety scores were considered as the target variables independently. Among the tested models, SVM and RF showed the best performance results for depression (SVM: 92.5%; RF: 76.4%) and anxiety (SVM: 92.4%; RF: 78.6%). Furthermore, the specificity for the SVM and RF models were 87.8% and 88.6% for depression, respectively, and 76.9% and 85.5% for anxiety, respectively. Of the 23 features selected, 16 features were correlated to instances of depression and anxiety, including physical, mental, and social health indicators. However, the other models showed acceptable performance scores in predicting depression and anxiety. Thus, the findings of our study are consistent with other studies that assessed ML models in predicting depression and anxiety among adolescents and adults [4,6,17,43-48]. In Priya et al [4], the NB model had the highest accuracy levels for anxiety, depression, and stress, whereas the F1-score showed that the RF model had the highest performance measure for stress symptoms. Furthermore, the results are consistent with other studies that assessed the ML models in predicting depression and anxiety among adults [44-46]. The studies showed that the ML models are efficient in predicting depression and anxiety symptoms.

Significant risk factors for schoolchildren's depression and anxiety were found. Poor family and school conditions, such as low levels of school and family support, home and school violence (bullying behaviors), and low levels of positive health perception were highly significant to the risk of suffering from severe and moderate depression and anxiety, mainly among boys. This has been observed through the implementation of ML models. Additionally, the same results were obtained when controlling and not controlling for school type, age, and place of residence.

Furthermore, the data have shown that health-associated factors also had a significant effect on students' growth, cognitive development, and academic performance [49]. Moreover, it has been found that negative health conditions, such as obesity and PTSD, had a direct negative impact on student's mental health and cognitive development. Conversely, mother's education, gender, age, locality, physical activity, and good nutrition had less significant effects on mental health issues than the abovementioned variables.

These findings are consistent with other related studies that have found a strong association between mental health problems and risk factors such as school and home violence or negative health conditions [3,43,50,51]. Similar to previous studies, the research has shown that specific conditions such as obesity and PTSD are significantly correlated to depression and anxiety [5,26,52]. Furthermore, the prediction accuracy results obtained from the implemented ML algorithms are equivalent to the prediction accuracy rates obtained from related studies in the fields of mental health, as the RF model proved to be the most significantly accurate model [4,53].

Moreover, this study shows that several ML algorithms can predict depression and anxiety and their associated risk factors. The used algorithms successfully managed to predict the target variables, and the NB algorithm had the lowest accuracy rate for both anxiety and depression. However, it could be considered for the prediction of mental health conditions among schoolchildren with the presented variables. The RF ML model, on the other hand, proved the most effective in predicting depression and anxiety when students' health (physical and social) and related risk factors are considered. Overall, the classification accuracies were all at a favorable level. These findings show the importance of integrating ML techniques in the fields of mental health. These findings are consistent with other studies that indicated the importance of using ML in psychiatric and mental health diagnosis [4,54,55]. In the study of Haque et al [56], the RF model reported the highest accuracy among other ML algorithms (RF, XGBoost, and DT) in detecting depression among children aged 4-17 years. Furthermore, Sau et al [57] assessed 5 ML algorithms (logistic regression, NB, RF, SVM, and CatBoost) in identifying risk factors associated with anxiety symptoms, with the CatBoost model reporting the highest accuracy among the other ML models.

In this study, the risk features importance rating for anxiety and depression was estimated, which showed that age, bullying behaviors, PTSD, life satisfaction, and anxiety are the 5 most important features in predicting depression symptoms, whereas psychosomatic symptoms, age, bullying behaviors, and depression symptoms are the most important features in predicting anxiety symptoms. The study findings are consistent with other studies that found that the children's age, academic score, family income, social and family support, school and home violence, and physical activities are significant and important factors in predicting schoolchildren's depression and anxiety [13,15]. An important contribution of this study is the classification of schoolchildren at high risk to develop anxiety and depression symptoms. The most important features in our model are consistent with previous studies, which found that the population with high risks of anxiety and depression has a higher rate of tobacco use, increased BMI, and decreased academic performance [21,58-60].

Strengths and Limitations

Currently, the standard mental assessment scales are used in detecting schoolchildren's depression and anxiety, and it is mainly based on the health care system screening programs, which are mainly used when abnormal symptoms are witnessed. Furthermore, the current practices might fail in detecting the main associated factors with a subsequent delay in detection and intervention. Our prediction model combined the different levels of risk factors, including physical, mental, and sociodemographic factors. Our model is less dependent on the schoolchildren's subjective awareness of health status and health care screening behaviors; thus, the model improved the automatic and early detection of schoolchildren's depression and anxiety.

Overall, our study strengthens the need for the implementation and deployment of ML in addressing mental health problems.

The early detection and prediction of risk factors associated with mental health symptoms (depression and anxiety) can enhance the development of intervention and prevention programs that improve children's growth and cognitive development. Thus, this research study not only introduces the ML techniques in predicting depression and anxiety but also provides the policy makers with the power of ML in the early prediction and diagnosis of schoolchildren's mental health problems.

The study is limited by the number of variables. Based on the findings presented in this paper, future research will benefit from expanding the study by adding additional associated factors, including cognitive development skills, in-school student behavior, social activities, and digital media activities. Furthermore, variables related to external factors, such as the incidence of violence in the community, presence of soldiers, checkpoints, and mobility restrictions are not present in this study, yet these variables would be very relevant to further investigate the risk factors associated with anxiety and depression among schoolchildren in the Palestinian context.

The presence of these variables would further enhance the accuracy of the ML prediction models for anxiety and depression.

Conclusions

The study assessed the accuracy and performance of 5 ML models in predicting the associated health factors on Palestinian schoolchildren's depression and anxiety. Based on the results presented, this research concludes that ML algorithms, particularly (but not exclusively) RF and neural network, are effective predictive models for students' mental health status. These models could be integrated into schools' information systems for the automatic prediction of students' depression and anxiety based on key features. In this manner, students, families, school staff, and administration will be able to tackle issues that might affect students' mental health using the obtained prediction results. Likewise, by making use of accurate ML techniques, such as RF, public health professionals, health care providers, and decision makers will be able to predict rising issues and implement relevant intervention programs to enhance students' health, education, and well-being.

Acknowledgments

The authors wish to thank Al-Quds University and the Palestinian Ministry of Education for authorizing us to conduct the study, as well as the study participants for their collaboration. We wish to acknowledge all fieldworkers, whose hard work made this research possible. We further wish to thank the Ministry of the Education team for their support in data gathering and collection.

Data Availability

The data sets generated and/or analyzed during the current study are available from the corresponding author on reasonable request.

Conflicts of Interest

None declared.

Abstract

Background: eHealth literacy is emerging as a crucial concept for promoting patient self-management in an overloaded hospital system. However, to the best of our knowledge, no tool currently exists to measure the level of eHealth literacy among French-speaking people. The eHealth Literacy Scale (eHEALS) is an easy-to-administer 8-item questionnaire (5-point Likert scale, ranging from strongly disagree to strongly agree) that has already been translated into many languages. Currently, it is the most cited questionnaire in the literature.

Objective: The aim of this study was to translate eHEALS to French and validate the French version of eHEALS (F-eHEALS).

Methods: The validation of the F-eHEALS scale followed the 5 steps of the transcultural validation method: double reverse translation, validation by a committee of experts (n=4), pretest measurement to check the clarity of the items (n=22), administration of the scale in French via a web-based quantitative study combined with two other questionnaires (Health Literacy Survey-Europe-16 and Patient Activation Measure-13; N=328 students), and finally test-retest (n=78) to check the temporal stability of the measurements obtained from the scale.

Results: The results obtained for the measurement of factor structure, internal consistency, and temporal stability (intraclass correlation coefficient=0.84; 95% CI 0.76-0.9; $F_{77,77}=6.416$; $P<.001$) prove the validity and fidelity of the proposed scale. The internal consistency of F-eHEALS was estimated by Cronbach α of .89. The factor analysis with varimax rotation used to validate the construct showed a 2-factor scale. The effect of the construct was analyzed using 3 hypotheses related to the theory. The F-eHEALS score was correlated with the Health Literacy Survey-Europe-16 score ($r=0.34$; $P<.001$) and the Patient Activation Measure-13 score ($r=0.31$; $P<.001$).

Conclusions: F-eHEALS is consistent with the original version. It presents adequate levels of validity and fidelity. This 2D scale will need to be generalized to other populations in a French-speaking context. Finally, a version taking into account collaborative applications (ie, Health 2.0; eg, Digital Health Literacy Instrument scale) should be considered on the basis of this study.

Introduction

Background

eHealth (or connected health) is an emerging field that incorporates various stakeholders, for instance, in the fields of medical informatics, public health, and companies [1]. This field can be an interesting opportunity to overcome the weaknesses of the current health systems and help health professionals and patients by making them active in their own health [1,2]. To benefit from this emerging field, connected medical devices available to the general public have to be accessible to all user profiles [3,4], regardless of the environment in which they are used. This means that patients must be able to use these tools correctly [5]. Using health information technology requires a specific set of knowledge and skills such as the ability to read, use computers, search for information, understand health information, and contextualize it [6]. All these skills relate to *eHealth literacy* [6]. In other words, assessing individuals' skills in using eHealth is equivalent to assessing their level of eHealth literacy. eHealth literacy scales have been developed to address this need [7].

eHealth Literacy: Definition and Theoretical Models

According to the *Institute of Medicine*, eHealth literacy refers to a person's skills "to search for, find, understand and evaluate health information from electronic sources and to apply the knowledge gained to treat or solve a health problem" [8]. This definition highlights the importance of contextual factors, including the media through which health information is disseminated and the level of health literacy in relation to these media [6]. Current media for the diffusion of health information include interactive tools for behavior change, such as applications, websites, and phone support services [9,10]. However, there is significant difference between the use of technology and the use of web-based health information (ie, digital literacy or eHealth literacy) [11], even if both the use of technology and the use of web-based health information are activities associated with eHealth literacy. Therefore, Norman and Skinner [6] aimed to identify the skills required to use this information.

Early studies in this field focused on *general literacy* (ie, "the ability to understand and use written information...to achieve personal goals and expand one's knowledge and abilities" (p12) [12]. Research has expanded into areas such as health literacy and eHealth literacy in relation to patient health [13]. The fundamental theories of eHealth literacy are, in part, based on social cognitive theories [14] and self-efficacy theories [15-17]. These theories consider self-confidence as a precursor of the behavior changes and skills needed to acquire high level of eHealth literacy. On the basis of these theories, Norman and Skinner [6] proposed a model of eHealth literacy (*lily model*) based on six different skills (or *literacies*) applied to health: (1) *traditional literacy* and numeracy, (2) health literacy, (3) information literacy, (4) scientific literacy, (5) media literacy, and (6) computer literacy. According to Norman and Skinner [6], eHealth literacy consists of a combination of all these 6 *core literacies*. These authors developed the *eHealth Literacy Scale* (eHEALS), an eHealth literacy rating scale to promote

eHealth and identify strategies to help patients use digital media in health. The eHEALS does not measure skills directly, but "measures consumers' *perceived* skills and comfort with eHealth" (p24) [6].

eHealth Literacy Scales and Cross-cultural Validations

Currently, several tools are available to assess eHealth literacy. In a systematic review of health literacy instruments [18], the authors identified 8 instruments including the eHEALS [7], *eHealth Literacy Questionnaire* [19], *eHealth Literacy Framework* [20], *Digital Health Literacy Instrument* (DHLI) [21], *eHealth Literacy Assessment Toolkit* [22], eHEALS-Extended [23], *Electronic Health Literacy Scale* [24], and *Transactional eHealth Literacy Instrument* [25]. To the best of our knowledge, none of these scales have been validated in French.

Several reasons led us to choose to validate eHEALS in French [7]. First, the eHEALS is a relatively short tool (8 items), making it easy to administer and combine with other scales. Second, currently, it is the most widely used scale for measuring eHealth literacy in international scientific literature [26]. This tool has been translated into different languages over the past 10 years [27-39]. This shows that it can be used in various languages and cultural contexts. However, currently, its French translation does not exist. Furthermore, one of the advantages of eHEALS is that it can be adapted to different populations and different contexts. The scale was administered to different categories of individuals, such as older people [40], young adults [41], nursing students [42], and teenagers [43].

The eHEALS Original Version

The original version of eHEALS, created by Norman and Skinner [7], is composed of 10 items relating to the 6 literacy types of the *lily* model mentioned previously. A total of 8 items assess users' knowledge; comfort; and perceived skills in finding, assessing, and applying digital health information to answer health questions. The scale also includes 2 additional items that focus on participants' perception of the use of the internet as a decision-making tool and its usefulness in collecting health information (these items are not included in the total score).

The psychometric characteristics of the original scale were assessed on a sample of teenagers (N=664; mean age 14.95, SD 1.24 years). Cronbach α was .88, and the test-retest reliability was 0.68 [7]. The authors used factor analysis and highlighted a single-factor solution (eigenvalue=4.479; 56% of the variance explained).

Factors Affecting eHealth Literacy

Several factors are associated with eHealth literacy: sociodemographic characteristics, health literacy, and commitment to health. Studies do not agree on the association with sociodemographic characteristics (gender, education level, and health outcomes) [38,44-46]. As some studies show differences in eHealth literacy according to these sociodemographic characteristics and others do not, obtaining an overview of the eHealth literacy level of a population is complex. Chesser et al [47] showed in a systematic review that

eHealth literacy was associated with the level of education and advanced age, even if there is some variability among the older population.

Contrary to the association with sociodemographic characteristics, there seems to be a consensus on the relationship between health literacy and eHealth literacy [38,45,48,49], health literacy being one of the components of eHealth literacy in the model suggested by Norman and Skinner [6]. Neter et al [49] found a positive, moderate, and significant correlation between the scores on Health Literacy Survey-Europe-16 (HLS-EU-Q16) and eHEALS ($r=0.36$; $P<.05$) in a sample of 199 adults. Similar results ($r=0.43$; $P<.001$) were obtained by Duplaga et al [48] on a sample of 199 young adults (aged 18-29 years). Wängdahl et al [38] also found a moderate positive correlation ($r=0.47$; $P<.05$) between the HLS-EU-Q16 and the Swedish version of eHEALS in a sample of 323 adults.

Furthermore, there seems to be a link between patient commitment to health and the level of eHealth literacy. Patient commitment to health, also known as *patient activation*, is commonly measured by the *Patient Activation Measure-13* (PAM-13) scale [50]. For instance, Lee et al [51] assessed the level of activation among 399 adults who were chronically ill, using PAM-13 and their eHealth literacy level using eHEALS. The authors showed a positive, moderate, and significant correlation between these 2 variables ($r=0.50$; $P<.001$).

In summary, previous studies agree on the link between health literacy and eHealth literacy and the link between patient health activation and eHealth literacy. However, the links between the sociodemographic characteristics of individuals and eHealth literacy seem to be less convergent.

Objective

The objective of this study was to translate eHEALS, which is already developed by Norman and Skinner [7], into French and validate it with a student population.

Methods

Procedure

To conduct the translation, adaptation, and validation of eHEALS [7], we followed the American Psychological Association guidelines [52] and the 5 steps recommended by Vallerand [53]: translation, validation with experts, pretest measurement, administration of the tool, and test-retesting. Figure S1 in [Multimedia Appendix 1](#), translated from Vallerand [53], shows these steps.

These 5 steps were conducted between December 2019 and March 2020.

Ethics Approval

This study complied with the principles set out in the Declaration of Helsinki of 1964 and its subsequent amendments. Before the experiment, the participants signed a web-based consent form, and the questionnaire was validated by the research ethics committee of the university Picardie Jules Verne. The participants did not receive any financial compensation for their participation, and they agreed to participate in the study.

The anonymity, confidentiality, and secure storage of the data were guaranteed to the participants and respected.

Step 1: Translation of eHEALS Into French by a Process of Double Reverse Translation—Preparation of a Preliminary Version

We have been authorized to translate the original eHEALS scale by its authors [7]. After authorization, we performed a double reverse translation of the eHEALS by 2 professional translators who had French as their native language, independently of each other. This method is considered “ideal for drafting the psychological instrument” (our translation; p665) [53]. Then, the 2 French versions obtained were retranslated into English by 2 professional translators who had English as their native language and had not seen the original version, again independently of each other. In total, 2 French versions and 2 preliminary English versions were produced at the end of this phase.

Step 2: Validation by a Committee of Experts

A committee of 4 experts, 3 (75%) of whom are authors of the manuscript, consisting of 1 (25%) expert in neuropsychology, 1 (25%) expert in cognitive psychology, and 2 (50%) other experts in ergonomics, met to examine the quality of the translations and agree on the best version. To do so, they compared the different translated versions with the original English version, taking into account the French cultural context and checking the clarity of the language. This committee made some minor changes to the selected items. A French version of eHEALS (F-eHEALS) was established after the committee’s intervention. The committee members discussed in detail the translation of the term *health resources*. The suggestions for translation were as follows: “ressources en santé,” “ressources sur la santé,” or “ressources de santé.” Members agreed on “ressources sur la santé” as being more inclusive and easy to understand. The committee was also unsure whether to propose the term “information” instead of “resources.” Finally, the term “resources” (“ressources” in French) was retained to not differ from the original version.

Step 3: Pretest Measurement for Clarity of Items

We performed a pretest measurement to check the clarity of the items (ie, unambiguous wording of the translated items). A total of 22 participants were asked to evaluate the items (including the instructions) using a web-based questionnaire. To do so, participants had to read each item and judge its clarity on a scale from 1 (*not at all clear*) to 7 (*very clear*). Items that were scored ≤ 4 needed to be reviewed. For each item, participants could also leave comments on potential ambiguities and justify their scores for each item. The results of this pretest measurement were used to create a final version of F-eHEALS.

Step 4: Administration

A total of 344 students aged 16 to 33 years responded to F-eHEALS, two additional scales (HLS-EU-Q16 and the PAM-13), and questions on their sociodemographic characteristics.

This population was relevant because the suitability of the tool for a population of young adults has already been demonstrated

[32,33,35,37,41,42]. To target this population, the scales were shared on Facebook groups of students from several French universities. All respondents had to be students and have French as their native language.

The instructions given to the participants explained the main objective of the study regarding the translation of the eHEALS scale and provided some explanations to justify the presence of the other questionnaires (ie, HLS-EU-Q16 and PAM-13): “It concerns your perceptions of your ability to search, find and process health-related information on the Internet, your involvement in your health.” As there appears to be a relationship among patient commitment, health literacy, and eHealth literacy, we chose to add PAM-13 and HLS-EU-Q16 to the questionnaires to measure concurrent validity.

Each participant had to consent to the study by means of electronic validation to be able to access the questionnaires. First, the participants completed information about their age, gender, level of education, and field of education and a question related to their health conditions. Then, they were asked to complete F-eHEALS, HLS-EU-Q16 [54], and finally, PAM-13 [50]. After completing the questionnaires, participants were asked if they wanted to be contacted again for the test-retest by providing an email address.

Step 5: Test-Retest

Test-retest stability is the best indicator of the metric quality of a scale relative to other fidelity indices [55]. This evaluation has the specificity of measuring the temporal stability of the measurements [53]. A total of 170 participants agreed to be contacted on a later date. The same questionnaires with the same format (instructions, consent, and questionnaires) were sent to the participants 1 month after their initial enrollment. Of the 170 participants, 84 (49.4%) participants responded to the questionnaires.

Measures: Questionnaires and Data Analysis

F-eHEALS Questionnaire

F-eHEALS, similar to the original version of eHEALS developed by Norman and Skinner [7], consists of 8 items measuring eHealth literacy on a 5-point Likert scale (ranging from 1=*strongly disagree* to 5=*strongly agree*). A total of 2 other items, related to the importance and usefulness that individuals attach to the internet for making decisions about their health, are included, but are not to be counted in the final rating. The eHEALS score depends on the points obtained for each item (*strongly disagree* scores 1 point and *strongly agree* scores 5 points). The eHEALS score ranges from 8 to 40 points. The higher the score, the higher the level of eHealth literacy. The analysis of the items was conducted on the 8 items that make up eHEALS [7].

HLS-EU-Q16 Scale

The *HLS-EU-Q16* [54] is the short version of *HLS* developed by Sørensen et al [56]. It has been translated into French [57]. This version consists of 16 items, 13 (81%) of which assess the 4 types of health literacy skills: the ability to access, understand, evaluate, and apply health information [56]. The respondent has to assess their own ability to access the information (eg,

“Please indicate on a scale from very easy to very difficult, how easy it is for you to understand your doctor’s or pharmacist’s instructions on how to take your medication?”). Overall, 4 categories of answers were proposed on a 4-point Likert scale. *Difficult* or *very difficult* responses do not score any points, whereas *easy* and *very easy* responses score 1 point. Then, the total score is calculated: the higher the score, the higher the level of health literacy.

French Version of PAM

PAM-13 [50], translated into French [58], is a 13-item scale that assesses a patient’s knowledge, skills, and confidence in self-managing their health or chronic illness. The respondent has to assess their ability to self-manage their health (eg, “All things considered, I am the person who is responsible for taking care of my health”). Respondents provide their answers on a 5-point Likert scale (from 1=*strongly disagree* to 5=*strongly agree*). Then, the total score is calculated based on the participants’ response to each item. The total score for the items ranges from 13 to 65 points; the higher the score, the higher the level of commitment to health.

Data Analysis

Overview

The results were analyzed using SPSS (version 22; IBM Corp). All the data of this study are in open access [59]. The fidelity assessment was performed by analyzing the internal consistency of the tool, as assessed by Cronbach α . Cronbach α was $>.7$, which indicates that the items in the study are consistent [60]. Construct validity was measured by means of three statistical analyses: (1) exploratory factor analysis (principal component analysis with varimax rotation), (2) analysis of interitem correlations, and (3) analysis of construct effects using Pearson correlations among HLS-EU-Q16, PAM-13, and F-eHEALS.

Exploratory Factor Analysis

To verify whether the measures are suitable for factor analysis, we used the Kaiser-Meyer-Olkin (KMO) and Bartlett sphericity tests. KMO values close to 1 are considered to be ideal, and statistically significant result in the Bartlett sphericity test shows that the correlation matrix is not an identity matrix. The multivariate normality test (distance of Mahalanobis) was used to ensure the normality of the data. If the Mahalanobis maximum value is less than the critical value, multivariate normality is existing. Then, we used principal component analysis (varimax rotation; Kaiser criterion >1), which is a multivariate interdependence technique that allows the associated variables and the measurement of latent constructs to be determined. To conduct this analysis, a minimum statistical power is required. Hair et al [61] consider it necessary to have a ratio of 10 participants per variable in the analysis, which will correspond to a minimum of 80 participants for our scale. Factor scores >0.71 were considered to be excellent, those >0.63 to be very good, those >0.55 to be good, those >0.45 to be acceptable, those close to 0.32 to be poor, and those <0.32 to be very poor [62].

Analysis of Interitem Correlations

The analysis of interitem correlations allows the internal coherence of the scale to be assessed. To measure this construct, the elements must be sufficiently correlated ($r > 0.4$).

Analysis of the Effects of Constructions

The construct effect makes it possible to verify the links between the construct and the variables identified in the literature [53]. We formulated 3 hypotheses about the links between health literacy and other variables that have previously been shown to be related to eHealth literacy. The measurement of the effect of the construction is based on 3 hypotheses: (1) the level of eHealth literacy is not correlated with sociodemographic characteristics (gender and health outcomes), (2) the level of eHealth literacy will be positively and moderately correlated with the level of health literacy, and (3) the level of eHealth literacy will be positively and moderately correlated with the level of patient activation. We used Pearson correlations to validate (or invalidate) the hypotheses.

Results

Translation and Equivalence Verification With the Original Version (Steps 1, 2, and 3)

During the pretest measurement to assess item clarity ($n=22$; mean age 38.47, SD 8.44 years; range 26-63 years), none of the F-eHEALS items were rated < 4 (Multimedia Appendix 2). All items had been rated a mean score of 6.27 (SD 1.15) and, therefore, were considered to be understandable and clear. Only items 5 and 6 were modified in a minor way by changing the term “ressources” to “informations,” the first term being considered to be very confusing by the respondents. This term had already been discussed by the expert committee.

Validation (Steps 4 and 5)

Sociodemographic Characteristics of the Sample

Of the 344 participants who responded to this scale, we excluded 15 (4.4%) participants: 7 (47%) participants were not students, 8 (53%) were aged > 35 years and thus considered to cause risk of age bias, and 1 (7%) did not give their consent. Thus, 95.3% (328/344) of the participants (mean age 21.22, SD 2.7 years; 274/328, 83.5% were women; 52/328, 15.9% were men; and 2/328, 0.6% were nonbinary) were eligible for step 4. Details of respondent characteristics are presented in Multimedia Appendix 3.

Internal Consistency and Temporal Stability

Of the 344 participants who responded to the questionnaires, 170 (49.4%) participants agreed to be recontacted for the retest. Of these 170 participants, 84 (49.4%) responded to the

questionnaire. Of the 84 participants, 6 (7%) participants had to be excluded because their identification did not allow a link to be made with the database of contacts from the first test. Thus, 93% (78/84) of the participants were included in the retest. The temporal stability of our sample was (intraclass correlation coefficient=0.84; 95% CI 0.76-0.9; $F_{77,77}=6.416$; $P < .001$). We also observed a strong and positive correlation between the 2 sessions ($r=0.72$; $P < .001$). The internal consistency of F-eHEALS was estimated by a Cronbach α of .89.

Assessment of Construct Validity

Exploratory Factor Analysis by Principal Component Analysis

The Bartlett sphericity test was significant ($N=328$; $\chi^2_{28}=1616.3$; $P < .001$), and the KMO index was 0.85. The multivariate normality test was performed (distance of Mahalanobis: dof=8; mean 7.976, SD 5.317; minimum=0.876; maximum=30.146). None of the outliers were removed.

The analysis of the main factor produced an eigenvalue of 4479. The first 2 factors were extracted on the basis of Kaiser criteria, because they have an eigenvalue > 1 . The first factor (item) alone explained 57.72% of the total variance of the 8 items analyzed. Thus, the first 2 factors (items) explained 71.54% of the total eigenvalue variance. In Multimedia Appendix 4, we can see that the Cattell scree test validates Kaiser criteria because it is located between item 2 and item 3.

Examination of the factor structure of the initial scale revealed 2 factor axes (Table 1). When analyzing components 1 and 2 in relation to the 8 items before rotation, we observed a loading of all items for the first factor. We also observed 2 similar correlations between the 2 factors and item 7. We proceeded to a varimax rotation to obtain a simple factorial representation. After varimax rotation, we observed that items 1, 2, 3, 4, and 5 loaded on the first factor.

Item 1 corresponds to “I know how to find helpful health resources on the Internet,” item 2 corresponds to “I know how to use the Internet to answer my health questions,” item 3 refers to “I know what health resources are available on the Internet,” item 4 refers to “I know where to find helpful health resources on the Internet,” and item 5 corresponds to “I know how to use the health information I find on the Internet to help me.” For factor 2, items 6 and 7 were loaded. Item 6 corresponds to “I have the skills I need to evaluate the health resources I find on the Internet” and item 7 refers to “I can tell high quality from low quality health resources on the Internet.” Item 8, corresponding to “I feel confident in using information from the Internet to make health decisions,” seems to straddle the 2 factors after varimax rotation.

Table 1. Principal component factor analysis before and after varimax rotation^{a,b}.

Item	Principal component analysis before varimax rotation		Principal component analysis after varimax rotation	
	Factor 1	Factor 2	Factor 1	Factor 2
1	<i>0.79</i> ^c	-0.36	<i>0.86</i>	0.12
2	<i>0.86</i>	-0.31	<i>0.89</i>	0.21
3	<i>0.86</i>	-0.27	<i>0.87</i>	0.23
4	<i>0.80</i>	-0.13	<i>0.74</i>	0.32
5	<i>0.79</i>	0.03	0.65	0.45
6	0.66	0.58	0.24	<i>0.85</i>
7	0.61	0.66	0.16	<i>0.88</i>
8	0.66	0.13	0.48	0.46

^aVariance accounted for=71.54%.

^bCronbach α =.89.

^cScores >0.7 have been italicized.

Patterns of Interitem Correlation

After analysis of the correlation matrix ([Multimedia Appendix 5](#)), we found that the 8 items in F-eHEALS are positively correlated with each other. The values were in the range of 0.30 to 0.86. The lowest correlation recorded was between item 1 and item 7 ($r=0.3$). In contrast, the highest correlation observed

was between item 2 and item 3 ($r=0.86$). Item 7 appeared to have the lowest correlation with the other items. The average interitem correlations ranged from 0.53 to 0.78 ([Table 2](#)). The means of the interitem correlations of the original eHEALS scale ranged from $r=0.51$ to 0.76 [7], which is close to the F-eHEALS results.

Table 2. Descriptive statistics by items (N=328).

Item	n (%)	Mean (SD) ^a	Range	Interitem correlation	Original interitem correlation, (Norman and Skinner [7])
1	328 (100)	3.31 (1.06)	1-5	0.69	0.68
2	328 (100)	3.25 (1.14)	1-5	0.78	0.70
3	328 (100)	3.32 (1.11)	1-5	0.78	0.68
4	328 (100)	3.53 (1.06)	1-5	0.71	0.76
5	328 (100)	3.48 (1.07)	1-5	0.71	0.73
6	328 (100)	3.22 (1.19)	1-5	0.59	0.63
7	328 (100)	3.72 (1.08)	1-5	0.53	0.55
8	328 (100)	2.34 (1.03)	1-5	0.57	0.51

^aOverall mean (SD)=26.16 (6.61).

Concurrent Validity of the Scale

The F-eHEALS score correlated positively and significantly with the HLS-EU-Q16 score ($r=0.34$; $P<.001$) and the PAM-13 score ($r=0.31$; $P<.001$). We did not observe significant difference between gender ($F_{3,324}=1.56$; $P=.20$), health outcomes (chronic disease; $F_{1,326}=0.017$; $P=.89$), and F-eHEALS score.

Discussion

Principal Findings

The objective of the study was to translate eHEALS to French and validate F-eHEALS in a student population. The results of this study validated its translation and adaptation, allowing us to propose a French version of the validated eHEALS scale ([Multimedia Appendix 6](#)).

Comparison With Previous Studies

Translation

The translation process highlighted the complexity of translating from English to French. Although the translated content must remain the same as the original version, reflecting the real meaning of the items, it also has to be adapted to the language and culture of the target population. During the double reverse translation, terms were discussed by the expert committee—specifically, *health resources*, having been mentioned in other translations [38,45], illustrates the universal complexity of translating from English to other languages. After conducting the pretest measurement to check the clarity of the items, the scale was presented to a sample of 328 students.

Validation

Fidelity

The fidelity of F-eHEALS was measured using internal consistency and temporal stability. Internal consistency was evaluated using Cronbach α , and temporal stability was evaluated by confidence index. In our study, internal consistency (Cronbach α =.89) was judged to be excellent according to recommendations of Nunnally [60]. Regarding temporal stability, we observed good fidelity [63] of our sample. These results are congruent with those of the original study [7], which obtained a similar result (Cronbach α =.88). Moreover, our results regarding fidelity are consistent with those of several studies that have shown a higher Cronbach α than the original (ie, >.88) [27-29,38-41].

Construct Validity

The Bartlett sphericity test was significant, and the KMO sampling precision index can be described as excellent. These results indicate that the correlations between the items are of good quality and thus legitimize the factor analysis. In addition, as the current sample includes 328 participants, this was correct and the statistical power was considered to be sufficient [61].

Construct validity highlighted a 2-factor (or 2D) structure. Although this contradicts some studies [27,28,33,35,40,41,64], other studies have also revealed a 2-factor structure [30,37,39,49,65-67]. This 2-dimensionality is fully consistent with the multidimensional property of eHealth literacy, which is composed of different literacies [6]. These results are consistent with 3 studies [65,67,68] that found the item structure similar to ours (ie, information seeking: items 1, 2, 3, 4, 5, and 8 and information appraisal: items 6 and 7). Nevertheless, in the systematic analyses, Lee et al [18] demonstrated the lack of high-quality evidence for structural validity and internal consistency for 2-factor scales in the 3 studies, which shows the instability of 2-factor scales. Therefore, it is important to remain cautious about this structure.

We observed a problematic load factor for item 8. In the item loading analysis, item 8 was in the first factor before rotation; however, item 8 straddles the 2 factors after varimax rotation. This analysis is consistent with the Italian translation and validation before rotation [65]. It is likely that if the authors had rotated, they would probably have found similar results. Many other similarities were observed between this study and the Italian validation study (eg, Cronbach α , variance accounted, and 2D scale). This is probably owing to the common Latin roots of French and Italian languages. However, these similarities are not observed in other Latin translations (eg, Portuguese and Spanish). Moreover, in an Italian validation with a population of nurses, De Caro et al [33] observed a unidimensionality. This shows the instability of eHEALS according to the population. Item 8 also seemed problematic in other validations observing a 2D scale [39]. This is likely owing to the fact that in the original article, the loading of item 8 was not excellent. Item 8 loads at 0.6 without rotation, which does not seem to be *good* [62]. However, to the best of our knowledge, no study on the validation of eHEALS has removed item 8 from the questionnaire, despite its weakness. Therefore,

despite the difficulties of discrimination and the ambiguous load factor of item 8, consistent with Dale et al [39], Gazibara et al [37], Richtering et al [66], and Shiferaw [30], we decided to retain it.

Depending on the language, item 8 can switch between the first [37] and second factors [65]. Items 1 to 5 begin with "I know," whereas items 6 and 7 refer to the notion of self-evaluation, such as "I have the skills" or "I can." Item 8 seems to be close to the notion of reliability and trust ("I feel confident") and, therefore, to the notion of self-evaluation including items 6 and 7. Thus, this double factor divides the items into two dimensions: those measuring information-seeking skills (items 1-5) and those measuring the evaluation of health information (items 6-8).

It would seem appropriate to measure a mean score for each underlying factor, rather than an overall score. However, considering the instability of some items, it seems more relevant to measure an overall score. Moreover, a score for each factor can compromise comparisons and standardization, with most studies using an overall score. Considering these indications, we suggest calculating scores for each factor and an overall score in future uses of F-eHEALS.

The variance explained by the 2-factor model in this study is also relatively high compared with that in other similar validation studies in other languages [27,32,35].

The quality of representation of the items (ie, whether the items are well represented by the dimensions of the construct) was judged to be excellent because all the items showed a score >0.45. Thus, we have decided to retain all items in the translation and validation of eHEALS. The means of the interitem correlations of the original eHEALS scale [7] are consistent with the F-eHEALS results. The effect of the F-eHEALS scale construction was acceptable. To validate its content, we formulated 3 hypotheses, which have proved to be correct. The first hypothesis, according to which there was no link between user characteristics (age, gender, and health status) and the level of eHealth literacy, was validated. We found no significant correlations between the F-eHEALS scores and the sociodemographic characteristics of our sample. These results are consistent with the results of other studies regarding gender [44,47] and health outcomes [44]. Our second hypothesis, according to which there was a link between health literacy and eHealth literacy, was validated. In addition, the health literacy score, measured using HLS-EU-Q16, was positively and moderately correlated with the F-eHEALS score. These results are consistent with those of other studies [38,45,48,49]. Our third hypothesis, expecting a link between the level of patients' health activation and the level of eHealth literacy, was validated. The patient health activation score, measured using the PAM-13, was positively and moderately correlated with the F-eHEALS score, which is consistent with the study by Lee et al [51].

Limitations

This study has some limitations. First, our sample was very homogenous in terms of important factors influencing eHealth literacy, as it was composed exclusively of young adult students for a practical reason. Moreover, this scale was administered to

different categories of individuals, such as older adults [40], young adults [41], nursing students [42], and teenagers [43]. Therefore, this scale should be validated in a more representative sample of French-speaking populations in a subsequent study. Second, the PAM-13 scale has only been partially validated. Only the analysis of internal consistency and temporal stability was conducted [58]. A more complete validation is necessary. Similarly, confirmatory factor analysis should be performed. Third, as F-eHEALS is a 2D scale, we recommend scoring the 2 subscales separately and measuring the overall score, as done in this study. Fourth, French scientific literature is relatively scarce in the area of health literacy. Our comparisons were made on the basis of a wide variety of cultures and languages. We hope that translations of scales, such as F-eHEALS, will promote studies in the field. Fifth, eHEALS, HLS-EU-Q16, and PAM-13 are subjective assessments [38], as the level of eHealth literacy is self-reported by respondents and may be overestimated or underestimated. Therefore, it will be interesting to clarify the links between subjective and objective assessments to better understand the margins of error in these tests.

Recently, since the development of interactive applications—social networks, forums, and so on (Health 2.0)—that help people communicate about their health, eHealth literacy is required to be considered as a broader skill [35]. To

bridge the *digital divide*, it will be important to use instruments that measure all varieties of eHealth literacy. Even if eHEALS is strongly correlated with DHLI [21], considering these aspects of interaction, we encourage French-speaking researchers to integrate new items related to these new forms of interaction into eHEALS or to translate and validate DHLI [21] to measure the variability of eHealth literacy encompassing the competencies from Health 2.0 and to allow the French-speaking community to catch up in this field.

Conclusions

This study was conducted with a population of young adult students for a practical reason, which allowed us to propose the first eHealth literacy scale that is validated in terms of fidelity and the validity of F-eHEALS to the French-speaking community. This 2D scale will need to be generalized to other populations in a French-speaking context. Finally, a version considering interactive applications (ie, Health 2.0 and DHLI scale) should be considered on the basis of this study. The value of such a scale seems to be even more relevant as eHealth has never been as much in demand as in recent years and will probably be even more so in the future, particularly owing to the increasing use of eHealth technologies. We hope that this study will enable other authors to initiate studies in the field of eHealth literacy in the French context.

Acknowledgments

This project was financially supported by the European Regional Development Fund, Evolucare, and *Programme d'Investissements d'Avenir*. The authors thank their translators, Catherine Jackson, Patrick Jackson, and Guillaume Fenger and the Maison des Langues de l'Université de Picardie Jules Verne (Amiens). The authors would also like to thank Yannick Gounden for his participation in the expert committees, Vanessa Laguette for the diffusion of the questionnaires, and all the students who agreed to participate in the study.

Abstract

Background: App-based mobile health exercise interventions can motivate individuals to engage in more physical activity (PA). According to the Fogg Behavior Model, it is important that the individual receive prompts at the *right* time to be successfully persuaded into PA. These are referred to as *just-in-time* (JIT) *interventions*. The Playful Active Urban Living (PAUL) app is among the first to include 2 types of JIT prompts: JIT adaptive reminder messages to initiate a run or walk and JIT strength exercise prompts during a walk or run (containing location-based instruction videos). This paper reports on the feasibility of the PAUL app and its JIT prompts.

Objective: The main objective of this study was to examine user experience, app engagement, and users' perceptions and opinions regarding the PAUL app and its JIT prompts and to explore changes in the PA behavior, intrinsic motivation, and the perceived capability of the PA behavior of the participants.

Methods: In total, 2 versions of the closed-beta version of the PAUL app were evaluated: a basic version (Basic PAUL) and a JIT adaptive version (Smart PAUL). Both apps send JIT exercise prompts, but the versions differ in that the Smart PAUL app sends JIT adaptive reminder messages to initiate running or walking behavior, whereas the Basic PAUL app sends reminder messages at randomized times. A total of 23 participants were randomized into 1 of the 2 intervention arms. PA behavior (accelerometer-measured), intrinsic motivation, and the perceived capability of PA behavior were measured before and after the intervention. After the intervention, participants were also asked to complete a questionnaire on user experience, and they were invited for an exit interview to assess user perceptions and opinions of the app in depth.

Results: No differences in PA behavior were observed ($Z=-1.433$; $P=.08$), but intrinsic motivation for running and walking and for performing strength exercises significantly increased ($Z=-3.342$; $P<.001$ and $Z=-1.821$; $P=.04$, respectively). Furthermore, participants increased their perceived capability to perform strength exercises ($Z=2.231$; $P=.01$) but not to walk or run ($Z=-1.221$; $P=.12$). The interviews indicated that the participants were enthusiastic about the strength exercise prompts. These were perceived as personal, fun, and relevant to their health. The reminders were perceived as important initiators for PA, but participants from both app groups explained that the reminder messages were often not sent at times they could exercise. Although the participants were enthusiastic about the functionalities of the app, technical issues resulted in a low user experience.

Conclusions: The preliminary findings suggest that the PAUL apps are promising and innovative interventions for promoting PA. Users perceived the strength exercise prompts as a valuable addition to exercise apps. However, to be a feasible intervention, the app must be more stable.

Introduction

Background

Motivating individuals to engage in regular physical activity (PA) is a global interest as physical inactivity can lead to numerous serious health issues such as cardiovascular diseases, cancer, and diabetes [1]. Therefore, individuals are recommended to engage in at least 150 minutes of moderate to vigorous PA (MVPA) every week. In addition, it is recommended to perform bone- and muscle-strengthening exercises at least 2 times a week [2] as they provide additional health benefits next to aerobic exercise [3,4]. However, many individuals do not meet these guidelines [5]. Recent data show that 58.3% of adults (aged >18 years) engage in sufficient moderate PA, and 82.2% engage in sufficient muscle and bone strength exercises, but only 52.9% engage in both [5].

A promising method to increase PA are mobile health (mHealth) PA apps [6,7] such as mobile phone apps. Mobile phones are well integrated into our daily lives [8]; they can continuously track PA behaviors with limited effort from the individual and provide real-time feedback on their behavior. In addition, by continuously tracking the behavior and context of the individual, it is now possible to develop highly personalized and context-based interventions that can offer the right support at the right time [9].

Previous studies have indicated that mHealth PA interventions are more likely to be effective when they are grounded in theory and, as such, contain adequate persuasive strategies [10,11]. Persuasive strategies (or behavior change techniques [12]) are theoretically underpinned elements of interventions intended to facilitate a positive behavior change (eg, rewards and goal setting). It is theorized that persuasive strategies can change the determinants of behavior, such as motivation and capability [13], which in turn influences the targeted behavior. Several studies have demonstrated that self-regulatory persuasive strategies such as goal setting, feedback, monitoring, and prompts are effective in changing PA behavior [7,10,14,15].

In addition, the research fields of human-computer interaction and design thinking emphasize the importance of the quality of the user experience for the success of the intervention [16,17]. *User experience* is an umbrella term that encapsulates concepts such as user satisfaction, perceived usefulness, esthetics, and user-friendliness [18]. Previous studies have demonstrated that apps that have a low subjective user experience are more likely to face low acceptance rates and the problem of nonadherence [19,20]. This is problematic as participants do not engage (sufficiently) with the behavior change components of the

intervention [17,21,22] and nonadherence has been shown to negatively influence intervention effectiveness [23,24]. Thus, both the selection of persuasive strategies and their design and implementation are of importance for the success of the intervention [25,26].

A likely effective persuasive strategy is to provide a prompt to engage in a certain behavior [27]. According to the Fogg Behavior Model (FBM) [28,29], the prompt also has to be sent at *the right time* to effectively change behavior. The right time, or *the moment of opportunity*, to send a message is when the individual is motivated enough and when they can perform the exercise. If the motivation and ability are high enough, the individual has crossed the *activation threshold* and can therefore be triggered to perform a behavior. In addition, a well-designed prompt can also increase the motivation (referred to as *spark prompts* [27]) or ability (referred to as *facilitator prompts* [27]) of an individual.

Interventions that aim to send messages at the right time are often referred to as *just-in-time (JIT) interventions* or *JIT adaptive interventions (JITAI)* [9,30,31]. With JIT interventions, the content and timing of the prompt supports the need of the user in real time and is triggered by the system based on predetermined factors. JITAI are similar except that they also have the ability to adapt the timing or content of the prompt over time to an individual's changing needs and wishes [9,30,32]. Although prompts are commonly included strategies in PA apps [33], only a few studies have examined the effect of timing on persuasiveness [34,35].

Objectives

Therefore, we set out to investigate 2 novel ways of JIT prompting for PA behaviors with an mHealth app, the Playful Active Urban Living (PAUL) app. First, to initiate running or walking behavior, the app sends JITAI reminder messages based on a reinforcement learning algorithm [36]. Second, during a PA session (outdoor running or walking), the individual receives JIT location-based strength exercise prompts containing instructional videos for performing strength exercises. These prompts are triggered by either beacons or preprogrammed GPS coordinates, allowing the app to send the right instruction video at the right location and time. For this study, 2 parks in Amsterdam (Sloterpark and Oosterpark) and 1 park in Utrecht (Park Transwijk) were selected as exercise locations. We will refer to these two prompts as *reminder messages* and *strength exercise prompts*, respectively, for the remainder of this paper.

To determine the proof of concept for the design and implementation of the 2 types of prompts, we conducted a feasibility study [37]. Examining the feasibility of a digital

intervention before a large-scale effectiveness study is an important step in the development phase. This offers insights into the subjective user experience and engagement with the app and can be used to establish if it is likely that the app will be effective in changing behavior [37,38].

The feasibility of the PAUL app was examined by exploring 4 factors [38]. First, we explored the perceptions and opinions of the users regarding the included persuasive strategies within the PAUL app, with a focus on the 2 novel ways of prompting. Second, the user experience with the PAUL app was examined. Third, we examined the users' behavioral engagement with the app and, finally, we explored whether the PAUL app has the potential to change the motivation and perceived capabilities of the users. In total, 2 versions of the app were examined: the Basic PAUL app and the Smart PAUL app. Both versions of the app are identical except that the Basic PAUL app sends reminder messages at randomized times, whereas the Smart PAUL app sends JITAI reminder messages based on the context and previous PA behavior of the user.

Methods

Participants

Participants were recruited by distributing promotional materials around Sloterpark, Oosterpark, and Park Transwijk. Facebook advertisements were issued targeting individuals aged between 18 and 55 years and living close (<3.5 km) to the parks. In addition, advertisement messages were posted on Facebook resident groups close to the parks (ie, residential groups of apartment buildings). Recruitment materials were also distributed at various universities in the Netherlands and on the social networks of the researchers. The recruitment phase lasted from October 1, 2019, to November 14, 2019.

Initially, we targeted participants aged between 18 and 55 years who lived close (≤ 1 km; 10-minute walk) to one of the parks used with the beacons (ie, Park Transwijk [Utrecht, Netherlands], Oosterpark [Amsterdam, Netherlands], or Sloterpark [Amsterdam, Netherlands]) and did not meet the PA

guidelines of 150 minutes per week (measured using the stages of change questionnaire) [39]. This resulted in too few individuals meeting these criteria; therefore, we changed the eligibility criteria by also including individuals who lived within a 20-minute bicycle ride of the parks (<5 km) and individuals who would like to become more active even if they met the PA guidelines. The exclusion criteria were having a medical condition that made it unsafe to engage in unsupervised PA (defined by the Physical Activity Readiness Questionnaire [40]), not owning an Android smartphone, currently participating in another PA or health-related intervention, or no proficient knowledge of the Dutch language.

The PAUL Apps

During this study, 2 closed-beta versions of the app were evaluated: Basic PAUL and Smart PAUL. The PAUL apps were developed by a multidisciplinary research team over a 2-year period [41]. The design of PAUL is based on theories of behavior change [13,28], technical implementations and design characteristics [33,42], user studies [43], and data mining studies [44,45]. In short, the PAUL apps are designed to function as a coach to help the user increase recreational walking or running behavior and motivate users to perform additional strength exercises during this walk or run. The apps apply 5 theory-based persuasive strategies: monitoring, feedback, goal setting, reminder messages, and instruction videos (Figure 1).

These persuasive strategies were selected as they are theorized to increase the perceived capability and motivation of the participants based on the Capability, Opportunity, and Motivation Behavior model [13] and the FBM [28]. The theoretical assumptions have been described in detail in an earlier paper on the development of the PAUL apps [41]. Table 1 provides a description of the persuasive strategies that are included in the app, the behavior change techniques [27], and the strategies of the persuasive design model [46]. A detailed description of the app and its development process is provided in the study by Sporrel et al [41] and in Multimedia Appendix 1 [41].

Table 1. A description of the modules in the Playful Active Urban Living (PAUL) app, including the implemented behavior change techniques (BCTs) and persuasive system design (PSD) principles.

PAUL functionality, subcategory, and description	BCTs [27]	PSD principles [46]
<ul style="list-style-type: none"> Strength exercise prompts: The user receives location-based strength exercise prompts (audio and pop-up messages) on predetermined GPS locations. The prompt contains an instruction video of the exercise (squat or push-up) in the direct environment of the user. Amenities in the park (eg, trees, benches, or lantern posts) are used for the exercises. Reminder messages: <ul style="list-style-type: none"> The user receives up to 14 short reminder messages each week containing a motivational suggestion and either information on the progress toward their goal or (affective) information on performing PA^a. The timing of the reminder messages depends on the group allocation (Basic vs Smart PAUL). 	<ul style="list-style-type: none"> Information on when and where to perform the behavior Information on how to perform the behavior Demonstrate the behavior Prompt practice Information provision (general) Provide feedback on performance Prompt practice 	<ul style="list-style-type: none"> Primary task support: <ul style="list-style-type: none"> Reduction Tunneling Rehearsal Normative influence Primary task support: <ul style="list-style-type: none"> Tunneling Tailoring Personalization Dialogue support: <ul style="list-style-type: none"> Reminders Suggestions
Monitoring		
<ul style="list-style-type: none"> PA behavior: The app records and stores PA metrics during app use (frequency, duration, speed, and distance). The user must press “start” to initiate behavior tracking. The app also records and stores situational characteristics during each session and when sending a reminder (weather type, calendar availability, time, and date). After receiving a strength exercise prompt, the user must log if they performed the exercise. Behavior outcome: The user can report notes on the training session and report on a 1-to-5 scale how they are feeling and how intense the workout was. To monitor how many strength exercises the participant has done, they must log whether they performed or skipped the exercises (during the walking or running activity). 	<ul style="list-style-type: none"> Automatic monitoring of behavior Self-monitoring of behavior Self-monitoring of behavior outcome 	<ul style="list-style-type: none"> Primary task support: <ul style="list-style-type: none"> Reduction Self-monitoring Primary task support: <ul style="list-style-type: none"> Self-monitoring
Feedback		
<ul style="list-style-type: none"> Sustained feedback: During running or walking, the user can view simple metrics on their screen (time, distance, current speed, average speed, and number of strength exercises), and the user receives audio feedback every 5 minutes on the duration of the activity. Cumulative feedback: After performing PA with the app, the user can view a summary of their activities (ie, a PA report) with the time, distance, and average speed and a map with their route. The user can access a history view that contains all PA reports. On the home screen, users can view their progress toward their goal. Praise: The user receives a pop-up praise message and a message on the landing page when the weekly goal is reached. Goal setting: To set a goal, the user must perform a short questionnaire. With this questionnaire, the user can set their own long-term walking or running goal (for frequency and duration). Furthermore, a tailored start goal (frequency and duration of activity) is given based on the current fitness level of the participant. The goal increases roughly 10% every week until the long-term goal is reached. 	<ul style="list-style-type: none"> Provide feedback on performance Provide feedback on performance Rewards contingent on successful behavior Goal setting (behavior) Setting graded tasks Review of behavior goals 	<ul style="list-style-type: none"> Primary task support: <ul style="list-style-type: none"> Personalization Self-monitoring Primary task support: <ul style="list-style-type: none"> Personalization Self-monitoring Dialogue support: <ul style="list-style-type: none"> Praise Primary task support: <ul style="list-style-type: none"> Tailoring Dialogue support: <ul style="list-style-type: none"> Suggestions

^aPA: physical activity.

The Smart PAUL app differs from the Basic PAUL app in that it can optimize the timing of reminders with a self-learning module [36]. The self-learning algorithm has the opportunity to learn *right* times (ie, JITAI) to send reminders based on the time of the day, the day of the week, previous PA behavior, and agenda availability [36]. Although the timing differed between the Basic and Smart PAUL apps, the content of the reminders was equal.

Both apps were programmed to send up to 14 reminders per week. However, during the intervention period, there were technical issues that prevented the app from sending the reminders (ie, the notifications were not activated in the app because of a processing error in the sent format). For Basic PAUL, this issue was resolved within the first week, whereas, for Smart PAUL, the issue was resolved after 3 weeks. Therefore, the Smart PAUL group only received the JITAI reminders in the last week of the intervention.

Study Design and Procedures

To determine the feasibility of the PAUL apps, a mixed methods pre-post intervention was performed. This study is part of a larger study that aimed to determine the feasibility of the PAUL apps and examine the user-app interactions with the JITAI reminders. In this paper, we describe the feasibility of the PAUL apps as a whole, whereas we have described the user-app interactions with the JITAI reminder messages in more detail in another paper [47].

Individuals were screened for eligibility using a web-based enrollment questionnaire on the participants' characteristics. Eligible participants were contacted by the main researcher (KS), and a face-to-face meeting was arranged. During this meeting, the participants were informed about the main objective of the study, the study requirements, and the data handling. When an individual had no further questions, they were asked to sign the informed consent form. The participant then received an accelerometer and an information pamphlet that summarized the most important study information.

All participants started with the baseline measurement either on November 11, 2019, or November 17, 2019. On the day before the start of the baseline measurement, the participants received the baseline questionnaire to assess the determinants of PA and self-reported PA as well as a reminder to wear the accelerometer for 7 consecutive days. A reminder to fill in the web-based questionnaire was sent when needed after 2 days.

After successful completion of the baseline period, the participants were manually randomized into the Smart and Basic PAUL groups by an independent researcher with a 1:1 ratio stratified by the 3 parks (ie, Park Transwijk, Sloterpark, and Oosterpark). The group allocation was double-blinded. In the following 4 weeks, the participants could use the PAUL app. The user was asked but not obligated to not turn off the reminder function (ie, push notifications) of the app and to give access to their digital calendar. The participants were informed that this would improve the function of the app without explaining any details of the differences between the 2 groups. During the

intervention, the participant received a visit from a researcher to download the accelerometer data.

At the start of the fourth intervention week, the user was reminded to wear the accelerometer again for 1 week. After 5 weeks, the individual received a link to the final questionnaire on the usability of the PAUL app, the determinants of PA, and the self-reported PA. After the intervention, all the participants were invited for an interview at a location of their liking. As a token of appreciation for participating in this study, the participants received a voucher for a cinema visit or a sports activity with a value of €30 (US \$31.32).

Measurements

Perceptions and Opinions of the PAUL App

To gain a better understanding of the users' perception of the PAUL app and its functionalities, all participants were invited for semistructured exit interviews of 20 to 40 minutes at a location of the participants' choice. The topics in the interview guide covered the perceptions of the included strategies, the design and implementation of the strategies, and the user experience of the strategies. During the interviews, the researchers and participants were still blinded to their group allocation.

User Experience

In addition, a web-based, 20-item, 7-point scale questionnaire on the user experience with the PAUL app was administered at the end of the intervention (acquired from the study by Mollie et al [18]). The questionnaire contained 4 subtopics—perceived effectiveness, usability, satisfaction, and esthetics. The participants could state how much they agreed with the subtopics, from 1 (not at all) to 7 (completely). An item was added to the questionnaire on how many technical problems they encountered.

Behavioral Engagement With the PAUL App

To determine how often the participants used the app during the intervention and, thus, were exposed to the intervention strategies (referred to as *behavioral engagement* [17] or *sustained use* [48]), we examined the number of times the users opened the apps on each intervention day. This was registered automatically by the apps.

Intrinsic Motivation and Perceived Capability

Perceived capability and intrinsic motivation were measured independently for the 3 behaviors of the app (running, walking, and strength exercise). The 6-item perceived competence subscale of the Intrinsic Motivation Inventory [49] was used to measure capability, and the 7-item interest and enjoyment subscale was used to measure intrinsic motivation. The subscales of the Intrinsic Motivation Inventory were back translated into Dutch. Each item could be scored from 1 to 7, with a score of 1 indicating *not at all true* and a score of 7 indicating *very true*. Subscale scores were calculated by reversing 3 items and subsequently averaging the items of the subscales.

PA Measurement

The PA behavior of the participants was measured using a hip-worn accelerometer, the ActiGraph GT3X+ (ActiGraph LLC), 1 week before the intervention (baseline) and in the last week of the intervention (after the intervention). Accelerometer measurements were considered sufficient if the participants wore the accelerometers for a minimum of 8 hours a day and for at least 3 weekdays and 1 weekend day. A total of 35% (8/23) of the participants did not meet these requirements for either the pre- or posttest measurement and were therefore excluded from the analysis.

Analysis

Perception of the PAUL App

The interviews were audio-recorded on the researchers' phones and transcribed verbatim. After transcribing the interviews, the text was imported into MAXQDA Plus (version 20.2.2; VERBI GmbH). Qualitative research cycle was used to code and analyze the data [50]. Before the analysis, a first version of the codebook was developed based on the topic list. Therefore, most codes were developed deductively. The transcripts were then coded. When new topics emerged from the interviews, they were added to the codebook. To ensure that the same coding system was used for all interviews, they were coded again after new codes were derived from the data. Memos were used and served as reminders to explore links between certain codes or to compare conflicting statements.

After coding all the data, the codes were analyzed by a researcher according to a cyclic process [50]. This included regrouping the codes into larger categories (such as *general perceptions of reminders* or *personal support*), exploring links between codes and categories (such as *weather constraints*, *goal setting*, and *reminders*), and comparing between participants. Codes were sometimes also uploaded to Microsoft Excel and subdivided into smaller categories (eg, positive and negative perceptions). The findings for each of the codes and categories were summarized. As this was a cyclic process, the codes were regrouped several times, sometimes into larger categories, and sometimes the codes were divided into subcodes.

User Experience

In addition to the interview data, the questionnaire responses were used to gain an overall perspective on the technical problems, perceived effectiveness, usability, satisfaction, and esthetics of the app. To this end, the questionnaire responses were uploaded to SPSS (version 25; IBM Corporation), and the item on technical issues was inverted. To determine the differences between the Smart and Basic PAUL apps, a Mann-Whitney *U* test was performed (1-tailed exact test with significance at $P < .05$). A participant did not complete this questionnaire and was therefore not included in the analysis.

Behavioral Engagement With the PAUL App

The behavioral engagement with the PAUL app data was uploaded from the servers of the PAUL app and subsequently cleaned by removing duplicate data. The data were validated by cross-checking the data sets of the PAUL app. For some participants (3/20, 15%), no data were recorded by the app. This

was likely due to a connection error with the back end of the app, which could be caused by several factors such as battery failure. Participants whose data were not recorded could not be included in the analysis. Descriptive statistics were calculated for the participants in the Basic and Smart conditions. Differences between the Smart and Basic PAUL apps were calculated using a Mann-Whitney *U* test with an exact test (1-tailed significance at $P < .05$).

Intrinsic Motivation and Perceived Capability

To analyze the changes in intrinsic motivation and perceived capability, we only included the measures for behavior that the participants wanted to change. That is, if the participants had set a goal with the PAUL app to increase their walking activity, we only used their scores for walking. If they had a running and walking goal, the scores were averaged. This also included changes that the participants made during the intervention. The scores for motivation and perceived capability to perform strength exercises were calculated for all participants. The scores were then uploaded to SPSS, and a descriptive analysis was performed. To determine if there were differences between the groups, the differential scores between the pre- and postintervention measurements were calculated, and Mann-Whitney *U* tests were performed (1-tailed exact test with significance at $P < .05$). To determine differences between pre- and postintervention measurements, Wilcoxon signed-rank tests were performed (1-tailed exact test with significance at $P < .05$). Nonparametric tests were used because of kurtosis in the data.

PA Analysis

To process the accelerometer data, they were downloaded using ActiLife (version 6.13.4, firmware 2.2.1; ActiGraph LLC), and the triaxial counts were summed as counts per minute (cpm). Episodes of at least 90 minutes were defined as nonwear episodes. Short interruption periods of a maximum of 2 minutes of 1 to 100 cpm were allowed as nonwear time to account for the possibility of accidental accelerometer movement. Only days with at least 8 hours of wear time were included in the analysis. Freedson Adult (1998) cutoff sets were used to define the time that the participants spent on MVPA (>1951 cpm). The average MVPA time was calculated while excluding nonwear time. To account for the differences in wearing time, the average time spent performing MVPA was calculated. The PA measurements were imported into SPSS, and a Mann-Whitney *U* test with the differential scores was used to determine the differences between Smart and Basic PAUL. A Wilcoxon signed-rank test was used to establish differences between pre- and postintervention measurements (both 1-tailed exact tests with significance set at $P < .05$).

Ethics Approval

The study method was approved by the local ethical committee (GEO S-19253), and the trial was registered in the Netherlands Trial Register (trial ID: NL8166). The study was conducted and reported according to the CONSORT-eHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist [51].

Results

Participants

Recruitment resulted in 122 individuals who were interested in participating in the study and completed the enrollment questionnaire. After checking eligibility and provision of informed consent, of the 122 interested individuals, 23 (18.9%) were enrolled in the study. The main reasons for exclusion were that the individuals did not live close enough to the parks equipped with beacons or did not own an Android phone. Of

the 23 participants, 3 (13%) discontinued their participation, leaving a total of 20 (87%) participants who completed the study. The participant flow diagram is shown in Figure 2.

The characteristics of the included 20 participants are shown in Table 2. Most participants were women (17/20, 85%), had an average age of 30.65 (SD 8.4) years and an average BMI of 24.52 (SD 5.23) kg/m², and were highly educated (16/20, 80%) and employed (14/20, 70%). Many participants engaged in regular moderate PAs (14/20, 70%), but most participants did not engage in intensive PAs (15/20, 75%).

PA Behavior and Determinants of PA Behavior

To examine to what extent the PA behavior of the participants changed over time, the accelerometer data of the participants were analyzed. A total of 35% (7/20) of the participants were

excluded from the analysis as they did not meet the required wear time. For the remaining 65% (13/20) of the participants, there were no significant differences between the participants in the Smart PAUL group and the Basic PAUL group ($U=16.00$;

$z=-0.714$; $P=.53$) in the differential scores of MVPA time (Figure 3). As there were no differences between the Smart and Basic PAUL apps, the 2 groups were treated as 1 to determine the differences in PA pre- and postintervention measurements. As shown in Figure 3, the percentage of time spent in MVPA slightly decreased over time, but no significant differences were found ($Z=-1.433$; $P=.08$).

Next, intrinsic motivation and perceived capability were examined for running or walking and strength exercises (Figure 4A and Figure 4B, respectively). The Mann-Whitney U test did not show differences between the groups in running and walking behavior motivation ($U=36.000$; $z=-0.736$; $P=.24$) and capability ($U=41.000$; $z=-0.327$; $P=.38$) or in strength exercise

motivation ($U=30.500$; $z=0.158$; $P=.45$) and capability ($U=18.000$; $z=-1.474$; $P=.08$). Thus, the Smart PAUL and Basic PAUL apps appear to influence motivation and capability equally.

To determine the differences in determinants before and after the intervention, a Wilcoxon signed-rank test was performed. As there were no differences between the 2 groups, we analyzed the 2 user groups as 1. Significant differences were found in running and walking motivation ($Z=-3.342$; $P<.001$) but not in capability ($Z=-1.221$; $P=.12$). Regarding the performance of strength exercises, both motivation ($Z=-1.821$; $P=.04$) and capability ($Z=2.231$; $P=.01$) significantly increased.

Figure 3. The pre- and postintervention MVPA time for the Smart and Basic groups. MVPA: moderate to vigorous physical activity; ns: not significant; PAUL: Playful Active Urban Living.

Figure 4. The pre- and postintervention intrinsic motivation (4A) and perceived capability scores (4B) of the participants enrolled in the Basic and Smart Playful Active Urban Living groups. ns: not significant.

User Experience

The user experience was examined using a questionnaire in which the user was asked to rate the app on a score from 1 (lowest) to 7 (highest). As shown in Figure 5, there were no differences in user experience between the 2 groups in terms of technical problems ($U=41.50$; $z=-0.298$; $P=.41$), perceived effectiveness ($U=40.5$; $z=-0.369$; $P=.37$), usability ($U=27.0$; $z=-1.485$; $P=.07$), satisfaction ($U=31.0$; $z=-1.15$; $P=.13$), and

esthetics ($U=33.5$; $z=-0.948$; $P=.18$). Both groups reported that they experienced many technical issues (mean 2.60, SD 1.64), which likely also resulted in a low perceived effectiveness of the app in changing their PA behavior (mean 3.26, SD 0.91) and a low satisfaction with the app (mean 3.23, SD 1.01). Compared with perceived effectiveness and satisfaction, the participants were more positive in terms of the usability (mean 4.06, SD 0.67) and esthetic appeal of the app (mean 4.79, SD 0.80).

Figure 5. User experience ranging from 1 (low) to 7 (high) of the Smart and Basic PAUL apps. PAUL: Playful Active Urban Living.

Behavioral Engagement With the PAUL App

To examine whether the participants used the app and, thus, were exposed to the included persuasive strategies, we explored the frequency of opening the app. As can be seen in Figure 6, there were a few frequent users of the PAUL app, and most participants opened it a couple of times a week. On average, the participants opened the app on 7.3 (SD 4.67) days of the 28 intervention days, with the most frequent user opening the app on 19 days and the least frequent user opening it on 2 days.

There were no significant differences between the 2 groups regarding the total frequency of opening the app ($U=28.5$; $z=-0.723$; $P=.48$) or the number of days the apps were open ($U=27.0$; $z=-0.875$; $P=.42$). However, it does seem that the Smart group continued using the app for a longer period as opposed to the Basic group. A likely explanation is that the Smart group started to receive the reminders in the last week, whereas the Basic group received the reminders throughout the intervention.

Figure 6. The daily frequency of opening the PAUL app from the day the Basic and Smart PAUL apps were downloaded. PAUL: Playful Active Urban Living.

Perceptions and Opinions of the PAUL Apps and the JIT Prompts

Overview

In this section, we describe the findings of the exit interviews. The perceptions and experiences of both PAUL apps are reported simultaneously to a large extent as the app functionalities are also largely similar. Only the results regarding the timing of the reminders are reported separately.

Perceptions and Opinions of the PAUL Apps

Overall, the participants thought that the included persuasive strategies were useful and that the most important features were present in the app. The app was perceived by most as “simple” and “basic,” which was liked by some of the participants as it made using the app clear with a simple goal:

And furthermore, it's nice that it's so clear, that you're not lost, or that you're somewhere in 7 steps and think: where am I? And that was nice. He was just clear. [Participant 6, female, aged 35 years]

Other participants indicated that they preferred a more elaborate app:

Um, all right in the general sense. But, um, in many ways, just a little basic. In terms of what you can do with it, of course.... I went running with my girlfriend during this research and she has a Nike running app, and yes, that's super interactive. [Participant 18, female, aged 22 years]

Well, I thought it was, in its essence, a really nice app to use, for instance for running. Here and there, there were some features of which I thought: “Oh those should be further developed.” [Participant 5, male, aged 32 years]

The improvements to the app mainly lay in the development of the implementation of a strategy rather than the addition of another strategy (eg, earning coins or a leaderboard). For instance, participant 18 (female, aged 22 years) would have liked more “interactions” with the app (eg, controlling whether she could perform the strength exercises in a particular exercise session and how many she could perform). By doing so, the users can personalize the apps themselves. Furthermore, the improvements to features that participant 5 (male, aged 32 years) mentioned were to provide more detailed and graphic information about his activities and add more types and locations for the strength exercises. Other participants would have liked “to know the idea behind” the goal setting functionality (participant 8, female, aged 30 years); thus, she would have liked additional information on how the goal was determined.

A frequently mentioned improvement in functionality was to automatically track all the PA activities of the user. Some participants hoped for an app that helped them integrate more PA into their daily activities (eg, cycling slightly further than normal or taking the stairs more often) as this fit better in their life than going for a recreational run or walk. Furthermore, as not all their activities were recorded, they felt as though the app did not give them credit for all their PA behavior:

What I also find unfortunate about it was that you physically had to say that you're going to move now. And a lot of my movements just happen in life, so to speak. So, when I walk to the supermarket, or when I go there or there for a bit. And I'm not gonna enter that. And he won't record that. Whereas for me, those are the moments that I could make a profit, that if he would record it. [Participant 6, female, aged 35 years]

In addition, we asked about the perceptions of 3 frequently used persuasive strategies in apps that were not included in the PAUL apps: rewards (eg, victory points, digital coins, or digital awards), social support, and competition. A few participants indicated that they had nothing against rewards but that they also did not see their added value. More than half of the participants indicated that they would like to be rewarded, but they explained that receiving feedback on their progress or on the number of activities they had done was already enough of a reward. The participants expected that such rewards would strengthen the feeling of having a competition with themselves. For some participants, this was perceived as motivating, whereas others were afraid to disappoint themselves.

Competition with others was disliked by most participants. A total of 10% (2/20) indicated that they would like competition with their friends as this was a fairer comparison and, therefore, more achievable. Sharing exercise outcomes on social media was disliked as this was viewed as a call for attention. A participant indicated that sharing running routes (within the app) would be a good addition to the app. Some participants also suggested other functionalities by themselves. These were to have a selection of running routes, information on why it is important to engage in PA, emails regarding progress, and a game element to motivate users to visit certain exercise locations.

Although the participants in general explained that the app contained the most important strategies, most participants reported that they only used the app a few times. Mostly, they stopped using the app because they encountered technical issues. There were also participants who explained “that's not the apps fault” (participant 6, female, aged 35 years) that they stopped using the app as they encountered barriers such as lack of time or bad weather. For instance, various participants explained that, because of the short winter days, it was already dark when they got home from work. This, together with colder and wetter weather circumstances, made it unpleasant to go outside for a run or walk:

Only I have to say that I used it less than I had hoped, because it was often bad weather, and very dark. And then you're less inclined to go outside. Normally earlier in the summer I would do something more quickly anyway. [Participant 19, female, aged 28 years]

When asking the participants how an app could help them overcome these barriers, they found it difficult to give an answer. After debating the issue, some suggested receiving encouragement to go for walks when there was still daylight; for instance, during lunch. Another participant suggested including a module that enabled them to perform the strength

exercises simply at home in case they were bound to stay there to watch their children or when the weather was bad.

Although some barriers to the uptake of the app lay outside the app, the biggest issue with using it were the technical problems the participants experienced. When encountering a technical problem, this evoked *irritation* and *frustration* in the users or the feeling that their efforts were not recognized by the app or of not being encouraged enough to do more activities. This ultimately resulted in app abandonment. For some participants, it even resulted in thinking that they had done something wrong (participant 5, male, aged 32 years). Various participants explained that, if the app had been more stable, they would have probably used it more often.

Perceptions and Opinions Regarding the Strength Exercise Prompts

Many participants did try out the location-based strength exercises. Of all the strategies that were implemented in the app, the participants were generally the most enthusiastic about the strength exercise prompts:

Well, the best part was that when I just walked through the park, that I always got one, one.... What's that called? That I got a sound [strength exercise prompt], and then I had to do something. I really liked that about it. [Participant 17, male, aged 25 years]

Owing to the novelty of this functionality, the participants became curious and motivated to try it out. Some participants were motivated to perform these strength exercises to increase their strength and fitness. According to these participants, complementing their running activity with strength exercises resulted in a more complete workout in which they trained not only their endurance but also their strength. Furthermore, receiving a strength exercise prompt was perceived as receiving a surprise, some kind of *game* or reward for going outside for a run or walk. The participants explained that it made a running or walking session more diverse and, therefore, more fun. Some participants even referred to the strength exercises as “a moment to catch your breath” for running. In addition, the participants enjoyed that the app gave suggestions on what they could do, similar to a coach, so they did not have to figure everything out themselves:

But I liked the mix, and that it's bound to certain parts of the park, so to speak. That also, when you do an exercise, it can tell you where to do it. So, yeah, I actually really liked that. [Participant 5, male, aged 32 years]

The app could give better suggestions for the strength exercises as it “knew” where the participant was. Some participants explained that it helped them view the park amenities (eg, benches) in a different light, as something they could use during their workout:

Well, what I found very interesting was the part of, uhm, location. That it would indicate those strength exercises at the right places, so to speak. [Participant 8, female, aged 30 years]

To *know* where the user is, the user must share their privacy-sensitive location data with the app. Although most participants did not express any concerns regarding privacy, others explicitly said they preferred not to do this. Several reasons were brought up, including mistrust of who manages these privacy-sensitive data. For instance, some participants were very hesitant to share data with commercial companies, whereas they were willing to share the data with the government or universities:

Well, if it's not commercial, then maybe I would. It depends. Where's it all going, huh? What does that app need to analyze it all? [Participant 16, female, aged 42 years]

In addition, some participants also considered that the privacy-sensitive data that are collected by the app must be of added value to them. In other words, they were willing to share data if they obtained something they wanted from them in return. For instance, one of the participants explained what he liked about the strength exercise prompts:

So, I guess that it shows you: you're here now, so it shows you the [strength exercise] possibilities. Somewhere it's a bit freaky, that he can follow me anywhere, but assuming that privacy is well guaranteed, it delivers a lot. [Participant 10, male, aged 28 years]

Although the app removed some barriers, other barriers remained. Some female participants mentioned that they would not perform the strength exercises as they did not like to do them in such public spaces where other people could “look at you like that” (participant 1, female, aged 27 years and participant 3, female, aged 23 years). Other participants expressed their concern about performing strength exercises without receiving feedback on their posture from a professional. Offered solutions to this problem were to organize a group training, only implement easy exercises, or motivate the participants to practice the exercises at home in front of a mirror. Another improvement that was suggested was offering the strength exercises in more locations so the participants did not have to travel to the location before they could start their run or walk. The participants would also like to have more types of strength exercises and combinations of strength exercises that could be tailored to their capabilities. Some participants indicated that they would like to see where the strength exercises were located so they were motivated to run there, “explore” the neighborhood, and discover new exercise locations.

Perceptions and Opinions Regarding the Reminder Messages

Reminder messages were perceived as important initiators of behavior by almost all participants. The participants said that the reminders “trigger” them (participant 20, female, aged 23 years) and that it “lowers the threshold” to engage in PA (participant 5, male, aged 32 years) and, therefore, increases the chances of engaging in PA. Thus, to some extent, the reminders function as a coach (ie, something that pulls the participants over when they have difficulty in performing the behavior themselves). Unfortunately, not all the participants received the reminder messages. However, these participants

also explained that they thought they would have used the app more if they had received them. As they did not receive the reminder messages, they often forgot the app and their intention to exercise more.

Some participants explained that a reminder message in itself was not enough to motivate PA. Rather, the motivation must come from within, and the reminder message can help overcome barriers or remind them of their plans:

Yes, then it's nice that one of those things reminds you of it, but then you think "yes, but I just don't have time for it right now".... So I'm more like, "yes, I'd like to try," but it doesn't really fit in my schedule. So, then it should be a bigger mind set of "okay, I think this is very important," that you really make that app a part of your daily rhythm, yes. [Participant 10, male, aged 28 years]

The participants highlighted the need for well-timed and highly personalized reminder messages. Although receiving a reminder message at a good time could serve as a trigger, receiving one at a bad time could lead to irritation or feeling like they were failing (participant 20, female, aged 23 years and participant 17, male, aged 25 years). The timing of the reminder message also seemed to influence the perception of its content. For instance, a participant explained that the reminder message was annoying and "preachy." Owing to a busy schedule, she did not have the time to go for a walk even though she had the motivation to exercise. Thus, a motivating message was not appropriate. However, she explained that she would design similar reminder messages herself as, if they were well timed, they entertained her. Furthermore, some participants explained that the content of the reminder message did not really matter at all and that receiving a prompt in itself was already sufficient. In line with these comments, several participants had issues with recalling the content of the reminder messages, indicating that the content indeed was not the most important quality of the reminder.

As the timing of the reminder message was perceived as important, the participants enjoyed the idea that the app knew their schedule by reading their agenda:

I think that's a plus compared to other things. That you can then, that you can link it that way. [Participant 8, female, aged 30 years]

However, some participants did express privacy concerns or did not use a digital agenda that could be integrated into the app.

During the interviews, participants in both groups were generally not positive about the timing of the reminder messages. The perceptions of the timing of the JITAI reminder messages were not more positive than those of the randomly timed reminder messages. A possible explanation for these findings is that the participants in the Smart PAUL group received too few reminder messages as they only received them in the last week of the intervention. Furthermore, owing to the short study duration, the reinforcement learning model could only use a prelearned delivery strategy to determine the timing of the messages. Thus, it was not able to adjust the strategy at an individual level.

As the participants were not satisfied with the timing, we discussed what they would have preferred. It seems that there were roughly 2 groups of participants—one group that liked to set their own times and one group that wanted to receive regular reminder messages throughout the day:

...if I already know that I can't run that day at all, because I must do all kinds of other things, then I think it would only be annoying that I would still get reminders for something.... But I am also someone who then, plans in advance which days she wants to walk, so to speak. [Participant 16, female, aged 42 years]

I'm not a planner, so, um, I get a bit itchy when I'm very tightly planned and know what I'm gonna do on what day. Especially when it's in my spare time. Um, so, I'd rather get [a reminder] every day. That sometimes you think: "oh, yeah, I want to work out." And sometimes I don't. [Participant 18, female, aged 22 years]

Participants who claimed that they always planned their (physical) activities liked to set times at which they wanted to receive the reminder message. In contrast, participants with a more flexible agenda or who did not like to plan liked to receive regular and well-timed reminder messages throughout the day and decide on the spot whether they wanted to exercise.

Discussion

Principal Findings

The feasibility of the Smart PAUL and Basic PAUL apps was examined by exploring the users' perceptions of the app, experiences, behavioral engagement and changes in PA behavior, and determinants of PA behavior. The main findings of the study were that the participants appreciated the included persuasive strategies, especially the strength exercise prompts. The strength exercises were motivating because of their novelty and because they offered variety during a run or walk and a more complete workout. Some participants even perceived the strength exercise prompt as a reward. Furthermore, the reminder messages were perceived as important initiators for PA by most participants, but they were not perceived as well timed.

Another finding was that there were little to no differences between the Smart PAUL and Basic PAUL groups regarding perceptions, opinions, and user experience. This is likely the result of the small difference between the 2 versions of the app, which became even smaller as the reminder messages were not sent during the first part of the study. Owing to this short duration, the Smart PAUL app could only apply a prelearned strategy to determine the timing of the reminders and was not able to adjust the timing to each individual participant. Finally, we found no improvement in the PA behavior of the participants, but we did find an increase in the perceived capability to perform strength exercises, and the intrinsic motivation for walking, running, and performing strength exercises did increase during the intervention. Taken together, we conclude that the PAUL apps are not feasible interventions in their closed-beta state but,

if they were more stable, they could be effective in promoting PA.

The increased motivation for running, walking, and performing strength exercises and capability to perform strength exercises supports the theoretical assumptions on which the PAUL apps were based [41]. However, despite the improvement in the targeted constructs, no increase in the PA behavior of the users was observed. A possible explanation is that PA behavior will only increase if other determinants, such as opportunity [41], increase as well. Another possibility is that the motivation or capability of the user must increase even more to influence PA behavior. Notably, these results must be interpreted with caution because of the small sample size and the lack of a control group. For instance, it is possible that, without the app, PA behavior would have decreased. A randomized controlled trial with a no-treatment control group should be performed to examine this.

By examining the feasibility of the PAUL app, we could explore the perceptions of 2 different types of JIT prompts: one to *initiate* the exercise session and one to initiate a specific behavior *during* exercise. The participants appeared to be especially receptive to the strength exercise prompts during exercise. A likely explanation for this is that, because the participants were exercising, they were already motivated, whereas the prompt itself increased the (perceived) capability of the participant to perform the exercise (ie, it is a facilitating prompt [27]). As explained by the participants, the prompt ensured that they did not have to think about what they should do. At the same time, the prompt nudged the participants to perform the behavior. Consequently, the strength exercise prompt could push the participants over the *activation threshold* while also triggering the behavior [28,29].

By including prompts to initiate a behavior during exercise, the PAUL app is among the first to make a combination of strength exercises and aerobic exercises. Thus far, only 2 other apps have been developed and evaluated: MOPET [52,53] and eCoFit [54,55]. Both MOPET and eCoFit offer exercises at fixed locations to which the participant must travel to exercise. However, based on the interviews in this study, having to travel to a different location could be a barrier to performing PA. Furthermore, the participants expressed a need for variation in terms of going to different locations and choosing different routes to run or walk and different strength exercise types. Thus, to keep an app interesting and surprising, future apps should enable users to use it everywhere. Notably, little is known about which outdoor locations could support the performance of strength exercises and which exercises are suitable. Therefore, future research is needed to examine this to optimize and improve this functionality.

The participants appeared to be less receptive to the second type of prompts, the reminder messages. The reminder messages were often sent when the participants did not have the opportunity or capability to exercise even though they were motivated to do so. Moreover, as the motivation message only aimed to motivate the participants and not to increase their capability, it was not *the right message at the right time*.

The interviews suggested several options to improve the reminder messages that support the FBM [29]. First, to increase the (perceived) capability to exercise, for instance, the exercises can be made easier to achieve by making it possible to do them at home. Second, the timing could be better tailored to the moments of opportunity of the individual (eg, when they do not have other obligations such as childcare or work). To this end, a future system should at least include calendar availability, weather, daylight, amount of PA performed, and the users' (exercise) routines according to the participants. Calendar availability, weather, and the amount of PA performed have been used in earlier studies on JIT reminders [34,56,57], but daylight and routine, to the best of our knowledge, have not been used. In addition, future systems should have longer periods to collect more data to learn the optimal strategy.

The need for a smart and personalized system contrasts with the need for privacy. The participants were very clear on why it is important to have state-of-the-art technology—to provide very personal support that contains the exact types of support they need. This recognizes that every individual is different and has different needs. However, some participants were hesitant to share the data that are needed for this type of support. In line with earlier research [58,59], participants in this study also made a careful trade-off in which the benefits must outweigh the costs (referred to as the *privacy-personalization paradox* [59,60]). Costs that were too high for some participants were the feeling that their information could be misused or that people could make a profit from their data. The participants explained that they would be willing to share data if they had a great added value in their lives or when their curiosity overruled the costs. Thus, careful considerations must be made when working with such technologies in terms of the information that is needed and the potential consequences, such as the exclusion of a part of the target group.

Strengths and Limitations

There are some limitations to this study. A major limitation of this study were the technical issues that overshadowed the results of the feasibility trial. This demonstrates that the beta version of the PAUL app is not stable enough in all devices and Android versions. Nonetheless, the participants could still experience and engage with the apps and their functionalities and, therefore, provide valuable insights into the apps. Second, the participants were mostly highly educated women (13/20, 65%), which limits our understanding of the perceptions of other potential user groups. Finally, as no control group was used, the quantitative analysis should be interpreted with caution [61].

There are also several strengths to our study. For instance, the dropout rate was relatively low, with 87% (20/23) of the participants completing the study. Furthermore, the app was designed based on theories of change and input from potential end users to increase motivation and capability [41], and the study demonstrated favorable effects. The main study strengths are that the Basic and Smart PAUL apps were tested in a real-life setting and the use of a mixed methods approach to gain insights and a deeper understanding of the feasibility of an intervention.

Acknowledgments

The authors thank Victor Zuniga Dourado, Paula Castro, and Maria do Socorro Simões for their contributions in the design of the study. They also thank David Tuhumena for assisting with participant recruitment and data collection. Furthermore, they would like to thank Victor Brunst for his support on the data management plan. Next, they thank *Nederlands Organisatie voor Wetenschappelijk Onderzoek (Dutch Research Council)* and *Nationaal Regieorgaan Praktijkgericht Onderzoek Stichting Innovatie Alliantie (Applied Research Innovation Alliance Foundation)* for funding this research under grant 629.004.013 and the municipality of Amsterdam for donating the beacons in Amsterdam. Finally, the authors would like to express their gratitude to the reviewers of this paper for sharing their thoughts and comments.

Authors' Contributions

All authors have read and approved this manuscript. KS performed the study. KS, MS, DDFE, and NN contributed to the study design and methodology. SW developed the reinforcement learning module. RDDdB developed the Playful Active Urban Living apps. SW cleaned the data. KS performed the analysis and prepared the original draft. RDDdB, SW, MS, and DDFE reviewed and edited the manuscript. MD, BJAk, MS, and DDFE contributed to the funding of this research.

Conflicts of Interest

None declared.

Multimedia Appendix 1

Description of the Playful Active Urban Living apps.

Abstract

Background: To address the epidemic burden of diet-related diseases, adequate dietary intake assessments are needed to determine the actual nutrition intake of a population. In this context, the eNutri web app has been developed, providing online automated personalized dietary advice, based on nutritional information recorded via an integrated and validated food frequency questionnaire (FFQ). Originally developed for a British population and their dietary habits, the eNutri tool has specifically been adapted to the German population, taking into account national eating habits and dietary recommendations.

Objective: The primary aim of this study is to evaluate the system usability and users' experience and feedback on the eNutri app in a small-scale preliminary study. The secondary aim is to investigate the efficacy of personalized nutrition (PN) recommendations versus general dietary advice in altering eating habits.

Methods: The app was piloted for 4 weeks by 106 participants from across Germany divided into a PN group and a control group. The groups differed according to the degree of personalization of dietary recommendations obtained.

Results: An overall System Usability Scale (SUS) score of 78.4 (SD 12.2) was yielded, indicating an above average user experience. Mean completion time of the FFQ was 26.7 minutes (SD 10.6 minutes). Across subgroups (age, sex, device screen sizes) no differences in SUS or completion time were found, indicating an equal performance for all users independent of the assigned experimental group. Participants' feedback highlighted the need for more personalized dietary advice for controls, while personalized nutritional recommendations improved the awareness of healthy eating behavior. Further improvements to the eNutri app were suggested by the app users.

Conclusions: In total, the eNutri app has proven to be a suitable instrument to capture the dietary habits of a German population sample. Regarding functionality, system usability, and handling, direct user feedback was quite positive. Nutritional advice given was rated ambivalent, pointing to several weaknesses in the eNutri app, minimizing the system's full potential. A higher level of personalization within nutritional advice subjectively improved the app's usability. The insights gained will be used as a basis to further develop and improve this digital diet assessment tool.

Introduction

Unhealthy diets and their consequences on health are still a matter of high relevance, especially regarding noncommunicable diseases such as diabetes, cardiovascular disorders, or cancer. According to the latest Global Burden of Disease Study [1], dietary risk factors (eg, high sodium intake, low consumption of whole grains and fruits) globally accounted for around 11 million deaths and 255 million disability-adjusted life-years in 2017. With the advent of the internet and computerization, digital applications are increasingly replacing traditional pen/paper methods for collecting nutritional data. Web-based tools were found to collect data of a similar quality compared with their handwritten origins and are preferentially used by younger populations [2].

In this context, *information and communications technologies* (ICTs), such as web-/computer-based services as well as mobile phones, are used to record dietary behavior. Data about nutritional intake can be captured passively through sensing or tracking techniques as well as actively by, for example, manual data entry [3]. Regarding (computerized) instruments, food frequency questionnaires (FFQs) are one of the most commonly used tools to track and assess dietary habits of individuals. Based on a preselected list of foods, individuals report the frequency of their habitual dietary intake. In general, consumption data are collected retrospectively over a recall period of a few weeks up to 1 year [4]. Various types of ICT solutions such as smartphone or tablets and desktops or laptops have been shown to be eligible for the application of digital FFQs [5-7]. The integration of dietary assessment tools into ICTs provides an unobstructive way to offer nutritional advice, which is comparable to nutritional guidance provided by nutrition professionals [8]. Advanced technologies are known to drive healthy changes in dietary intake [9], but to promote long-term use of digital health technologies and behavior change, focus should be placed on user experience and content [3]. Time-consuming data entry and poor overall user interface negatively affect users' experience [10], whereas inclusion of energy and macronutrient content are promoting factors for user system interaction [11].

ICT apps capable of providing personal nutritional advice have attracted considerable attention in recent years [12]. To date, very few apps are equipped with the necessary decision engine for generating automated dietary recommendations in a personalized format that are also valid [13]. To address this need, the eNutri web app has been developed at the University of Reading (Hugh Sinclair Unit of Human Nutrition, United Kingdom) to provide automated personalized nutrition (PN) recommendations with a high degree of personalization [13]. As part of this approach, a validated web-based graphical FFQ illustrating different portion sizes of food items has been integrated into the eNutri app. The app provides personalized dietary recommendations based on retrospectively collected data of users' food consumption habits, considering individual dietary preferences, BMI, sex, and possible dietary restrictions (eg, abstaining from meat consumption). In addition to personalized advice (by nutrition experts) [14], the app can show generic dietary recommendations based on national

guidelines with a low level of personalization [15]. Results of the evaluation of the eNutri app suggest a good usability and acceptance for the online dietary intake assessment [16]. In collaboration with the University of Reading, a German version of the eNutri app was developed, which was adapted to German food consumption habits and underwent some minor modifications (eg, translation into German language, data protection adjustments, replacement of the UK food and nutrient database of McCance and Widdowson [17] by the German Food Code and Nutrient Database or BLS [18]). The dietary recommender system in the app was acquired from the British research partners without modification. In a subsequent 4-week pilot study (eNutri2019 study), the app was field tested in a German population sample [19]. The study was part of the European Institute of Innovation and Technology (EIT) Food Quisper (Quality Information Services and Dietary Advice for Personalized Nutrition in Europe) Project, which aims to create a digital platform for evidence-based PN services and data [20].

In this study, the primary objectives were to assess the eNutri app's suitability for use in a healthy adult population in Germany and to gather user feedback regarding its usability and content. An additional aim was to identify the scope for improvement based on the users' feedback data. Furthermore, this study aimed to evaluate the effectiveness of PN recommendations over generic dietary advice.

Methods

Study (eNutri2019) Design

The German eNutri app was applied within the eNutri2019 pilot study, which was conducted in November and December 2019 in a German population sample. A subsample of the overall study results has been published earlier, comparing specifically the dietary behavior of female vegetarians with omnivores [19]. The analyses contained within this report refer to all study participants (106 participants overall) and are not limited to a selected subset. Participants' dietary intake was assessed retrospectively at 2 different time points, first at baseline (time point 1 [t1]) and second after 4 weeks at the end of the study (time point 2 [t2]). After the baseline survey, study participants were provided with dietary recommendations either in a personalized or in a generic format, according to the group (PN or control) they were assigned to.

Data Collection

Overview

To participate in the eNutri2019 pilot study, individuals had to register online. After passing the inclusion criteria, participants were granted access to the eNutri app via an anonymous alias email address to ensure protection of privacy. Dietary intake, physical activity, anthropometrics, device information, system usability, and feedback were gathered within the eNutri app. Data input was requested at t1 and t2. Participants received reminders via email on dietary recommendations provided after the first survey and to announce the second survey date.

Anthropometric and Sociodemographic Data Collection

For anthropometric measurements, study participants were provided with step-by-step instructions to accurately measure their body height and weight by themselves. Self-reported sex, body height, and weight were gathered within the eNutri app, which automatically calculated the BMI (kg/m^2) as the weight-to-height ratio. Both sex and body height were recorded at t1, whereas only body weight was captured at both time points.

Dietary Assessment

At time points t1 and t2, dietary intake of the previous 564 weeks was assessed retrospectively via a self-administered FFQ integrated in the eNutri app. Before starting the survey, participants received guidance through a tutorial on how to correctly complete the FFQ within the app, which they could return to at any time. The food list and portion sizes used for the FFQ were based on the validated questionnaire of the Food4Me study, a pan-European randomized controlled dietary intervention study [21]. The food list was adapted regarding country-specific popular German food items (eg, pretzels, rusk, fruit nectar, sweet egg dishes). The final FFQ comprised 156 food items. Foods and respective portion sizes were presented as photos, based on representative servings as defined in the BLS [18]. For each food item, a total of 7 different portion sizes were displayed, 3 of which were illustrated with photos, plus arrow buttons on either side of each image to select smaller/larger portion sizes than the ones depicted. Intake frequencies were determined based on 9 different options to choose from (<1/month, 1-3/month, 1/week, 2-4/week, 5-6/week, 1/day, 2-4/day, 5-6/day, or $\geq 7/\text{day}$). An illustrative example of the eNutri input and output visualization module is provided by Fallaize et al [22]. Energy and nutrient intake values were calculated automatically by the system in reference to the BLS.

Diet Quality Score

The nutritional value of the reported dietary habits was quantified using an 11-item Diet Quality Score (DQS) developed for a Western European population [22]. Each individual's DQS was calculated from the eNutri FFQ data at t1 and t2. The scoring system was developed and validated by the University of Reading, based on data from the EPIC (European Prospective Investigation into Cancer) Norfolk cohort study. It is calculated based on 7 food components scoring positively (vegetables; fruit; wholegrain products; healthy fats; oily fish; nuts and seeds; and pulses), and 4 scoring negatively (free sugar, salt, alcohol, and red/processed meat). Scores of all components contributed equally to the overall DQS (interval 0-110). The DQS was reported to be predictive of cardiovascular disease, inflammatory heart disease, acute myocardial infection, and all-cause mortality risk reduction [15].

Dietary Recommendations (System Feedback)

Data collected from study participants were used to generate personalized nutritional feedback. The self-reported data provided by a user (ie, sex, weight, height, food intake, and frequency) are processed to compute an individual's BMI and DQS, and an integrated decision engine (algorithm) calculates

a "healthiness score" for each FFQ item, equivalent to which foods/drinks would have the greatest/worst impact on the DQS if an additional portion per day would be consumed. This score is translated into dietary recommendations within the app, visualized in 5 output sections, namely, "foods to boost," "foods to try," "foods to reduce," "foods to keep eating," and "foods to keep avoiding." A more detailed description of the recommender system of the eNutri app is provided by Fallaize et al [22]. A *tip* section featuring explanations and background information on the specific food recommendation was integrated into the dietary feedback to support users to implement their food-based recommendations into their dietary habits.

Aiming to assess the effectiveness of the personalized dietary advice, participants were randomly assigned to either the control or the PN group, according to their sex, BMI, and age classification, using the method of minimization [23]. After completion of the baseline questionnaires, participants in the control group received generic population-based nutritional recommendations based on national dietary guidelines (German Nutrition Society [DGE]) [24]. The participants assigned to the PN group were provided with personalized dietary feedback, based on their individual FFQ responses and their stated food preferences [22]. After the administration of second questionnaire at t2, both groups received personalized dietary feedback.

System Recording of Time Stamps and Device Screen Size

As a background process, the system automatically recorded time stamps, including the date and the start and end time of FFQ processing. A record was also made of whether a questionnaire was completed in full or only in part. Completion time was calculated based on collected time stamps (for FFQ, system usability and feedback items), which were recorded upon user activity within the app for the first survey (t1). Information on screen sizes was collected as part of the browser details. Device screen sizes were categorized into 3 groups: small <480 pixels, medium 480-1240 pixels, and large >1240 pixels [16].

System Usability Scale and Participants' Feedback

For assessing the efficiency, effectiveness, and satisfaction of app usage [25], the overall System Usability Scale (SUS) score achieved was displayed as a graphical progress bar with corresponding numeric values within the eNutri app after completion of the baseline FFQ. The underlying SUS questionnaire surveyed 10 items in total, addressing the app's usability based on statements such as "I found the system unnecessarily complex" [26]. Each item provides 5 response options ranging from "strongly agree" (equal to 5 points) to "strongly disagree" (equal to 1 point). The qualitative metrics are converted into a numerical scale yielding a total score between 0 and 100 points. Scores higher than 68 points are considered as above average [27,28]. It has been shown that the SUS score is positively correlated with user acceptance [28].

Additional questions were displayed after completing the second eNutri FFQ at t2. Participants were provided with a series of 5-level Likert scale and multiple-choice questions, as well as with a free-text question regarding their subjective feedback on

the eNutri app. Feedback questions were focused on the overall user-friendliness of the eNutri app, the impact of the app on perceptions of a healthy dietary behavior, changes in dietary intake due to the app intervention, and the evaluation of the (dietary) recommendations. Furthermore, participants were asked to rate the user-friendliness of the eNutri app, as well as the app in its entirety, according to a 5-star rating system as commonly applied in app stores (eg, Google Play or iTunes), with 5 stars for the highest and 1 star for the worst rating. Willingness to pay was queried based on several preset pricing options to choose from (€0.00, €0.50 [US \$0.53], €1.00 [US \$1.07], €2.50 [US \$2.67], €5.00 [US \$5.34], and >€5.00 [>US \$5.34]).

Statistical Analysis

The statistical analysis was directed toward usability metrics, where we focused on SUS scores and feedback questions. Furthermore, subgroups were defined by age, sex, and device screen sizes to compare the usability of the eNutri app across different user groups. Feedback questions were analyzed with respect to participant's group assignment (PN and control). Categorical answer options were transformed into numerical answer options with numerical gradation from 1=strongly disagree to 5=strongly agree. Likert-scale coded data and data from the feedback questionnaire at t2 were analyzed by applying nonparametric tests (chi-square test, Fisher exact test, and

Mann–Whitney *U* test). Parametric tests (unpaired *t* test) were applied to check for statistical difference between subgroups and SUS analyses. In addition, written feedback on free-text questions was summarized and then categorized into main topics. Statistical data analysis was performed using Microsoft Excel 2016 (Microsoft Corporation) and R 3.6.0 (R Foundation). *P* values $\leq .05$ were considered statistically significant.

Ethics Approval

Ethical approval was granted by the Research Ethics Committee of the Technical University of Munich (approval no. 328/19S).

Results

Study Population

A total of 792 potential participants registered for the eNutri2019 pilot study ([Multimedia Appendix 1](#)), among which 297 registrants were found eligible. Of these, 167 study participants created an account within the eNutri app and 158 completed the first FFQ; 4 participants actively withdrew from the study and 29 were lost to follow-up. After data cleaning (removing missing, imprecise, or implausible information, such as BMI >60 kg/m² or <15 kg/m²; total energy intakes <600 kcal/day or >4500 kcal/day), a total of 106 participants remained. The sociodemographic characteristics of the study participants included in the data analysis are listed in [Table 1](#).

Table 1. Sociodemographic characteristics of study participants and selected outcome parameters.

Participant characteristics	Total (N=106), n (%)	Total, mean (SD)	PN ^a group (n=53), n (%)	PN group, mean (SD)	Control group (n=53), n (%)	Control group, mean (SD)

^bN/A: not applicable.

Evaluation of the Systems Usability

The first survey (FFQ and SUS questionnaire) did not differ between both groups except for the dietary recommendations, which were displayed only at the end of the first survey, after all data were collected from the participants. The mean SUS across all 106 study participants was 78.4 (SD 12.2). PN participants evaluated the eNutri app (mean SUS 79.9, SD 12.5) insignificantly higher than control participants (mean SUS 76.9, SD 11.9; $P=.14$). Female participants had a higher mean SUS score of 78.7 (SD 12.1) compared with male participants, who had a mean score of 76.4 (SD 13.5; $P=.59$). Regarding age groups, younger participants (<40 years) recorded a higher mean SUS of 78.8 (SD 12.0) than older participants (≥ 40 years), who recorded 75.2 (SD 13.5; $P=.39$). Additionally, SUS scores were considered with respect to the screen size of the device participants used to complete the surveys. Participants with small screen sizes (29/106) rated the app best with a mean SUS of 79.4 (SD 12.3), followed by those with medium-size device screen (7/106) with a mean SUS of 78.9 (SD 13.1) and those with large screen size (70/106), who had the lowest mean SUS of 77.9 (SD 12.2; $P=.85$). Across all subgroups, the mean SUS was greater than 68, indicating a good usability.

Analysis of Average Survey Completion Times

Completion time could not be assessed for all participants, due to repeated log-ins by some participants. Thus, completion time was analyzed only for 87 participants, who exhibited an average duration of 26.67 minutes (SD 10.6 minutes). Participants of the control group entered their data (mean completion time of 23.81 minutes, SD 7.8 minutes) faster than those of the PN group (mean completion time of 29.45 minutes, SD 12.3 minutes; $P=.05$). Female participants (75/87, 86%) completed the survey faster, with a mean completion time of 25.37 minutes (SD 9.2 minutes), than male participants (12/87, 14%), with a mean completion time of 34.75 minutes (SD 15.4 minutes;

$P=.05$). Younger participants (77/87, 89%) had a mean completion time of 25.84 minutes (SD 10.2 minutes) compared with older participants (10/87, 11%), who had a mean completion time of 33.00 minutes (SD 12.42 minutes; $P=.07$). Regarding screen sizes, participants using a medium device screen size for answering the questions (7/87, 8%) were fastest with a mean completion time of 22.86 minutes (SD 7.4 minutes), followed by participants with small screen sizes (20/87, 23%), who had a mean completion time of 25.65 minutes (SD 8.9 minutes). Participants with large screen sizes (60/87, 69%) took longest, with a mean completion time of 27.45 minutes (SD 11.4 minutes; $P=.76$).

Evaluation of the System’s User-Friendliness

To assess participant’s perception of the user-friendliness of the eNutri app, a series of Likert-scale questions were asked at t1, after completion of the first FFQ and before displaying the first dietary report (Figure 1).

Overall, very high Likert-scale scores (above 4; equivalent to very high agreement rates among the study participants) were recorded for the statements regarding “ease of use of the system,” the “rapid learnability” of the system, and the “confidence in using the system” (all with a median of 4.0 for control/PN). Lowest Likert-scale scores (below 2; equivalent to strong or medium disagreement) were detected for the “need of technical support” to use the system, the “need to learn a lot of things before using the system” (both with a median of 1.0 for control/PN), and the “operation awkwardness” of the app (median of 2.0 for control/PN). Spanning from neutral to agreeing, and at a median of 4.0, feedback on the statements “to use the system frequently” and its “well integration” leveled off. For the statements concerning “system complexity and inconsistency,” the interquartile ranges were between 1 and 3 on the Likert scale with a median of 2.0 each.

Figure 1. Box plot analysis of the Likert-scale ratings.

Participants' Feedback On System Usability

An extended feedback collection conducted after completion of the survey at t2 and after transmission of personalized dietary reports to both PN and control groups (Figure 2) was aimed at providing information about participants' reflections on their own diets or dietary habits.

The distribution of responses to the various survey statements revealed that, with all interquartile ranges spanning between Likert scale scores of 2 and 4, a significantly higher proportion of study participants in the PN group agreed that the eNutri "encouraged them to eat more healthily, even if only for a short period of time" (median control 3.0; median PN 4.0; $P=.02$). Greater deviation in feedback was further observed for the statement "the app changed their perception of what is a 'healthy' diet." With a median of 2.0, most participants in the control group disagreed, while significantly ($P=.02$) more respondents in the PN group (median 3.0) stayed neutral or agreed. A similar tendency was observed for the statements that the app "encouraged me to eat foods that I would normally not eat" (median control 2.0; median PN 3.0), and "It made me feel more confident about making positive changes to my diet" (median control and median PN 3.0). Referring to the statements "It taught me how different foods impact on my health," and "I am still following aspects of the advice and consider my diet to be healthier now," the ratings were quite identical in both groups (median control and median PN 3.0). When asked if participants "plan to continue following aspects of the device though the study has ended," the median was 4.0 for both groups, signaling that the vast majority of study participants agree.

Regarding the question if participants would "recommend the eNutri app to their family and friends," on average 35.8% (38/106) of all participants indicated that would *likely* or *highly likely* recommend the app, with same response frequencies in both PN and control groups. Furthermore, participants were asked "What are the reasons for not following your dietary recommendations?" (Table 2), and the most frequently chosen option was "I did not like the recommended food" (total: 30/106, 28.3%; control: 6/53, 11%; PN: 24/53, 45%; $P<.001$). This was followed by the response "I lacked ideas for including the recommended food into my diet" (total: 29/106, 27.4%; control: 17/53, 32%; PN: 12/53, 23%; $P=.28$) and "recommended foods did not fit into my usual meal plans/recipes" (total: 25/106, 23.6%; control: 10/53, 19%; PN: 15/53, 28%; $P=.25$). In total, 24.5% (26/106) of all participants indicated that "other people shop and cook for me" (control: 11/53, 21%; PN: 15/53, 28%; $P=.37$), while on average 13.2% (14/106) responded that they "will not change certain aspects of their diet, regardless of the advice" (control: 4/53, 8%; PN: 10/53, 19%; $P=.09$). Nearly 10.4% (11/106) of all study participants disagreed with the dietary recommendations provided by the eNutri app because they were incompatible with their dietary restrictions. It is also worth mentioning that on average 13% (14/106; $P=.01$) of the study population indicated that "the recommended foods were expensive," of which almost 21% (11/53) belonged to the PN group. The overall mean star rating of the eNutri app reached 3.3 stars (SD 0.9) out of 5.0. Participants in the PN group rated the eNutri app insignificantly higher (mean stars 3.4, SD 0.9), compared with those in the control group (mean stars 3.2, SD 0.9; $P=.27$).

Figure 2. In-app feedback related to eNutri-induced changes in dietary behaviour.

Table 2. Feedback on dietary recommendations provided by eNutri2019 study participants (N=106).

Feedback on nonadherence to dietary recommendations	Control group (n=53), n (%)	PN ^a group (n=53), n (%)	P value
What are the reasons for not following your dietary recommendations?			
I did not like the recommended food	6 (11)	24 (45)	<.001
I lacked ideas for including the recommended food into my diet	17 (32)	12 (23)	.28
The recommended foods did not fit into my usual meal plans	10 (19)	15 (28)	.25
Other people shop and cook for me	11 (21)	15 (28)	.37
I will not change certain aspects of my diet, regardless of the advice	4 (8)	10 (19)	.09
I did not agree that the advice would result in a healthier diet for me	11 (21)	9 (17)	.62
I was not willing to try new foods	1 (2)	1 (2)	.99
The recommended foods were expensive	2 (4)	1 (2)	.01
I did not know what to eat instead when replacing less healthy foods	4 (8)	2 (4)	.68
My dietary restrictions were not considered	3 (6)	2 (4)	.99
The health benefits of making these changes were unclear	2 (4)	2 (4)	.99
I was concerned my weight would change	0 (0)	2 (4)	.50

^aPN: personalized nutrition.

Participants were additionally asked “What is the maximum you would be willing to pay to purchase the eNutri app for unlimited personal use?” (Figure 3). Across subgroups, 31.1% (total: 33/106; control: 22/53, 42%; PN: 11/53, 21%; $P=.04$) would not pay anything at all to purchase the eNutri app,

whereas 55.7% (59/106) would pay between €0.50 (US \$0.53) and €2.50 (US \$2.67). In total, 13.2% (14/106) would pay €5.00 (US \$5.34) or more. Overall willingness to pay did not significantly differ between the PN group and the control group ($P=.3$).

Figure 3. Willingness to pay for the eNutri app across PN and control group.

Open-ended feedback, suggestions, or problems encountered during the eNutri2019 study were collected from 84 participants (control: 45/53, 85%; PN: 39/53, 74%). A categorization was made into 3 main topics: app in general, FFQ, and dietary recommendations.

Respondents positively highlighted the high intuitiveness of the eNutri app in general, coupled with good comprehensibility and ease of use (total: 22/106, 20.8%; control: 10/53, 19%; PN: 12/53, 23%). In terms of the FFQ, the time-consuming process

of data entry was remarked as too long and extensive (total: 12/106, 11.3%; control: 8/53, 15%; PN: 4/53, 8%). Many participants found it difficult to remember the foods and their quantities they had eaten in the previous month and to enter them in the correct section of the FFQ (total: 18/75, 24%; control: 6/40, 15%; PN: 12/35, 34%). At the same time, 12% (9/75) of participants noted positively the photos of the food in different portion sizes included in the FFQ and considered them as very helpful in answering the survey questions. A rather small percentage (7/106, 6.6%) of the responders (control: 3/53, 6%;

PN: 4/53, 8%) suggested a superordinate categorization into food groups (vegetables, meat, etc.), as this would have made it easier to keep track and thus to answer the FFQ. Regarding the dietary recommendations, 45.3% (48/106) of the study participants gave feedback. Nutritional advice in the PN and control groups should be considered in a differentiated manner. In the control group, 58% (31/53) indicated that the nutrition report was rather impersonal, superficial, and too general, yet contained good, easy-to-understand nutrition tips; however, they lacked helpful information for the implementation into everyday life. In the PN group, conversely, 32% (17/53) stated that they would have liked a more detailed nutrition report including more specific information about the amounts of foods to be increased; 16% (17/106) of all respondents (control: 11/53, 21%; PN: 6/53, 11%) reported that the dietary recommendations were not tailored to their individual diet or were incorrect according to the information indicated in the FFQ (eg, no meat consumption as a vegan followed by a recommendation to eat meat).

Discussion

Principal Findings

One of the objectives of the eNutri2019 pilot study as part of the EIT Food Quisper project was to introduce the German eNutri app and evaluate its usability metrics in a real-life setting. From a secondary perspective, this study sought to assess whether the provision of personalized dietary recommendations by the eNutri app provides greater benefits related to nutrition behavior changes than generic dietary advice.

Analysis of the system's usability yielded an overall mean score of 78.4, indicating that using the eNutri app is clearly above an average experience (SUS 68) [29]. As no statistically significant differences between groups could be identified, a good performance across all users can be assumed. Ferrara et al [30] reviewed diet-tracking apps and, inter alia, evaluated the usability of the top 7 diet-tracking apps found within the most popular online app stores in 2017. Across all apps considered, a mean value of 71 (range 46.7-89.2) was obtained. In comparison, the eNutri app achieved a similar usability SUS score, putting it on par. As an indicator for technical and perceived usability performance in terms of effectiveness, efficiency, ease of use, and user satisfaction, the high SUS score of eNutri stands proxy for high user acceptability and great usability.

Within app stores, most nutrition-related apps are free of charge to download but include additional fees to purchase a premium version to get access to more features. The price of an app can be seen as one key criterion for selecting an app within the app stores [31]. One-third of the eNutri2019 study participants stated that they would not pay anything at all to purchase the eNutri app. More than half would pay between €0.50 (US \$0.53) and €2.50 (US \$2.67). These results are in line with qualitative and quantitative research, showing a tendency toward a reluctant willingness to pay for nutrition apps [32,33].

Another aspect showing the value of an app is the common star rating. Overall, participants rated the app with 3.3 out of 5 stars

on average, with no significant differences between the PN and the control group. Among other popular nutrition apps, such as MyFitnessPal, Lifesum, or Freeletics Nutrition, 72% hold an average rating between 4 and 4.5 stars [34], indicating the need to further improve the eNutri app. Ratings are a reflection of user experience that involves a multidimensional interplay of system usability, context of use, expectations, perceived utility, and emotions before and after using an app [35]; thus, a rating of 3.3 stars implies that eNutri exhibits likely shortcomings in these areas that require further investigation and remediation.

A significant factor in this context is also the FFQ. FFQs are commonly integrated within diet-tracking apps to assess dietary behavior. Depending on the number of food items included, the completion time varies between 30 and 60 minutes [36]. The completion time of an FFQ is positively correlated with the potential to create typical biases [37], therefore a shorter completion time is desirable. The mean completion time for the eNutri app was 26.7 minutes, with no significant differences between groups. Franco et al [16] reported a mean completion time of 22.9 minutes in their formative study on the UK version of the eNutri app. Although the completion time of the eNutri FFQ is within a comparable range, its length was burdensome for respondents, as reflected in the open-ended feedback. To decrease the effort for the user, investigations on how to streamline the FFQ without reducing its quality need to be undertaken.

Comparison With Prior Work

Regarding the potential of the eNutri app to change a users' dietary behavior, the majority of the participants stated via open feedback that using the app motivated them to make changes in their diets and improved their awareness of healthy eating behavior. The eNutri app was positively evaluated by users, stating that the process of monitoring their dietary intake initiated a self-reflecting process, rising their awareness about unbalanced and unhealthy dietary habits. This process has also been described in various theories on behavior change, identifying *consciousness raising* as a crucial point in the process of change [38]. Furthermore, studies demonstrated a positive effect of food intake recording on the awareness of food quality and quantity [39]. This is in line with previous research indicating that perceived app utility and personalization positively affect the continuance usage intention [39-41]. Participant's feedback suggests that the personalized dietary recommendations tended to being more effective than the generic recommendations, at least in providing nutrition knowledge and support for targeted dietary adjustments tailored to an individual and his/her FFQ-derived food preferences.

Strengths and Limitations

The purpose of this study was to assess the usability of the German version of the eNutri app. Therefore, the design of a pilot study was applied.

First, the implementation of the validated and well-established graphical FFQ strengthens the design of the study. An FFQ is a commonly used dietary assessment instrument that provides information on the type, frequency, and quantity of foods consumed and allows for population estimates. However, FFQs

are prone to over- and underreporting due to their retrospective character and the time-consuming and demanding nature. By contrast, the application of prospective dietary assessment methods reduces recall bias and shows higher validity and precision, such as a food diary with a higher validity and precision [42]. The application of a prospective instrument such as a food diary should therefore be reconsidered.

Second, participants' open feedback revealed a high burden due to the long completion time. At the same point, participants' responses showed that the more personalized a dietary recommendation was, the better it tended to be accepted by them. This highlights the importance of collecting detailed food intake information via the FFQ, to enable the system to detect individual consumption patterns and preferences to subsequently provide tailored recommendations. Therefore, it was essential that the same foods in different processing stages were repeatedly queried in the FFQ (eg, vegetables in raw or cooked condition), because changes in food texture and consistency can greatly influence personal food preferences. For instance, it does not necessarily mean that if someone likes to eat raw vegetables, which can be quite crunchy in consistency, this person will also like them in cooked form with more smoothness. In return, this also means that if the FFQ was shortened, relevant information about food preferences cannot be obtained. A detailed and comprehensive FFQ, by contrast, improves the dietary recommendations, but the temporary burden to fill in the high number of items poses the risk of dropouts. This results in a certain dichotomy, and thus a balance between information demands and effort for completion needs to be found.

Third, evidence suggests that females tend to underreport in nutritional surveys [43]. Overall, there was a high proportion of women among the eNutri study population. This may be due to several reasons, one of which is the observation that women can be quite successfully recruited via social media (eg, Twitter, Facebook) [44], which was also the primary recruitment channel in the eNutri2019 study. Further, gender differences in health information-seeking behavior are known, just as a higher motivation and interest of females to deal with health-related information, coupled with a higher consciousness of nutrition [45,46]. Therefore, we will redesign our recruitment materials to appeal to a broader spectrum of the population for a follow-up study.

Fourth, an important issue arising from the eNutri pilot study is the focus on a healthy adult population. Thus, dietary recommendations provided by the eNutri app are tailored to this target group, while people with special diets requirements (eg, food intolerances, allergies) or certain nutrition-related diseases are excluded. To make the app more compatible for a broader and heterogeneous target audience, it should be adapted to diverse (nutritional) needs, taking into account not only anthropometric, physical characteristics, and individual food preferences, but also medical and behavioral traits or even genetic factors.

Fifth, the main aim was to assess the usability of the German eNutri app. Results revealed that the tool is appropriate for different user groups. The focus of the differentiation between the PN and control groups was concentrated on the open feedback. To perform an in-depth comparison of advice given to the PN and control groups, further studies with longer study periods are needed.

Further Directions

To effectively adopt positive dietary changes, a long-term implementation of the recommendations into daily habits is essential. Considering that many study participants reported having difficulties in implementing the received dietary recommendations, additional features such as a recipe database or cookbook need to be integrated directly into the app. Further improvements in the usability can be achieved by providing some external links to credible databases or scientific literature references or links to the federal Nutrition Society. This is beneficial to expand the app users' knowledge on food and nutrition, if desired. It has also been shown that coaching sessions as well as web-based coaching classes positively influence the success of dietary interventions [47]. The integration of features enabling more personal guidance (eg, chat or video coaching) within the eNutri app is another suggestion for improvement. Some nutrition apps were already designed integrating chatbot functions to support weight loss interventions [48]. To boost long-term user engagement, more in-app personalization, for example, features enabling personal goal setting and progress tracking [49], or integration of personal avatars, is advisable. Incorporating gamification elements to better communicate nutrition knowledge and raise awareness about healthier food choices is also an option with proven benefits [50].

Conclusions

The eNutri app is a field-tested feasible and usable web tool to assess habitual dietary intake. The eNutri app is unique in that it is specifically tailored to the eating habits of a Western European population, more precisely a German population. It takes country-specific food items and eating habits into account and was developed by nutrition experts. The image-based validated food quantification and the app's ease of use contributed positively to an above average usability experience of the eNutri2019 study participants. Users' experience on the eNutri app's usability was above average across different user groups. A higher level of personalization within nutritional recommendation was seen as more supportive for the implementation of positive dietary changes, in the short as well as in the long term. However, the eNutri app needs to be further adapted and extensions regarding behavioral change features need to be included. In total, the German eNutri app represents a promising tool for assessing habitual dietary intake and could become a valuable instrument to support the accomplishment of healthy dietary habits within a wide spectrum of different user groups. As a time- and cost-effective tool, it has the potential to alleviate the burden of diet-related diseases on the health care system.

Acknowledgments

This research was funded by the European Institute of Innovation and Technology (EIT) Food, the EIT, a body of the European Union, under Horizon 2020, the European Union (EU) Framework Program for Research & Innovation (Project ID: Quisper 2018 ID18064 and 2019 ID19075). The authors are grateful to all research partners involved in the eNutri2019 pilot study, and especially the colleagues from the Hugh Sinclair Unit of Human Nutrition at the University of Reading (United Kingdom), who developed and provided the eNutri app. We are also grateful to all participants who took part in this study and submitted their feedback to help us further improve the eNutri app.

Authors' Contributions

BK, TS, PMF, and KG have made substantial contributions to the conceptualization and design of the eNutri2019 study, as well as to data acquisition, data analysis and interpretation, and writing of the original draft. BK and TS contributed equally to author this manuscript. KG and PMF critically revised the manuscript. All authors approved the final version of the manuscript.

Conflicts of Interest

BK, TS, and KG declare that there are no conflicts of interest. PMF is a member of the European Food Information Council (EUFIC) governance Board of Directors representative.

Abstract

Background: Although lifestyle interventions are useful in the prevention and management of diabetes, they can be expensive and time-consuming. There is some evidence on the effectiveness of automated mobile technology for health self-monitoring; however, few studies have used such devices in the occupational health field.

Objective: We aimed to examine the effectiveness of a digital self-monitoring device on glucose levels and activity of workers with diabetes in Japan. The primary outcomes were changes in blood glucose levels, and the secondary outcomes were changes in weight and BMI.

Methods: A 2-arm randomized controlled pilot trial was conducted with workers from 23 organizations. The intervention group (n=50) wore an armband activity monitor, a body composition monitor, and a blood pressure monitor for 3 months and received semiautomated weekly email messages tailored to their device data. The control group (n=53) engaged in no self-monitoring. Messages were developed by a physician and a dietician. Postintervention changes in blood glucose levels, weight, and BMI were compared between the intervention and control groups, using blood tests and questionnaires.

Results: At the end of 3 months, the intervention group showed significantly lower blood glucose levels (HbA_{1c}: intervention group mean 6.4% (SD 0.3%) vs control group mean 6.6% (SD 0.3%); Cohen $d=0.7$, 95% CI 0.2-1.1; $P=.009$). There were no significant between-group differences in weight and BMI.

Conclusions: Mobile digital self-monitoring was effective in improving blood glucose levels in workers with diabetes. The use of digital health devices is a cost-effective way of implementing health self-monitoring for large numbers of individuals in the workplace. However, due to the large volume of missing values in this study, we need to be careful in interpreting the results, and well-designed intervention studies need to be conducted.

Introduction

The number of people with diabetes is increasing, and it is a global public health challenge [1]. In Japan, 18.7% of men and 9.3% of women are at high risk of diabetes [2]. Type 2 diabetes mellitus (T2DM) is associated with both genetic factors and modifiable risk factors such as obesity [3] and physical inactivity [4]. Early detection and prevention of T2DM using lifestyle interventions is preferable to treatment. Even a small amount of weight loss (3%) can improve metabolic status [5]. Additionally, higher daily step count (6000-8000 steps/day) can reduce morbidity [6] and mortality [7]. Lifestyle interventions can reduce T2DM incidence or improve diabetes outcomes [8-14]. However, such interventions often rely on coaching by health professionals, whose skills can affect results [11]. Additionally, the cost and time burdens of lifestyle interventions may preclude their availability to all patients with diabetes.

Interest is growing in the potential benefits of automated wearable or mobile technology as a cost-effective way of monitoring health in large populations [15-17]. A recent review indicated that web-based health behavior change interventions are often as effective as face-to-face interventions, particularly if they feature some type of person-to-person human support to provide encouragement and feedback [18].

Wearable technology devices and smartphones have been used to monitor health in workers with various conditions. Some recent reviews indicate that digital mental health interventions improve workers' well-being and effectiveness [19] and are also effective in preventing and managing diabetes; such tools may be adopted more widely with the growth of medical device innovations [20]. Two core components of mobile health tools are self-monitoring (eg, of diet, blood glucose levels, activity, and weight) and messaging (eg, educational or motivational comments and self-monitoring data feedback or reminders) [20]. Several randomized controlled or pragmatic trials have examined the use of digital health interventions for diabetes [21-28]. However, these studies show inconsistent results for glycemic improvement, and they were conducted in primary health care settings and not in the workplace. There is a small amount of evidence that message-based interventions can improve diabetes outcomes in workers [29], but more studies are needed.

The aim of this study was to examine the effectiveness of a 3-month, digital, semiautomated behavior improvement program on blood glucose levels, BMI, and health-related behavior of workers with diabetes.

Methods

Study Design

A 3-month, 2-arm randomized controlled pilot trial was conducted on Japanese workers with diabetes between June 2016 and August 2016. This was a parallel study with a 1:1 allocation ratio.

Participants

The aim of this study was explained to companies and health insurance unions, and 23 organizations agreed to participate. In Japan, regular medical examinations are conducted once a year, and most companies obtain employee blood glucose measurements (ie, HbA_{1c}). Workers with blood glucose measurements within 3 months before the baseline, whose HbA_{1c}—as per the National Glycohemoglobin Standardization Program (NGSP)—was 6.5%-7.0%, were invited to participate. The inclusion criteria were having 20-65 years of age at the time of participation and permission for participation by the attending doctor or occupational physician.

We excluded workers (1) who received regular diabetes treatment and used insulin or hypoglycemic drugs, (2) had stage ≥ 4 diabetic nephropathy, (3) were on dialysis or hospitalized, and (4) had been diagnosed with malignant tumors in the last 5 years, as well as (5) pregnant or potentially pregnant women. At the beginning of the study, participants were asked if they wished to seek treatment for diabetes and were informed that they could consult with the company occupational physician if they wished.

Randomization

One of the researchers conducted a block randomization and analyzed the data, but he was not involved in the intervention. Two sets of blocks of four (2 from the intervention and 2 from the control group) random combinations were generated using computer-generated randomization codes. Randomization was performed 7 times (corresponding to 7 recruitment periods).

Intervention

The transtheoretical model was used to develop the intervention. The individualized, transtheoretical model-based intervention was an effective strategy for weight management in the primary health care setting [30]. The intervention comprised self-monitoring and tailored feedback email messages. We distributed an armband activity monitor (Moveband 2 WMB-02C-K, LB, BR; NTT DoCoMo Inc) [31], a body composition monitor (HBF-254C; Omron Healthcare Co, Ltd) [32,33], and a blood pressure monitor (HEM-7270C; Omron Healthcare Co, Ltd) [32,34] to the intervention group. Participants were asked to wear the armband activity monitor throughout the day and night except when bathing. The activity monitor measured daily steps. We encouraged participants to measure their body weight and blood pressure at least once a day. The body composition monitor measured body weight and BMI. The blood pressure monitor measured systolic or diastolic blood pressure. The data recorded by the 3 devices were merged into 1 data set. Participants could check their activity status via the 3 devices and their own smartphones. We checked participants' self-monitoring results once a month. If the rate of wearing the activity monitor or measuring the weight was low, we contacted the participants individually and communicated with them to ask them to measure it.

We conducted biochemical examinations (Sunpre Co, Ltd) using a small amount of blood collected from the fingertip [35] for the intervention and control groups at two time points: baseline and after 3 months. To assess the effect of the intervention, the

same examinations were conducted with just the intervention group after 1 month and after 2 months from the baseline. The examinations assessed HbA_{1c} (as per NGSP), total cholesterol, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol, triglycerides, total protein, albumin, glutamic oxaloacetate transaminase, glutamate pyruvate transaminase, γ -glutamyltransferase, urea nitrogen, creatinine, and uric acid. For blood collection, participants warmed their hands and wiped the finger with a sterilizing cloth. They made a small puncture at the fingertip and drew blood into a collecting tool. They mailed the specimen to the laboratory. A biochemical automated analyzer (JCA-BM6050; JEOL Ltd) was used to measure biochemical data. Participants were able to access their examination results 1 week later via their smartphones, tablets, or personal computers.

We sent a semiautomated, tailored email message to participants once a week. The content of the messages was developed by a medical doctor and registered dietician based on Prochaska's transtheoretical theory of health behavior change [36]. The Japanese Ministry of Health, Labour and Welfare's health check and guidance manual [37] is based on this theory, and we have applied the text of this manual to this study. This theory emphasizes the important role of self-efficacy and tailored interventions to improve health behavior [38,39]. We sent messages according to the number of steps measured by the participants. The messages were designed to motivate participants to walk; for example, if a participant walked more than 10,000 steps a day, they would be praised (eg, "Great! You have focused on your walking. Keep up the good work"). If a participant walked less than 3000 steps, they would get the message "let's first focus on walking! Try walking 3 days a week, not every day. It is also effective to take a small walk or change the way you walk." We also added the message about self-monitoring and how to use the equipment. The overall message structure is provided in [Multimedia Appendix 1](#).

Participants in the intervention group were given the above-mentioned measurement devices free of charge.

Participants in the control group were allowed to seek health guidance from their company's occupational physician or nurse, but we did not record whether such guidance was sought. Participants who had high HbA_{1c} levels after 3 months were advised to seek medical advice.

Outcome Measures

Demographic information was collected at baseline. Blood tests and questionnaires assessing motivation for changing physical activity were administered to both groups at baseline and 3 months post intervention ([Multimedia Appendix 2](#)). The motivation question was related to changes in physical activity. We asked participants the following question: "do you plan to start, or have you already started, lifestyle modifications to increase your physical activity?" There were 3 response options: "I have no plan to change," "I currently have a plan to change," and "I already changed my activity." This question and response options were based on a standard questionnaire used in Specific Health Checkups [40], a detailed manual developed by the Japanese Ministry of Health, Labour and Welfare for medical

checkups required by the National Health Insurance Unions [37], and Prochaska's transtheoretical theory of health behavior change [36]. The primary outcome measure was changes in HbA_{1c} (in mmol/mol or equivalently in % as per NGSP) from baseline to 3 months. The secondary outcomes were changes in weight and BMI.

Sample Size Calculations

Sample size calculations assumed an overall 2-sided 5% significance level to be distributed equally between the intervention and control groups. A sample size of 41 in each group was estimated to have at least 80% power to detect a difference of 5 mmol/mol of HbA_{1c} (as per NGSP) post intervention, assuming an 8 mmol/mol SD of HbA_{1c} (as per NGSP) and a significance level of .05. Sample size calculations were performed using the Power and Sample Size software program (version 3.1.6; WD Dupont and WD Plummer) [41]. We assumed a dropout rate of 5% and calculated an overall minimum sample size for each group of 46.

Process Evaluation

For the purpose of evaluating the intervention process, we calculated the average rate per 30 days of available values from the digital devices (armband activity monitor and body composition monitor) in the intervention group. Especially the mean steps per 30 days by the armband activity monitor was described from the first month to the third month for the purpose of confirming whether the behavior of the intervention group continued over the 3-month period. Additionally, the steps were described, stratified by a BMI with the cutoff point of 25 kg/m² based on Japanese obesity criteria [42] and 27.5 kg/m² based on Asian population obesity criteria [43]. A previous study indicated that participants with a higher BMI had lower average daily steps [44].

Statistical Analysis

All analyses were performed by an intention-to-treat approach. To examine the effect of the intervention, we conducted chi-square tests and 2-tailed *t* tests post intervention. Effect sizes were calculated using Cohen *d* for continuous variables. *P* values <.05 were considered significant. All analyses were conducted using Stata software (version 16.1; StataCorp).

Ethical Considerations

The occupational physicians of the companies in the study determined that there were no problems with the participation in the study. In addition, the participants were not restricted from receiving regular occupational health services from the occupational health staff of their companies. We planned that if blood pressure measurements were persistently excessively high during the study period, the investigator, a physician, would contact the individual directly and recommend that he or she see a doctor. However, in reality, none of the participants were directly recommended to see a doctor.

The medical research ethics committee of the University of Occupational and Environmental Health, Japan, approved the study protocol (H28-056). Written informed consent was obtained from all participants. This study is registered with the

University Hospital Medical Information Network (UMIN000023651). Trial development and reporting was guided by the CONSORT and CONSORT-EHEALTH statements.

Results

Figure 1 shows the flow of study participants. A total of 406 individuals were assessed for eligibility criteria. After exclusions ($n=303$), 103 participants were allocated to 50 intervention and 53 control groups. Table 1 shows demographics and clinical characteristics at baseline. Among intervention and control groups, 10 (20%) and 8 (15%) were women, respectively.

Post intervention, there was a significant between-group difference in HbA_{1c} : the effect size (Cohen d) was 0.7 ($P=.009$), and the mean HbA_{1c} for the intervention group (mean 6.4%, SD 0.3%) was 0.2% (2.2 mmol/mol) lower than the mean HbA_{1c} for the control group (mean 6.6%, SD 0.3%; Table 2). There was no significant effect on weight and BMI at postintervention.

In terms of weight change (kg and %) before and after the intervention, the mean weight change for the intervention group was -1.36 (SD 3.6) kg and -1.35% (SD 4.2%), whereas for the control group, it was -0.53 (SD 2.1) kg and -0.72% (SD 2.6%), with no significant difference between the two groups ($P=.23$ vs $P=.46$).

There was a significant between-group difference in motivation for changing physical activity post intervention ($P<.001$).

Additionally, the average rate per 30 days of available values from the digital devices (armband activity monitor and body composition monitor) in the intervention group was very high compared to the control group (84% and 69%, respectively). The mean number of steps per day for the first, second, and third month in 3 months was 7226, 7431, and 7609, respectively (Table 3). Participants with a higher BMI had a lower mean number of steps. Using a BMI cutoff point of 25 kg/m², the mean number of steps remained high for those with a BMI <25. The intervention group experienced no adverse effects.

Discussion

Principal Findings

This is a randomized controlled pilot trial to evaluate the effects of a digital health intervention on blood glucose, BMI, and health behavior in workers with diabetes. After 3 months, HbA_{1c} levels significantly improved in the intervention group, but this was not the case for weight and BMI. The intervention group also showed greater motivation for changing their daily physical activity.

There was a significant improvement in HbA_{1c} values between the intervention and control groups. HbA_{1c} levels reflect the mean blood glucose level over the past 1-2 months and may reflect the effect 1-2 months after the start of the intervention. Few studies have used glycemic markers as an efficacy index in digital health interventions for diabetes prevention and weight loss. According to recent reviews, the median change in fasting glucose is -0.2 mmol/L [45], and the mean change is -0.1 mmol/L [46]; these changes are smaller than those found in this study. Even a relatively small drop of 0.5% in HbA_{1c} values is clinically important in individuals with values of 6.5-7.0, as reducing HbA_{1c} to <6.5 can help prevent microvascular complications such as retinopathy [47,48]. A previous study [28] of tailored behavior support for physical activity, diet, weight loss, stress coping, and sleep compared blood glucose levels after 6 months of weekly email interventions; HbA_{1c} was -0.26% in the intervention group and -0.18% in the control group [28]. However, another study of a mobile health intervention for patients with diabetes showed no difference in HbA_{1c} values between the intervention and control groups one year later [21]; therefore, evidence is inconsistent, perhaps because of between-study differences in populations and intervention programs. Since the number of steps taken before the intervention is unknown, it is difficult to say for sure, but the number of steps taken by the intervention group increased slightly over the 3-month intervention period (Table 3), suggesting that the increase in activity may have led to an improvement in HbA_{1c}. The daily self-monitoring of weight using scales may have boosted self-motivation to increase physical activity [49]. The questionnaire responses after 3 months revealed that motivation to increase physical activity

had increased significantly more in the intervention group. This motivation may lead to the behavior change of walking. Participants with a BMI of 27.5 kg/m² or higher had a decrease in their mean number of steps over the course of 3 months. How to get people with obesity to be active and how to maintain their behavior is an important public health issue.

There was no between-group difference in the secondary outcome—changes in weight and BMI. The weight reduction among the intervention group was 1.4 kg in 3 months, which is lower than previously reported reductions of 2.3 kg (over 12 months) [46] and 2.4 kg (over 3 months) [50] for diabetes lifestyle interventions. One reason for the lack of weight loss may be inadequate subscription to the diet.

Several randomized controlled trials have examined the use of digital health interventions for diabetes when the HbA_{1c} of participants was more than 7.5 [22] or more than 8.0 [21,24]. The new finding of this study was that intervention in subjects with an HbA_{1c} as low as 6.5-7.0 was effective in reducing HbA_{1c} levels. The interventions in this study were via self-monitoring and semiautomated tailored email messages. However, the latter did not elaborate an individualized message, unlike previous studies that individualized them [20,28]. The actual messages are all shown in [Multimedia Appendix 1](#). Although this is a weakness of the study, it shows that self-monitoring may be effective even without individualized messages. Self-monitoring is an intervention method that requires less professional involvement and is more economical. In the workplace, workers may show the results of their self-monitoring to each other and encourage each other. This will increase the motivation for behavior change and will sustain it.

There were some limitations in this study. First, there were a large volume of missing data in the questionnaires and biochemical tests. It is unclear how the bias of the missing data affects the results. Intervention studies need to be designed and conducted in such a way that missing data will be minimal. Second, only 103 (25%) ultimately agreed to participate, although 406 individuals were recruited by being directly approached about participating in this study. Participants in this study received incentives such as blood pressure monitors, but many workers decided not to participate. This suggests that it is difficult to change people's behavior. In addition, participants

in this study were likely to have a high level of awareness of behavior change, so we need to be careful in interpreting the results of this study. Third, the primary outcome of this study, changes in HbA_{1c} levels, reflects blood glucose levels over the past 1-2 months. The effect of the study should be verified by follow-ups for at least 6 months. However, in this study, we were only able to follow up for 3 months after the start of the intervention due to difficulty in securing a budget for the research project. Since there was an improvement in HbA_{1c} in the intervention group within 3 months, it is possible that a longer follow-up would have resulted in a greater effect. It is necessary to verify the results by long-term follow-ups in the future. Fourth, participants were from relatively large companies, and it is unclear whether the findings can be generalized to workers of small companies. Fifth, as body weight was self-measured, the validity and reliability of BMI values were limited. Sixth, it may be possible that occupational stress

may have affected the findings; however, this is unlikely, as there was no difference in occupation and job position between the intervention and control groups.

Conclusions

The 3-month, digital health intervention for self-monitoring and the semiautomated tailored messages were effective in reducing HbA_{1c} levels in workers with diabetes. This study shows that physical activity can be increased, and blood glucose control can be improved without imposing a professional workload. However, we need to take into account the large number of missing values in this study and be careful in interpreting the results; further well-designed intervention studies need to be conducted. Despite the fact that many people were approached to participate in this study, few actually did so. It may be necessary to develop interventions that would encourage a wider range of workers to participate.

Acknowledgments

This work was supported by a JSPS KAKENHI grant (JP16K19264) and a 2015 infrastructure development project for creating a new industrial model of the Internet of Things by the Ministry of Economy, Trade and Industry of Japan.

We thank Shigeki Kobayashi (from Ewel Inc) for his support and advice in conducting this study. We thank Diane Williams, PhD, from Edanz Group for editing a draft of this manuscript and helping to draft the abstract.

Authors' Contributions

TN played a lead role in the study design and writing of the manuscript. TN and SA contributed to the data interpretation and data analysis. MT carried out all the work, including the coordination of the study. MN and KM reviewed drafts of the manuscript. All authors gave their final approval for the submitted version of the paper.

Abstract

Background: Childhood obesity prevention interventions routinely focus on changing maternal parenting practices. Failure to assess how fathers' weight-related (ie, diet and physical activity) parenting practices contribute to children's energy balance behaviors limits the understanding of their paternal role within the family. Examining the independent and interacting effects of fathers' and mothers' weight-related parenting practices on children's diet and physical activity addresses this important research gap.

Objective: This study used ecological momentary assessment (EMA) to investigate the within-subject and between-subject independent and interactive effects of maternal and paternal encouragement to eat and preparation of fruits and vegetables (F/V) and encouragement of and taking their child to be physically active on their child's self-reported F/V intake and physical activity engagement.

Methods: Participants included mother-father-child triads (n=22 triads, n=205-213 prompts/occasions) in the Mothers and Their Children's Health Study and the University of Southern California Fathers Study. Simultaneously, mothers and fathers (ages_{mean} 44.2 years, SD 5.6, and 45.2 years, SD 8.1, respectively), and their children (age_{mean} 12.0 years, SD 0.7) completed up to 8 randomly prompted EMA surveys per day on separate smartphones for 7 days. At each prompt, mothers and fathers each reported whether they did the following in the past 2 hours: (1) encouraged their child to eat F/V, (2) prepared F/V for their child, (3) encouraged their child to be physically active, or (4) took their child to be physically active. Children self-reported whether they consumed F/V or were physically active in the past 2 hours.

Results: Results from Bayesian multilevel logistic models (all in log-odd units) indicated that at the within-subject level, greater maternal encouragement ($\beta=2.28$, 95% CI 0.08 to 5.68) of eating F/V was associated with greater child report of eating F/V, but paternal encouragement ($\beta=1.50$, 95% CI -0.83 to 4.52) showed no effects above and beyond maternal encouragement. Additionally, greater than usual paternal encouragement ($\beta=2.28$, 95% CI 0.08 to 5.54) and maternal encouragement ($\beta=2.94$, 95% CI 0.36 to 6.69) of physical activity had significant independent effects and were associated with greater child report of physical activity. No other within-subject or between-subject associations nor interactive effects were significant.

Conclusions: Findings from this study suggest that fathers play a role in supporting their children's physical activity but not their intake of F/V. Future EMA studies should recruit larger samples to evaluate the independent and interacting roles of mothers' and fathers' weight-related parenting practices on child's obesogenic behaviors.

Introduction

Child obesity prevalence has increased over the past five decades, with 41% of US children classified as overweight, obese, or severely obese [1]. Adverse health outcomes among obese children include hypertension and hypercholesterolemia [2], which track from childhood into adulthood, placing these children at greater risk of early mortality. Parents play a critical role in shaping their children's weight-related behaviors [3]. Thus, childhood obesity prevention interventions have focused on parental behavior change. However, these interventions have demonstrated limited success with preventing increases in children's BMI [4]. One reason may be that the vast majority of these interventions address the practices and behaviors of mothers [5] while excluding the influential role of fathers within the family.

Research informed by family systems theory indicates that behaviors among family members are part of an interrelated system that cannot be examined in isolation [6]. Studies have explored the key role mothers play in providing support for children's healthy eating and physical activity. Cross-sectional between-subjects research examining the relationships between the home environment and children's fruit and vegetable (F/V) consumption showed that parental encouragement of F/V consumption was positively associated with children's F/V consumption [7-10]. Between-subjects results from an ecological momentary study showed that children whose mothers prepared more F/V compared to other mothers had greater odds of eating F/V. Within-subjects results from this study indicated that when mothers expressed greater encouragement and preparation of F/V than usual, their children had greater odds of eating fruits and vegetables at the next prompt [11]. Using the same participants from the aforementioned study, children whose mothers reported taking their children someplace to be physically active engaged in more moderate-to-vigorous physical activity (MVPA). When mothers reported taking their children someplace to be physically active more than usual, their children engaged in more MVPA [12]. These results highlight the influential role mothers have in energy balance behaviors of their children.

Due to limited research conducted among fathers, missing from these analyses are the effects of paternal parenting practices on children's energy balance behaviors [5,13]. This gap is concerning because fathers are parenting and caring more for their children, with a reported increase from 2.5 to 7.3 hours per week over the last 45 years [14], perhaps due to the increased percentage of working mothers, up from 47% in 1975 to 70% in 2014. Furthermore, 2 million US fathers are stay-at-home dads, up from 1.1 million in 1989 [15]. Although the number

of stay-at-home dads in the United States increased 100% in the past 21 years, extant research regarding the role of fathers in children's obesity risk is limited, due in part to the difficulty in recruiting fathers for child health studies [16].

These concerns are further exemplified by a recent review examining fathers' role in children's physical activity that indicated only 1.5% of observational between-subject studies conducted between 2009 to 2015 met study criteria that included the following: included fathers as study participants, presented fathers' data separately from mothers' data, and collected data on fathers' physical activity parenting behaviors and/or fathers' physical activity and children's physical activity. The authors concluded that among the associations examined, more than half were positive, albeit modest, associations between fathers and their children's physical activity [17]. For example, one article reviewed indicated that explicit modeling of physical activity by fathers was positively associated with their sons' accelerometer-measured MVPA and vigorous physical activity [18]. A systematic review of 23 between-subject studies examining fathers' feeding behaviors concluded that paternal modeling of healthy eating, own energy intake, and limit setting of unhealthy eating had a positive effect on children's diet and reinforcement for healthy choices provided by the mother and father were positively associated with children's healthy dietary choices [19]. This emerging evidence warrants further examination to determine how fathers' own diet and physical activity along with their dietary and physical activity parenting practices influence children's diet and physical activity.

Parenting practices may vary within days and across days due to interpersonal interactions, situational encounters, and changing demands and expectations and may negatively affect children's obesogenic behaviors [20,21]. Research is beginning to explore how daily variability in parenting practices contributes to children's obesity risk [22,23]. Participation of fathers in child obesity prevention studies poses challenges including the lack of targeted recruitment specific to fathers, time commitments that overlap with employment schedules, and failure to focus on long-term benefits of fathers' participation [24]. To the best of our knowledge, no studies have examined the effects of within-day variability in fathers' parenting practices on children's energy balance behaviors (ie, diet, physical activity), resulting in a significant gap in childhood obesity research. Failure to assess how fathers' weight-related parenting practices contribute to children's energy balance behaviors limits the understanding of their parental role within the family.

In addition to the lack of research on fathers' influence on their children's energy balance behaviors, prior studies are also limited because they only assess between-subject effects, which

limits our understanding of when parents may have greater influence on children's energy balance behaviors and precludes the tailoring of intervention strategies. Ecological momentary assessment (EMA) is a methodology that uses an intense longitudinal design to collect self-reported data multiple times per day over multiple days. A prompting schedule for participants to respond to mobile phone-based surveys over the course of the day was developed specifically for the individual study. Using EMA allows for real-time data capture of parenting behaviors that increases ecological validity and addresses the lack of examination of within-subject variability. It can capture within-day fluctuations for constructs that change frequently throughout the day (eg, stress). EMA allows for disentangling of within-subjects and between-subjects effects that may ultimately assist in designing effective parenting interventions that can adjust for intra-individual differences. Additionally, EMA helps reduce recall bias found in retrospective studies as reliance on memory to inform on performed behaviors is reduced through the frequent prompting schedule. This exploratory study used EMA to investigate the within-subject and between-subject independent and interactive effects of maternal and paternal encouragement and preparation of F/V and encouragement of and taking their child to be physically active on their child's self-reported F/V intake and physical activity engagement. Based upon cross-sectional studies that examined the role of mothers and fathers on children's physical activity, we hypothesize that there will be a significant positive relationship between fathers' parenting behaviors and their children's F/V intake and physical activity independent of mothers' parenting behaviors. Further, we hypothesize that there will be a significant relationship between mothers' parenting behaviors and their children's F/V intake and physical activity. We hypothesized that there would be a significant interactive effect of maternal and paternal behaviors on children's F/V intake and physical activity.

Methods

Study Design and Participant Characteristics

Participants included a subsample of mother-child dyads and fathers (n=22 mother-father-child triads) enrolled in the Mothers and Their Children's Health Study (MATCH; mother-child dyads) who were also enrolled in the University of Southern California (USC) Fathers Substudy. Participants enrolled in the MATCH study and Fathers Substudy lived in the greater Los Angeles area. Inclusion criteria for the MATCH study comprised mother having at least 50% custody, children aged 8 to 12 years, and the mother and child having the ability to read and write in English or Spanish. Exclusion criteria for the MATCH study included mother currently pregnant, mother works more than 2 weekday evenings or works on weekend days, mother or child taking medications for a psychological condition or oral or inhaled corticosteroids, mother or child experiencing health issues that prevent or limit physical activity, and child enrolled in a special education program. Inclusion criteria for the Fathers Substudy comprised father/father figure with a child currently participating in the MATCH study, having at least 50% custody, and the ability to read and write in English or Spanish. The objective of the larger MATCH study was to examine the

long-term effects of mothers' stress on their children's energy balance behaviors (ie, diet, physical activity, sedentary time). The goal of the USC Fathers Substudy was to examine the role of fathers' weight-related parenting behaviors on their children's energy balance behaviors. MATCH received approval through the USC institutional review board and Northeastern University; the USC Fathers Substudy received approval through the USC institutional review board.

Mothers and their children participated in MATCH over a 3-year period, with 7-day data collection waves occurring every 6 months [25]. During the final 7-day data collection wave of the MATCH study in spring 2018, fathers were contacted via email and phone to determine interest in participating in the USC Fathers Substudy. If fathers expressed interest in participation, they were asked to accompany their spouse/child's mother and child to their upcoming scheduled MATCH data collection appointment at which fathers reviewed and completed informed consent with research staff. Fathers without Android phones were provided moto g (Motorola Mobility LLC) smartphones for collecting EMA data. If participants owned an Android phone, they were instructed to download the appropriate app. Effects of siblings and peers of the enrolled child in the MATCH study were not included in this study.

Mothers, fathers, and their children completed up to 8 randomly prompted EMA surveys per day on their respective smartphones for 7 days. Weekday prompts began between 3 PM to 4 PM, ending between 7 PM to 8 PM for the child (total of 3 prompts) and 9 PM to 10 PM for the mother and father (total of 4 prompts). No prompting occurred during school hours. Weekend prompts started between 7 AM to 8 AM, ending at comparable times for weekday prompts. At each prompt, mothers and fathers independently reported whether they spent time with their child in the past 2 hours by answering the question, "Over the last 2 hours, have you spent time with your child (together in the same location)?" If a yes response was indicated, mothers and fathers subsequently independently reported if they did the following in the past 2 hours: (1) encouraged their child to eat F/V, (2) cooked or prepared F/V for their child, (3) encouraged their child to be physically active, and (4) took their child to be physically active. Response options for each of the 4 questions were yes or no. At each prompt, children reported if they did the following in the past 2 hours: (1) consumed F/V and (2) participated in exercise, sports, or physical activity. Response options for each of the 2 questions were yes or no. In addition to the EMA surveys, fathers completed paper surveys that included sociodemographic information (eg, age, marital status). Mothers previously completed paper surveys that included sociodemographic information (eg, age, marital status, child sex, and ethnicity).

Ethics Approval

MATCH received approval through the USC institutional review board and Northeastern University (HS-12-00446); the USC Fathers Substudy received approval through the USC institutional review board (HS-17-00797). No other approvals were necessary for study completion.

Statistical Analyses

Participant sociodemographics were analyzed using SPSS (version 27, IBM Corp). Means and standard deviations were calculated for mothers, fathers, and children's ages. Percentages were determined for parents' marital status and child sex and ethnicity.

For each child outcome (ie, whether children consumed F/V or were physically active; 1=yes, 0=no), we separately examined whether parental encouragement for eating F/V and physical activity and parental support (ie, cooking or preparing F/V and taking the child to be physically active) had predictive power. The data had a nesting structure with repeated EMA observations (level 1) nested within families (level 2). Given the small number of clusters (ie, families in our data) and the focus on binary outcome variables in our study, we used Bayesian estimation with weakly informative prior distributions to improve the stability of the results [26]. For each child outcome, we fitted 2 two-level Bayesian multilevel logistic models with repeated EMA observations nested within families and the following structure:

where t indicates time and i indicates family, and X^{mo} and X^{fa} are binary predictors for mother and father encouragement or support, respectively. The β s are the fixed effects and the u s are the random effects. To account for the potential time dependence, we also specified an autoregressive error [1] structure for observations within the same day.

For each outcome, we entered the predictors in 3 steps. In step 1, we included the intercept and the main effects of person-mean centered maternal (X^{mo}) and paternal (X^{fa}) encouragement/support at the occasion level as well as mean levels of maternal and paternal encouragement/support for each family. The use of family-mean centering allows us to decouple the between-family and within-family associations [27]. In step 2, we tested the interaction between the father and the mother variables.

For each model, we analyzed only observations where the child answered the EMA prompt and both parents also answered the prompts within the same 2-hour period. Observations were excluded if only one of the parents answered the prompt.

We used the R package (R Foundation for Statistical Computing) brms [28] to perform Markov chain Monte Carlo sampling. For each model, we used 4 chains, each with 2000 iterations. The first half of the samples were used as warmups, resulting in 4000 total Markov chain Monte Carlo samples. All models achieved convergence, as indicated by the potential scale reduction factor being less than 1.01 [29]. Posterior means were used as point estimates, and coefficients were considered significant statistically when the 95% credible interval excluded zero.

Results

The total number of prompts sent was 765 for fathers, 692 for mothers, and 561 for children. The response rates were 80.0%

(612/765) for fathers, 85.0% (588/692) for mothers, and 85.9% (482/561) for the child. The number of prompts where all 3 members in a family answered in the same 2-hour interval was 322, but there were missing data for specific items as reflected below in the model-specific sample sizes.

Mothers and fathers were comparable in age (ages_{mean} 44.2, SD 5.6, and 45.2, SD 8.1, respectively). Children had a mean age of 12.0 (SD 0.7) years. A total of 73% (16/22) of parents indicated being married or living as married. Of the 22 children, 55% (12/22) were female and 41% (9/22) identified as Hispanic/Latino. Child BMI z-scores had a mean value of 0.17 and ranged from -2.5 to 2.0. Table 1 shows the correlations among the parental variables and the child outcomes. We found strong correlations between encouragement and support from the same parent for the same child outcome ($r=.55$ to $r=.83$). In addition, a parent's encouragement/support for physical activity was moderately correlated with the same parent's encouragement/support for eating F/V ($r=.09$ to $r=.53$). There were also moderate correlations between father's and mother's encouragement/support ($r=.13$ to $r=.38$). Child reports of being physically active and eating F/V were moderately associated with parental encouragement and support ($r=.09$ to $r=.26$).

As shown in Table 2, results from Bayesian multilevel logistic models indicated that, at the occasion level, greater than usual maternal encouragement ($\beta=2.28$, 95% CI 0.08 to 5.68, in log-odds units) for eating F/V was significantly associated with greater likelihood of child report of eating F/V, but evidence was not significant for paternal encouragement ($\beta=1.50$, 95% CI -0.83 to 4.52) above and beyond maternal encouragement. Figures 1 and 2 show the model-predicted overall and family-specific probabilities with only mother's or father's encouragement reported in the brms package, computed using the model coefficients (ie, probability = $1 / [1 + \exp(-\eta)]$ where η is the model predicted log-odds). Based on the model, when there was no father encouragement, the predicted probability of eating F/V was 0.39 with mother encouragement, compared to 0.22 without mother encouragement. However, the coefficient for paternal encouragement was not significant, and thus, only predicted probability of eating F/V with mother encouragement is reported. No statistical evidence was found for the between-family level associations, and the interactions between maternal and paternal encouragement for F/V intake were not significant.

When fathers ($\beta=2.28$, 95% CI 0.08 to 5.54) and mothers ($\beta=2.94$, 95% CI 0.36 to 6.69) each have higher levels of encouragement of physical activity than their usual level, children were more likely to report physical activity in the past 2 hours. In other words, holding mothers' encouragement as constant, fathers' encouragement was positively associated with children's physical activity (individual responses shown in Figures 3 and 4). There were also significant differences in the coefficients of maternal and paternal encouragement across families, as indicated by the significant random effect standard deviation (for father, estimate=1.14, 95% CI 0.04 to 3.61; for mother, estimate=2.40, 95% CI 0.15 to 6.62). Specifically, the predicted probability of the child performing physical activity was 0.21 with neither mother nor father encouragement, 0.42

with only mother encouragement, 0.37 with only father encouragement, and 0.59 with both father and mother encouragement. No statistical evidence was found for differential associations at the between-subject and the within-subject levels, and the interaction between maternal and paternal encouragement for physical activity was not significant. The nonsignificant between-level coefficients indicate insufficient evidence for different between-level and within-level coefficients. The random effects were similar in Stage 1 models and were only reported in those final models (Table 2).

F/V: fruits and vegetables.

Table 3 shows the model results when using parental support (preparing F/V for the child and taking the child to be physically active) as predictors of children’s reported health behaviors. Although some of the coefficients were in the positive direction, none of them were significant. The nonsignificant between-level coefficients indicate insufficient evidence for different between-level and within-level coefficients. Parental support refers to mother/father preparing fruits and vegetables or taking the child somewhere to be physically active. The random effects were similar in stage 1 models and were only reported in those final models (Table 3).

Discussion

Principal Findings

This exploratory study investigated the within-subject and between-subject independent and interactive effects of maternal and paternal encouragement and preparation of F/V and maternal and paternal encouragement of and taking their child to be physically active on their child's self-reported F/V intake and physical activity engagement. There were no significant between-subject associations for (1) maternal or paternal encouragement of or preparation of F/V on children's consumption or (2) maternal or paternal encouragement of or taking the child to be physically active on children's physical activity. However, given the small number of participants, this study provides insufficient power for between-subject associations. Within-subjects results indicated that greater than usual maternal encouragement was associated with children's greater likelihood of EMA-reported F/V consumption in the past 2 hours; however, paternal encouragement was not associated with children's likelihood of reporting F/V consumption. Additionally, greater than usual maternal encouragement and greater than usual paternal encouragement were independently associated with greater likelihood of children's EMA-reported physical activity in the past 2 hours. No within-subjects results for parental support (ie, taking the child someplace to be physically active, preparing F/V for the child) were significant.

Our previous EMA study using the same MATCH participants without fathers' data showed the positive relationship of maternal encouragement with children's subsequent F/V intake [11], but cross-sectional between-subjects research conducted among Norwegian families (85% mothers, children ages 10 to

11 years) indicated no relationship between parent-reported encouragement of F/V consumption and child-reported F/V intake [30]. In a similar between-subjects study conducted among Icelandic families (85% mothers, children aged 11 years), there was either no relationship between child-reported parental encouragement for F/V consumption and child-reported F/V intake [31] or a negative relationship between maternal-reported encouragement and children's self-reported F/V intake [31]. In our study, mothers and fathers independently reported their encouragement of F/V consumption and children self-reported F/V intake, aligning with the parent-reported cross-sectional results and EMA results. Given the mixed findings in the literature, future research should engage more families and explore within- and between-effects from individual influences provided by mothers and fathers.

Another cross-sectional study that examined differences in children's F/V consumption by race/ethnicity indicated greater child-reported social support for F/V intake among non-Hispanic White children compared to African American and Hispanic children [32]. The authors created a composite parental social support score that included several measures: providing children with prepared F/V, eating F/V, encouraging the child to eat F/V, and wanting the child to eat F/V. Stratified analyses showed that the greater the support provided, the higher reported vegetable consumption among Hispanic children [32]. In this study, we were not able to stratify our analyses by ethnicity due to the small sample size. However, nearly half of the children in our sample identified as Hispanic/Latino, illustrating that maternal encouragement of F/V consumption may be well received by both non-Hispanic White children and Hispanic/Latino children.

This study did not find statistically significant effects of mothers' preparation or fathers' preparation of F/V on children's F/V intake. Previous longitudinal EMA research reported that greater than usual maternal preparation of F/V and greater maternal preparation of F/V when compared to other mothers resulted in increased odds of child-report of F/V consumption [11]. Results from other cross-sectional research indicated a positive association between adolescent-reported F/V consumption and fathers' parenting practices that included preparation of F/V [33]. The lack of a relationship between F/V preparation and child F/V consumption may be due to the proximity of children's ages to adolescence (age_{mean} 12.0 years, SD 0.7) in this study. As children age, they gain more independence for preparing their own snacks and thus, their parents may not spend as much time preparing F/V for them [34]. Additionally, the provision of F/V as snacks may not require extensive preparation, and thus parents may not view this as a considerable amount of time.

In this study, paternal encouragement of physical activity was associated with greater child-reported physical activity. Thus, fathers may play a larger role in supporting children's physical activity than their intake of F/V. One study examined sports participation among low socioeconomic status youth and reported that strong paternal influence may be salient to encouraging children's participation [35]. Previous qualitative research conducted among mothers indicates that they perceive fathers to play an active role in their children's physical activity including encouraging the child to perform physical activity [36]. Additionally, in our study, maternal encouragement of physical activity was also associated with children's physical activity. Our findings are also supported by previous longitudinal EMA research using the same MATCH participants (without fathers' data) that indicates children's MVPA levels were higher when mothers reported encouraging their child to be physically active within the same 2-hour window [12]. Our results also align with previous research indicating that maternal support for physical activity was positively associated with children's device-measured activity levels [37]. In this study, parental encouragement plays a larger role for physical activity promotion rather than F/V intake. This may reflect differences in these behaviors such as the potential planning required to facilitate children's physical activity, whereas home availability of F/V may not necessitate promotion. Thus, children may make more independent choices related to diet but still rely on parents for physical activity (eg, driving child somewhere to be physically active).

In contrast to parental encouragement, there were no statistically significant effects of the parent providing support by taking a child somewhere to be physically active on child-reported PA. Our previous EMA research using the same MATCH participants (without fathers' data) indicates that children were more physically active when mothers reported taking their child somewhere to be physically active [12]. Cross-sectional research that examined the relationship between activity-related parental logistic support included a measure of taking the child somewhere to be physically active. Findings showed mothers had higher mean levels of support for girls' physical activity compared to fathers, but there was no relationship among

paternal and maternal logistical support and objectively measured child physical activity [18]. These contrasting findings may be due to the lack of separation of support into individual components in previous studies along with variability in reporting children's physical activity [38,39]. For example, a study examining the cross-sectional associations between parenting practices and children's pedometer-assessed physical activity combined measures for instrumental support (eg, taking the child somewhere to be physically active) and emotional support (eg, encouraging the child to be physically active). Results indicated that child-reported parent support was positively significantly associated with both boys' and girls' physical activity [38]. Another study found children's perception of parental support was positively associated with both boys' and girls' questionnaire-assessed physical activity [39]. Future research should consider incorporating both child report of mothers' and fathers' support for physical activity and child perceptions of parental support to inform on children's interpretations of parenting behaviors that may affect their own physical activity and identify areas on which to intervene (eg, just-in-time parenting interventions) at the family level.

Strengths and Limitations

There has been limited research on the role of fathers' parenting practices (ie, encouragement and support) on children's energy balance behaviors. Thus, a major strength of this study includes the triadic design within everyday family contexts that allowed assessment of the independent and interactive influences of maternal and paternal parenting weight-related practices on children's diet and physical activity. Additionally, the use of EMA methods to assess parenting and children's behaviors in real time is an additional strength. However, this study is not without limitations. Due to the small sample size, we are unable to generalize our study findings to a broader population. Additionally, we are unable to stratify our results to assess potential moderators such as child sex or ethnicity. The 2-hour time window used for analysis may not have perfectly overlapped among mother-, father-, and child-reported behaviors. We also cannot establish temporality within the 2-hour period. For example, it is unknown whether the mother and/or father encouraged the child to be physically active or eat F/V before or after the child reported engaging in physical activity or eating F/V. We also did not control for environmental contexts including weather conditions, physical location, and level/type of physical activity, which have been shown to influence activity levels [40]. Mothers and fathers were not provided with a specific definition for the term *encourage* as it pertained to children's physical activity and healthy eating. Thus, answering questions related to encouragement of consumption of F/V and physical activity may have been interpreted in various ways. However, they were given the opportunity to ask clarifying questions during orientation to the study and provided with a contact number to ask any questions that arose. We are unaware whether the mother or father ate or exercised in the presence of their child. It is possible that the child reported eating or being physically active because these behaviors were not only encouraged but also modeled by the parent to their child. Last, parenting practices and support, along with children's outcomes of F/V consumption and physical

activity, were self-reported rather than objectively measured and therefore open to recall bias and social desirability bias [41].

Conclusion

Our results indicate children who are encouraged to eat F/V report greater F/V consumption and children who are encouraged to be physically active report greater physical activity. Furthermore, fathers' encouragement of physical

activity has an independent effect to mothers' encouragement of physical activity on children's EMA-reported physical activity. These findings have implications for future just-in-time parenting interventions to promote children's F/V consumption and physical activity. For example, prompting of parental encouragement from both mothers and fathers during times when children can eat F/V and engage in physical activity may result in greater consumption of F/V and higher levels of physical activity.

Acknowledgments

This research was supported by grant 12-5176-2302 from the University of Southern California Fathers Study, Southern California Clinical and Translational Science Institute (Acting principal investigator: NL); grant 5R01HL119255 from Maternal Stress and Children's Obesity Risk, National Heart, Lung, and Blood Institute (principal investigator: GFD); and the Cancer Control and Epidemiology Research Training Grant T32CA009492 from the National Cancer Institute (principal investigator: Maryann Pentz)

Authors' Contributions

NVL conceptualized the USC Fathers Substudy, and GFD conceptualized the MATCH study. NVL, CHY, and MHCL conceptualized the current analysis. MHCL analyzed the data. NVL and MHCL wrote the first draft of the manuscript. NVL, MHCL, CHY, GFD, and BRB reviewed and revised the manuscript. All authors approved of the final version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The prevalence of smoking in the United States general population has gradually declined to the lowest rate ever recorded; however, this has not been true for persons with HIV.

Objective: We conducted a pilot test to assess the feasibility and efficacy of the Lumme Quit Smoking mobile app and smartwatch combination with sensing capabilities to improve smoking cessation in persons with HIV.

Methods: A total of 40 participants were enrolled in the study and randomly assigned 1:1 to the control arm, which received an 8-week supply of nicotine replacement therapy, a 30-minute smoking cessation counseling session, and weekly check-in calls with study staff, or to the intervention arm, which additionally received the Lumme Quit Smoking app and smartwatch.

Results: Of the 40 participants enrolled, 37 completed the follow-up study assessments and 16 used the app every day during the 56-day period. During the 6-month recruitment and enrollment period, 122 people were screened for eligibility, with 67.2% (82/122) deemed ineligible. Smoking criteria and incompatible tech were the major reasons for ineligibility. There was no difference in the proportion of 7-day point prevalence abstinence by study arm and no significant decrease in exhaled carbon monoxide for the intervention and control arms separately. However, the average exhaled carbon monoxide decreased over time when analyzing both arms together ($P=.02$).

Conclusions: Results suggest excellent feasibility and acceptability of using a smoking sensor app among this smoking population. The knowledge gained from this research will enable the scientific community, clinicians, and community stakeholders to improve tobacco cessation outcomes for persons with HIV.

Trial Registration: ClinicalTrials.gov NCT04808609; <https://clinicaltrials.gov/ct2/show/NCT04808609>

Introduction

The prevalence of smoking in the general US population has gradually declined to 12.5% in 2020, the lowest rate ever recorded [1]. However, this has not been true for persons with HIV, who have disproportionately high smoking rates (34% to 47%) [2-4]. Across several studies of persons with HIV in New York City, Schnall et al [5] found that 47.1% of study participants were cigarette smokers, providing further evidence of the high prevalence of tobacco use in this population [6,7]. High rates of smoking have grave health implications for persons with HIV, placing them at increased risk for bacterial pneumonias [8], acute bronchitis and tuberculosis [9-16], early development of emphysema [17-22], and lung and cervical cancers at a younger age than the general population [23-28]. These disparities are partly due to a higher prevalence of tobacco use in persons with HIV than the general population and partly attributable to exacerbated comorbidities such as cardiovascular disease, lung cancer, and diabetes in persons with HIV who smoke compared to smokers without HIV [29-31]. For persons with HIV, apart from achieving and maintaining a suppressed viral load, tobacco cessation is the most important health behavior they can undertake to maximize both quality of life and life expectancy [32]. Indeed, persons with HIV who quit smoking upon entering HIV care gain more than 5 years of life expectancy as compared to those who enter HIV care and continue smoking [33,34]. Consequently, persons with HIV experience substantial tobacco-related morbidity and mortality.

Given the high prevalence of cigarette smoking among persons with HIV and the benefit of smoking cessation, there is an urgent need to intervene to reduce tobacco use rates. However, the currently available evidence for improving tobacco cessation among persons with HIV is inadequate. Few tobacco cessation interventions have been tested among persons with HIV, and of those that have, there is very low quality evidence that they were effective in the short term and moderate quality evidence indicating similar outcomes to controls in the long term [35-39].

In recent years, the use of mobile health (mHealth) technologies for tobacco cessation, such as Text2Quit [40] and SmokeFree Text from the National Cancer Institute [41], has gained popularity. While these programs have demonstrated positive effects in some populations [42-45], their functionality is limited because text messaging is unable to automatically capture instances when assistance is required to resist cravings or when smoking relapse occurs. To address this need, our study sought to use more advanced technology, comprising a mobile app and smartwatch, that functioned as a sensor to integrate behavioral assessment and a just-in-time cessation intervention for smokers. The app and watch sensor provided smoking relapse prevention to supplement the cessation intervention of traditional nicotine replacement therapy (NRT). Watch sensor data, in conjunction with the app, functioned to prevent smoking relapse immediately following the initiation of NRT (quit date). The purpose of this pilot study was to determine the feasibility and acceptability of the Lumme Quit Smoking app for improving tobacco cessation outcomes in persons with HIV who smoke.

Methods

Study Design

The study was conducted with 40 persons with HIV who smoke who were randomized to 2 study arms. Participants were randomly assigned to receive the Lumme Quit Smoking app (active) or a control condition (standard smoking cessation counseling session). Participants had in-person study visits at baseline and 12 weeks following their baseline visit. The primary objectives of the study were to assess the feasibility and acceptability of the Lumme Quit Smoking app; the study was not powered to assess efficacy. A secondary goal was to establish the effect size needed to conduct a fully powered intervention trial.

Recruitment

Study participants were recruited by posting flyers at a local HIV clinic and from an existing database of persons living with HIV who had participated in earlier studies and agreed to be recontacted for future studies. Study enrollment took place from September 28, 2020, to April 19, 2021.

Inclusion criteria were (1) persons with HIV, (2) aged 18 years and older, (3) own an Android smartphone, (4) understand and read English, (5) not pregnant or breastfeeding, (6) have permanent contact information, (7) smoke 5 or more cigarettes per day for the past 30 days [46], (8) interested in quitting smoking within 30 days, and (9) have an exhaled carbon monoxide (eCO) level of more than 5 parts per million (ppm) at baseline.

Exclusion criteria were (1) self-report having HIV-negative or unknown status; (2) pregnant, breastfeeding, or planning to become pregnant during the study period; (3) planning to move within 3 months of enrollment; (4) positive history of a medical condition that precludes use of the nicotine patch; (5) current use of NRT or other smoking cessation medications (eg, Chantix or Zyban); (6) current enrollment in another smoking cessation program; or (7) eCO of 5 ppm or less at baseline.

Biochemical verification of abstinence appears to be increasingly important, especially in clinical trials, and increases scientific rigor, as both social norms relating to smoking behavior and an increasing number of personal factors (eg, age, pregnancy, hospitalization status, and socioeconomic status) are related to misreporting of smoking behavior. eCO is a useful assessment tool for measuring recent smoking abstinence [47].

Ethics Approval

The Columbia University institutional review board approved this study before commencement of study activities, and the study was registered with ClinicalTrials.gov [NCT04808609].

Procedures

Potential study participants provided verbal informed consent to complete a phone screening to assess eligibility. Eligible participants were then invited to attend an in-person baseline visit at the Columbia University School of Nursing. Upon arrival to the study site, scheduled participants were asked to provide a breath sample to determine eCO level and confirm study

eligibility. Breath samples were analyzed for eCO levels (in ppm) using a breathalyzer (Micro Basic Smokerlyzer, Bedfont Scientific Ltd). Those identified as ineligible were given a Metrocard to thank them for their time. Those identified as initially eligible were asked to complete a written informed consent form. Study staff guided participants through the form and answered any questions.

After providing written consent, participants completed a baseline questionnaire that included demographic characteristics, tobacco use history, illicit substance use history, alcohol use history, psychosocial characteristics, and pharmacotherapy use (Multimedia Appendix 1). Survey instruments were collected via Qualtrics. Following completion of the baseline study assessments, study participants were randomized (1:1) to the Lumme Quit Smoking app arm or the control arm.

Randomization

We did not stratify the sample by any demographic characteristic (ie, age, sex, gender, race, or ethnicity) since this was a pilot study with a small sample. We concealed randomization status from staff and participants until after completion of the baseline assessment to minimize bias. The study statistician who performed the data analysis was blinded to the treatment groups.

Participants in both arms received a smoking cessation counseling session and were provided with NRT in the form of the NicoDerm CQ Patch (GSK Group of Companies) under the supervision of a nurse. Each participant received an 8-week supply of NRT, which was enough to follow the 3-step program. However, they were encouraged not to begin NRT until 2 weeks after the baseline visit. Participants in both study arms set a quit date for 2 weeks after the baseline visit. Dosing of the NRT was based on standard prescribing guidelines. Participants in both arms also received a 30-minute smoking cessation counseling session and weekly check-in calls from the study staff.

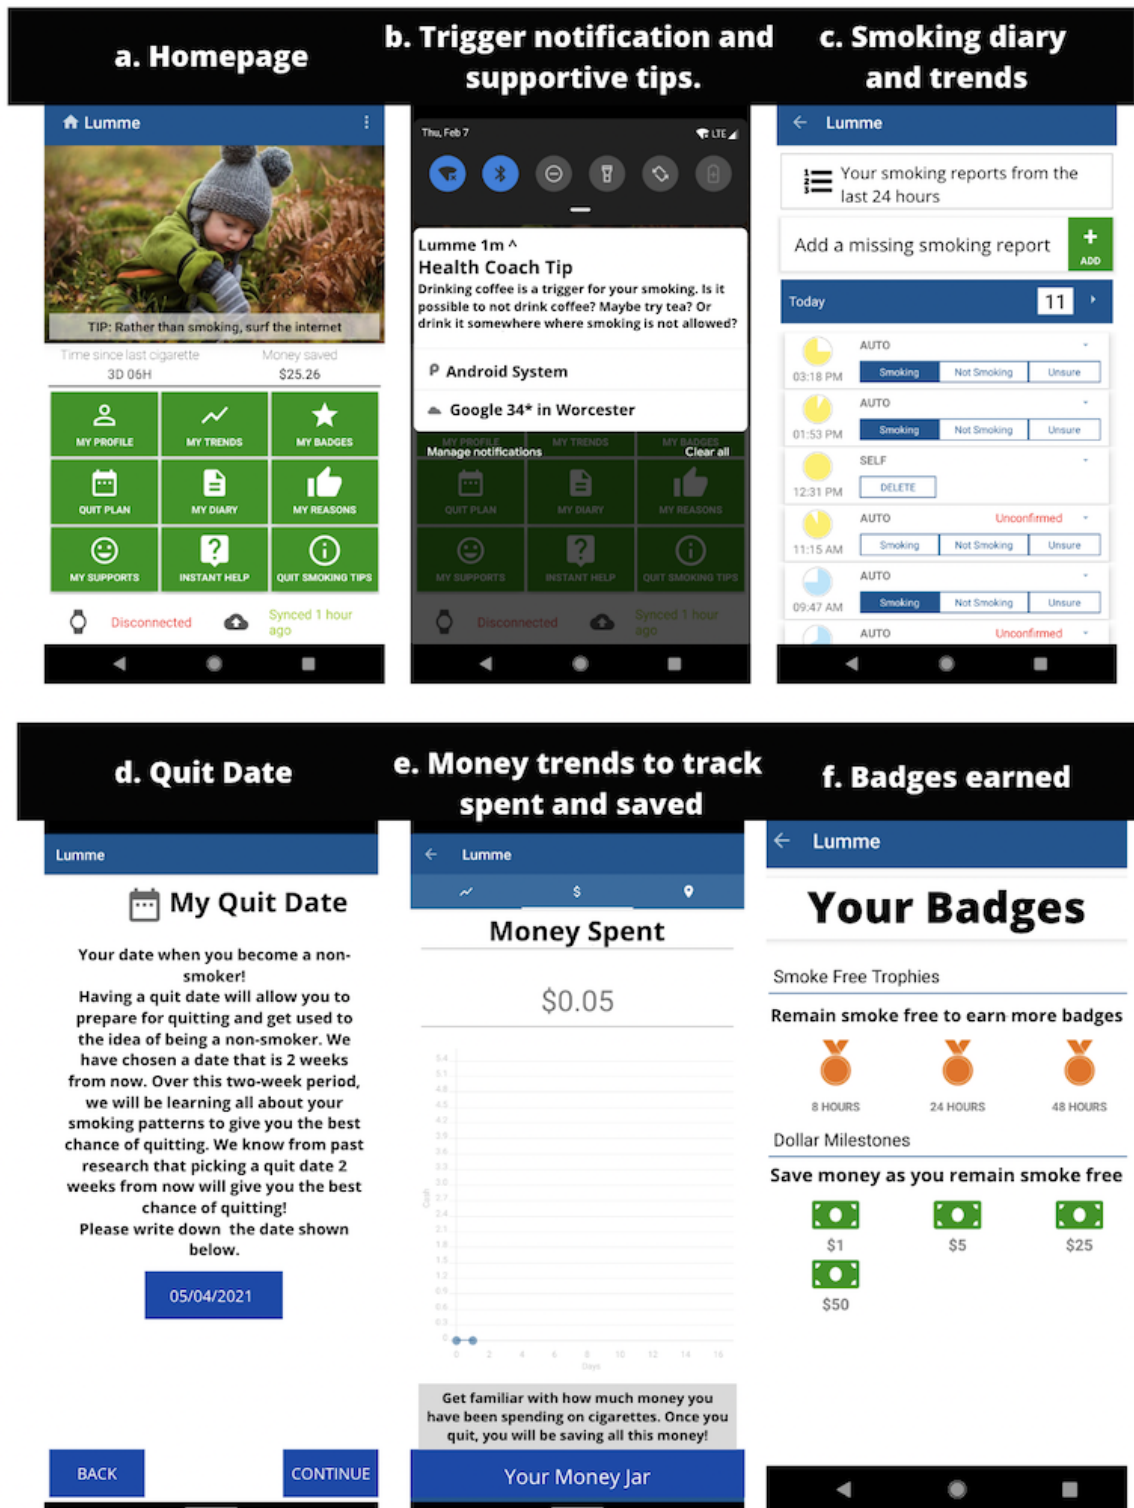

Participants in the intervention arm received a Vapor 2 (Misfit) or Falster 2 (Skagen Denmark) smartwatch (Figure 1). Both smartwatches are compatible with the Lumme Quit Smoking app. The Lumme Quit Smoking app was paired with the smartwatch so that smoking was detected by the smartwatch and the information sent directly to the Lumme Quit Smoking app. The smartwatch detected hand movements indicating a study participant was picking up a cigarette to smoke or a user manually entered a smoking session. The Lumme Quit Smoking app was then able to predict cravings, target users with notifications to prevent individuals from smoking, refine the notifications for each user, and display their change in smoking behavior and money saved in a smoking diary (Figure 2). Users were also able to see their quit plan with their assigned quit date for 2 weeks after baseline, along with smoking trends, supportive tips, and badges earned from the amount of money saved.

Intervention arm participants created an account with the Lumme Quit Smoking app, which passively collected smoking data, such as when the user smoked (time of day, day of week, before/after eating, after waking up/before going to sleep, before driving to/from work, while driving), where the user smoked, and who was nearby when the user smoked (based on repeated detection of the same Bluetooth static address; Lumme does not collect identities), during the first 2 weeks of the study period. At the end of the baseline visit, all enrolled participants were compensated \$40 for their participation in the form of a preloaded debit card. On the day before their quit date, study staff under the supervision of a nurse called participants in both arms to remind them of their quit date and to start using their NRT patches on the morning of their quit date. Additionally, participants in both the control and intervention arm received weekly check-in calls from study staff members. Staff conducted these calls to monitor adherence to NRT, to provide technology assistance to those in the intervention arm who might be experiencing difficulties with the smartwatch or app, and to encourage participant engagement in the study.

Figure 1. Sample picture of smartwatches used by study participants.

Figure 2. Screenshots of the Lumme Quit Smoking app.

Study Measures

To determine feasibility, we examined retentions rates, compliance rates, dosing, eligibility criteria, recruitment and enrollment rates, missing data, and study measures. Retention rates were measured as the number of enrollees who remained in the study; 80% retention was the threshold for feasibility. Compliance rates were calculated as the number of days participants used the Lumme Quit Smoking app divided by the

56 days of the study intervention program with at least 80% of participants having completed at least 75% of the intervention content set as the threshold. Dose was measured as the number of app sessions completed by the participants. Eligibility criteria were assessed to determine if the number of individuals who screened out of the pilot study was too high, indicating criteria that were too stringent. Recruitment and enrollment pace were assessed by dividing the total number of enrolled participants by the number of months in the recruitment period. The study

measures and missing data were evaluated to determine if the survey questions needed adjustment by assessing the extent and patterns of missing data and the length of time needed to complete the study measures.

Primary outcome 7-day point prevalence abstinence was measured by self-report and biochemically verified via eCO at 12 weeks. Baseline nicotine dependence was measured using the Fagerström Test for Nicotine Dependence [48]. Baseline tobacco use was measured through self-reported number of cigarettes smoked per day. Baseline alcohol use was measured using the CAGE (cut, annoyed, guilty, and eye) Alcohol Abuse Screening Tool [49]. Depression was measured using the Center for Epidemiologic Studies–Depression Scale (CES-D) at baseline and 12 weeks [50].

At the 12-week follow-up visit, semistructured in-depth interviews were conducted with study participants. No additional compensation was provided for participation in the interviews. These interviews aim to fill gaps in the literature by taking a qualitative approach to understanding the acceptability of the Lumme app as a smoking cessation tool in the intervention arm and learn more about the perceptions of all participants on the recruitment and enrollment process. Both groups answered the following questions: How would you modify the outreach and recruitment process to improve it or make it easier? How comfortable were you with the recruitment, screening, and enrollment process? How can we improve the current screening process? The intervention group completed a questionnaire (Multimedia Appendix 2-5) that included the following questions, among others: Please describe your general perceptions and expectations of the app. How often did you use the app? How helpful was the app for tobacco cessation?

Data Analysis

Descriptive statistics were used to detail the study sample by condition and as a total sample. Descriptive statistic *P* values were calculated by *t* test, chi-square test, or Fisher exact test. Point estimates and corresponding confidence intervals were calculated for each measure by arm. Because of our small sample sizes, we used Clopper-Pearson exact confidence intervals based on the binomial distribution and reported effect sizes (using relative risk or Cohen *d* depending on the

distribution of the outcome measures) as well as *P* value (calculated by chi-square test for binary outcomes and independent samples *t* test for continuous outcomes) to examine differences in primary outcome (7-day point prevalence abstinence) and secondary outcomes (eCO decrease from baseline to 12-week follow-up, self-reported number of cigarettes smoked per day, and CES-D and CAGE scores) by study arms. The 7-day point prevalence abstinence was calculated as the proportion of participants who reported no smoking/tobacco use in the 7 days prior to their 12-week follow-up visit, biochemically verified by eCO collected at 12 weeks. Participants with eCO levels less than 6 ppm at 12 weeks were classified as abstinent while participants with eCO levels 6 ppm or more at 12 weeks were classified as not abstinent. Participants lost to follow-up were included in the analyses as smokers. We also assessed the time trends of eCO by each study arm and in both arms using paired *t* tests (used to calculate effect size and *P* value) because a total sample size of 37 is sufficient to detect a medium effect size when assessing within-subject effect, the time trend effect. All analyses were performed in SAS (version 9.4, SAS Institute Inc).

All in-depth interviews were transcribed verbatim and then coded using the Fit Between Individuals, Task, and Technology (FITT) framework along 3 dimensions: task-technology fit, individual-technology fit, and individual-task fit [51]. The FITT framework has been successfully used to determine the usability of mHealth technology in prior studies, proving to be a useful framework to guide this analysis [52,53].

Results

Demographic Characteristics

The demographic characteristics of participants are described in Table 1. There was no significant difference in study characteristics between study conditions. The mean age of study participants was 54 years, 50% (20/40) of participants identified as male, 78% (31/40) identified as Black/African American, and 23% (9/40) identified as Hispanic/Latinx. Participants had a mean CES-D score of 15.65 (SD 11.1). CAGE scores indicated that 22% (8/37) of participants had clinical indications of an alcohol use problem.

Smoking Characteristics

Participants had a mean eCO at baseline of 13.8 (SD 6.4) and reported smoking an average of 11.5 (SD 4.7) cigarettes daily in the past month. Participants reported smoking for a mean of 33 (SD 12) years. Menthol cigarettes were used by 90% (36/40) of participants and 92% (36/39) reported that Newport was their usual cigarette brand. Per the Fagerström Test for Nicotine Dependence, participants had a mean nicotine dependence level of 6.4 (SD 2.0). Nearly half of participants (19/40, 48%) reported trying to quit smoking in the past year. There were no significant differences in smoking characteristics by study arm.

Feasibility and Retention Rates

Of the 40 participants who enrolled in the study, 37 returned to complete the follow-up study assessment at 12 weeks. Of the 3 participants who did not finish the study, 1 was withdrawn and 2 were lost to follow-up. The 3 participants who failed to complete the study were all assigned to the control arm (Figure 3). Dose was operationalized as the number of app sessions completed by the participant; 80% (16/20) of participants used the app every day during the 56-day period. Of the 16 participants, 14 used the Lumme Quit Smoking app for at least 2 weeks past the official program end date.

Figure 3. Smoking cessation pilot CONSORT (Consolidated Standards of Reporting Trials) flowchart. ART: antiretroviral therapy; NRT: nicotine replacement therapy.

Eligibility Criteria

During the recruitment and enrollment period, 122 people were screened for eligibility with 67.2% (82/122) screening ineligible. Smoking criteria and incompatible tech were the most frequently occurring reasons for ineligibility. During the study's 6-month recruitment and enrollment period, approximately 6 participants were enrolled per month.

Study Measures and Missing Data

All 40 enrolled participants completed the baseline survey, and 37 participants completed the follow-up survey at 12 weeks. Among the 77 completed survey responses, missing data were evenly distributed across study arms. On average, study participants completed the baseline survey in 79 (SD 45) minutes and completed the follow-up survey in 30 (SD 16) minutes.

Acceptability

Table 2 displays descriptive statistics and associated 95% confidence intervals for primary, secondary, and other outcome measures.

The relative risk of 7-day prevalence abstinence was 1.27 between the intervention and control groups, indicating that the 7-day abstinence prevalence was 27% higher in the intervention group than in the control group; the effect size of eCO decrease was small (Cohen $d=0.21$); for other secondary outcomes, the effect sizes were less than small (Cohen $d<0.20$). There was no significant difference in decrease in eCO for the control arm or intervention arm. Average eCO decreased significantly over time (baseline 13.8 [SD 6.4], 12-week follow-up 11.4 [SD 8.2]; $P=.02$) when analyzing both arms together (Table 3).

Table 2. Differences in outcome measures by study arm.

Measure	Control (n=20) ^a		Intervention (n=20)		Total (n=40)		Effect size (95% CI)	P value
	Value	95% CI	Value	95% CI	Value	95% CI

^aeCO: exhaled carbon monoxide.

NRT Use

At the follow-up study visit, participants self-reported their NRT use. A total of 46% (17/37) of all study participants reported daily NRT use, 45% (9/20) in the intervention arm reported daily NRT use, and 47% (8/17) in the control arm reported daily NRT use. There was no significant difference in NRT use between participants in the study arms.

In-depth Interviews

Findings from the in-depth interviews are organized according to the FITT framework, which provided for a better understanding of the factors contributing to the engagement and perceived usefulness of the intervention. Sample quotes that are exemplars of each of the constructs of the framework are detailed in [Table 4](#).

Table 4. Exemplars of findings from the in-depth interviews organized by the Fit Between Individuals, Task, and Technology framework.

FITT ^a framework construct	Sample quotes from in-depth interview
Task-technology fit	<ul style="list-style-type: none"> “And it does really help you. It tells you when your day is over. It goes, ‘You have such-and-such more days before you quit.’ That was a good reminder...” “I looked at it a couple times a day. In the beginning when I was smoking, I looked at it almost every time I smoked just to see if it recorded. But after I stopped smoking, I would look at it still...” “...this watch is going to monitor my movement of my hand... I’m not going to be smoking all the time and moving my hand... I already knew that... that I would have to check in and be honest. Honesty was one of my biggest, like I expected to be honest. And that’s what I’ve been...”
Individual-technology fit	<ul style="list-style-type: none"> “The tips were very useful because everything it says in the tips is true...pros and cons...which is another way you can sit there and say is smoking good or bad. Having the support system on there was cool... anytime I wanted to I could contact the support system anytime I needed to speak to somebody...” “[I used the watch] everywhere. If I was in the bathroom; if I was making a delivery if I was at work. It didn’t matter where it was... I was able to text through the watch... I find that very cool, too.” “I think this whole experience was something good for me... I’ve always wanted to stop smoking... I’ve slowed down enough to maybe be able to stop. And it gave me the encouragement, the power and the push to do it in a way that’s not hard...” [51]
Individual-task fit	<ul style="list-style-type: none"> “It’s extremely helpful, it definitely helped me cut back. I’m more confident with the app and like I said, it’s like a little coach with you all the time, 24/7...” “...[the app] did make things very clear, as far as really specifying your habits... In that respect, it’s been good, because it made you conscious of how much you’re smoking, even though you do it normally without the app and you just smoke, and you don’t think about it...” “[The app was] 100% helpful for an individual that’s really focused on not smoking, on quitting, being focused on quitting and wanting to... I mean that was amazing... to have a watch on and when you’re going like this or you know... they always give you the option to say, well, no, I wasn’t smoking at that time; I was eating or something like that... the individual has to be honest, with themselves...”

^aFITT: Fit Between Individuals, Task, and Technology.

Discussion

Principal Findings

This study focused on testing a multicomponent intervention, Lumme Quit Smoking app with nicotine replacement therapy (NRT) and smoking cessation counseling to improve smoking cessation in persons living with HIV. This is especially important given that tobacco use causes increased morbidity and mortality in persons with HIV, and tobacco-related harm is substantially higher in persons with HIV than in smokers in the general population. There were several innovative components of this intervention. The algorithm for detecting the smoking arm movement can be used to interpret data from a smartwatch [54]. The Lumme Quit Smoking app uses a validated sensor to detect participants’ smoking behaviors in real time. This intervention combined biometric data with behavioral interventions specific to smoking behavior, an advancement and innovation not previously tested in persons with HIV. Findings from this study suggest that the intervention was both feasible and acceptable in this population. Participants wore the sensor and used the app. Retention in the study was very good. The high completion rate and continued use of the app for weeks beyond the program end indicates that the dose was not burdensome and could be extended for future smoking cessation studies. Notably, the loss to follow-up and withdrawal were all among control group participants. Therefore, consideration of whether this loss to follow-up is associated with treatment group will need to be considered in the next trial, although it is noted that retention was overall very good, and numbers of participants who dropped out of the study are small.

This pilot study was underpowered to detect statistically significant differences between conditions on efficacy outcomes. There were only 2 participants who quit the smoking in the control group and 3 in the intervention group, verified through biochemical testing. Based on the self-reported quit rates, there were 4 (control) versus 6 (intervention) participants who quit smoking. Nonetheless, these findings allowed us to estimate that the intervention was able to improve the prevalence of 7-day abstinence by 27% in the study sample, and there was a decrease in the eCO over time with an almost medium effect size (Cohen $d=0.44$) in the intervention group.

The ability for a mobile app to deliver content that would burden participants and require staff and clinician time and resources is an innovative approach to the delivery of a tobacco cessation intervention. Importantly, mHealth is a feasible platform for delivering this intervention since there is extremely high mobile phone penetration in the United States [55], especially among racial/ethnic minority groups [56]. mHealth technology can be used for achieving health equity in vulnerable groups because it is a widely available and relatively inexpensive tool for health behavior change [57] and can be adapted to meet the needs of its end users [58-61]. Our work has shown that even the lowest income and most health disparate persons own and use smartphones [62]. Therefore, the Lumme Quit Smoking app is timely, relevant, scalable, and likely to improve health outcomes in persons with HIV who smoke. Even when successful, however, there are barriers to widespread adoption and successful scale-up of tobacco interventions [63,64]. While leveraging accessible mHealth technologies is a strength, our study team acknowledges the target population may not have

access to smartwatches outside of the research study. Nonetheless, if efficacious, the cost of the smartwatch is half of the cost of purchasing cigarettes for 1 month in New York City, estimated at \$320 per month [65] and even more minimal in comparison to the annual cost (\$170 billion) for direct medical care for persons who smoke in the United States [66].

Limitations

There were several important limitations of this study. First, we relied on self-report of NRT use among study participants, and while we tracked our distribution of NRT to study participants, we were limited in our ability to validate whether participants used the NRT. We carefully considered our control condition and ultimately the robustness of the control condition (smoking cessation counseling session and NRT administration) may have underestimated the effect of the Lumme Quit Smoking app.

Conclusion

Notably, smoking cessation efforts have largely been aimed at the general population. Consequently, it is not clear whether

they are suitable or effective for cohorts with population-specific concerns and clinical issues such as persons with HIV [11,22,67,68]. While the Lumme Quit Smoking app is undeniably an innovation in combining sensors, real-time feedback, and behavioral interventions, it was developed for the general population of smokers and was not in any way targeted or tailored for the needs of persons with HIV. This may have contributed to the findings that this intervention was not significantly more efficacious at improving smoking cessation than a standard of care control condition. Future research should focus on identifying the behavioral factors specific to persons with HIV who smoke and developing an intervention to meet their needs. Additionally, the counseling component of the intervention may need to be tailored to persons with HIV. A recent study found that persons with HIV did not understand the relationship between HIV and smoking and described wanting more information about the health effects of smoking for persons with HIV [69].

Acknowledgments

This work was supported by grant 1R21CA265961-01 from the National Cancer Institute. The content is solely the responsibility of the authors and does not necessarily represent the official views of the National Cancer Institute. The funding source had no role in the design of the study; the collection, analysis, and interpretation of data; the writing of the report; or the decision to submit the paper for publication.

Authors' Contributions

RS, PC, and MH conceptualized the study. RS and PC were responsible for methodology. RS was responsible for supervision. RS, JL, GA, and SG wrote the original draft. JL and SG curated the data. JL and SG were responsible for the formal analysis. GA, TP, and SB were responsible for investigation. GA, SG, and PT reviewed and edited the manuscript. TP and SB were responsible for project administration. MH was responsible for software and resources.

Conflicts of Interest

None declared.

Abstract

Background: Internet-based self-management programs and telerehabilitation initiatives have increased and have been extensively used for delivering health care in many areas. These programs overcome common barriers that patients face with traditional face-to-face health care, such as travel expenditures, lack of time, and high demand on the public health system. During the COVID-19 pandemic, this mode of web-based health care delivery had become more popular. However, there is still a lack of studies testing this mode of delivery in low- and middle-income countries. To gain a better understanding of the context, feasibility, and factors involved in the implementation of a web-based program, pilot and implementation studies are necessary. These studies can better inform whether a strategy is feasible, acceptable, and adequate for its purposes and for optimizing resource allocation.

Objective: This study aims to evaluate the feasibility, usability, and implementation context of a self-management internet-based program based on exercises and pain education (ReabilitaDOR) in people with chronic musculoskeletal pain and to compare this program with a program using only a web-based self-management booklet.

Methods: The study design was a parallel pilot study of a prospectively registered, assessor-blinded, 2-arm randomized controlled trial with economic evaluation. This study was performed using waiting lists of physiotherapy and rehabilitation centers and advertisements on social media networks. The participants were 65 patients with chronic musculoskeletal pain aged between 18 and 60 years. The effects of an 8-week telerehabilitation program based on exercises and pain education (intervention group) were compared with those of a program based only on a web-based self-management booklet (control group). The main outcome measures were implementation outcomes of patients' perceptions of acceptability, appropriateness, feasibility, and usability of the program and the societal costs and feasibility of the main trial at 8-week posttreatment follow-up. Adverse events were also analyzed.

Results: In total, 56 participants were analyzed at the 8-week follow-up. The intervention group showed responses with a mean of 4.5 (SD 0.6) points for acceptability, 4.5 (SD 0.5) points for appropriateness, and 4.5 (SD 0.6) points for feasibility measured on a 1 to 5 scale. All patients in the intervention group showed satisfactory responses to the system usability outcome. There is

satisfactory evidence for the feasibility of the main trial. For costs related to the interventions, health care, patients, and loss of productivity at 8 weeks, we found a total expenditure of US \$278.30 per patient in the intervention group and US \$141.52 per patient in the control group. No adverse events were reported during the intervention period.

Conclusions: We found that the ReabilitaDOR program is feasible, appropriate, and acceptable from the users' implementation perspective. This system was considered usable by all the participants, and the main trial seemed feasible. Cost data were viable to be collected, and the program is likely to be safe.

Trial Registration: ClinicalTrials.gov NCT04274439; <https://clinicaltrials.gov/ct2/show/NCT04274439>

KEYWORDS

telerehabilitation; musculoskeletal pain; implementation science; feasibility study; chronic pain; pain; pilot study; eHealth; exercise; telehealth; self-management

Introduction

Chronic pain is broadly defined as pain that persists for more than 3 months [1,2]. The most common chronic pain conditions are back and neck pain and knee and hip osteoarthritis, which are part of a broader group often called as chronic musculoskeletal pain [3-5]. Recent literature classifies chronic musculoskeletal pain as conditions characterized by persistent inflammation of infectious, autoimmune, or metabolic etiology [1]. This is a group of pain conditions that affects millions of people around the world and is responsible for an enormous economic burden, which impacts health services globally [5,6]. Chronic musculoskeletal pain is also the major cause of years lived with disability globally [5].

The management of chronic musculoskeletal pain is primarily multimodal, with noninvasive and nonpharmacological therapies as first-line options. These therapies include exercise, pain education, psychological, and physical therapies [7-11]. Although these recommendations from clinical practice guidelines are clear and usually do not involve complex programs [12,13], many people do not have access to adequate and affordable treatments. This can be due to geographical barriers (eg, people living in rural areas or Indigenous communities) or health care systems that may be overstretched with no capacity to provide timely and equitable access to health services [14]. Thus, there is a need for the development of remote strategies such as telerehabilitation [14,15] to improve access to health care.

Telerehabilitation is defined as the use of remote mechanisms and technologies for screening, diagnosis, education, treatment, and monitoring of a given condition [15,16]. Telerehabilitation can be delivered through telephone calls, smartphone apps, websites, or digital platforms that guarantee the population's access to multimodal treatment strategies for chronic pain [14,15]. The use of telerehabilitation strategies has grown exponentially in the past years; however, the great majority of clinical trials and implementation studies of telerehabilitation are still being conducted in high-income countries [17]. Hence, there is a clear need for more clinical studies assessing telerehabilitation in low- and middle-income countries [14,17].

One important step before conducting a large clinical trial is to test the feasibility of the process involved in the main study, such as recruitment rates and the resources needed [18-20].

Trials using web-based interventions may also need to test the user's usability of the system (ie, the degree to which a system is fit to be used) to ensure that the system is accessible, clear, and easy to use [21,22]. A final aspect of testing an intervention is to understand implementation processes and context, such as the acceptability and appropriateness. Feasibility, usability, and other implementation-related outcomes are all important to the translation of research into practice, providing better insights into service delivery [23]. The aim of this study was to test and evaluate the feasibility and usability through an implementation perspective of an internet-based pain education and exercise program for chronic musculoskeletal pain and to compare this program with a program consisting of an intervention with only a web-based self-management booklet.

Methods

Ethical Considerations and Study Design

This is a pilot study of a prospectively registered (NCT04274439), parallel, assessor-blinded, 2-arm randomized controlled trial with economic evaluation. This study was submitted and accepted by the ethics committee Comitê de Ética em Pesquisa da Universidade Cruzeiro do Sul (CAAE 02892918.0.0000.8084), and the study protocol of the main trial has been published elsewhere [24].

Settings and Eligibility

We recruited patients from the waiting lists of physical therapy and rehabilitation centers and through advertisements on social media networks. We included patients aged between 18 and 60 years, who were seeking treatment or who would like to undertake a physical therapy program for any chronic musculoskeletal pain, were able to read and understand Portuguese, and had internet access. We included patients with chronic musculoskeletal pain (pain lasting more than at least 12 weeks) [1] and pain intensity of at least 3 points on a 0-10 Numeric Pain Rating Scale [25]. We did not include patients who had nerve root compromise, serious pathologies (eg, fracture, tumor, inflammatory, autoimmune/infectious diseases), cardiovascular and metabolic diseases (eg, coronary heart disease, heart failure, decompensated diabetes), recent orthopedic surgery (in the last 12 months), surgery scheduled for the next 6 months, or were pregnant. Patients were also excluded if there was any contraindication to exercise measured

with the Physical Activity Readiness Questionnaire Portuguese version [26,27].

Procedures

The conduct of the study as well as the evaluations and 8-week follow-ups were carried out completely remotely through web-based platforms and telephone calls. We invited patients from waiting lists of rehabilitation centers via phone call, or participants seeking physiotherapy care could also contact the researchers of the study. After confirming eligibility of the participant, we scheduled the assessment session (baseline) through a videoconference. This session was performed using the platform Whereby to access an encrypted and personalized room with the patient and the researcher conducting the assessment. In this session, the researcher explained the study and all procedures as well as double checked the eligibility of the participant. Then, the participant received a consent form (signed electronically), completed the baseline assessment of the study, and finally received a login and password to access the study website [28] to be randomized automatically to one of the 2 groups at the first login.

Outcome Measures

Primary Outcomes

All outcomes were measured after the intervention period (8 weeks) through an electronic form, with a study evaluator blinded to the treatment allocation. The primary outcomes were program fit (acceptability, appropriateness, and feasibility), system usability, societal costs, and feasibility of the main trial.

Program Fit

Program fit was measured using 3 measures composed of 4 items each that can be used independently or representing 1 single score [29]:

1. Acceptability of Intervention Measure (AIM): Acceptability is the perception among implementation stakeholders that a given treatment, service, practice, or innovation is agreeable, palatable, or satisfactory [29].
2. Intervention Appropriateness Measure (IAM): Appropriateness is the perceived fit, relevance, or compatibility of the innovation or evidence-based practice for a given practice setting, provider, or consumer, and perceived fit of the innovation to address a particular issue or problem [29].
3. Feasibility of Intervention Measure (FIM): Feasibility is defined as the extent to which a new treatment or an innovation can be successfully used or carried out within a given setting [29].

These measures are composed of 4 items, and the participant can answer as “totally agree,” “agree,” “neither agree nor disagree,” “disagree,” or “strongly disagree.” A value from 1 to 5 is assigned to each answer with a total value of 20 points possible for each measure. There are no cutoff points for these measures, but values closer to 5 in each answer and 20 in the total measure indicate better results for the proposed outcomes.

System Usability

To assess system usability, we used the System Usability Scale [30,31]. The System Usability Scale is composed of 10 items where the patients respond with “strongly disagree,” “disagree,” “neither agree nor disagree,” “agree,” or “strongly agree.” A value from 1 to 5 is assigned to each answer. The responses are summed and multiplied by 2 so that the total score ranges from 0 to 100 points, where scores closer to 100 indicate better usability results.

Societal Costs

We measured societal costs by the estimate of trial intervention costs, health care costs (visits to general practitioners, physiotherapists, alternative therapists, medical specialists, as well as the use of emergency, hospitalization, and medication), patients costs (transportation: the number of public transport tickets needed to get to the health care service), and lost productivity costs (absenteeism). Costs were measured based on the participants’ reported use of the resources by using a cost diary given to the participants at baseline. Participants were asked to send the completed cost diary to the evaluators or respond with the diary data in a web-based questionnaire. The health care costs were also divided into health insurance costs, public health system costs (*Sistema Único de Saúde*), and private costs (out-of-pocket costs). All costs were collected in BRL, inflated to the reference year of the study (2020) using the consumer price index and converted into USD using purchase power parities [32].

The intervention costs were estimated based on the total costs of website development, creation of the content included in the physical therapy program, internet hosting, and costs of text messages and phone calls present in each work group. The development and creation costs were considered from the perspective of using the program for over 5 years, based on the time of updating the information for the treatment in clinical practice guidelines. The value for 5 years of use was divided by the number of patients who would benefit from the treatment in each of the main clinical trial groups.

The unit prices of the health care services were calculated based on the Brazilian database (*Banco de Preços em Saúde*) [33] or from the Brazilian professional regulatory councils [34]. The unit prices of the medications that were not present in the Brazilian database were valued through a web-based commercial consultation in pharmacy chains (the unit average of these medications was calculated using the prices found in 5 pharmacy chains).

The transportation costs were estimated using the public transport price in the city of São Paulo, Brazil [35]. The lost productivity costs included absenteeism from paid work. Absenteeism was estimated by asking patients the number of hours not worked owing to chronic musculoskeletal pain and valued according to the Human Capital Approach using sex-specific price weights [36].

Feasibility of the Main Trial

The criteria to judge the feasibility of progressing to a full trial were as follows:

1. Fifty percent or more of the invited participants were willing to be recruited into the feasibility study.
2. Seventy percent or more of the participants in the intervention group have completed the 8-week program (compliance).
3. Data on key outcomes were collected at postintervention for $\geq 70\%$ of participants.
4. Less than 10% of adverse events are caused by the intervention.

We also collected the response rate at follow-up and adherence to the program.

Secondary Outcomes

A key aim of the pilot study was to determine whether the primary and secondary outcomes for a proposed full trial could be measured for all the participants. This pilot study was not powered to detect significant differences in these measures but was able to describe observed changes between time points and their direction. Thus, the secondary outcomes of this study were pain intensity and function measured at baseline and postintervention (8 weeks) and adverse events measured during the intervention period.

1. Pain intensity was measured using the Numeric Pain Rating Scale [25], a numerical scale where 0 indicates no pain and 10 indicates the worst possible pain.
2. Function was measured with the Patient-Specific Functional Scale [25], a self-reported scale specific for the measurement of functionality, where the patients nominate up to 3 activities relevant to them and rate their ability to perform each activity on a 0 to 10 scale, with 0 representing the inability to perform that activity and 10 the total capacity to perform the activity. The sum total of the values for the 3 activities will be considered the final score on a 0 to 30 scale.
3. Adverse events: number and percentage of participants experiencing any adverse events during the intervention period (eg, exacerbation of symptoms).

Random Allocation

The random allocation sequence was generated using computer software with a 50% chance of allocation for each of the groups. After the initial screening and baseline outcome assessment, patients were given a login and password to access the study site. As soon as the participant entered the site for the first time, they were randomly allocated to one of the 2 study groups.

Blinding

The outcome assessor was blinded to the treatment groups. Owing to the nature of the interventions, it was not possible to blind the patients or the therapists.

Interventions

Intervention Group: Internet-Based Pain Education and Exercise Program

The patients allocated to the intervention group received a login and password for individual access to the website developed for the study [28]. The content of this intervention included videos and animations based on pain education, promotion of

physical activity, and general exercises. The pain education component was based on the e-pain intervention developed by Reis et al [12], which had 9 main features: (1) acceptance, (2 and 3) pain education, (4) sleep hygiene, (5) recognition of stress and negative emotions, (6) increased positive coping in lifestyle, (7) exercise, (8) communication, and (9) prevention. The exercise program was created by professional physiotherapists with at least 5 years of clinical experience, who are specialists in the treatment of chronic pain and who used exercise-based treatment. After its elaboration, it was submitted to a round of suggestions and adjustments to the program by a panel of experts. After this round of suggestions, the exercise component was sent by email to a group of experts who are references in the treatment of chronic pain in São Paulo, Brazil. After the last round of suggestions and corrections, the exercise program was modified to be simple and assertive for the population studied. The exercise component included general exercises with the aim of improving strength, flexibility, control, and coordination.

The total duration of the intervention was 8 weeks. There was new content every week of the intervention, and the patients were instructed to perform the video exercises at least 3 times a week and watch the videos as necessary. Patients in this group also received weekly text messages and a health coach over the phone. The text messages included information on the benefits of exercise and motivational and positive messages on how to deal with pain. The health coaching sessions were conducted once a week until the end of the intervention (8 weeks) by a physiotherapist with 5 years of experience and prior training for the coach's performance. The goal of the health coach component is to keep patients motivated to continue with the program. This included encouragement, motivation, coping, revision of instructions and, if necessary, adaptation of the content of the intervention. For example, if a patient felt some discomfort when doing an exercise, the coach slightly modified the exercise (eg, dose, range of motion).

Control Group: Web-Based Self-management Booklet

Patients allocated to the control group had access to a web-based booklet containing general information on self-management of chronic pain, including pain education, advice on healthy lifestyle and sleeping habits, and promotion of physical activity. They also received a call in week 4 and motivational text messages once a week during the study period.

Statistical Methods

Calculation of the Sample Size

For the pilot study, we determined a value of at least 40% of the total sample size of the main study. Our sample size calculation determines that a minimum of 160 individuals would be required for the main study analysis; therefore, at least 64 patients were necessary for the pilot phase.

Data Analysis

The normality of the data was tested by visual inspection of the histograms. The baseline characteristics of the participants were analyzed using descriptive statistics and summarized in a descriptive table. We consider the system's usability greater

than 53 points on a scale from 0 to 100 to be satisfactory in at least 70% of the responses observed. Primary and secondary outcomes were presented descriptively with means and standard deviations or number of participants and percentages for each group. Results were all presented in descriptive tables.

Results

Participant Characteristics

A total of 65 participants were recruited between February 2020 and June 2020. Of these, 64 was randomized in the study. One

participant was not randomized due to contraindication to exercise. A total of 31 participants were randomized to the intervention group and 33 participants to the control group (Figure 1). The participants were mostly women (43/64, 67%), with a mean age of 39.5 (SD 11.3) years, mean pain intensity of 6.3 (SD 1.6) points, and a median duration of symptoms of 36 (IQR 11-90) months. For the location of pain characteristics, patients were able to name more than one pain site. There was no difference between the groups at the baseline. A summary of the characteristics of the participants is shown in Table 1.

Function (0-30), mean (SD)	18 (6.5)	17 (6.3)

Adherence to the Trial Protocol

A total of 56 responses were obtained after the 8-week period of initiation of treatment in our study: 26 in the telerehabilitation group and 30 in the control group. Eight patients dropped out from the study because they did not answer our questionnaires on the correct date of follow-ups. For this pilot study, answers to questionnaires sent after the follow-up deadline were disregarded in order to calculate the possible sample loss. Adherence to the 8-week program (telerehabilitation group) was high, with a mean of 7.2 (SD 1.4) intervention weeks accessed by the patients on the program website. The weekly health coaching was successful in 92% (24/26) of the patients.

Program Fit

All patients in the telerehabilitation group showed acceptable responses with satisfactory scores in all the responses for AIM, IAM, and FIM. Patients in the intervention group showed responses with a mean of 4.5 (SD 0.6) points for AIM, 4.5 (SD 0.5) points for IAM, and 4.5 (SD 0.6) points for FIM. For patients in the control group, satisfactory scores were found in 95% (114/120) of the responses for AIM, 95.8% (115/120) of the responses for IAM, and 99.2% (119/120) of the responses for FIM. Patients in the control group showed responses with a mean of 4.1 (SD 0.9) points for AIM, 4.1 (SD 0.8) points for IAM, and 4.3 (SD 0.6) points for FIM (Table 2).

Table 2. Description of the implementation outcomes of acceptability, appropriateness, feasibility, and usability.

Measures	Intervention group (n=26)	Control group (n=30)
Acceptability of Intervention Measure, mean (SD)		
I approve the ReabilitaDOR program	4.68 (0.6)	4.3 (0.7)
ReabilitaDOR program is appealing to me	4.36 (0.7)	3.86 (1.0)
I like the ReabilitaDOR program	4.48 (0.6)	4.2 (0.8)
I welcome the ReabilitaDOR program	4.48 (0.7)	4.23 (0.8)
Total score	4.5 (0.6)	4.1 (0.9)
Intervention Appropriateness Measure, mean (SD)		
ReabilitaDOR program seems fitting	4.56 (0.5)	4.23 (0.8)
ReabilitaDOR program seems suitable	4.52 (0.5)	4.2 (0.8)
ReabilitaDOR program seems applicable	4.48 (0.5)	4.2 (0.7)
ReabilitaDOR program seems like a good match	4.6 (0.5)	4.13 (0.8)
Total score	4.5 (0.5)	4.1 (0.8)
Feasibility of Intervention Measure, mean (SD)		
ReabilitaDOR program seems implementable	4.62 (0.6)	4.26 (0.6)
ReabilitaDOR program seems possible	4.72 (0.5)	4.26 (0.7)
ReabilitaDOR program seems doable	4.56 (0.6)	4.33 (0.5)
ReabilitaDOR program seems easy to use	4.48 (0.7)	4.33 (0.6)
Total score	4.5 (0.7)	4.3 (0.6)
System Usability Scale		
Worst imaginable (0-20.5), n (%)	0 (0)	1 (3)
Poor (21-38.5), n (%)	0 (0)	0 (0)
Average (39-52.5), n (%)	0 (0)	2 (7)
Good (53-73.5), n (%)	3 (12)	12 (40)
Excellent (74-85.5), n (%)	7 (27)	11 (37)
Best imaginable (86-100), n (%)	16 (62)	4 (13)
Total score, mean (SD)	87 (10.7)	70 (17.9)

System Usability

All patients in the intervention group showed satisfactory responses to the usability outcome, with 16 patients responding as “best imaginable,” 7 responding as “excellent,” and 3 responding as “good” for all system features. The total mean score for usability in the intervention group was 87 (SD 10.7) points, classifying the usability by this group as “best imaginable.” In the control group, we observed 4 patients responding as “best imaginable,” 11 responding as “excellent,” 12 as “good,” 2 as “average,” and 1 responding as “worst imaginable.” The total mean score for usability in the control group was 70 (SD 17.9) points, classifying the usability by this group as “good” (Table 2).

Societal Costs

A total of 55 responses were obtained from the cost diaries in the 8-week assessment. One patient in the control group did not respond to the cost diary; thus, the costs of this patient were not analyzed. The cost diaries of 29 patients in the control group and 26 patients in the intervention group during the 8-week

period were analyzed. The intervention costs were US \$210.60 per patient in the intervention group and US \$20.62 per patient in the control group. The health care costs related to the private costs were US \$54.17 per patient in the intervention group and US \$107.23 per patient in the control group. For the public health system costs, we did not observe any cost in the intervention group, but we observed an expenditure of US \$2.75 per patient in the control group. For the health insurance costs, we observed an expenditure of US \$8.53 per patient in the intervention group and US \$6.63 per patient in the control group. The total sum of individual private costs of the 2 groups presented an expenditure of US \$62.73 per patient in the intervention group and US \$116.63 in the control group. Regarding the transportation used by patients, the intervention group used 72 fares, totaling an expenditure of US \$5.07 per patient. The control group used 68 fares, totaling an expenditure of US \$4.29 per patient. The lost productivity costs for the intervention group were 3.3 hours per patient, totaling an expenditure of US \$64.63 per patient and those for the control group were 15.5 hours per patient, totaling an expenditure of US \$217.30 per patient. All cost values are shown in Table 3.

Table 3. Description of costs at 8-week follow-up.^a

Costs	Intervention group (n=26)	Control group (n=29)
Intervention costs	\$210.60	\$20.62
Health care costs		
Private costs	\$54.10	\$107.23
Public costs	\$0	\$2.75
Health insurance costs	\$8.53	\$6.63
Total health care costs	\$62.63	\$116.61
Patient costs		
Transport	\$5.07	\$4.29
Absence from work		
Hours not worked	\$64.63	\$217.30
Total societal costs	\$342.93	\$358.82

^aAll costs are estimated in USD per patient.

Feasibility of the Main Trial

The feasibility of the main trial was confirmed with regard to our prespecified criteria. A total of 98% (64/65) of the patients who were initially evaluated to enter the study were able to randomize and participate in the trials. A total of 20 patients (77%) of the 26 patients in the intervention group finished the 8-week program, 2 patients (8%) reached at least 6 weeks of the program, 2 patients (8%) reached 5 weeks of treatment, and 2 patients (8%) did not reach half of the treatment.

Pain Intensity and Function

Both groups reported a decrease in pain intensity and improvement in function after 8 weeks. For the intervention

group, we observed a mean of 6 (SD 1.8) points for pain intensity at the baseline and a mean of 3.4 (SD 2.4) points at the 8-week follow-up. In the control group, we observed a mean of 6.5 (SD 1.5) points for pain intensity at the baseline and a mean of 5.6 (SD 1.9) points at the 8-week follow-up. For function, in the intervention group, we observed a mean of 18 (SD 6.7) points at the baseline and a mean of 23 (SD 6.3) points at the 8-week follow-up. In the control group, we observed a mean of 17 (SD 6.4) points at the baseline and a mean of 20 (SD 5.5) points at the 8-week follow-up. No statistical inferential tests were conducted, as this was not the purpose of this pilot study. The means of pain intensity and function are shown in Table 4.

Table 4. Description of the secondary outcomes (pain intensity and function).

Outcome	Baseline		8-week follow-up	
	Intervention group (n=26)	Control group (n=30)	Intervention group (n=26)	Control group (n=30)
Pain intensity, mean (SD) ^a	6.0 (1.8)	6.5 (1.5)	3.4 (2.4)	5.6 (1.9)
Function, mean (SD) ^b	18 (6.7)	17 (6.4)	23 (6.3)	20 (5.5)

^aPain intensity is measured on a 0-10 scale; lower values mean less pain.

^bFunction is measured on a 0-30 scale; higher values mean greater function.

Adverse Effects

No serious adverse effects were observed in carrying out the proposed interventions related to our study. One patient in the intervention group reported having been diagnosed with COVID-19 during the study. The same patient did not answer the posttreatment questionnaire. A patient in the intervention group reported a foot injury, resulting from the fall of a heavy object during a domestic task.

Discussion

We found that the ReabilitaDOR program is feasible, appropriate, and acceptable from the users' implementation perspective. This system has been considered usable by all the participants, and the main trial seems feasible. Costs and clinical outcomes were viable to be collected, the program was unlikely to cause harm, and no adverse events were reported during the intervention period. We had a low loss with follow-up and good levels of adherence and engagement with the health coach. The results of this study can demonstrate the feasibility of the main cost-effectiveness trial without major changes to the program.

Over the last few decades and in the past years of the COVID-19 pandemic, we have observed an increase in studies involving telerehabilitation platforms for patients with chronic pain [17]. However, it is important to emphasize that the intervention implementation processes are dependent on the context, cultural diversity, and characteristics of the population [37,38]. Thus, this study is innovative and novel because it included a population that was never been exposed to telerehabilitation before. Brazil incorporated the first regulation on telehealth in March 2020 after the social isolation policies imposed by the COVID-19 pandemic. These results may pave the way for new initiatives involving telehealth in low- and middle-income countries, since previous studies with this proposal were predominantly carried out in high-income countries [39].

The observation of results in low- and middle-income countries is necessary and meets the needs of care and equity provided by the World Health Organization [14,39]. To reach that, it is extremely important to design studies that prioritize the analysis of outcomes that are related to the implementation process [23,40]. Implementation science can help reduce the actual implementation time of interventions and provide many benefits to science and clinical practice. Thus, the writing of this study followed the recommendations of the CONSORT statement for feasibility and pilot studies [41] and is based on a concrete proposal on how to use implementation science and design studies with this objective, thereby being a differential among

several pilot studies [20,42]. Although we were unable to carry out an intervention mapping process, we followed the observation of the outcomes such as acceptability, adoption, appropriateness, feasibility, program fidelity, and costs [23,40,43].

The future implications of the results observed in this study are toward a better understanding of the processes of use of telerehabilitation in countries that do not have a regulation for its use or have a recent regulation. Our study explores the results of a sample that has never been exposed with the type of intervention that was performed, being extremely important for the real visualization of the implementation outcomes in populations that would benefit from telerehabilitation but for whatever reason did not have this experience. In addition to the clinical implications, this study aims to test the feasibility of the main study, which will provide specific data on the effectiveness and cost-effectiveness of the tested program. Conducting a pilot study with a representative sample can provide insights into the future implementation and feasibility results [44] and should be encouraged, as many pilot studies do not demonstrate outcomes inherent to their role [42].

Our study has some limitations that may be important for the general interpretation of the results. The 3 implementation outcomes tested were initially proposed to measure the acceptability, adoption, and feasibility of clinicians and stakeholders in implementing evidence-based practices [29]. In our study, implementation outcomes were not collected from the stakeholders' perspective; instead, we approached the patients directly. We believe this is also important because asynchronous telerehabilitation strategies are dependent on patients' adherence, acceptance, appropriateness, usability of the system, and willingness to navigate the platform [23,40]. Our research group is also investigating users' barriers and facilitators through qualitative methodologies within the main clinical trial. The arrival of SARS-CoV-19 in Brazil and the declaration of a pandemic by the World Health Organization brought the emergency need for measures to contain the disease, which included social distancing and quarantine [45]. In the period in which we began to recruit patients on the waiting lists of physiotherapy clinics, we faced a drastic decrease in the search for physiotherapy and health care services [46]. Thus, recruitment was carried out primarily through social media, giving the profile of our sample a specific characteristic of patients who already used the internet.

In conclusion, we found that the ReabilitaDOR program is feasible, appropriate, and acceptable from the users' implementation perspective. This system has been considered

usable by all the participants, and the main trial seems feasible. Cost data were viable to be collected and the program is unlikely to cause harm, as no adverse events were reported during the intervention period. Both groups reported being overall satisfied with the platform and the proposed program content.

Abstract

Background: The number of single-living workers separated from their spouses and families has been increasing due to the need to create a balance between life and work. Workers are assigned everywhere in globalized workplaces while also caring for their family members in the context of Japan's aging society. At the same time, the mental and health status of persons living separately from their families is a matter of concern. The development of interpersonal communication means using information and communications technology (ICT) tools and the internet is remarkable, enabling simultaneous 2-way communication across distances and national borders. The easy accessibility to simultaneous communication is expected to improve the psychosocial status of isolated family members.

Objective: This study aims to clarify the health benefits of ICT by using a psychosocial health assessment, the characteristics of ICT tools, and the frequency of communication among the workers and their families who live separately.

Methods: This was a cross-sectional study planned and conducted in Japan. Study participants, including adults who live separately from other family members or have separately living family members due to work, were recruited to answer a web response survey about ICT usage status, health status, and life and society evaluation. This study recruited 73 participants divided into 2 groups by their communication tools and frequencies, and their separated life, health, and psychosocial status were statistically compared.

Results: Among the 73 study participants, 15 were categorized in the high communication-skilled (HCS) group that used both types of ICT tools to communicate frequently: "live," such as video chat and voice call, and "nonlive," such as SMS text message service and email. A simple comparison between the HCS and reference groups showed significant differences in the cohesion with the neighborhood ($P=.03$), perceived social position ($P=.01$), and happiness ($P<.001$); however, there were no significant differences in the health (psychological distress, $P=.08$; self-rated health, $P=.07$), lifestyle (drinking, $P>.99$; current smoking, $P=.37$), and dyadic trust in family members living separately ($P=.80$). Further, in a multivariate regression analysis adjusted for confounding factors, such as educational history, age, gender, and job status, poor subjective health showed a prevalence odds ratio of less than 1 (OR 0.17, 95% CI 0.03-1.02). The HCS group showed significant positive relationships in the cohesion score with the neighborhood ($P=.01$; $\beta=2.40$, 95% CI 0.56-4.24), perceived social position ($P=.03$; $\beta=1.17$, 95% CI 0.11-2.23), and happiness score ($P=.002$; $\beta=1.46$, 95% CI 0.58-2.34) in the same multivariate regression models.

Conclusions: This study suggested that people who frequently communicate with separated family members by taking advantage of various ICT tools can maintain a better mental state and better social relations among those who live alone and are separated from their families.

Introduction

In Japanese working households, couples may have a period of living separately due to raising children or caring for parents at the opportunity of a job transfer of a family member. Most Japanese workers are employees, accounting for almost 89% of the workforce [1]. Given that the Japanese company organization adopts the membership system [2], there are many cases where they follow transfer orders by their company until they reach retirement age under lifetime employment [3]. Because Japanese companies have domestic and overseas branches and departments, employees usually experience several different workplaces every few years unless they change companies. Employees belong to the company's membership system; even if their company orders them to change their workplace, it is rare for them to leave their company because of that system. Therefore, if there are family circumstances, such as a child attending a competitive elite school or parents needing care, when workers are ordered to transfer, only the worker will leave and move to a different workplace alone. In Japan, where the birthrate is declining and the population is aging, children's education is an important concern for families [4]. At the same time, caring for aged parents is often managed by some family members with less manpower [5]. In addition, as the working-age population is relatively small, companies have to allocate a small number of employees to various places and suitable positions. The human resource department of Japanese companies usually transfers their employees from one job to another or from one branch to other branches rather than hiring new workers to allocate necessary jobs or branch. Because they are taking the membership employment system, hiring workers means to approve the person as a member. Therefore, such an approval process is fateful and serious, and the human resource department hesitate to make decisions easily. From the high economic growth era until today, many Japanese company organizations seem not to change the membership employment system [2].

The number of single-living workers separated from their spouses and families is increasing. Although it is difficult to determine the accurate number, it has been partially figured out by the government, for example, through the Comprehensive Survey of Living Conditions and the National Census. For instance, available information aggregates male spouses who are single households as single job-transferred workers based on these national statistics [6]. According to this information, there were 750,000 single-living married men in 2015 [6], equivalent to 2.4% of the households with couples. In addition, since 1997, the Ministry of Internal Affairs and Communications has begun reporting the number of female workers living alone,

although they have spouses in the Employment Status Survey. The number has also increased for women from 0.5% of female workers in 1997 to 1.2% in 2017 [7]. Thus, the percentage of single job-transferred workers for both men and women is not high in all households or workers, but it has steadily increased in the past 30 years.

The mental and health status of solitary members living apart from other family members has been a concern according to the increasing number of single job-transferred workers. Several studies on the health (in particular, mental health centered on psychological stress) of single job-transferred workers and their families were published between the 1980s and 2000s. In some studies, the health status of single job-transferred workers did not necessarily deteriorate because the age at the time of transfer, personal qualities (whether or not the transfer is positively considered), and significance of the transfer (whether or not it involves promotion) affected the situation. Therefore, the worsening effect of single job transfer on mental health did not necessarily occur in all cases [8,9]. In addition, a survey was conducted on couples in which one of them was assigned to work alone. An unpredictable life, such as not making a life plan due to an unknown assignment period, was a stress factor, although it depended on the spouses' age and the length of the assignment [8].

Recently, physical health has been also evaluated for single job-transferred workers compared with workers living with their families. With respect to their lifestyle habits, increased smoking and frequency of drinking were higher among those assigned to work alone, and many of them did not eat breakfast [10,11]. Studies have concluded that these were due to stress. The study also reported several symptoms, such as headaches, gastrointestinal disorders, and colds, among single job-transferred workers [10]. In addition, they had a higher prevalence of mental stress, such as irritation, anxiety, and depressive mood, than workers living with family [11]. Comparing the results of health checkups of single job-transferred workers with those of workers living with their families, cholesterol levels and other values were worse for the former [11].

Workers living alone and separated from their families tend to consult with their families about health problems rather than with their close colleagues and medical staff at the working place [10]. It is suggested that communication with their families is important for maintaining their health even when they are isolated physically from them. However, few studies have focused on the communication of single job-transferred workers. Therefore, it is meaningful to evaluate the state of communication as a factor that leads to a better state of life and health of an isolated person living away from the family.

The means of communication available to families living separately have increased dramatically since the 1990s when the official number was first estimated. The development of interpersonal communication means using information and communications technology (ICT) tools is remarkable. In particular, the free call service using the internet network enables simultaneous 2-way communication across distances and national borders. When video functions are added, it enables visual communication and sharing of information by nonverbal transactions. Messenger apps in smartphones, such as WhatsApp, Facebook Messenger, and WeChat, are popular and each has more than 1 billion active users [12]; additionally, these apps have regional characters. In East Asia, LINE is popular in Japan, Kakao Talk is famous in South Korea, and WeChat is used the most in China [13]. These free calling apps over the internet have hundreds of millions of users worldwide and contribute as a communication tool.

Under the background of developing ICT tools, communication means in Japan has also changed. The number of general users of free calling apps, a recent method, is increasing rapidly [14]. According to the Ministry of Internal Affairs and Communications' Communication Usage Trend Survey, the number of communications and communication hours via conventional telephones have decreased in recent years. By contrast, the number of email and social networking service (SNS) users has become more than half. It is reported that 3.8 billion people not only in Japan but also worldwide are using some kind of SNS tool today [15].

Considering communication to build interpersonal relationships, it can be said that the association between social support and health status has been known for a long time [16]. The number of people to talk to daily has been used to determine the effects of social support. The greater the number of individuals with whom one communicates, including those met face-to-face and those who communicate by email, telephone, and SNS, the higher one's self-reported health [17]. In addition, sharing life-related information among family members through various means increases the family's well-being [18]. In the case of spouses, increased sharing of information reduces the incidence of mental disorders in families living apart and improves their mental health [19]. It also positively affects family relationships based on affection and growth [20]. Regarding the level of sharing information, these studies evaluated the frequency of communication between families using internet-based applications (eg, Viber, Imo, and Facebook) and the number of messages sent by instant messaging as an index.

The types of ICT tools used for individual communication have been influenced by socioeconomic factors [18,21]. Nowadays, these tools are regarded as a means for maintaining and promoting health. Effective use of the internet is observed in older adults of higher socioeconomic status and in those who reported less depressive and anxiety symptoms [22]. In addition, increased access behavior to health information has been observed, as internet users are not in the lowest socioeconomic level [23]. In Japan, trials have been conducted by simultaneously sharing photographs [24] and using telemonitoring systems of television's operating state [25] to ensure a secure and safe feeling among family members living

separately. However, these are case reports of experiments among a few families, and psychological health has not been examined. In Japan, where the number of single job-transferred workers is increasing, the relationship between the physical and mental health of separated couples and their families and the usage and frequency of communication tools widely employed today is expected to be examined fully.

Currently, while numerous people are benefiting from ICT to obtain psychological support from remote family and friends, the health of those who live away from their families has not been fully evaluated in this context. Therefore, this study investigated the association between the communication via ICT and the emotional advantages among couples and families who temporarily choose to live separately because of work. This study aimed to clarify the health benefits of ICT by conducting a psychosocial health assessment as well as evaluating the characteristics of ICT tools and the frequency of communication.

Methods

Study Design

This was a cross-sectional study planned and conducted in Japan. Study participants were adults who live separately from families or have separately living family members due to work. Recruitment was conducted for 5 months from November 2019 to March 2020. The survey asked about ICT usage status, health status, and life and society. All answers were collected by the web response system and analyzed statistically.

Participants

The researchers approached their acquaintances to introduce the survey to their family, friends, and colleagues. Most acquaintances were also researchers, specialists, and businessmen working in universities, research institutes, and companies with many branches located both domestically and abroad. They had experienced living alone remotely from their family and were expected to know those temporarily separated for work reasons or who had such families. As the reason for living separately, work and family care were included but not for divorce, family troubles, or other reasons. University students were excluded because many of them were usually not expected to be responsible for the life of the rest of their family members, although many of them lived alone apart from their families.

Participants were recruited by the snowball sampling method. First, by meeting directly, sending email, or calling over the telephone, the researchers asked them to be the first introducer. The researchers then asked them to send a recruitment message to the mailing list of the Young Scientist Group of the Japan Epidemiological Association. If the potential participant accepted to be an introducer, the researchers asked him/her to introduce them to 1-3 acquaintances who met the inclusion criteria and send an email of the survey site link, a token key, and the research explanatory material. If a reader of the mailing list wanted to participate in the survey and was confirmed that he/she met the criteria of living separately, the researchers directly sent a similar email with the information of a link, a token, and a research explanatory material. If the first applicants

accepted the research conditions and participation in the survey, they anonymously started answering the questionnaire using the token key received. Once they finished answering the questions, a new token key and a message appeared, which asked them to send the token key to the family living separately from the first participants to allow them to participate in the survey. Finally, 73 participants were chosen to have given valid responses, and it included 12 family pairs living separately.

Survey Variables

The survey was conducted using a free and open-source online statistical survey web app, LimeSurvey [26], and responses were collected using an anonymous self-completed survey form. Separated family pairs were identified by the tokens distributed with the survey guide. Regarding the ICT usage status, the following items were suggested to understand the types of communication tools often used: “phone calls by cellphone and telephone,” “online free calls,” “video chat using the Internet,” “short text message on cellphones,” “group text chats like LINE, FB messenger, etc.,” and “e-mail” as well as the frequency of communication with each tool from the following options: “never use,” “once a month,” “few times a month,” “once a week,” “two or three times a week,” “four or five times a week,” and “almost every day.” The detailed questionnaire is presented in [Multimedia Appendix 1](#). In addition to the basic attributes, the researchers asked about their separated living status, such as the relationship status for participants, period of separation, time and cost required to meet, and frequency of meeting.

The outcome indicators for the evaluation of the communications were mental health; K6, a 6-item screening scale for psychological distress [27]; subjective self-rated health [28]; and lifestyle habits, such as drinking and smoking. Moreover, this study investigated trust with the family [29]; subjective happiness level [30]; perceived social position, as assessed by a social stratification ladder called the Cantril Ladder [31]; and cohesion with neighborhoods [32]. These validated indicators were selected to assess the psychosocial health status.

Statistical Analysis

First, a simple tabulation was presented about the basic attributes and separation status of the research participants. Furthermore, the communication tools were divided into 2 groups: “live,” which included voice and video options, such as phone call, internet free call, and video call; and “nonlive,” which included sending texts via email, group text chats such as LINE, and SMS text message. Communication frequency was calculated as the average score for each combination of the most frequently used tool and the next most frequently used tool. Participants with high-frequency scores, including both live and nonlive tools used as the first and second choices, were classified into the high communication-skilled (HCS) group and compared with the remaining participants, now treated as the reference group. For statistical comparison, the Student *t* test or the Wilcoxon rank-sum test was used for continuous variables depending on the observed data distributions. Similarly, the chi-square test or Fisher exact test was used for categorical variables. After making a simple comparison, the effects of HCS were estimated by adjusting the educational history, age,

gender, and having a job or not, which were thought to be confounded by a multivariate regression model. For the statistical estimation of the effects of HCS on psychological health-related outcomes, logistic regression was used for dependent variables with a binary value of 0 or 1, and ordinary least-squares linear regression was used for continuous dependent variables. The significance level (*P* value) of all statistics was 5%, and analysis was performed using Stata version 16 (StataCorp, Inc.).

Ethics Approval

The Kyushu University Medical District Institutional Review Board for Clinical Research approved the protocol of this verification study in 2018 (approval no. 30-335). The main study has also been approved for implementation.

Results

Among the study participants who agreed to join the survey, 73 completed the questionnaire, including 61 family pairs consisting of couples or parent-child relationships. Their basic demographic characteristics and the status of separate living are summarized in [Table 1](#). Mobility data on returning home to meet the family differed according to distance, and these were summarized based on the difference between domestic and international travels. A total of 53 pairs lived separately in the same country, 7 pairs were separated internationally, and 1 pair did not provide their residence status.

[Figure 1](#) shows the types of ICT tools used in family communication and the communication frequency among family members. ICT tools were divided into 2 types of systems: live and nonlive. Phone calls were the most frequently used option by study participants for family communication among the live-type systems. Among nonlive-type systems, most used email every day.

The study participants were summarized for each combination of the most frequently used and the second most frequently used tool for family communication. The average value of the scores of communication frequencies for each combination and the number of participants are shown in [Table 2](#). The combination tools that had the highest average score for frequency of use of the combined tools (ie, both live and nonlive systems) were (1) phone calls and SMS text messages (score 16.3 + 6.4; n=9), video calls and group messages (15.5 + 4.6; n=6), or video calls and SMS text messages (score 14; n=1). The 15 people included in these combinations were chosen as the HCS group. We then compared the health and psychosocial states of the HCS group with the rest of the participants, who were considered the reference group.

[Tables 3](#) and [4](#) list and compare the attributes of the HCS and reference groups. The HCS group included more graduates (15/16, 94%) than the reference group (29/57, 51%). However, there were no statistically significant differences in other attributes, such as age (*P*=.37), gender ratio (*P*=.94), engaged in a job (*P*=.58), or living status (*P*=.70). In addition, there was no difference in the status of separation between the HCS and reference groups on the frequency of actual meeting with the separated family, the travel time, and the cost.

A simple comparison was conducted with the reference group regarding health status, lifestyle, and evaluation of life and surroundings in the HCS group (Table 5). No significant differences were observed in health (psychological distress, $P=.08$; self-rated health, $P=.07$) or lifestyle (drinking, $P>.99$; current smoking, $P=.37$). The HCS group also showed no

statistical difference in dyadic trust in family members living separately with that of the control group regarding interpersonal relationships ($P=.80$). However, the HCS group had higher scores of neighborhood social cohesion ($P=.03$), perceived higher social positions ($P=.01$), and higher level of happiness ($P<.001$) than the reference group.

^cStatistically significant values are in italics.

One’s level of education, communication methods, and evaluation of life may be influenced by educational history. Therefore, a multivariate regression analysis adjusted for confounding factors, such as educational history, age, gender, and job status, was performed (Tables 6 and 7). As a result, poor subjective health showed a prevalence odds ratio of less than 1 (0.17, 95% CI 0.03-1.02), but psychological distress ($P=.09$), lifestyle (drinking, $P=.60$; current smoking, $P=.36$),

and dyadic trust with a family partner ($P=.93$) showed no significant association with those of the reference group, as was the case with the simple comparison. In the HCS group, the cohesion score with the neighborhood ($\beta=2.40$, 95% CI 0.56-4.24), perceived social position ($\beta=1.17$, 95% CI 0.11-2.23), and happiness level ($\beta=1.46$, 95% CI 0.58-2.34) were all higher.

Table 6. Results of multivariate regression of the association of health and lifestyles with the high communication–skilled group who used various types of information and communications technology tools for higher frequent communication with family.

Discussion

Principal Findings

In this study, people who frequently communicated using ICT took more advantage of its characteristics even if they were separated from their families, experienced more social cohesion with their neighborhood, and exhibited a higher degree of social position and a higher level of happiness in their life than people who did not communicate frequently using various ICTs. There was no relationship between the variety and frequency of communication methods and the sense of trust in the other

family member living separately. In addition, as long as they communicate with each other with sufficient frequency by taking advantage of ICTs, separated persons from family maintained good health, although it was not statistically significant.

Separation, such as a single job transfer process without family, causes a great inconvenience in life, making the health condition worse. Therefore, single job-transferred workers have reported worse health than workers who move with family at job transfer [10,11]. However, this study could modify these findings. Our results show that a separated person who communicates more using various ICT tools may have a useful skill in maintaining

good mental health. The study design was different from previous studies, and people who were not separated were not evaluated as a reference group in this study. However, good psychosocial effects were achieved by taking advantage of ICT tools and having enough frequency of communication, which can be useful for mitigating the inconvenience and stress in the life of single job-transferred workers in the future. Preferably, to identify the effective intervention methods necessary to improve the quality of life of separated families, additional studies are needed to evaluate the relationship between the state of detailed communication and the sociopsychological health status of both individuals separated and not separated.

It would be meaningful to evaluate the psychological health status of separated families considering their current infrastructure background, as ICT tools are now highly developed and the mobility of traffic movement has become increasingly flexible. In Japan, family members often separate temporarily for job reasons, and single job transfers were introduced by many Japanese companies during the period of high economic growth starting in the 1960s and 1970s and have been widely accepted among families. According to Japan's public employment statistics, a survey on the number of households having a worker of single job transfer began in 1981. Since then, several evaluations have been conducted, focusing on the stress status of family members, the roles of parents, and the development of children [8]. Recent studies have also revealed that single-living workers separated from their families have poor lifestyles, poor psychological conditions, and poor medical examination results [10,11]. However, new communication devices, such as smartphones and tablets, are expected to significantly enhance the effects of communications using the internet, which were introduced after 2009 and have developed continuously. When using a smartphone, there were a few technical difficulties, such as the need for other devices and systems, at the time of its introduction. The communication cost is relatively low because the existing internet network can be used. In addition to texts, it is possible to communicate with a large amount of information, such as images and videos, so it has become possible to evaluate psychological health conditions considering the relationship of health conditions with both quality and quantity of communication methods. In Japan, the ownership rate of different information and telecommunications devices indicated that smartphones were the most common, accounting for up to 83.4% in 2019 [14].

Previous studies have already pointed out that the psychological state of single job-transferred workers may be improved by improving communication. It has been observed that when single-living employees have a health problem, more than half of them consult with a family member living far away rather than with colleagues or medical staff closer to them [10]. Thus, there is a possibility that sociopsychological indicators can be kept high by mastering and using diversified means of communication. As ICT is expected to continue to develop in the future, our results suggest evaluating the current transitional situation. In any case, as long as people learn and use ICT tools appropriately, the range of communication means will expand, eventually giving more merit.

Limitations

As this study used a cross-sectional design, causal relationship cannot be proven. The relationship between cause and effect was not evaluated, such as whether the sociopsychological utility, such as happiness level, has increased due to sufficient communication, or whether the communication has become active because separated individuals had an insufficient connection with the surroundings and a suitable level of perceived social position. A longitudinal research design in the near future can be adopted to monitor life evaluation changes and the physical and mental health status before and after the start of separation or during separation and after the end of the separation period together with the quality and quantity of communication.

In addition, because only few participants ($n=73$) were evaluated in this study, there is a possibility that participants' characteristics are biased. Looking at the attributes, it is possible that a large number of highly educated individuals with high socioeconomic status have gathered, so caution should be exercised when generalizing the results. Comparing single job-transferred employees with those living with family members, many single job-transferred employees held executive and managerial posts [11]. The annual incomes of these single job-transferred employees were usually higher than the average annual income of Japanese employees [8]. Therefore, participants in this study possibly had higher education and socioeconomic status than general people in households, including no single job-transferred members. In other words, highly educated people were likely to have family members living separately, so the results may apply to many households whose members live separately.

Moreover, this study used subjective health evaluation and did not use objective indicators, such as health checkup measurements, as in past studies. No statistically significant difference in the health indicators considered in this study might be attributed to the small number of participants, and the power was low. As we did not extract households, including single job-transferred workers, from a specific company or group, the diversity of evaluation targets was one of the strengths of the study when generalizing the findings. However, the small number of study participants threatened the reliability of research evaluation.

Conclusions

Despite the aforesaid research limitations, those who frequently communicate with separated family members by taking advantage of various ICT tools can maintain a better mental state and better social relations among those who live alone and are separated from their families. This study suggested that cohesion with the surroundings, subjective social position, and happiness level are higher among those who communicate better using various tools and more frequently than those who have less communication. It is expected that there will be increasing opportunities to go to a new location, workplace, or school alone away from the family in this contemporary society according to ICT development and the increasing frequency of mobility. Therefore, it would be useful to evaluate how to communicate

better to maintain a good mental state using technical aspects and frequency indicators in future studies.

Acknowledgments

This research was supported by the Funding Program of the Telecommunications Advancement Foundation Research Investigation (grant number FY2018-2019), and by JSPS KAKENHI (Japan Society for the Promotion of Science Grants-in-Aid for Scientific Research; grant number JP21K12142). Abstract

Background: Visualizations of illness and treatment processes are promising interventions for changing unhelpful perceptions and improving health outcomes. However, these are yet to be tested in patients with type 2 diabetes mellitus (T2DM).

Objective: This study assesses the cross-cultural acceptability and potential effectiveness of a brief visual animation of T2DM at changing unhelpful illness and treatment perceptions and self-efficacy among patients and family members in 2 countries, New Zealand and Saudi Arabia. Health care professionals' views on visualization are also explored.

Methods: A total of 52 participants (n=39, 75% patients and family members and n=13, 25% health care professionals) were shown a 7-minute T2DM visual animation. Patients and family members completed a questionnaire on illness and treatment perceptions and self-efficacy before and immediately after the intervention and completed semistructured interviews. Health care professionals completed written open-ended questions. Means and 95% CIs are reported to estimate potential effectiveness. Inductive thematic analysis was conducted on qualitative data.

Results: All participants rated the visual animation as acceptable and engaging. Four main themes were identified: animation-related factors, impact of the animation, animation as an effective format for delivering information, and management-related factors. Effect sizes (ranged from 0.10 to 0.56) suggested potential effectiveness for changing illness and treatment perceptions and self-efficacy among patients and family members.

Conclusions: Visualizations are acceptable and may improve the perceptions of patients' with diabetes in a short time frame. This brief visual animation has the potential to improve current T2DM education. A subsequent randomized controlled trial to investigate the effects on illness and treatment perceptions, adherence, glycemic control, and unplanned hospital admission is being prepared.

Introduction

Background

Type 2 diabetes mellitus (T2DM) is a metabolic condition characterized by high blood sugar levels owing to a loss of pancreatic beta cell function [1]. An estimated 463 million people had diabetes worldwide in 2019, and T2DM accounts for 90%-95% of all diabetes cases [2]. In New Zealand, 5.5% of people aged ≥ 15 years have diabetes [3]. Māori (indigenous New Zealanders) and Pacific groups are disproportionately affected by diabetes, with the latest report showing the prevalence rate of diabetes is 1.8 and 2.6 times higher in Māori and Pacific groups than non-Māori and non-Pacific groups [3]. In Saudi Arabia, the incidence rate of diabetes has substantially increased over the past 30 years, and the prevalence of diabetes was 18.3% in adults aged 20-79 years in 2019 [4].

T2DM requires ongoing self-management and lifestyle changes to achieve glycemic control and minimize the risk of complications [4]. Patients with T2DM are recommended to engage in a range of self-care behaviors, including taking medications as prescribed, following a healthy diet, and being physically active. Other self-care behaviors include blood glucose testing, foot care, smoking cessation, and attending clinic appointments [5].

However, research has shown that low adherence to diabetes self-care behaviors is common [6], and approximately 50% of patients with T2DM in New Zealand and Saudi Arabia do not reach glycemic control (HbA_{1c}) targets [7,8]. Ethnic disparities in T2DM management exist, where the Māori and Pacific groups are at greater risk of exhibiting lower adherence to metformin (first-line glucose-lowering oral medications; [6]), higher HbA_{1c} levels [9], and experiencing more diabetes-related complications compared with New Zealand European groups [8]. This is concerning because low adherence is associated with suboptimal glycemic control, increased medical cost, hospitalization, and mortality [10,11].

There is a growing awareness of the importance of psychosocial factors in the management of diabetes, as highlighted by recommendations to integrate psychosocial support into routine diabetes care [12]. Evidence-based psychological interventions for patients with diabetes include illness-perception interventions [13,14]. These interventions are based on the common sense model (CSM) [15,16], in which patients are active problem-solvers who use coping strategies based on their cognitive and emotional representations of illness. Research has demonstrated that these mental representations (known as illness perceptions) are associated with health outcomes [17-22]. The central dimensions include perceptions of the identity, timeline, causes, consequences, and control of illness.

Related to CSM is the necessity-concerns framework, which proposes that patients also have beliefs about medicine and that these beliefs influence adherence to treatment [23,24]. Patients who perceive medicine as necessary and have fewer concerns about its side effects are more likely to adhere to medication [24].

In diabetes, systematic reviews have established that patients' perceptions of personal control over their illness are associated with better glycemic control, whereas greater illness identity perceptions (attributing more symptoms to diabetes), greater consequences perceptions (perceiving diabetes to have severe consequences), higher emotional distress, and concern perceptions about diabetes were associated with suboptimal glycemic control [17,22]. Illness perceptions have also been linked to other outcomes in diabetes, including adherence to self-care behaviors [25], quality of life, and depressive and anxiety symptoms [26]. Similarly, evidence from reviews shows that higher necessity beliefs and fewer concerns about side effects were associated with higher adherence to medicines across studies [27,28].

Illness perceptions of family members can also influence patients' health behaviors, as many self-care behaviors in diabetes occur within patients' social contexts. Patients with chronic conditions tend to have better health outcomes when their perceptions align with those of their family members [29]. In diabetes research, mediation studies have shown that partners' perceptions can mediate the effects of patients' perceptions on adherence to self-care behaviors [30,31]. For example, a study with recently diagnosed patients with T2DM and their partners found that partners' personal control and treatment control perceptions fully mediated the effects of patients' perceptions on their adherence to blood glucose testing (mediation effects of 0.050 and 0.095, respectively). Partners' consequence perceptions also mediated the effects of patients' consequence perceptions on their adherence to exercise, foot care, and blood glucose testing, with mediation effects ranging from -0.052 to 0.062 [30]. This research highlights the importance of family members' perceptions of diabetes and the need to involve family members or significant others when designing interventions to improve patient health outcomes [32].

Research suggests that addressing unhelpful illnesses and treatment perceptions can result in better coping behaviors and improved health outcomes [29]. Interventions to change illness perceptions have shown promising results in patients with T2DM. For example, a family-based intervention resulted in improved understanding of T2DM, increased perceptions of personal and treatment control, fewer symptoms attributed to T2DM, and decreased concerns and emotional distress [14]. This intervention also improved adherence to diet, exercise, self-efficacy, well-being, and family support at 6-month follow-up [14]. Other similar interventions have resulted in improved adherence to self-care behaviors [13]. Although these interventions improve diabetes management and other psychological outcomes, they are time-consuming and are often conducted over multiple sessions. Owing to short medical consultations and constrained health budgets, illness perception interventions need to be more scalable to increase clinical utility [33]. The inclusion of visualization (eg, an animated pictorial explanation) of illness and its treatment could reduce delivery time.

Robust theoretical models (eg, cognitive theory of multimedia learning) and published empirical studies support the use of visuals to improve learning [34,35]. In health psychology research, visualizations have been shown to be an effective

medium to deliver information about illnesses and treatment processes, help explain abstract concepts, and show how treatment processes work inside the body [36]. Other benefits are that visualizations can be brief (eg, 10-15 minutes), improve visual appeal, do not require advanced training to deliver, and can be delivered in all settings (eg, in person or on the web; [33,37-39]). Research has shown that visualizations improve not only perceptions but also health behaviors [37,40]. For example, visual interventions with acute coronary syndrome, osteoporosis, HIV, and oncology patients have been shown to improve understanding and control perceptions in a short timeframe [33,38], increase adherence to antiretroviral therapy [41,42], increase exercise and improve return to normal activities [33], and improve postoperative mobility [43]. This research suggests that visualization can improve patients' perceptions and health-related behaviors in a number of conditions.

Objectives

Research on the effects of visualization on illness and treatment perceptions of T2DM is lacking. Therefore, this pilot study aimed to explore the cross-cultural acceptability of a brief visual animation of T2DM among patients and family members across 2 countries and collect feedback from health care professionals (HCPs) to highlight ways in which the visual animation could be improved. The study also assessed potential effects of the visual animation on illness and treatment perceptions and self-efficacy to inform a future trial on adherence to medication, diet and exercise behaviors, and health outcomes (eg, glycemic control and unplanned hospital admissions).

Methods

The authors followed the Standards for Reporting Qualitative Research [44] and CONSORT (Consolidated Standards of Reporting Trials) guidelines for pilot studies [45].

Design and Sample Size

This pilot study used a mixed methods design, involving pre-post assessment and semistructured interviews with patients with T2DM and family members across 2 countries (New Zealand and Saudi Arabia). This study also explored views about the visual animation among HCPs in New Zealand using open-ended questions. Given its exploratory nature, this study was not powered to detect statistical significance; however, it assessed potential effects on illness and treatment perceptions and self-efficacy by looking at changes in mean scores from before to after the intervention. The effect sizes were calculated from the means and SDs, which may be useful for a power calculation for a future trial. A previous study using visual animation found small effect sizes for illness identity perceptions and return to normal activities in patients with acute coronary syndrome [33], but effect sizes may differ in this population. To meet the study aims, we planned to recruit 32 patients (16 patients from each county) and as many family members as possible.

Participants

Primary participants were patients with T2DM. Patients were eligible to participate if they were aged ≥ 18 years, had a formal diagnosis of T2DM for ≥ 1 year, were prescribed diabetes

medications, lived in New Zealand (for the New Zealand participant group) or Saudi Arabia (for the Saudi Arabia participant group), and had access to the internet and a smartphone or computer. Eligible participants were encouraged to invite their family members to participate in the study. A family member was defined as a relative in regular contact with a person with T2DM. Participating family members had to be aged ≥ 18 years, living in New Zealand or Saudi Arabia, and with access to the internet and a smartphone or computer. Patients were allowed to participate by themselves if they did not want to invite a family member. Family members were also allowed to participate by themselves if they found it more convenient for them.

HCPs were consulted for feedback on the visual animation. In addition to working at an outpatient diabetes clinic, there were no other inclusion or exclusion criteria for this group. All participants were recruited between March and July 2021.

Brief Visual Animation of T2DM

The brief visual animation was developed by a multidisciplinary team including health psychologists, endocrinologists, and developers. The developmental process involved iterative feedback from the multidisciplinary team to refine the visual content. Māori and Pacific HCPs were consulted to ensure cultural appropriateness.

The visual animation is a 7-minute video that begins with introductory statements explaining the focus and purpose of the visual animation. The visual animation shows the production of glucose in the body after food consumption, glucose levels in the blood, and how glucose and insulin interact to allow glucose to enter body cells using the lock-and-key analogy. The visual animation then depicts what happens when patients have T2DM (eg, glucose cannot enter body cells because of inadequate insulin or insulin resistance, which leads to increased glucose levels in the blood). Symptoms and long-term complications associated with T2DM are visually depicted. The visual animation shows how treatment (with a particular focus on metformin, healthy eating, and regular exercise) can help control blood glucose levels. The visual animation concludes with an emphasis on the importance of family and significant others as a source of support and motivation. We developed 2 versions of the visual animation, one in English suited for the New Zealand context and one in Arabic suited for the Saudi context. Differences included the appearance and dress of the characters, food depicted, and pictures of the environment when the character was exercising outside (Figures S1-S11, [Multimedia Appendix 1](#)).

Procedure

Participants were recruited from an outpatient diabetes clinic at the Greenlane Clinical Centre in Auckland, New Zealand, a specialized diabetes clinic at a tertiary hospital in Riyadh, and Facebook diabetes support groups and community groups. Patients and their family members were approached in the waiting rooms by a student researcher (New Zealand sample) or a medical intern (Saudi sample) who introduced the study and invited them to participate. A study flyer was posted on community and diabetes support pages on Facebook outlining

brief information about the study and the research team contact details. Interested participants were provided with a link to the study on Qualtrics (web-based software for data collection; [46]).

On Qualtrics, participants confirmed their eligibility, viewed and downloaded participant information sheets, provided web-based consent, completed baseline questionnaires, and chose a time for the interview. At the beginning of each semistructured interview, participants were shown the brief visual animation either on web using Zoom software (New Zealand sample) or face-to-face at a clinic in an office room (Saudi sample). The participants then completed a web-based questionnaire immediately after the intervention. Participants were then interviewed, and only the participants and interviewers were present. All interviews were audio recorded and lasted for up to 60 minutes (Multimedia Appendix 2 provides the interview schedule). As a token of appreciation for their time, each participant in the New Zealand sample received a NZ \$50 (US \$31) voucher. The participants in the Saudi patient sample did not receive compensation.

The interviews were conducted by the first author (MA), a male PhD health psychology student originally from Saudi Arabia but studying or residing in New Zealand, and a female medical intern living in Riyadh, Saudi Arabia. The interviewers had no relationships with the participants before the commencement of the study.

HCPs working at an outpatient diabetes clinic at the Greenlane Clinical Centre in Auckland, New Zealand, were asked to provide feedback about the visual animation. The first author (MA) gave a presentation during the clinic staff meeting and showed the brief visual animation of T2DM. HCPs responded to 7 written open-ended questions related to the visual animation (Multimedia Appendix 2 provides the open-ended questions).

Measures

Patients with T2DM provided their age, sex, ethnicity, marital status, educational level, partnership status, employment status, type of prescribed diabetes medications, and duration of T2DM. Family members also provided information on age, sex, ethnicity, educational level, and relationship with the patient.

At baseline, patients' perceptions of T2DM were assessed using 4 items of the Brief Illness Perception Questionnaire (B-IPQ; [47]). The items included consequence, personal control, coherence, and concern perceptions. These 4 items were chosen as they have been consistently identified to be related to outcomes in diabetes (eg, glycemic control; [17,22], and perceptions of personal control and coherence are among the most frequently changed perceptions in trials using CSM in diabetes [32]. These perceptions were targeted in the intervention. These items were scored on a scale from 0 to 10, with higher scores indicating stronger perceptions. The B-IPQ has been previously used with Māori, Pacific, and Saudi patients with T2DM [48,49] and with family members [50]. The B-IPQ has demonstrated robust psychometric properties [17,47].

Patients' perceptions regarding the effectiveness of treatment (medication, healthy eating, and regular exercise) in controlling T2DM were assessed using 3 items adapted from previous

research ([25]; eg, *How much do you think your medication can help control your diabetes?*). Patients' confidence in managing their T2DM (self-efficacy) was evaluated using a single item (*How confident do you feel in managing your diabetes?*). These items were scored on a scale from 0 (not helpful or not confident at all) to 10 (extremely helpful or extremely confident). Patients' beliefs about the necessity of taking diabetes medications daily were assessed using a single yes or no question. Participants were asked to explain their answer as to whether they perceived it necessary to take diabetes medication every day.

Immediately after watching the visual animation, patients completed the same questionnaire administered at baseline. Participants further completed 3 yes or no questions related to their perceptions of T2DM (eg, *Did the animation make you think about [the potential consequences of your diabetes, [things you could do to help control your diabetes, and [your diabetes medication]?*). These questions were designed to assess whether the visual animation prompted the patients to actively think about their T2DM.

Family members completed similar questionnaires at baseline and immediately after viewing the visual animation; however, the questions were slightly modified to ask about their perceptions of their family members' T2DM (eg, *How much control do you feel your family member has over their diabetes?*).

Data Analysis

Qualitative Data

Interviews with Saudi patients were translated and transcribed into English by an independent researcher from Saudi Arabia who held a bachelor's degree in English literature. The transcriptions were then checked against the original recordings for accuracy by the first author (MA), who was fluent in Arabic and English. Interviews with patients from New Zealand and family members were transcribed by the first author (MA). Transcriptions were emailed to participants who wished to review their interview transcriptions and were instructed to return any comments within 2 weeks. All qualitative data from interviews and responses to open-ended questions provided by HCPs were coded and analyzed using an inductive thematic analysis approach [51]. Thematic analysis and coding were conducted independently by 2 researchers: the first author (MA) and a female health psychology researcher (ML) experienced in thematic analysis. Both researchers followed the 6 phases of thematic analysis [51].

First, data familiarization was achieved through manually transcribing, reading, and rereading the data. During this phase, a list of initial ideas regarding the data set was generated. Second, the entire data set was coded and each code was matched to the data extracts. Third, the generated codes were sorted and combined to form the initial themes and subthemes, and all relevant coded data extracts were collated within each initial theme and subtheme. All coded data extracts were reviewed to ensure coherence and meaningfulness. Themes were then further refined in relation to the entire data set to ensure that each theme was distinct. Themes and subthemes were assigned labels that captured their essence. Discussions

between the researchers ensued until a consensus was reached on the themes and the strongest quotes to support each theme and subtheme.

Quantitative Data

Descriptive statistics were used to analyze the data. Frequencies and percentages were calculated for dichotomous data. Continuous data were summarized using the mean and 95% CI at baseline and immediately after the intervention. Effect size (*r*) was calculated and interpreted using Cohen’s guidelines (*r*=0.1, small; *r*=0.3, medium; and *r*=0.5, large) [52] to determine the sample size calculation for a subsequent trial. All the analyses were performed using SPSS (version 27; IBM Corp).

Ethics Approval

This study was reviewed and approved by the Auckland Health Research Ethics Committee (reference number AH3217) and

the General Directorate of Health Affairs, Najran Institutional Review Board, Saudi Arabia (IRB 20 - 040E).

Results

Overview

There were 52 participants (n=15, 29% New Zealand patients; n=17 (33%) Saudi patients; n=7, 13% New Zealand family members; and n=13, 25% HCPs). Figure 1 provides the participant flowchart. Mean age of the participants was 54 (SD 11.16) years for patients and 44.1 (SD 11) years for family members. Patients had been living with T2DM for an average of 9 (SD 7.09) years. Table 1 shows the participant characteristics. The participating family members included 1 parent, 3 spouses, 2 children, and 1 other family member of the patient with T2DM. Most HCPs were diabetes nurses (6/13, 46%), followed by medical and nursing students (4/13, 31%), doctors (2/13, 15%), and a diabetes care coordinator (1/13, 8%).

Qualitative Findings (Patients and Family Members)

Overview

Four main themes were identified from the patients' and family members' combined data set: (1) animation-related factors, (2) impact of the animation, (3) animation as an effective format, and (4) diabetes management-related factors. Subthemes have been presented in the text using *italics*. A small number of quotes have been included in the main text to illustrate the major points, and further quotes are provided in [Multimedia Appendix 3](#).

Theme 1: Animation-Related Factors

This theme covered participants' perceptions and views of the visual animation. Participants viewed the visual animation as *succinct and simple*, which provided basic "need to know"

information on T2DM. The simplicity and short length of the visual animation helped to keep the participants engaged. Participants highly appreciated this and reported that this animation might be more suitable for people who do not want too much detail or people who are newly diagnosed with T2DM.

Participants reported that a longer visual animation would have probably made them lose interest. A few participants from New Zealand noted that the visual animation was slow with some unnecessary pauses, whereas some family members and participants from Saudi Arabia reported that it was too fast for them.

The use of simple nonmedical language and creative visuals were identified as important elements that made the visual animation *easy to understand*, especially for older adults and those with low health literacy. Participants reported that the visual animation was *informative*, and increased their

understanding of T2DM and its management. The participants appreciated that the visual animation not only focused on explaining what T2DM is, its symptoms, and related complications but also on what can be done to help control T2DM. This made them feel that their T2DM was manageable by taking medication as prescribed, eating healthy food, and exercising regularly in addition to other self-care behaviors such as self-monitoring of blood glucose levels and foot care:

I felt I can be more in control now by doing the simple three stuff, take my medication every day, eat healthy and watch my portions and exercise daily. [Saudi female patient 2, 49 years]

I suppose we know it's manageable, what it made me think was I've got to make it more manageable. [New Zealand male patient 15, 56 years]

Participants identified with the *characters* in the visual animation and said that they were “relatable.” The main character showed emotions (eg, happy and sad), which made them look more realistic than the static pictures found in brochures and pamphlets. More participants from Saudi Arabia identified with the characters compared with participants from New Zealand, and this might be because New Zealand is more multicultural than Saudi Arabia; therefore, it is harder to make the animated characters relatable for all cultures in New Zealand.

Participants highlighted the importance of making the characters context-specific, where characters reflect culture. This made the visual animation feel inclusive of minority groups such as the Māori and Pacific groups in New Zealand who are at higher risk of developing T2DM. Participants from Saudi Arabia also appreciated that the visual animation was custom-made to suit their cultural context.

Some participants felt that they would relate more to the animated characters if they were personalized to match participants' demographics. However, others acknowledged that diabetes can affect anyone regardless of ethnicity or gender and said that personalizing the animated characters was unnecessary.

Theme 2: Impact of the Animation

This theme was related to the perceived impact of the visual animation, in which *participants reflected on their' and their family members' T2DM*. The visual animation made patients think about the status of their T2DM (eg, whether controlled or uncontrolled) and the importance of adhering to the treatment regimen. For some participants, the visual animation was “a wake-up call” that reinforced the fact that diabetes is a chronic illness and the potential consequences of uncontrolled diabetes and motivated them to make positive lifestyle changes:

It is sort of a bit of a wakeup call now that I can understand it better. Sort of how important it is to follow that [lifestyle changes]. [New Zealand female patient 5, 62 years]

For others, the visual animation reinforced what they had been told in the past about the importance of self-care behaviors and reassured them that diabetes medications work to control their blood glucose levels. Other participants who managed their

T2DM well felt reassured that they were on the right track. A few participants reflected on their low adherence to diabetes self-care behaviors and reported feelings of guilt.

Of note, participants from Saudi Arabia reported that the visual animation specifically made them think about the potential complications of T2DM and the need to improve their adherence to delay or avoid these events, whereas participants from New Zealand did not. Participants from New Zealand reported general concerns about T2DM-related complications, but this was not related to the visual animation itself:

I thought about the consequences of diabetes, especially on the body organs. I felt that if I really do not control my diabetes, I will suffer more, and I will have more serious complications than I have so far. [Saudi female patient 6, 59 years]

For family members, the visual animation made them reflect on what they were already doing and what they could do to better support the patient, including preparing healthier meals and reminding them to take their medications. For those who lived apart from the patient, there was some uncertainty about whether the patients were, in fact, adherent to self-care behaviors:

That worked well for him, cutting down his portions yeah. It gives you a sense of control. That's what you should be eating and aiming for. [New Zealand female family member 19, 58 years]

Family members reported a sense of pride about their relatives with T2DM who were making significant lifestyle changes to control their T2DM. They were seen as role models who could influence other family members to have a better lifestyle, including improving physical activity and watching the type and portions of their food:

I was thinking about how he's doing all that like every day, whether it rains or shines, he gets up and goes for his exercise. And even the food, even if he likes certain food, he restricts the amount that he eats, which also makes other people in the family realize OK you have to control your portion of food that you're eating even if you really love it. [New Zealand female family member 16, 57 years]

Theme 3: Animation as an Effective Format

This theme covered the participants' perceived reasons for why the visual animation was an effective format. Information that participants had come by or received in the past (either written or verbal) was often described as confusing and medical. Many participants reported not reading diabetes pamphlets available at clinics and pharmacies, and those who read them thought they were often limited and primarily diet based. The visual animation was regarded as superior to written information as *visuals helped participants conceptualize T2DM and its treatment processes*. Some abstract thinking is needed to understand T2DM, and the participants acknowledged the value of being able to “see inside the body,” what it meant to have T2DM, the role of insulin, and how metformin works inside the body. Visual information is easier to understand and retrieve from the memory. Participants perceived the visual animation

as more engaging compared with other forms, such as written information. The visual animation was also regarded as culturally responsive to people with limited education, low health literacy, and diabetes-related vision problems:

We have seen pamphlets, but we often throw them out. They are hard to understand and too many words...I think the video is much better because you can see inside the body. I knew things before, but in my mind, I never pictured it. Now, I know how insulin works. [New Zealand male patient 8, 71 years]

It is powerful, you know, seeing how food is broken down into sugar, going through the bloodstream, and used for energy. How insulin is essential for this process and without it, like in type 1 diabetes, you can die. [Saudi male patient 11, 43 years]

It is culturally responsive to a whole section of society that might find it valuable, because it's not just written literature, that it is very medical with medical speak. I think that the visual aspect is very good. [New Zealand female family member 3, 48 years]

Despite having been living with T2DM for years, the animation presented *new information* for some participants. For example, using the lock-and-key analogy to explain the role of insulin was new to most participants. Participants reported having not previously been told about some of the explanations covered in the brief visual animation, including how metformin and insulin work inside the body. In some instances, there was a complete lack of knowledge about self-testing of blood glucose and foot care despite the importance of these behaviors. Participants reported that the visual animation helped bridge this knowledge gap and motivated them to discuss these issues further with their care team:

It is more than what I have been told by anybody else basically...I had no clue about that, testing your sugar levels daily! [New Zealand female patient 2, 61 years]

I got to know more about diabetes, most of which I hadn't known previous to watching the video. [Saudi female patient 13, 60 years]

Theme 4: Diabetes Management–Related Factors

This theme covered general issues around diabetes management (knowing and doing are 2 different things), which were not related to the visual animation itself. Participants identified main *barriers to adherence* to medication, healthy eating, and exercise, including poor understanding of the chronicity and progression nature of diabetes, forgetfulness, older age, intentionally skipping doses as they felt okay, busy work or personal schedules, physical disability, poor weather, lack of willpower and motivation, and stress.

Participants expressed *concerns* and *frustrations* related to diabetes management. These included concerns about medication side effects, especially insulin, such as weight gain. A few participants reported hesitancy about going on insulin despite being asked a few times by their doctors. This was in part because of poor understanding of the progressive nature of diabetes, and going onto insulin was seen as a sign of personal failure to control diabetes:

I've actually had an aversion to the idea of insulin, but before this meeting, I was saying to myself if I go on insulin, then it's over for me basically. [New Zealand male patient 10, 36 years]

Participants expressed frustration about the cost and funding for new diabetes medications such as empagliflozin (Jardiance). This medication is funded in New Zealand only for people with T2DM if they fulfill various eligibility criteria such as being at high risk of heart and kidney complications. Patients who wanted to go onto this new medication but did not meet the eligibility criteria chose to pay the cost themselves, creating financial strain and additional concerns. Another frustration patients and family members experienced was the dismissal by HCPs in instances where patients came to their appointments having done some research on the internet and prepared their questions.

Other participants were concerned about long-term complications if they did not control their T2DM. For some participants, understanding the chronicity and progressive nature of T2DM, in addition to being fearful of potential complications, pushed them to improve their adherence and make serious lifestyle changes.

The impact of culture, especially around eating habits, was highlighted as a factor that could hinder people's ability to manage their T2DM. In some instances, it is considered rude and unacceptable to refuse food, especially when invited to someone else's house.

Support from family members and significant others was seen as important for optimal management. Family members can remind patients to take medications and motivate them to eat healthily and exercise regularly. Participants acknowledged the social impact of T2DM and that caring for someone with T2DM could be highly stressful. One way to mitigate this is through a better understanding of T2DM.

Problems can arise when patients do not want help or live alone, or when family members are not supportive for any reason, including low health literacy. Participants expressed frustration when, for example, family members cooked unhealthy meals or perceived T2DM as something that is easily fixed and not chronic.

Qualitative Findings (HCPs)

Inductive thematic analysis of the HCPs' data set resulted in a single theme consistent with the first theme identified from the patients' and family members' data set, "animation-related factors." HCPs perceived the visual animation as *brief and succinct, easy to understand, informative, and culturally appropriate* (Multimedia Appendix 4 provides themes, subthemes, and supporting quotes).

Suggested Changes to the Visual Animation

Participants from all groups provided suggestions for improvement, including using a less formal and female voiceover, changing medical terms to lay terms (eg, chronic to long-term, glucose to sugar), personalizing the animated characters based on the patient's demographics, and adding subtitles to accommodate those with hearing difficulties. The

participants also suggested adding greetings in Te Reo Māori and other Pacific languages.

Furthermore, the participants expressed a need for more visual content that covered other important issues in diabetes such as how insulin therapy works, daily self-monitoring of blood glucose, HbA_{1c} testing, and foot care. Brief, simple, and accessible educational digital content in the form of animated videos could be developed for each topic.

Potential Effects on Illness and Treatment Perceptions and Self-efficacy

Data support the potential effectiveness of the brief visual animation on patients' perceptions and self-efficacy (Table 2). Increases in means from baseline to immediately after intervention for perceptions of consequences, personal control, coherence, medication effectiveness, and self-efficacy among patients from New Zealand suggest medium to large effects ($r=0.43-0.56$). Changes in mean concern, healthy eating, and perceptions of regular exercise effectiveness were smaller. A

similar pattern of positive changes was observed among patients from Saudi Arabia, with medium effects ($r=0.34-0.47$) for increases in personal control perceptions, coherence perceptions, medication effectiveness perceptions, healthy eating effectiveness perceptions, and self-efficacy. Changes in consequences, concerns, and perceptions of regular exercise effectiveness were smaller. Finally, perceptions of family members from New Zealand changed in the expected direction, with effect sizes ranging from small to large ($r=0.10-0.55$).

All patients and family members (100%) believed that it was necessary to take diabetes medication every day at baseline and after the intervention. The cited reasons included controlling blood glucose levels, avoiding and delaying complications, and having a better quality of life. After the intervention, most patients and family members reported that the brief visual animation made them actively think about the potential consequences of T2DM, things they could do to control their T2DM, and diabetes medications.

Table 2. Illness and treatment perceptions and self-efficacy scores at baseline and immediately after the intervention.

Variable	Baseline, mean (95% CI)	Immediately after intervention, mean (95% CI)	Effect size (<i>r</i>)
NZ^a patients (n=15)			
Illness perceptions			
Personal control	5.40 (4.11-6.69)	8.07 (7.03-9.10)	0.52
Coherence	6.67 (5.35-7.98)	9.07 (8.42-9.71)	0.56
Consequences	7.53 (6.47-8.60)	9.27 (8.69-9.84)	0.43
Concerns	7.87 (6.61-9.12)	8.67 (7.98-9.35)	0.27
Treatment perceptions			
Medication	7.67 (6.55-8.79)	9.33 (8.88-9.79)	0.48
Eating healthy food	8.53 (7.58-9.49)	9.07 (8.42-9.71)	0.19
Regular exercise	7.87 (6.46-9.27)	8.93 (8.17-9.70)	0.27
Self-efficacy	6.13 (4.73-7.54)	8.40 (7.78-9.02)	0.52
SA^b patients (n=17)			
Illness perceptions			
Personal control	7.18 (5.53-8.82)	8.59 (7.77-9.40)	0.36
Coherence	7.65 (6.05-9.24)	9.00 (8.19-9.81)	0.41
Consequences	8.00 (6.33-9.67)	9.18 (8.57-9.79)	0.23
Concerns	6.88 (5.15-8.62)	5.59 (4.06-7.12)	0.24
Treatment perceptions			
Medication	8.12 (6.89-9.35)	9.29 (8.67-9.92)	0.47
Eating healthy food	8.18 (6.89-9.46)	9.18 (8.69-9.67)	0.38
Regular exercise	8.71 (7.52-9.89)	9.41 (9.09-9.73)	0.24
Self-efficacy	7.71 (6.22-9.19)	9.06 (8.47-9.65)	0.34
NZ family members (n=7)			
Illness perceptions			
Personal control	6.71 (3.57-9.86)	8.43 (6.93-9.93)	0.44
Coherence	7.14 (5.90-8.39)	8.57 (6.98-10.16)	0.37
Consequences	8.86 (7.40-10.31)	9.00 (7.81-10.19)	0.10
Concerns	8.00 (5.38-10.62)	6.71 (4.23-9.20)	0.39
Treatment perceptions			
Medication	6.71 (4.11-9.31)	9.43 (8.03-10.83)	0.51
Eating healthy food	7.86 (5.44-10.27)	9.29 (8.59-9.98)	0.40
Regular exercise	8.57 (7.39-9.75)	9.57 (8.84-10.30)	0.55
Self-efficacy	6.14 (3.56-8.73)	7.57 (5.66-9.49)	0.23

Discussion

Principal Findings

This pilot study showed that a brief animation was acceptable and engaging for patients with T2DM and their families. Inductive thematic analysis revealed 4 main themes related to the brief animation, the impact of animation, animation as an effective format for delivering information, and diabetes

management-related factors. Preliminary analysis showed potential cross-cultural effectiveness for improving illness and treatment perceptions and self-efficacy in all patients and family members, with larger effect sizes observed in the New Zealand patient group than in the Saudi patient group. Room for change in the New Zealand patient group may have been larger given the lower baseline means for many of the perception dimensions. Given the explanatory nature of this study, baseline

characteristics were not used in the analysis but could be used in a subsequent trial.

The visual animation was well received. Nearly all patients and their family members reported that the visual animation was informative and understandable. This is consistent with previous studies that have shown that visual interventions (eg, animations covering general information about diabetes, symptoms, risk factors, and management) improved diabetes health literacy [53] and knowledge about foot care [54].

Visualizing both the illness and its treatment are important [36]; this is because visualizing T2DM, related symptoms, and serious complications can potentially increase anxiety and fear. Heightened negative emotions alone are not sufficient to elicit changes in perceptions and behaviors; therefore, information on how T2DM can be managed is essential. This visual animation explained T2DM and how treatment (eg, metformin) works inside the body to help control T2DM, which was highly appreciated by the participants. Participants felt that their T2DM was more manageable and increased their control perceptions, self-efficacy, and motivation to make lifestyle changes. This finding is in line with previous research that showed visualizations can increase the motivation to for taking medicine in patients with osteoporosis [38].

Many of the reported barriers to adherence to self-care behaviors (eg, poor understanding, forgetfulness, and concerns about medication side effects and costs) are similar to previous findings [55]. One additional barrier is known as “psychological insulin resistance,” where patients are hesitant to initiate and or adhere to insulin therapy [56-59]. This barrier represents a complex set of beliefs (eg, sense of failure and incompetency) and attitudes (eg, fear of injections and hypoglycemia) toward insulin therapy [56].

Some participants reported avoiding going onto insulin therapy despite the necessity as going onto insulin was seen as a sign of personal failure for not being able to control their T2DM through oral medications and other self-care behaviors. This phenomenon is not uncommon in the literature [60]. This was reported by patients from New Zealand but not by patients from Saudi Arabia, which could have been because the interviewer for the Saudi participants did not encourage the patients to comment further on their perceptions and attitudes toward diabetes insulin therapy. Nonetheless, studies with insulin-naïve patients including patients from Saudi Arabia with T2DM have reported that approximately 30% of the patients were unwilling to initiate insulin therapy if recommended because of various factors including perceptions of failure and self-blame [61-63]. Therefore, it is important that HCPs listen to and address patients' concerns about insulin and provide accurate and adequate education on the progressive nature of T2DM and the ultimate need for insulin therapy at some point early on.

Although it has been established that illness perception interventions, often delivered over multiple sessions, can change perceptions and improve outcomes in T2DM [13,14], it is encouraging to find that a brief visual intervention (as short as 7 minutes) has the potential to change patients' perceptions. This brief visual animation may improve current T2DM education and, if incorporated within larger illness perception

interventions, could reduce intervention delivery time and therefore increase clinical utility.

This evidence is consistent with the findings from previous randomized controlled trials using different patient samples [37]. For example, both 3D models and an animation on osteoporosis increased perceived consequences, personal and treatment control, coherence perceptions and treatment motivation, and medication necessity beliefs, and decreased timeline perceptions and medication concerns [38]. A similar study found not only positive changes in perceptions (eg, increased treatment control and timeline perceptions and decreased identity perceptions) but also improved exercise and faster return to normal activities in patients with acute coronary syndrome compared with the control group [33]. Other visualization trials have reported improved adherence to antiretroviral therapy using viral load in patients with HIV [41,42] and increased postoperative mobility in oncology patients [43].

Family members' perceptions have been shown to mediate relationships between patients' perceptions and outcomes [30,31]. A recent review of CSM interventions in T2DM found that the inclusion of family members was important for improving patients' glycemic control [32]. This study suggests that diabetes visualizations are also suitable for family members.

Strengths and Limitations

A key strength of this study was the inclusion of 2 culturally specific versions of the visual animation and the cross-cultural patient samples. A second strength is the mixed methods design, which allowed us to gather both quantitative and qualitative data regarding the utility and acceptability of the visual animation. However, this study has a few limitations. First, patients and family members were not involved in co-designing the initial storyboards, scripts, or the visual animation assessed in this study; therefore, valuable input may have been missed. Second, because of convenience sampling, pre-post pilot design, and lack of a control group, our findings on changes in perceptions and self-efficacy must be interpreted with caution, and the study was not sufficiently powered to analyze scores by ethnicity (Māori, Pacific groups). Third, all patients perceived diabetes medications as necessary, and therefore it would be interesting to find out what a less receptive audience thinks about the visual animation and how it may influence their illness and treatment perceptions. Finally, data collection for this study was handled differently for the New Zealand and Saudi samples. Although extensive efforts were made to conduct the study completely on web, face-to-face recruitment from diabetes clinics was more successful in both countries. The New Zealand sample was comfortable using technology and therefore interviews were conducted over Zoom. Patients in the Saudi sample opted to perform the study in person at the clinic, either while waiting to be seen by the clinician or immediately afterward. In doing so, the opportunity for family members to participate was severely limited. Nonetheless, this study did help demonstrate the cross-cultural applicability of the visual animation. This also informs the practical aspects of recruitment for planning a future trial.

Implications for Our Brief Visual Animation and Future Research

The brief visual animation will be adapted in light of the participants' suggestions and feedback. This will include adding greetings in Te Reo Māori (for the New Zealand version), using a female Māori narrator voice, simplifying the language to overcome health literacy barriers, personalizing the animated characters to match the viewer's gender and ethnicity, and adding subtitles to accommodate patients with hearing difficulties. The next step is to conduct a cross-cultural randomized controlled trial to investigate the effects on illness perceptions, adherence to medication, diet and exercise behaviors, glycemic control, and unplanned hospital admissions.

The effect sizes found from this preliminary analysis will inform the sample size; therefore, the study will be sufficiently powered to conduct subgroup analyses by ethnicity. This future trial will ensure the recruitment of Saudi family members by offering incentives and allowing web-based participation for convenience. The inclusion of family members in the intervention is likely to have a larger impact on families and community health and improve the quality of life. This future trial could use the visual animation intervention as a stand-alone or as a component of a larger illness perception intervention. This future research would also look at how such an intervention could reduce or eliminate ethnic disparities and contribute to health equity.

Acknowledgments

This work was supported by the University of Auckland School of Medicine Performance-Based Research Fund under grant number (71603). MA is receiving financial support to complete his PhD from the Saudi Ministry of Higher Education (King Salman Scholarship Program) and the University of Auckland Student Funds. Funding agencies were not involved in the design of the study, the collection, analysis and interpretation of data, writing the report, or the decision to submit the report for publication.

The authors would like to acknowledge and thank Jane Wilkinson, Stephanie Duckworth, and Roxanne Henare from Auckland District Health Board (Greenlane Clinical Centre) for facilitating data collection. The authors would also like to acknowledge and thank the New Zealand and Saudi participants for their participation in this study.

Abstract

Background: Large-scale health communication challenges during the COVID-19 pandemic, such as widespread misinformation and distrust in health care professionals, have influenced reluctance to take the COVID-19 vaccine, also known as vaccine hesitancy. Trust in health professionals, adequate health literacy, and high self-efficacy are key components of actively pursuing preventative and protective health care measures. These factors may be associated with intentions to seek and complete a COVID-19 vaccine dosing.

Objective: The objective of this analysis was to identify factors associated with COVID-19 vaccine hesitancy.

Methods: In February 2021, US adults (N=5872) responded to a web-based survey on COVID-19 vaccine hesitancy and components of health communication (trust in sources of health information, health literacy, and self-efficacy). Multivariable logistic regression models were used to explore associations between these factors and vaccine hesitancy while adjusting for key demographics. We hypothesized that low levels of trust, health literacy, and self-efficacy would be associated with increased vaccine hesitancy.

Results: The adjusted odds of vaccine hesitancy was greater among those who placed little to no trust in health professionals compared to those who held a lot of trust (adjusted odds ratio [AOR] 8.54, 95% CI 6.52-11.19). The odds of vaccine hesitancy was also greater among those who felt frustrated about finding health information compared to those who did not (AOR 2.10, 95% CI 1.62-2.70). Participants who had little to no confidence in receiving health advice or information had greater odds of vaccine hesitancy compared to those who had a lot of confidence (AOR 3.05, 95% CI 2.34-3.97).

Conclusions: This study underscores the importance of trust between health professionals and their patients, and a need for improving health literacy regarding vaccines. Perceptions of mistrust and low levels of health literacy were associated with high levels of vaccine hesitancy, providing empirical support of framing these factors as perceived barriers to vaccine uptake.

vaccine hesitancy; health literacy; COVID-19; COVID-19 vaccine hesitancy; health communication; vaccination; health professional; health information

Introduction

Background

Between March 2020 and February 2022, the spread of the SARS-CoV-2 virus led to over 500 million cases of COVID-19 disease and over 6 million deaths globally [1]. Since the start of the pandemic, efforts to slow or prevent the spread of COVID-19 have included business lockdowns and stay-at-home policies; international border closings and movement restrictions and mandating or encouraging mask wearing, frequent handwashing, and physical distancing imposed by federal, state, and local governments [2]. More recently, COVID-19 vaccine acceptance and uptake as well as booster completion have become critical components to decreasing the incidence of COVID-19 and ultimately ending the pandemic. However, within the United States, there have been large-scale health communication challenges regarding the COVID-19 vaccines that have impeded efforts toward achieving herd immunity. These challenges include concerns regarding vaccine safety, the spread of misinformation, belief in personal freedom and choice, and lack of access to reliable public health information [3,4]. A reluctance to taking a vaccine, also known as vaccine hesitancy, poses significant dangers to public safety during a pandemic given that unvaccinated individuals can more easily contract and spread disease to others and may contribute to development of strains not contained by the vaccine [5].

Vaccination Rates and Related Factors

In the United States, vaccine rollout began in late December 2019 prioritizing health care professionals and residents of long-term care facilities before expanding to other essential workers and businesses, and eventually to all adults. COVID-19 vaccination rates have consistently climbed since the vaccine was made available to all persons over the age of 18 years on April 19, 2021 [6]; as of February 2022, over 550 million doses of the vaccine have been administered, amounting to approximately 78% of the population with at least one dose. From April 2021 to the present, there have been challenges in reaching those who might be vaccine-hesitant. Most commonly reported reasons for vaccine hesitancy include skepticism of the vaccine, more specifically a lack of knowledge surrounding the components and safety of the vaccine [5,7,8]. Further, some are now using the term “pandemic of misinformation” to describe the circulation of mixed messaging and potentially inaccurate news being shared via social media [9-11]. The Edelman Trust Barometer Report, one of the longest-running surveys on trust, found that globally in 2021, over 70% of respondents were worried about the spread of false news, and reported high levels of distrust in government entities and media [12]. This skepticism coupled with the spread of misinformation have led to widespread reluctance in uptake of the COVID-19 vaccine across the United States.

Definitions

Source Credibility and Health Literacy

Health communication refers to the study and practice of delivering information intended to promote health and well-being among a particular audience. Activities in the health communication space range from large-scale, multifaceted public health campaigns to private patient-provider interactions [13]. Broadly speaking, health communication seeks to improve public health through increasing awareness of a health issue or influencing individual behaviors and practices through a variety of messaging approaches (eg, demonstrating the benefits of a health intervention). Appraisal of health messages by a particular audience depends on many different intersecting factors, including source credibility and health literacy [4,13-15].

Source credibility—or the extent to which an information source is perceived as believable [16]—is one factor that is thought to influence message acceptance by an audience [17]. Theoretically, the vast majority of conceptualizations surrounding source credibility distinguish between two overlapping yet distinct perceptions involved in gauging credibility: (1) trustworthiness of the source and (2) expertise of the source. Within the credibility literature, trustworthiness has been defined as “the degree of confidence in the communicator’s intent to communicate the assertions he considers most valid,” whereas expertise is understood to mean “the extent to which a communicator is perceived to be a source of valid assertions” [18]. Moreover, while information accuracy is thought to be involved in the message appraisal process, the degree to which information is accurate is conceptually different from perceptions around the credibility of a source [16], which has important implications for understanding and responding to disinformation and misinformation campaigns related to COVID-19 vaccinations.

In the context of COVID-19 vaccine hesitancy, some preliminary qualitative findings from Bateman and colleagues [19] suggested that mistrust is an important factor that may be influencing the widespread COVID-19 vaccine hesitancy among Latinx and African American communities in the Deep South. More specifically, the authors identified interesting subthemes within the data differentiating between (1) historical *mistrust*, or *mistrust* that is related to systemic racism and historical oppression; (2) vaccine development *mistrust*; and (3) *mistrust* in politicians [19]. However, another survey among a US sample living in Phoenix, Arizona, and New York City, New York, found that those who held higher trust in government were less likely to intend to get vaccinated against COVID-19 [20]. Several studies have shown that, in multiple contexts, trust in self-seeking information is critical to behavior change [21-23]. Therefore, given these preliminary findings, there exists a critical need to clarify the way source trustworthiness is associated with COVID-19 vaccine hesitancy within the United States.

Health literacy is also a critical factor that can either facilitate or thwart the process of appraising health information. Aligning with the findings from a systematic review [24] examining common definitions and conceptualizations related to the construct, we view health literacy as being

linked to literacy and entails people's knowledge, motivation and competences to access, understand, appraise, and apply health information in order to make judgments and take decisions in everyday life concerning healthcare, disease prevention and health promotion to maintain or improve quality of life during the life course.

Some recent evidence demonstrates robust and intricate relationships between health literacy and COVID-19 vaccine hesitancy. For instance, Kricorian and colleagues [25] determined that vaccine-hesitant individuals were more likely to find information related to the COVID-19 vaccine difficult to comprehend compared to individuals who did not express hesitancy. Furthermore, in a study of adults residing in China, researchers determined that higher levels of health literacy were protective against COVID-19 vaccine-hesitant attitudes, although this protective effect was only observed among individuals with low to moderate levels of stress [26]. Additionally, Turhan and colleagues [27] determined that a sample of Turkish social media users were more likely to report hesitant attitudes if they held low levels of health literacy and high levels of distrust in government. Their study further showed that “health literacy mediated the relationship between health care system distrust and vaccine hesitancy,” which implicates health literacy as an important factor to be considered in the design of health communication campaigns and health promotion interventions that attempt to modify COVID-19 vaccine hesitancy among communities [27].

Self-efficacy Theory

Self-efficacy is a cornerstone construct in the study of motivation and behavior. Originally stemming from Albert Bandura's Social Cognitive Theory developed in the 1960s, self-efficacy refers to an individual's perceptions of their capacity and capability to learn or behave in a particular way [28]. Since its inception, the construct has been applied and adapted to various theories of health behavior, including the Health Belief Model [29], Theory of Planned Behavior [30], and Transtheoretical Model of Behavior Change [31].

High levels of self-efficacy have been previously associated with intentions to be vaccinated against COVID-19. For example, Guidry et al [32] determined that those who scored high in self-efficacy to overcome vaccination barriers were more likely to form intentions about receiving the COVID-19 vaccine. Another online study of Korean internet users examined the relationships between self-efficacy and health literacy in the context of COVID-19 vaccine hesitancy, and reported that self-efficacy was negatively associated with hesitancy. These authors also reported that individuals who maintained high levels of eHealth literacy—a specific subtype of health literacy—were more likely to exhibit high levels of self-efficacy. Aligning with evidence from other health contexts, these scholars ultimately advance that given their findings, it is

important for interventionists to target health literacy in prevention activities as a potential mechanism to enhance an individual's self-efficacy and thus prevent COVID-19 vaccine hesitancy [33]. However, other studies—such as that conducted by McElfish et al [34] with a sample of individuals residing in Arkansas, United States—have found no significant difference in COVID-19 vaccine hesitancy according to levels of protection self-efficacy, operationalized as an individual's belief in their ability to protect themselves against COVID-19. Given this mixed evidence, it is imperative to further elucidate the role self-efficacy has in the larger issue of COVID-19 vaccine hesitancy.

Purpose and Hypothesis

Trust in sources of health information, adequate health literacy, and high self-efficacy are key components of actively pursuing preventative and protective health care measures. These factors may be associated with intentions to seek and complete a COVID-19 vaccine dosing. In this study, we (1) evaluated the relative levels of these constructs among a population of US adults who use social media and (2) quantified the relationships between these constructs on COVID-19 vaccine hesitancy. We hypothesized that distrust in sources of health information, inadequate health literacy, and low self-efficacy are associated with being unsure about or choosing not to get the COVID-19 vaccine.

Methods

Sample Description

From February 3 to March 2, 2021, a web-based self-report survey was disseminated through social media platforms (eg, Facebook, Instagram, LinkedIn, Twitter) and through email lists accessible to the authors. Specifically, the survey was disseminated on the lead author and principal investigator's personal and professional social media accounts. Social media users could follow the shared link and were first asked eligibility questions regarding their age and US residence status. If users were younger than 18 years or resided outside of the United States, they could not proceed with the survey. No incentives were provided for taking the survey.

Ethical Considerations

Institutional review board approval was obtained prior to survey dissemination (HSC-SPH-20-0346). Participants met eligibility criteria if they were 18 years or older and resided within the United States. Before the start of the survey, participants were informed about the purpose and estimated time required to complete survey, that their participation was voluntary, and that they could skip any questions they did not wish to answer. All respondents provided written consent to participate before proceeding to the questions.

Measures

Primary Outcome

The survey asked participants “Have you taken the COVID-19 vaccine?” Participants could select “Yes” or “No”; if a participant selected “No,” they were then prompted with the question “Will you receive the COVID-19 vaccine when it is

available to you?"; participants could then select "Yes," "No," "Unsure," or "I prefer not to say." Vaccine hesitancy is understood to mean reluctance to take a vaccine; therefore, those who selected "No" or "Unsure" about their plans to receive the vaccine when available were considered to be vaccine-hesitant. Those who either already received or planned to receive the vaccine were the referent group. The "I prefer not to say" responses were treated as missing since the attitude toward the vaccine could not be determined (n=7; 0.3%).

Exposures

There were several measurements of the two major components of health communication that were explored in this analysis. All health communication questions were adapted from the Health Information National Trends Survey questionnaire [35]. The survey asked participants to report on a Likert scale (ie, *A lot*, *Some*, *A little*, and *Not at all*) their level of trust in the following sources of health or medical information: (1) government agencies, (2) a doctor or health professional, (3) family or friends, and (4) religious organizations and leaders. Responses *Some*, *A little*, and *Not at all* were collapsed to represent "Not a lot of trust or not at all"; the variable was a binary variable to reflect "A lot of trust" and "Not a lot or not at all." Participants were also asked about health communication accessibility and comprehension as a measurement of health literacy. Specifically, the survey asked participants to report on a Likert scale (ie, *Strongly agree*, *Somewhat agree*, *Somewhat disagree*, and *Strongly disagree*) how much they agreed or disagreed with the following statements based on the results of their most recent search for information about health or medical topics: (1) *It takes a lot of effort to get health or medical information you need* and (2) *Felt frustrated during your search for health or medical information*. Responses *Strongly agree* and *Somewhat agree* were collapsed to represent "Agree," while the responses *Somewhat disagree* and *Strongly disagree* were collapsed to represent "Disagree"; the variable was a binary variable to reflect "Agree" and "Disagree." Finally, the survey asked participants a question regarding confidence in one's ability to find, understand, and make health-related choices (ie, self-efficacy). The survey asked participants to report on a Likert scale (ie, *Strongly agree*, *Somewhat agree*, *Somewhat disagree*, and *Strongly disagree*) how much they agreed or disagreed with the following statement: *Confidence in getting advice or information about health or medical topics*. Responses *Strongly agree* and *Somewhat agree* were collapsed to represent "Agree," while the responses *Somewhat disagree* and *Strongly disagree* were collapsed to represent "Disagree"; the variable was a binary variable to reflect "Agree" and "Disagree."

Although these Likert-scale questions have previously been analyzed both on a continuous scale and categorically [36,37], the response categories for the exposure variables were collapsed due to one or more of the following reasons: the sample sizes were small (<1%) within categories, the distinction between "strongly agree" and "agree" (and other responses) was minor or indistinguishable, or analyses were run that included the original exposure variable categories and odds of vaccine hesitancy did not vary significantly across the categories that were ultimately collapsed (results not shown).

Covariates

Sociodemographic variables (ie, covariates) included age in years (on a continuous scale), self-identified sex (male/female), race/ethnicity (white non-Hispanic/other), education level (less than college/college or more), and annual household income based on 2019 Medicaid expansion guidelines (138% below poverty; <US \$30,000/year; US \$30,000-\$80,000/year; and >US \$80,000) [38].

Statistical Analyses

Summary statistics are used to describe the study sample. Frequencies were tabulated and χ^2 tests were performed for each health communication and literacy factor and the sociodemographics and outcome (vaccine hesitancy). Multivariable logistic regression was used to further explore the associations between the outcome and each exposure. Separate models were run for each exposure while adjusting for key demographics (age, sex, race, income, and education level). A posthoc exploratory analysis was performed to find political ideology and gender differences in vaccine-hesitant status (results not shown). Analyses were performed using Stata statistical software version 15.1.

Results

The survey instrument captured a total of 6471 respondents; of those, 6452 (99.71%) met the eligibility criteria and 5872 (90.74%) consented to participate. Ultimately, 5356 participants responded to the series of vaccine plans-related questions, which was the final analytical sample size. The mean age of the sample was 45 years (SD 11.5); the majority were female and non-Hispanic white. As of February 2021, just over 50% of the sample had already received at least one dose of the COVID-19 vaccine. Of those who did not, approximately 5% reported that they were not going to receive it or were unsure (vaccine-hesitant). Over 50% of the total sample placed little to no trust in government agencies for health or medical information and 79% placed a lot of trust in doctors or health professionals (Table 1).

Table 1. Descriptive characteristics of the study sample (N=5872).

Characteristics	Value
Sociodemographics	
Age (years), mean (SD)	44.8 (11.5)
Sex, n (%)

Annual household income prior to the pandemic (US \$), n (%)	
<30,000	131 (2.5)
30,000-\$80,000	987 (18.6)
>\$80,000	4190 (78.9)
Already received the COVID-19 vaccine, n (%)	
Yes	2744 (50.7)
No	2665 (49.3)
Plan to get a COVID-19 vaccine when available as of February 2021, n (%)	
Yes, or already received	5077 (94.8)
No or unsure (vaccine-hesitant)	279 (5.2)
Trust in resources regarding health or medical information, n (%)	
Government agencies	
A lot	2136 (36.4)
Not a lot or not at all	3075 (52.4)
A doctor or other health professional	
A lot	4612 (78.5)
Not a lot or not at all	604 (10.3)
Family or friends	
A lot	176 (3.0)
Not a lot or not at all	5035 (85.8)
Religious organizations and leaders	
A lot	94 (1.6)
Not a lot or not at all	5102 (86.9)
Health literacy, n (%)	
It takes a lot of effort to get health or medical information you need	
Disagree	3354 (57.1)
Agree	1834 (31.2)
Felt frustrated during your search for health or medical information	
Disagree	3490 (59.4)
Agree	1664 (28.3)
Confidence in getting advice or information about health or medical topics	

Characteristics	Value
Extremely or very confident	4193 (71.4)
Little to no confidence	992 (16.9)

Overall, the vaccine-hesitant sample appeared to be younger, disproportionality more male, disproportionately having less than a college degree, and disproportionately having an annual household income of US \$30,000-\$80,000 than the nonvaccine-hesitant sample. Lack of trust in doctors and health professionals was more prevalent in the vaccine-hesitant compared to those who already received a COVID-19 vaccine or had plans to. More vaccine-hesitant participants reported that it takes a lot of effort to access necessary health information and felt frustrated during their search for health information compared to those who already received or planned to receive the vaccine. Over three-quarters of those who already received or planned to receive the vaccine were extremely or very confident in getting advice or information about health or medical topics compared to only slightly more than half of those who were vaccine-hesitant (Table 2).

After adjusting for covariates, the odds of being vaccine-hesitant were greater among those who lacked trust in doctors or health professionals and those who felt frustrated about finding health

information, as compared to those who placed a lot of trust in either resource. Similarly, the adjusted odds of being vaccine-hesitant were almost eight times greater among those who placed little to no trust in government agencies regarding health or medical information compared to those who placed a lot of trust in government agencies. The adjusted odds of being vaccine-hesitant were 75% lower among those who placed little to no trust in religious leaders and organizations, compared to those who placed a lot of trust in religious leaders and organizations. Participants who had little to no confidence in getting advice or information on health topics had 3.05 greater adjusted odds of vaccine hesitancy compared to those who already received or planned to receive the vaccine. Participants who felt frustrated during their search for health or medical information had 2.10 greater odds of being vaccine-hesitant, and participants who agreed that it takes a lot of effort to obtain the health or medical information they need had 1.59 times greater odds of being-vaccine hesitant compared to the referent group after adjusting for covariates (Table 3).

Table 2. Bivariate relationships between planning to get the COVID-19 vaccine when available as of February 2021 and health communication factors (N=5356).

Characteristics	Planning to get COVID-19 vaccine		P value

Government agencies	
A lot	Reference
Not a lot or not at all	7.79 (5.05-12.02)
A doctor or other health professional	
A lot	Reference
Not a lot or not at all	8.54 (6.52-11.19)
Family or friends	
A lot	Reference
Not a lot or not at all	1.30 (0.60-2.83)
Religious organizations and leaders	
A lot	Reference
Not a lot or not at all	0.25 (0.14-0.44)
Health literacy	
It takes a lot of effort to get health or medical information you need	
Disagree	Reference
Agree	1.59 (1.23-2.04)
Felt frustrated during your search for health or medical information	
Disagree	Reference
Agree	2.10 (1.62-2.70)
Confidence in getting advice or information about health or medical topics	
Extremely or very confident	Reference
Little to no confidence	3.05 (2.34-3.97)

^aSeparate models were run for each variable and adjusted for age, sex, race, income, and education level.

^bVaccine-hesitant: those who reported “no” or “unsure” regarding plans to get the COVID-19 vaccination.

^cOR: odds ratio; odds are in relation to those who already received or planned to receive the vaccine.

Discussion

Principal Findings

This analysis explored components of health communication that are related to vaccine hesitancy among a large convenience sample of US adults. Distrust in health professionals, lack of access to health information, and inadequate health literacy were significantly associated with vaccine hesitancy. Specifically, trust in health care professionals is a fundamental piece of the patient-doctor relationship that can significantly impact personal and public health [39]. According to a 2018 New York Times article, trust in health professionals is on the decline in the United States [40]. According to a 1966 poll, 73% of respondents reported confidence in medical professionals, and by 2012 that number had dropped to 34% [41]. Studies and surveys have shown that trust in the health care system is directly related to following treatment plans, consistently taking medications, and health competence [42,43]. Specifically in the context of COVID-19, Antinyan et al [44] found that, on a global scale, having a health care system that citizens trust is more

likely to encourage treatment-seeking behavior upon development of first COVID-19 symptoms. This evidence underscores the importance of trust in health professionals as an element that influences vaccine uptake, and also speaks to the ability to follow COVID-19 preventative measures such as mask-wearing, handwashing, and physical distancing.

Comparison With Prior Work

Lack of trust in religious organizations and leaders was associated with a decreased odds of vaccine hesitancy, while the opposite can also be concluded (ie, trust in religious organizations may be associated with increased vaccine hesitancy). Multiple surveys and polls have shown that certain faith communities within the United States are among the least vaccinated demographic groups, and contain the highest proportion of vaccine-hesitant individuals due to personal religious beliefs, wariness of science, and distrust in institutions [45-47]. This supports our finding that trust in religious organizations may be associated with increased vaccine hesitancy. Our finding also highlights the role religious leaders play in individuals' decision-making regarding their health. If

those who are vaccine-hesitant are more likely to trust their religious organizations for health and medical information, and alternatively, if in some cultures religious leaders are considered authorities on health and medical issues [48,49], religious organizations should be equipped with the tools and knowledge to provide constituents with evidence-based advice. Religious groups and leaders should not be excluded from conversations about COVID-19.

Access to health information and confidence in one's ability to use health information may be one of the most critical aspects in decision-making regarding COVID-19 vaccine uptake. This study found that those who felt frustrated during their search for health information and those who lacked confidence in finding health information had greater odds of being vaccine-hesitant. Both of these factors are also related to inadequate health literacy, specifically eHealth literacy. Regular and reliable access to health information and services is associated with increased quality of life, and is known to prevent disease and disability due to early detection of illnesses and health conditions [50]. However, the literature also outlines the negative impact that health information found on the internet has on patient health. In one survey, 85% of physicians reported a patient bringing internet information regarding their health to a visit and expressed that it made the visits less efficient [51]. Additionally, information found on the internet regarding health and medicine can be harmful toward patient health since it can be misleading or entirely fabricated, whether intentionally or unintentionally [52,53]. For example, in the early stages of the pandemic, a video was widely shared on social media platforms that expressed cynicism and distrust in governmental figures and agencies, and made false claims about an eventual COVID-19 vaccine that had yet to be fully developed at the time [54]. This video changed the global and national conversation regarding the vaccines and the pandemic itself, causing significant damage to COVID-19 prevention efforts [55]. Misleading, false, and confusing health-related information can lead to frustration and deteriorate confidence when it comes to finding reliable information. This finding is echoed by the results in the Edelman Trust Barometer Report [12]. Studies have explored why conspiracy theories tend to take a stronghold on popular thought during traumatic large-scale events [56]; although there are several influential factors, one is a lack of access to accurate information due to the inherent novelty of the event [57,58]. The findings of this study underscore the importance of regaining trust in doctors and health professionals, and the importance of including nonhealth-related groups and organizations (ie, religious organizations) in the larger conversation about health education. The COVID-19 pandemic points to needs in partnerships for doctors and health professionals to work with trusted community lay health workers or community workers that may have greater trust in their community and reach to populations most at risk.

Limitations

The results of this analysis should be considered in light of a few limitations. Primarily, all data collected were self-reported, which may be impacted by social desirability bias. However, the experiences reported were collected across a large sample. Further, the cross-sectional nature of this study limits our ability

to assess temporality between our exposures (health communication components) and our outcome (vaccine hesitancy). Given the ongoing pandemic, the cross-sectional data do represent pandemic periods across variants. In the future, longitudinal data would be helpful to assess the impact of these critical components on increasing vaccine uptake. Finally, due to the convenience sampling method, the sample is not representative of the entire United States; therefore, the findings may not be generalizable to the national population. Specifically, 5.2% of our sample was vaccine-hesitant, which, in some states, is less than the proportion of the population who is vaccine-hesitant. According to the Centers for Disease Control and Prevention, the rate of vaccine hesitancy across states ranges from 2.9% to 27% [59]. In the United States, the vaccine-hesitant tend to be younger in age, less educated, and female, with some studies showing that non-Hispanic Black Americans have higher odds of vaccine hesitancy than non-Hispanic white Americans [60-62]. While our total sample consisted of primarily educated, non-Hispanic white, middle-aged women, our vaccine-hesitant sample tended to be less educated, younger, non-Hispanic white, and mostly women. While there are some similarities between our vaccine-hesitant sample and samples in the recent literature, there are also several differences, notably regarding race/ethnicity. Aside from demographic factors and related lived experiences contributing to vaccine hesitancy, others have found that political ideology is strongly associated with COVID-19 vaccination plans. Specifically, those who hold conservative ideologies tend to be more vaccine-hesitant [59-62]. Therefore, we conducted a posthoc exploratory analysis of political ideology and gender with vaccine-hesitant status, and found that significantly more vaccine-hesitant respondents identified as Republican (45% vs 12%, $P < .001$) and significantly more men identified as Republican (22% vs 13%, $P < .001$) in this sample. The political ideology divide could explain the slightly higher prevalence of men in the vaccine-hesitant sample within this study. The disparities between the vaccine-hesitant demographics in our sample compared with those of other studies is likely due to the primary recruitment strategy being through social media platforms among the study investigators (who are public health professionals). Despite this, these findings demonstrate the importance of trustworthiness of health professionals, adequate health literacy, and self-efficacy in decision-making to receive a COVID-19 vaccine. The small differences in the percentages found in our bivariate analysis could be due to the large and overpowered sample size.

Conclusions

In 2019, the World Health Organization listed vaccine hesitancy as one of the top 10 threats to global public health [63]. While the factors explored in this analysis are critical elements in the discussion of vaccine hesitancy, there are a myriad of factors and external influences (eg, philosophical ideals, political affiliation, situational factors) that intersect with an individual's decision-making regarding the COVID-19 vaccine, and vaccines in general [4]. The findings of this study underscore the importance of building trust between health professionals and their patients, involving nonhealth-related institutions in the

conversation regarding health, and easing access to and raising self-efficacy in finding accurate and reliable health information.

Abstract

Background: In November 2020, WA Notify, Washington State's COVID-19 digital exposure notification tool, was launched statewide to mitigate ongoing COVID-19 transmission. WA Notify uses the Bluetooth proximity-triggered, Google/Apple Exposure Notification Express framework to distribute notifications to users who have added or activated this tool on their smartphones. This smartphone-based tool relies on sufficient population-level activation to be effective; however, little is known about its adoption among communities disproportionately impacted by the COVID-19 pandemic or what barriers might limit its adoption and use among diverse populations.

Objective: We sought to (1) conduct a formative exploration of equity-related issues that may influence the access, adoption, and use of WA Notify, as perceived by community leaders of populations disproportionately impacted by the COVID-19 pandemic; and (2) generate recommendations for promoting the equitable access to and impact of this novel intervention for these communities.

Methods: We used a 2-step data collection process to gather the perspectives of community leaders across Washington regarding the launch and implementation of WA Notify in their communities. A web-based, brief, and informational survey measured the perceptions of the community-level familiarity and effectiveness of WA Notify at slowing the spread of COVID-19 and identified potential barriers and concerns to accessing and adopting WA Notify (n=17). Semistructured listening sessions were conducted to expand upon survey findings and explore the community-level awareness, barriers, facilitators, and concerns related to activating WA Notify in greater depth (n=13).

Results: Our findings overlap considerably with those from previous mobile health equity studies. Digital literacy, trust, information accessibility, and misinformation were highlighted as key determinants of the adoption and use of WA Notify. Although WA Notify does not track users or share data, community leaders expressed concerns about security, data sharing, and personal privacy, which were cited as outweighing the potential benefits to adoption. Both the survey and informational sessions indicated low community-level awareness of WA Notify. Community leaders recommended the following approaches to improve engagement: tailoring informational materials for low-literacy levels, providing technology navigation, describing more clearly that WA Notify can help the community, and using trusted messengers who are already engaged with the communities to communicate about WA Notify.

Conclusions: As digital public health tools, such as WA Notify, emerge to address public health problems, understanding the key determinants of adoption and incorporating equity-focused recommendations into the development, implementation, and communication efforts around these tools will be instrumental to their adoption, use, and retention.

KEYWORDS

COVID-19 exposure notifications; digital public health; health equity; mHealth; mobile health; mHealth equity; digital health tool; public health; surveillance; COVID-19; smartphone; health inequity; sociodemographic factor; epidemiology

Introduction

WA Notify

In the spring of 2020, public health authorities partnered with Google and Apple in the development of smartphone-based COVID-19 exposure notification (EN) tools that could be activated on Android and iPhone devices. Public health officials hoped that these tools would supplement public health measures—such as manual case investigation and contact tracing, masking mandates, guidance regarding physical distancing and limited social gatherings, and COVID-19 testing—to mitigate the spread of COVID-19 [1]. WA Notify uses the privacy-preserving Google/Apple EN Express framework to distribute Bluetooth proximity-triggered notifications to users who have added or activated this tool on their smartphones [2]. Digital EN tools send alerts to smartphone users to let them know that they have potentially been exposed to someone who has tested positive for COVID-19. To do this, digital EN users who test positive for COVID-19 (ie, index cases) verify their test results through the tool which anonymously alerts other users of their potential exposure.

Recent evidence suggests that these tools can help mitigate the spread of COVID-19 [3-5]. However, their performance relies, in part, on sufficient adoption by smartphone owners [6]. Identifying the challenges to adoption could inform strategies to increase activations and communicate the value of digital EN tools to improve retention. In particular, understanding the barriers and facilitators to adoption and use by communities disproportionately impacted by the COVID-19 pandemic [7-11] could help tailor marketing campaigns to promote adoption and increase the likelihood that all populations benefit from this new public health technology.

On November 30, 2020, WA Notify, the Washington (WA) State digital EN tool, was launched statewide [2]. Early in the development and testing phases for WA Notify, the WA State Department of Health (DOH) and the University of Washington School of Public Health entered into an interagency agreement to conduct an evaluation of WA Notify as a public health strategy to mitigate COVID-19 transmission. One aim of this evaluation sought to identify the barriers and facilitators to the statewide adoption and use of WA Notify and ascertain potential unintended impacts of this novel technology. Between its launch and the time period in which this study was conducted (from November 30, 2020, to September 05, 2021), WA Notify had been activated on over 2.4 million smartphones across the state, representing an adoption rate of 54.8% of the state adult population. Privacy constraints do not allow for users, user characteristics or demographics, or their location to be identified,

so it is not possible to know whether the residents of communities most disproportionately impacted by COVID-19 were adopting or benefiting from WA Notify.

Equity and Mobile Health Interventions

Health equity research focused on mobile health (mHealth) tools investigates how to address, simplify, and remove structural barriers to act upon and benefit from health information presented in public health interventions [12,13] and ensure that the technology does not create additional barriers for different subpopulations [14,15]. The wide adoption and penetration of smartphone ownership across diverse subpopulations [16,17] has supported a proliferation of smartphone-based tools, programs, and interventions. Along with this growth, there have been concerns that interventions delivered solely through these devices may result in inequalities that exacerbate, rather than mitigate, existing health inequities [13,15,18-21]. Approaches suggested to address these issues and encourage a wider adoption of mHealth tools include providing training and technical assistance, leveraging familial and community connections, partnering with trusted institutions, and offering users control over the levels of privacy and anonymity [18-24], as well as developing these tools using user-centered and participatory design processes that engage community members and other potential end users [21,25].

However, identifying the optimal design elements and implementation strategies that enable a novel mHealth tool to promote health equity requires time. The COVID-19 pandemic was unprecedented in scope and urgency. There was little time to engage in formal research, iterative design cycles, or systematic evaluations before the launch of WA Notify. Additionally, public health's ability to conduct equity, accessibility, and usability studies were constrained by a rapidly shifting landscape and competing priorities such as COVID-19 vaccine distribution efforts [26]. Our work aimed to address this gap in understanding by speaking directly with community leaders about their experiences, concerns, and opinions about WA Notify.

Methods

Ethical Considerations

The project plan was reviewed by the University of Washington Institutional Review Board and determined to be a public health surveillance quality improvement activity that did not require human subjects research review.

Sample

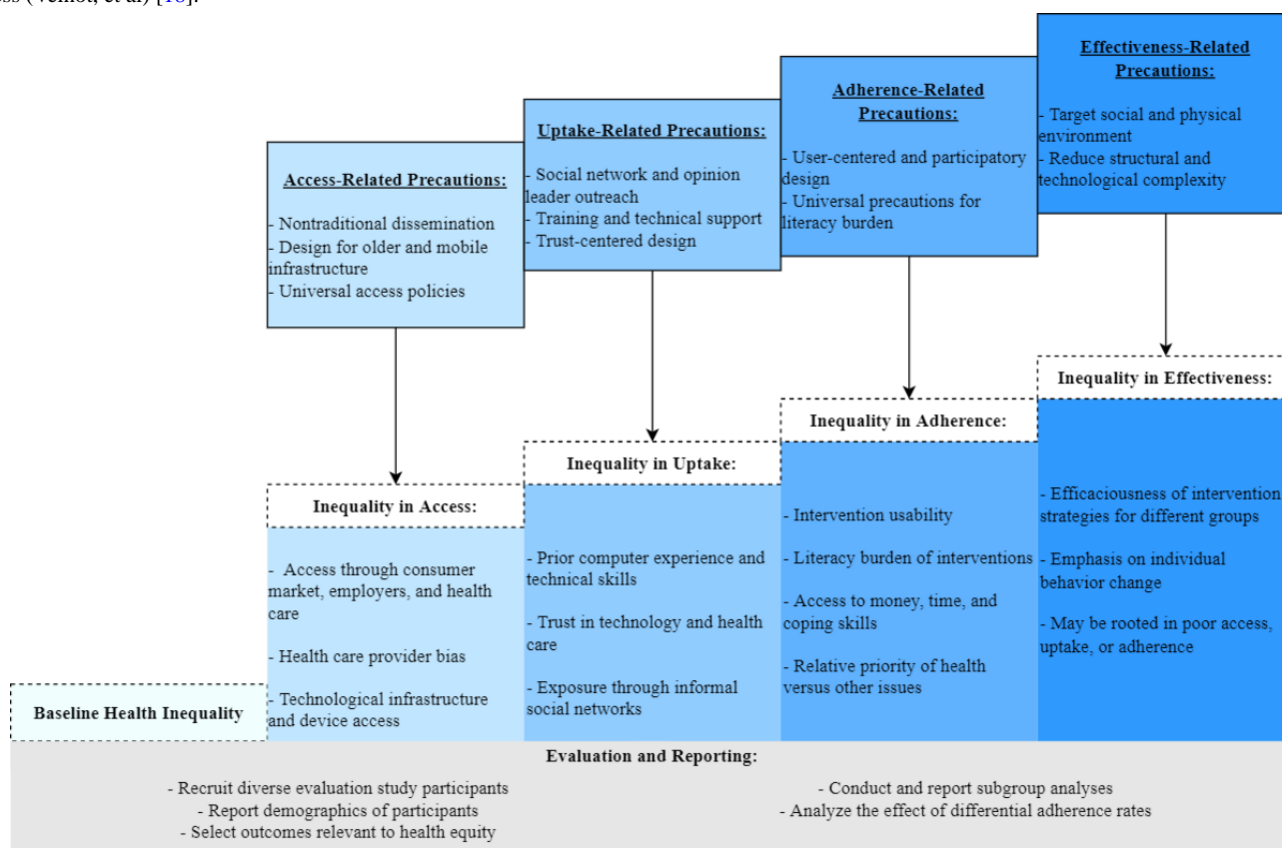

We sought to enroll community leaders that were engaged with community-based COVID-19 mitigation efforts and representative of the diversity of populations and regions across WA state. Information and outreach about the project were circulated to key stakeholders, organizations, and equity advocates with the assistance of the WA State DOH COVID-19 Vaccine Implementation Collaborative (VIC), a group working to ensure equitable COVID-19 vaccine access across the state [27]. VIC membership includes community-based organization (CBO) leaders; community and social service group advocacy representatives; tribal health, public health, and health care organization representatives; and interested community members. These individuals were recruited because of their deep knowledge of their communities and their experience

directly engaging community members around COVID-19 interventions including masking, vaccination, and WA Notify.

Framework

We used Veinot et al [18]’s model for intervention-generated inequality as a framework to inform our data collection efforts and contextualize our findings (Figure 1). This model proposes that inequalities in mHealth access, uptake, adherence, and effectiveness determine how these interventions influence pre-existing inequities [18]. Our data collection efforts primarily focused on investigating the potential access and uptake inequalities of WA Notify as the community-level adoption of this tool will influence its downstream effectiveness for diverse subpopulations. Additionally, we used this model to conceptualize how the issues and recommendations reported by participants influence the ability of this novel intervention to promote equitable health outcomes.

Figure 1. Intervention-Generated Inequality (IGI) Prevention Model adapted for clarity of presentation, used with permission of Oxford University Press (Veinot, et al) [18].

Procedures

Exploratory Sequential Approach

For this evaluation, we used 2 data collection instruments: an informational survey followed by semistructured listening sessions. This exploratory sequential approach was chosen to quantify the levels of awareness, facilitators, barriers, and concerns with activating WA Notify across diverse settings and subsequently investigate the underlying community contexts that may influence the adoption of WA Notify. The 2 instruments were designed and used as follows.

Informational Survey

The survey was designed to take no more than 15 minutes to complete. In addition to gathering information regarding the respondent’s role or position in their community or organization, survey items focused on respondents’ description of conditions or contributors to the disproportionate impacts of COVID-19 on their communities (such as access barriers, underlying health conditions, and systemic inequities); the level of familiarity with WA Notify; perceptions regarding the effectiveness of WA Notify in limiting the spread of COVID-19; and the barriers and facilitators to the adoption and use of WA Notify by their community members.

The survey was programmed and distributed through the REDCap web-based platform (REDCap Consortium) [28] and available in hard-copy format upon request. The recruitment of CBO leaders and community advocates serving on the VIC was conducted by email in April 2021. Surveys closed in August 2021.

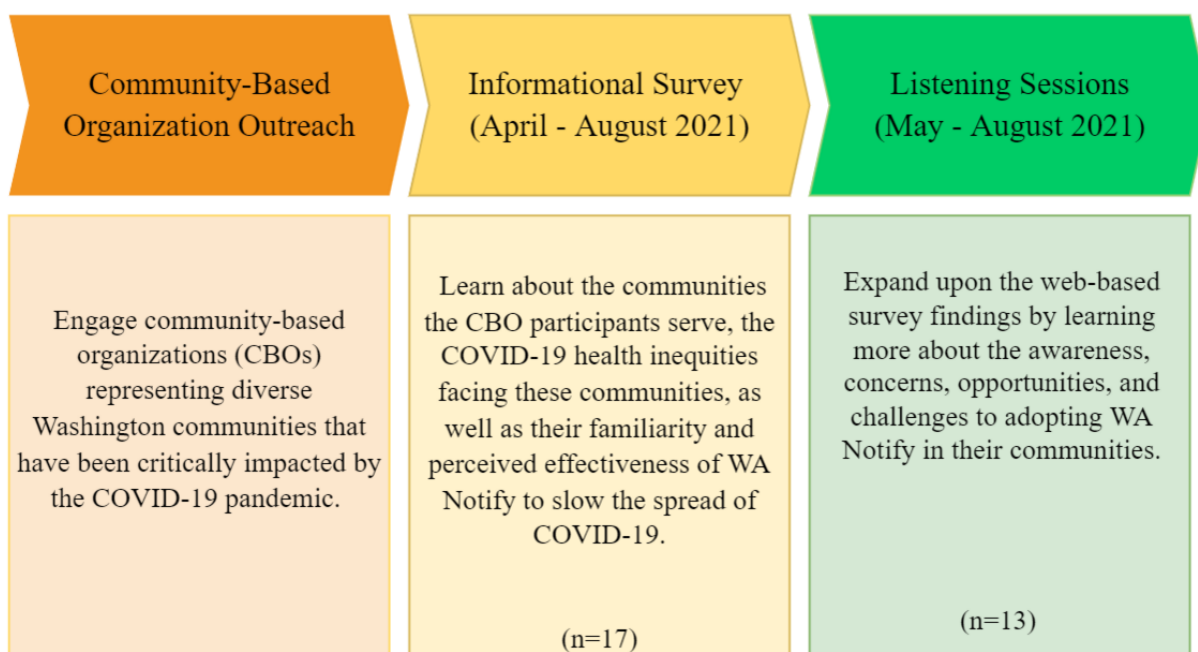

Semistructured Listening Sessions

The listening sessions were designed to capture details regarding the impact of COVID-19 in the participants’ community; awareness of WA Notify, how it works, and what communications have been received around its adoption and use; community concerns about using a digital EN tool;

challenges and opportunities that might be leveraged to improve communications about WA Notify; and feedback regarding the best avenues for informing their communities about the value of using digital EN tools to protect oneself and loved ones.

Listening sessions were designed to last approximately 1 hour and were conducted remotely over Zoom software (Zoom Video Communications) at the participant’s convenience. Sessions were recorded to aid in notetaking with the participant’s permission. CBO leaders and community advocates who completed the informational survey were invited to participate in the listening sessions by email. The listening sessions were conducted between May and August 2021 (Figure 2).

Figure 2. Equity and accessibility evaluation procedures.

Analysis

Descriptive statistics were used to summarize the survey data. Listening session notes were qualitatively analyzed by 2 team members to identify emergent themes related to the intervention-generated inequality concepts of mHealth tool access, uptake, adherence, and effectiveness. Survey and listening session findings were synthesized to generate the results and recommendations for further outreach and communications that may improve the adoption and use of WA Notify in communities disproportionately impacted by COVID-19.

Stakeholder Reflection

The synthesis of results and themes were circulated to DOH stakeholders and all participants in November 2021 to gather feedback on the results as well as capture any changes in perceptions on the adoption and use of WA Notify in participants’ communities. This input was incorporated into the thematic synthesis of results described in the next section.

Results

Participants

In our participant sample, 17 individuals completed the informational survey and 13 subsequently participated in listening sessions (Table 1). Community and CBO representation was broad, with participants from across the state and including CBO leaders and those advocating for or representing the following groups: older adults; low-income families; people with disabilities; essential and frontline workers; justice-impacted communities; individuals whose health care access is limited or impacted by stigma and bias such as individuals who identify as Lesbian, Gay, Bisexual, Transgender, Queer/Questioning, Asexual, and other identities (LGBTQIA+); American Indian or Alaska Native, Asian, Black or African American, Latinx, Muslim, and multiracial communities; immigrant, refugee, and undocumented communities; and rural and frontier communities (Table 1).

Table 1. Informational survey and listening session participants.

Represented communities ^a	Informational survey (n=17)	Listening session (n=13)
Essential workers and seniors with disabilities	✓	✓
Black, Indigenous, and People of Color; disabled; and justice-impacted communities	✓	✓
African American communities	✓	
Latinx communities, immigrants and refugees, and rural and frontier communities	✓	✓
Youth and seniors that cannot gain access to COVID-19 vaccines	✓	
Low-income families with young children, immigrants, and refugees	✓	✓
Amharic-speaking communities	✓	✓
Undocumented individuals and Latinx communities	✓	✓
Arabic-speaking immigrants and refugee	✓	✓
Muslims communities, individuals whose health care is impacted by stigma and bias, and LGBTQIA+ ^b communities	✓	✓
Latinx communities	✓	✓
Asian American Pacific Islander, Black, Indigenous, Latinx, and multiracial communities	✓	✓
People with disabilities	✓	
Immigrants and refugees from Arabic countries (Afghanistan, Iran, Iraq, Somalia, India, and Pakistan)	✓	
Essential and frontline workers	✓	✓
Blind, low-vision, and deafblind communities with various intersectional identities	✓	✓
Low-income older adults and people with disabilities	✓	✓

^aOverlap and intersectionality among the communities represented listed above reflects the descriptions provided by participants.

^bLGBTQIA+: Lesbian, Gay, Bisexual, Transgender, Queer/Questioning, Intersex, Asexual, and other identities.

WA Notify Awareness

Participants perceived that the awareness and adoption of WA Notify was low in their communities. In the listening sessions, 1 participant who advocates for justice-impacted communities pointed out how they had not heard about WA Notify outside of their engagements with the DOH's VIC, whereas most other participants mentioned only seeing communications during WA Notify's initial launch in the fall of 2020. Participants also reported that without a basic understanding of what WA Notify is and how it works, adoption and use would be unlikely. For community members who wish to learn more about WA Notify, they currently need to actively seek information about the tool (via the DOH website, fact sheets, or videos), which was

perceived as a barrier. Promotion by community leaders was identified as a key strategy to elevate community awareness; however, participants stated that unless community leaders themselves understand the "ins and outs" of WA Notify, they may be hesitant or ill-equipped to advocate in the community on its behalf.

Possible contributors to the limited awareness and penetration of the tool were identified in the survey question, "Of these known barriers to adding WA Notify to a smartphone, which are relevant for your community?" (Figure 3) and further investigated during the listening sessions. The latter activity additionally captured suggested mechanisms or approaches for improving awareness, acceptance, and adoption.

Figure 3. Perceived barriers to adding WA Notify to a smartphone by the communities represented by the survey respondents (N=17).

Thematic Synthesis

Themes

Digital expertise and confidence, privacy and security concerns, trust, and health and digital literacy levels emerged as key

determinants of WA Notify awareness, acceptance, and adoption among vulnerable communities that might benefit from using WA Notify to help limit the spread of COVID-19 (Textbox 1).

Textbox 1. The 5 emergent themes after the synthesis of survey and listening session results.

Themes

- Limited experience, expertise, and comfort with technologies, as well as access to smartphones, are substantial barriers to the adoption and use of WA Notify.
- Concerns about data security, tracking, and privacy outweigh or diminish the perceived value, benefits, and performance expectations of WA Notify for limiting the spread of COVID-19.
- The mistrust of government, law enforcement, and technology companies and the fear of negative consequences from engaging with exposure notification tools are substantial barriers to adoption.
- Language translations alone are not sufficient to ensure that WA Notify is accessible to communities with diverse health literacy, digital literacy, numeracy, and preferences for accessing information.
- Uptake may be improved by lowering literacy burdens, providing technology navigators, and disseminating tailored outreach and informational materials through trusted community social networks and opinion leaders.

Theme 1: Limited Experience, Expertise, and Comfort With Technologies, as Well as Access to Smartphones, Are Substantial Barriers to the Adoption and Use of WA Notify

The top 2 barriers to WA Notify adoption identified by survey respondents (N=17) concerned technology—the lack of an up-to-date phone (n=16, 94%) and lack of confidence to use a tool such as WA Notify (n=16, 94%; Figure 3). After exploring these issues further during our listening sessions, participants reported that a portion of their community members do not own or have access to a smartphone. In addition, CBO leaders working with immigrant and refugee communities noted a technology access divide based on gender and age, reporting that mobile phones are typically owned by men or household “breadwinners.”

Regarding community members who own or have access to a smartphone, there were concerns about the digital knowledge and skills required to use WA Notify. The process of adding or activating WA Notify requires several steps. Navigating through menus and downloading apps, even if the information is provided in the smartphone user’s native language, may be unfamiliar for those with limited digital skills.

Theme 2: Concerns About Data Security, Tracking, and Privacy Outweigh or Diminish the Perceived Value, Benefits, and Performance Expectations of WA Notify for Limiting the Spread of COVID-19

Survey respondents perceived privacy concerns (14/17, 82%) and misinformation (11/17, 65%) as barriers to adoption (Figure 3). Although WA Notify does not track its users or their locations, security and privacy were universal concerns reported

during the listening sessions. In some communities, CBO leaders reported that misinformation about data privacy persists, perhaps due to a lack of information readily available to rectify this misperception or few opportunities for the community to present their questions or concerns. Additionally, an LGBTQIA+ community advocate highlighted that without a proper understanding of how WA Notify works, community members cannot fully discern the benefits it may provide them.

Related to Theme 1, to understand WA Notify’s benefit, some level of digital fluency is required to accept the premise that contact between 2 users is determined by proximity (via the exchange of randomized codes over Bluetooth), not location. Furthermore, unless communities understand what WA Notify is and how it works, its value in helping to protect community members and limit the spread of COVID-19 is not apparent.

Theme 3: The Mistrust of Government, Law Enforcement, and Technology Companies and the Fear of Negative Consequences Are Substantial Barriers to Adoption

Survey respondents identified the mistrust of government (14/17, 82%), tech companies (10/17, 59%), public health organizations (9/17, 53%), and corporations (8/17, 47%) as barriers to adoption within their communities (Figure 3). During the listening sessions, participants pointed out that the historical context between the government and their communities and the fear of repercussions influence the willingness to adopt an intervention such as WA Notify. Gaining trust in these communities from the “outside” is challenging. Related to Themes 1 and 2, in the absence of a clear understanding of how WA Notify works and how it can help both the individual user and their community without jeopardizing privacy and security, the risks of adoption outweigh the potential benefits.

When asked, “Who do you think members of your communities would be worried about having access to the information from the WA Notify tool?” respondents (N=15) identified the US federal government (n=14, 93%) and local law enforcement (n=13, 87%) as the entities of greatest concern (Figure 4).

Although WA Notify’s anonymous design appears to cater to the preferences of some communities to remain anonymous from the government, CBO leaders working with undocumented communities noted concerns that information could be collected by WA Notify and put individuals at risk of deportation. In communities that have seen cooperation between local government and the US Immigration and Customs Enforcement leading to deportation, this fear is especially prevalent. As noted by 1 participant, community members are always asking themselves, “Am I opening myself up to deportation by doing this?” In Afghani immigrant communities, CBO leaders reported that those with Special Immigrant Visas will avoid any activity, such as activating WA Notify, that could potentially jeopardize their residency status.

The negative consequences associated with employers (9/15, 60%) accessing information through WA Notify were also brought up in the listening sessions. Included in a WA Notify alert of possible exposure is public health guidance to engage in protective behaviors such as getting tested and quarantining (quarantine guidance during the time of this evaluation was 10 days). Participants noted that low-income community members may be particularly vulnerable to the consequences of receiving an EN and cannot risk losing multiple days of income. To activate WA Notify, these community members need a compelling answer to the question, “What am I getting out of this?” as well as assurance that comprehensive resources and support will be available to them upon receiving an EN.

Figure 4. Entities of greatest concern to community members for accessing information through WA Notify (N=15).

Theme 4: Language Translations Alone Are Not Sufficient to Ensure That WA Notify Is Accessible to Communities With Diverse Health Literacy, Digital

Literacy, Numeracy, and Preferences for Accessing Information

Listening session participants representing non-English-speaking, immigrant, and refugee communities

repeatedly stated that the translation of materials into languages other than English is not an end point for ensuring equitable access to WA Notify. First, community members are often unaware that translated resources are available. In addition, even when translated, existing public health outreach materials and graphics may be difficult to understand for community members with lower levels of digital and health literacy. Multiple participants pointed out that current informational materials, while appropriate for individuals who are college educated, would need to be simplified to be appropriate for all members of their communities.

Listening session participants that advocate for diverse disability communities also identified the need to evaluate to what extent

WA Notify is interoperable with critical assistive technologies (such as text-to-speech systems or screen readers) and identify strategies to ensure that the information and resources provided by this tool are accessible in a variety of formats.

Theme 5: Uptake May Be Improved by Lowering Literacy Burdens, Providing Technology Navigators, and Disseminating Tailored Outreach and Informational Materials Through Trusted Community Social Networks and Opinion Leaders

During the listening sessions, CBO leaders shared suggestions for improving the acceptance and adoption of WA Notify in their communities ([Textbox 2](#)).

Textbox 2. Participant recommendations for improving the acceptance and adoption of WA Notify.

Recommendations

- Ensure that communication and informational materials are accessible at all literacy levels and work with assistive technologies
- Provide technology navigators
- Use trusted messengers who are known, credible, and already engaged in the community

Recommendation 1: Ensure That Communication and Informational Materials Are Accessible at All Literacy Levels and Work With Assistive Technologies

CBO leaders advocated for WA Notify and its promotional materials to use simple, easy-to-understand design elements. One CBO leader who had been providing Wi-Fi hot spots to immigrant and refugee families during the initial phase of the COVID-19 pandemic recalled needing to configure the devices to (1) limit the number of taps or clicks needed to access information; (2) use symbols to simplify navigation; and (3) provide a readily available technical support telephone line for troubleshooting. This participant emphasized that it is the responsibility of implementers, not the community members, to ensure that WA Notify is easy to understand and use.

Recommendation 2: Provide Technology Navigators

Activating WA Notify on a smartphone is difficult without technical or hands-on support. CBO leaders suggested that technical assistance be paired with existing community outreach activities, such as tabling sessions, workplace initiatives, and community health worker programs. CBO leaders also noted that for some families in their communities, the adult parent or guardian's initial exposure to technology occurs through their children. For these communities, youths, particularly high school- and college-aged students, might be engaged as technology navigators due to their high digital literacy and familiarity with community networks. In addition, leveraging schools and libraries to provide technology assistance may help resolve some technology barriers. In summary, there is a need for interactive, low-barrier assistance to ensure that community members with limited digital skills are supported in activating and using WA Notify.

Recommendation 3: Use Trusted Messengers Who Are Known, Credible, and Already Engaged in the Community

Engaging trusted messengers was viewed as an effective means of circulating accurate information about WA Notify, especially

for individuals not reached through previous communication efforts. Trusted messengers referenced during listening sessions include faith-based organizations, community health workers, health care providers, and CBO leaders. Providing information through these messengers could not only help elevate the awareness of WA Notify but may also address the dual challenges of mistrust and misinformation that limit adoption. One participant who advocates for immigrant and refugee communities articulated that their community members would likely ignore or scroll by WA Notify advertisements unless they were shared by a familiar organization. Engaging trusted messengers could help facilitate greater bidirectional communication between the DOH and communities regarding WA Notify, where trusted messengers could serve as nonjudgmental resources that directly engage with their community about their concerns and advocate for the requested changes to WA Notify.

Discussion

Principal Findings

This evaluation sought to uncover the equity and accessibility issues that may influence the access, adoption, and use of digital EN tools among diverse populations disproportionately impacted by COVID-19. Our findings suggest that digital literacy, trust, and information accessibility are key determinants of the adoption and use of WA Notify. Consistent with other mHealth equity evaluations of tools and interventions delivered over smartphones to disadvantaged and diverse populations, our results predominantly concerned limited health literacy, the ease of adoption and use, and issues related to the accessibility, relevance, and clarity of delivered content. However, misinformation and the fear of negative consequences related to using a digital EN tool emerged as unique determinants. These concerns may be barriers unique to a digital EN intervention or may be part of broader concerns among disenfranchised groups related to COVID-19 mitigation

measures such as masking, contact tracing, and vaccination [29].

This evaluation also sought to generate recommendations from populations experiencing COVID-19–related health inequities to prevent WA Notify from contributing to the adverse effects of public health interventions and ensure that it is accessible, relevant, useful for diverse communities. To address inequalities in technology access and digital skills, we recommend providing technology navigation through social networks and as extensions of existing community-based programs. To prevent inequalities in adoption, we recommend expanding partnerships with trusted messengers to elevate awareness, address misinformation, and promote trust in this novel technology, especially among community members who may not have been engaged through previous communication efforts. To address inequalities in using or adhering to WA Notify, information should be simple, easy to navigate, and accessible in a variety of formats. Lastly, to prevent inequalities in effectiveness and ensure that digital EN tools actively narrow COVID-19–related health inequities, implementers need to identify critical structural barriers faced by vulnerable populations and develop strategies to help users address, navigate, or simplify these barriers. In essence, WA Notify should serve a dual purpose: (1) to notify individuals of a COVID-19 exposure and (2) provide comprehensive resource navigation to ensure that all users are able to engage in protective behaviors. By developing effective connections with CBOs, local health jurisdictions, and other social support or medical services, WA Notify could ensure greater benefits for disadvantaged individuals and maximize its potential impact against COVID-19–related morbidity and mortality.

Limitations

This evaluation is subject to several limitations. First, although the project focused on identifying factors that could help WA Notify promote health equity, the direct measurement of the impact of WA Notify on COVID-19–related outcomes or health equity was not possible. Estimating the impact of digital EN systems is an ongoing area of evaluation, but the privacy-preserving design of this intervention does not allow for the identification of specific users, let alone their health

status. Second, recruitment efforts were concentrated on a small, purposive sample of community leaders. Although these leaders provided invaluable insight into their communities, these individual perspectives are unlikely to capture the heterogeneity of lived experiences, insights, and recommendations of their communities or state. Additionally, leaders participating in both the survey and informational sessions identified themselves as representing more than one community, so it is not possible to know whether the perceptions they shared were those of one specific community. Subsequent phases of this evaluation will seek to engage community members directly to supplement and expand upon the insights shared by the community leaders. Lastly, our findings reflect the conditions experienced by diverse communities during the first year of WA Notify's implementation. As the pandemic landscape changes, some of our results may no longer be generalizable to this new context. In the months following the completion of this evaluation, WA Notify has undergone iterative design changes, new variants (eg, Omicron) have emerged, and COVID-19 guidance has been modified. Future evaluations will need to take this altered landscape into account.

Conclusion

WA Notify is more than just a digital EN tool. It is an intervention on an individual's phone that represents public health and serves as a novel opportunity for public health agencies to communicate, alert, and engage with the communities they serve. WA Notify is part of a larger shift toward digital public health, which encompasses emerging tools such as vaccine verification initiatives and symptom-monitoring platforms, and seeks to improve the efficiency, scalability, and acceptability of traditional public health workflows. As an innovation that is changing how public health and outbreak response are conducted, WA Notify can empower its users to engage in the protective measures needed to keep themselves, their families, and their communities safe. Incorporating our equity-related findings and recommendations into the development, implementation, and communications efforts around digital pandemic and emergency preparation and response tools such as WA Notify will ensure that all communities can benefit.

Acknowledgments

We would like to thank Christymarie Jackson (Washington State Department of Health), Yenifer Baynes (Washington State Department of Health), the Washington State Vaccine Implementation Collaborative, and our participants for sharing their perspectives on the implementation of WA Notify and recommendations to improve the access, adoption, and use of this new tool within their community.

This work was funded through an Interagency Agreement between the Washington State Department of Health and the University of Washington School of Public Health (HED Contract 25742).

Abstract

Background: The Latinx population in the United States has experienced high rates of infection, hospitalization, and death since the beginning of the COVID-19 pandemic. There is little data on the knowledge, attitude, and practices (KAP) specifically in Latinx communities in the United States.

Objective: We aimed to assess COVID-19 KAP and vaccine hesitancy among a Latinx cohort in the early stages of the COVID-19 pandemic (from July 2020 to October 2020), at a unique time when a vaccine was not available.

Methods: Participants aged ≥ 18 years were recruited at a primary care clinic in Southern California and asked to self-report sociodemographic characteristics, KAP, and vaccine hesitancy. A subset of the participants answered the vaccine hesitancy assessment as it was added after the start of data collection. KAP items were summed to create composite scores, with higher scores reflecting increased COVID-19 knowledge, positive attitudes toward the COVID-19 pandemic, and disease prevention practices. Bivariate and multivariable regression models were fitted to test associations between sociodemographic characteristics and KAP scores. For our analysis, we only included patients who self-identified as Latinx.

Results: Our final data set included 265 participants. The participants had a mean age of 49 (IQR 38.5-59) years, and 72.1% (n=191) were female, 77% (n=204) had at most a high school degree, 34.7% (n=92) had an annual income <US \$25,000, and 11.7% (n=31) had previously tested positive for COVID-19. We found high knowledge regarding transmission and spread; moderate knowledge regarding symptoms awareness; overall negative attitudes, which included high pessimism in government public health efforts and high amounts of fear, anxiety, and frustration due to COVID-19 pandemic; and moderate participation in preventive practices. A college education was positively associated with a higher knowledge score than those without a college education ($\beta=0.14$, 95% CI 0.01-1.60; $P=.04$) when adjusted for covariates. Male gender had a positive association with COVID-19 attitude scores compared to female gender ($\beta=1.61$, 95% CI 0.50-2.72; $P=.05$), and male gender was negatively associated with the COVID-19 practices score compared to female gender ($\beta=-0.16$, 95% CI -0.56 to -0.06; $P=.03$), when both were adjusted for covariates. Among a subset of 203 patients, 26.6% (n=54) indicated that if the vaccine was available, they would not take a COVID-19 vaccine, and 18.7% (n=38) were unsure.

Conclusions: Good knowledge and preventative practices in the population may have reflected effective public health messaging and the implementation of public health laws during the first wave of the pandemic; however, the overall fear and anxiety may have reflected the negative impact that the pandemic had on vulnerable populations such as the Latinx community. Although our data are a reflection of a previous time in the pandemic, we believe it captures a critical time that can be used to provide unique insights regarding potential avenues to better protect the Latinx communities against future vaccine-resistant COVID-19 strains.

Introduction

In early 2020, the global community was overwhelmed by the COVID-19 pandemic caused by the SARS-CoV-2 virus, leading to quickly rising incidence and death rates with no available vaccine. By December 2020, COVID-19 had infected almost 20 million people and caused more than 300,000 deaths in the United States [1]. As cases of COVID-19 climbed across the United States throughout 2020, racial/ethnic minority populations were more likely to be infected, experience complications, and die from COVID-19 than the general population during a time when the vaccine was not available [2]. Although Latinx populations made up only 38.9% of the total population in California, they accounted for almost 60% of COVID-19 cases and approximately 50% of COVID-19-related deaths during the early pandemic in 2020 [3].

In 2021, the Moderna and Pfizer vaccines were made accessible to thousands of Latinx individuals in California [4], especially due to outreach and advocacy by organizations such as the Latin Community Foundation, Hispanic Federation, and the Orange County Public Health Department [5-7]. Despite this important milestone in the pandemic, the Latinx, Black, and American Indian or Alaska Native communities had similarly slow rates of vaccine uptake throughout 2020 and 2021 compared to Asian and White populations. As expected, Black and Latinx communities reported increased vaccine hesitancy compared to White and Asian populations in the United States [8,9].

The Latinx community remained one of the most vulnerable groups in terms of infection and death rates compared to the rest of the state population in the emergence of the new Omicron variant [10].

As we enter the third year of the COVID-19 pandemic, we still have not fully investigated the risk factors that predisposed the Latinx population in California to significantly higher incidence rates in the first year of the pandemic compared to other communities. In addition to the greater lack of access to care in the Latinx community, there are many other structural disparities that contribute to decreased health equity and increased risk behaviors in this population [11-14]. The Knowledge, Attitude, and Practices (KAP) theory is a health behavior theory based on the belief that knowledge is the foundation of behavior change and helps form attitudes and practices that drive behavior change [15,16]. Numerous global

studies from the beginning of the pandemic showed that a lack of COVID-19 knowledge, negative attitudes toward the pandemic, and the lack of disease preventative practice were more common in communities with high disease rates [14,17-21]. Further, vaccine hesitancy has been a persisting issue for the last few decades during the presence of numerous pandemics, especially within minority populations [22,23]. In the beginning of the COVID-19 pandemic, few studies measured the vaccine hesitancy of a potential COVID-19 vaccine before the vaccine was made available [24,25]. It is possible that if this data was measured early on, there would be more information to assist public health programs to combat vaccine misinformation and mistrust at the start of the vaccine release to the public [26]. There have been a small number of other studies that have explored the differences in KAP between different ethnic groups and genders in the United States, but none have specifically focused on the Latinx population.

In this study, we sought to investigate COVID-19 KAP and vaccine hesitancy among a Latinx population in Southern California. Specifically, we aimed to capture information on KAP and vaccine hesitancy from a critical time early in the COVID-19 pandemic when the vaccine was not available. The findings of this work provide unique insights regarding vulnerabilities and potential avenues for better protecting Latinx communities in future pandemics and against new vaccine-resistant COVID-19 strains, such as the currently circulating Omicron strain.

Methods

Study Design

We conducted a cross-sectional study from July to October 2020 in Southern California, during the “stay at home” order period that was implemented by the state government of California. We carried out our surveys at 2 primary health care centers in Santa Ana and Anaheim, California. Using consecutive sampling methods, we predominately recruited and surveyed patients presenting for telehealth appointments but also recruited patients presenting for in-person appointments at the clinics. Patients were eligible for study participation if they were (1) aged ≥ 18 years and (2) an enrolled patient of Amistad Medical Clinic Santa Ana or Amistad Medical Clinic Anaheim. For this analysis, we only included participants who self-identified as Latinx. Our study design, which included

in-person and telemedical recruitment, and data collection methods have been previously described [27].

Survey Validation

Our KAP survey was adapted from the World Health Organization's (WHO) Guide to Developing Knowledge, Attitude, and Practice Surveys [15], in addition to the few existing global COVID-19 KAP studies from the time period [28-30]. The most current COVID-19 symptoms included in the knowledge survey were identified using Centers for Disease Control and Prevention symptom reports that were the most current at the time of data collection. No standardized questionnaire for COVID-19 KAP had been created at the time of the study due to the early nature of the pandemic. Therefore, we pretested our KAP survey among 10 participants before implementing it.

Questions about vaccine hesitancy were added to the survey after the start of data collection. The vaccine hesitancy questions were adapted from the Vaccine Hesitancy Scale by WHO's Strategic Advisory Group of Experts on Immunization [31]. The survey was pretested among 10 participants before including it in our data collection.

Measures

Sociodemographic Characteristics

We asked participants to self-report sociodemographic characteristics including age (in years); gender (male vs female); education level completed (elementary school, middle school, high school, college degree, or graduate degree); annual income (less than US \$25,000, US \$25,000 to US \$49,999, US \$50,000 to US \$99,999, and US \$100,000 or more); marital status (single/never married, married, divorced, separated, or widowed); ethnicity (Latinx vs non-Latinx); and employment status (currently employed, recently unemployed or on temporary leave due to COVID-19, unemployed before COVID-19, retired, or a student). We also asked participants to self-report whether they had ever tested positive for COVID-19 (yes vs no).

COVID-19 KAP Survey

The COVID-19 KAP survey was comprised of 3 parts: (1) COVID-19 knowledge, (2) COVID-19 attitudes, and (3) COVID-19 practices. Knowledge included questions about disease transmission and spread through 12 dichotomous (yes vs no) questions and 1 open-ended question. It also measured knowledge of the most common COVID-19 symptoms through a multiple mark-style question in which participants were able to endorse 1 or more symptoms. All items were then summed to create a composite knowledge score ranging from 0 to 12, with higher scores indicating greater COVID-19 knowledge. Correct answers were based on current COVID-19 data at the time that was disseminated by the WHO to the general public [32].

COVID-19 attitudes were assessed through 5 items regarding confidence in the government control of the pandemic and emotions about the pandemic. All items were measured on a 5-point Likert-type scale ranging from 1 (strongly disagree) to 5 (strongly agree) and were summed to create a composite

attitude score, ranging from 5 to 25, with lower scores indicating more negative attitudes. COVID-19 practices consisted of 2 items that assessed participants' engagement in behaviors that reduce COVID-19 transmission. Both items were measured using a 5-point Likert-type scale ranging from 1 (never) to 5 (always) and were summed to create a composite practices score, ranging from 2 to 10, with higher scores indicating greater engagement in COVID-19 preventative behaviors.

COVID-19 Vaccine Hesitancy

Additionally, a question regarding vaccine hesitancy was added to the study after the start of data collection, and a subset of participants provided information on their willingness to take a potential COVID-19 vaccine through their responses (yes, maybe, or no) to the following question, "If a COVID-19 vaccine was available, would you get one?" Those who indicated "no" or "maybe" to this question were then asked to report their reason for their vaccine hesitancy. Response options included "I don't think it would work," "I'm concerned about the possible side effects," "I'm worried about the cost," "I don't think it's necessary," and "Other people will get it so I won't need to."

Statistical Analyses

We performed descriptive analysis for participant sociodemographic characteristics and COVID-19 vaccine hesitancy. Bivariate linear regression models were fitted to test associations between sociodemographic characteristics and COVID-19 KAP scores. Multivariable linear regression analyses were then conducted to further test the associations between sociodemographic characteristics and COVID-19 KAP scores while controlling for covariates found to be associated with the variables of interest in the bivariate analyses ($P < .05$). As determined a priori, variables associated with COVID-19 KAP in the bivariate analysis were retained for inclusion in the multivariable analysis. In addition, other sociodemographic variables previously found to be associated with COVID-19 KAP in the literature (ie, age, education, gender, income, gender, and marital status) were also included as covariates in the multivariable models [33-35]. All analyses were conducted in SPSS statistical software (version 9.8.0; IBM Corp).

Ethical Approval

The study was exempted from review by the University of California, San Diego Institutional Review Board on June 22, 2020. Patients' names or other identifying information were not collected. Participants were informed of the confidential nature of the study and were allowed to terminate the survey at any time.

Results

Demographics

A total of 323 participants completed the COVID-19 KAP survey. Our final data set included 265 participants after 58 individuals who did not self-identify as Latinx were excluded from analysis. Among the 265 participants, the mean age was 49.3 (IQR 38.5-59) years, and 191 (72.1%) identified as female, 139 (52.5%) were married, 109 (41.1%) indicated they had a middle school education or below, 89 (33.6%) had lost their

job or were on temporary leave due to COVID-19, 92 (34.7%) reported a current or previous positive test for COVID-19 (Table 1). had an annual income less than US \$25,000, and 31 (11.7%)

Table 1. Sociodemographic and clinical characteristics among Latinx clinic attendees in Southern California (N=265).

Variable, category	Participant
Gender, n (%)	
Female	191 (72.1)
Male	74 (27.9)
Age (year), mean (IQR)	49.3 (38.5-59)
Marital status, n (%)

Previously tested positive for COVID-19, n (%)	
Yes	31 (11.7)
No	234 (88.7)

COVID-19 Knowledge

Of the total 265 participants, 254 (95.8%) correctly knew that COVID-19 is spread when an infected person coughs, sneezes, or speaks; 251 (94.7%) correctly knew that COVID-19 is spread through touching contaminated surfaces and then touching the eyes or mouth; and 243 (91.7%) correctly knew to stand 6 feet or more away from another person to be safe from COVID-19

(Table S1 in [Multimedia Appendix 1](#)). However, 212 (80%) participants incorrectly believed that only older individuals (aged >65 years) are susceptible to COVID-19. Additionally, 196 (74%) participants correctly knew that individuals with pre-existing medical conditions are more susceptible to COVID-19, and 224 (84.5%) correctly identified that asymptomatic individuals with COVID-19 can still infect someone else. When asking participants for common symptoms

of COVID-19, 171 (64.5%) correctly identified fever, 111 (41.9%) correctly identified cough, 109 (41.1%) correctly identified headache, 100 (37.7%) correctly identified shortness of breath, 91 (34.3%) correctly identified body aches, 46 (17.4%) correctly identified loss of taste, and 34 (13.6%) correctly identified loss of smell.

In the multivariate analysis, when adjusting for age, gender, annual household income, and education, having a college degree was significantly associated with a higher knowledge score than those who completed middle school or below ($\beta=0.14$, 95% CI 0.01-1.60; $P=.04$; [Table 2](#)).

COVID-19 Attitudes

Among the 265 total participant, 104 (39.2%) strongly disagreed or disagreed that the government would help stop the spread of the virus; 198 (74.7%) strongly agreed or agreed that they felt nervous about how the COVID-19 pandemic would impact their future; 120 (45.3%) strongly agreed or agreed that they had felt

angry or frustrated because of the COVID-19 pandemic; and 147 (55.5%) strongly agreed or agreed that they had felt scared to leave their home because of COVID-19. However, a majority 72.5% (n=192) of the participants strongly agreed or agreed that they had felt hopeful about the future ([Table S2 in Multimedia Appendix 1](#)).

In the multivariate analysis, when adjusting for marital status and education, male gender had a positive association with COVID-19 attitude scores compared to female gender ($\beta=1.61$, 95% CI 0.50-2.72; $P=.005$; [Table 3](#)).

COVID-19 Preventative Practices

Among the 265 participants, when asked about preventative practices to stay safe from COVID-19 transmission, 161 (60.8%) indicated that they washed their hands most of the time when entering their homes, whereas 92 (34.7%) indicated that they never engage in this practice. Interestingly, 248 (93.6%) indicated that they always wear a mask outside of their home,

whereas none indicated that they never wear a mask outside their home (Table S3 in [Multimedia Appendix 1](#)).

In the multivariable regression analysis, controlling for marital status, annual household income, and education, male gender was negatively associated with the COVID-19 practices score compared to female gender ($\beta=-0.16$, 95% CI –0.56 to –0.06; $P=.03$; [Table 4](#)).

Table 4. Bivariate and multivariable analysis of factors associated with COVID-19 attitudes among Latinx individuals in Southern California (N=265).

COVID-19 Vaccine Hesitancy

We asked a subset of 203 participants about their views on a potential COVID-19 vaccine before the COVID-19 vaccine was made available. Within this subset (N=203), 111 (54.7%) indicated that they would take a vaccine if it were available, but 54 (26.6%) indicated that they would not take a vaccine, and 38 (18.7%) indicated that they were unsure (ie, answered “maybe”). Of those who indicated they would not take a vaccine (n=54), 23 (43%) indicated that they were concerned with

possible side effects, 18 (33%) indicated that they didn’t think it was necessary, 8 (15%) indicated that they didn’t think it will work, and 1 (2%) indicated that they are worried about the cost and financial burden. Of those who indicated they were unsure (n=38), 27 (71%) indicated that they are concerned about possible side effects, 3 (8%) indicated that they didn’t think it will work, 2 (5%) indicated that they didn’t think it’s necessary, and none indicated that they are worried about cost and financial burden (Table 5).

Table 5. COVID-19 vaccine hesitancy before vaccine availability (N=203).

View on vaccine, reasons for hesitancy	Participants, n (%)
Willing to take the vaccine (n=111)	111 (100)
Unsure about taking the vaccine (n=38)	
Don't think it's necessary	2 (5)
Don't think it will work	3 (8)
Concerned about the possible side effects	27 (71)
Worried about the cost and financial burden	0 (0)
Refused to answer	6 (16)
Not willing to take the vaccine (n=54)	
Don't think it's necessary	18 (33)
Don't think it will work	8 (15)
Concerned about the possible side effects	23 (43)
Worried about the cost and financial burden	1 (2)
Refused to answer	4 (7)

Discussion

Principal Findings

Since the start of the COVID-19 pandemic in Southern California, the Latinx population has been disproportionately affected by disease incidence, morbidity, and mortality. Our data demonstrate that this population had good knowledge of COVID-19 transmission and spread; moderate knowledge of COVID-19 symptoms; overall negative attitudes including high pessimism in government public health efforts and high amounts fear, anxiety, and frustration due to COVID-19 pandemic; but high optimism about the future. Our data also show moderate participation in preventative practices and moderate vaccine hesitancy within a Southern California Latinx community during the first wave of the pandemic before the vaccine was available. In addition, our data show a significant association between college education and a higher COVID-19 knowledge score; male gender and a more optimistic attitude; and male gender and a lower practices score. We believe that observational data from this period are critical to identifying how a pandemic can initially affect vulnerable populations' understanding of disease, since knowledge helps form attitudes and practices that drive behavior change [36].

Comparison to Prior Works

Participants were particularly aware of the common physical symptoms of COVID-19 illness, such as cough, headache, and fever. Relatively few participants, however, identified loss of taste and smell as common COVID-19 symptoms. The lack of knowledge around these very specific symptoms may have been due to the unusual nature of the symptoms and the public health messaging at the time that was emphasizing "coughing" as an identifiable symptom to be aware of [37,38]. When participants were asked about their knowledge regarding COVID-19 transmission and susceptibility, most knew that transmission could happen when an infected person coughs, sneezes, or speaks and that the disease could be spread by touching contaminated surfaces and then touching the eyes or mouth.

Most also knew to stand 6 feet or more away from others to prevent disease transmission. However, our data show that over half of our participants felt that only older people were susceptible to COVID-19 infection.

Our findings also demonstrate that younger age was associated with lower knowledge scores, a finding supported by Alsan et al [39], which reported that people aged <55 years were less likely to know how the disease is spread and the symptoms of COVID-19. Higher education and income were associated with higher knowledge scores, which is supported by global COVID-19 studies from 2020 that showed higher education and income allowed for greater knowledge regarding the disease [34,40,41].

When participants were asked about their COVID-19 attitudes, only one-third agreed or strongly agreed that the government would stop the spread of the virus, whereas more than half disagreed or strongly disagreed. Focus groups among Latinx farmworkers in the central valley reported similar themes of mistrust in government institutions regarding COVID-19 vaccinations and testing [42]. This finding is in-line with the Latinx community's growing mistrust in the American government's medical and public health policies [43].

The participants also expressed feelings of fear, anxiety, and frustration. Widespread fear, anxiety, and depression related to COVID-19 has been well-documented in the United States, and recent research has shown that these feelings have been magnified in Latinx populations where the loss of employment has been widespread [44-46]. In our study, nearly one-third of the participants reported COVID-19-related "temporary leave" or lost jobs during the pandemic. This substantial change in employment status may have also contributed to the participants' reports of feeling angry or frustrated due to COVID-19. However, despite the negative attitudes toward COVID-19, over half of the participants indicated that they were still hopeful about the future. A positive outlook aligns with research that shows that specific Latinx populations have high resilience during stressful situations and carry optimism for the future

despite dissatisfaction with the present and the multiple obstacles and stressors they face [47].

Our data show that men had more COVID-19–related positive attitudes about government response and the pandemic’s effect on their lives compared to women. Our data differ from other European- and South American–based studies that have shown no significant association between gender and COVID-19–related positive attitudes in the Latinx community [48,49]. However, our results could be explained by women having reportedly higher levels of fear and stress and negative perceptions of government actions than men during the pandemic [50]. Multiple studies conducted globally and in the United States have indicated that women have been carrying high burdens of care (eg, caring for and teaching children in the absence of in-person learning environments) and emotional labor [51–53]. Consequently, this gendered division of labor could potentially have contributed to the gender differences in positive attitudes found in our study.

Additionally, when asked about COVID-19 preventative practices, almost all participants indicated that they always wore a mask when they went outside of their home. This strong knowledge base and the corresponding safety practices regarding COVID-19 may indicate that there was effective public health messaging regarding transmission and preventative practices that had penetrated the community. In addition, local laws possibly contributed to higher compliance with COVID-19 preventative practices, such as wearing masks [54]. Our data indicate that men had decreased preventative practices compared to women. This aligns with a study by Alsharawy et al [50] indicating that women engaged in more preventative practices during the pandemic and were more risk averse.

Our data captured vaccine attitudes and acceptability between July and October 2020—a period before COVID-19 vaccines were approved for essential workers in December 2020. The most common reasons given for an expressed reluctance to accept vaccination in our study were concern about possible side effects, thinking it was not necessary, and thinking it would not work. After the vaccine was released, studies documented mass vaccine hesitancy in Latinx and Black communities across the United States who had historically faced government oppression and had mistrust in the intentions of public health medical interventions [55,56]. Our findings have built upon these studies and provided further evidence of relatively high vaccine hesitancy in marginalized populations, and we suggest that in future pandemics, more focused effort should be expended on both vaccine education and interventions that are targeted toward combatting medical mistrust in marginalized communities prior to vaccine distribution.

Acknowledgments

The authors would like to thank all of the participants for their willingness to participate and all study staff for their support. SAMP was supported by National Institute of Drug Abuse grants R01 DA039950 and T32 DA023356.

Limitations

Our study had several limitations. First, due to the cross-sectional nature of the study, we are unable to report whether the KAP was casually associated with the covariates examined. In addition, we had a limited set of questions due to time constraints in the clinical setting. Lastly, the reliance on self-reporting may have introduced response bias due to participants’ fear of judgement from health care providers regarding COVID-19 practices. To mitigate these challenges, we made sure that our survey administrators were not health care providers, were well-trained, and approached surveys in a nonjudgmental manner and that the participants were informed of the confidential nature of the study and allowed to terminate the survey at any time. Additionally, our vaccine acceptance questions were asked before a vaccine was approved, hence we recognize that these findings may not reflect current attitudes toward vaccines for our population. Additionally, the cross-sectional nature of our study did not allow us to track data over time but rather enabled us to capture data at one point in time. We acknowledge that the situation with COVID-19 has changed rapidly, and therefore, KAP in populations can change over time.

We believe, however, that our data capture important information related to symptom awareness, knowledge, attitudes, and practice, in addition to vaccine hesitancy during a critical time in the history of the COVID-19 pandemic; this data might provide important insights into the future implementation of critical public health interventions and policies serving Latinx populations.

Conclusion

We found high knowledge regarding transmission and spread; moderate knowledge regarding symptoms awareness; overall negative attitudes which included high pessimism in government public health efforts and high amounts of fear, anxiety, and frustration due to the COVID-19 pandemic; and moderate participation in preventive practices. We also found moderate vaccine hesitancy in the Latinx community in Southern California during the first wave of the pandemic. Good knowledge and preventative practices in the population may be a reflection of effective public health messaging and the implementation of public health laws during the first wave of the pandemic; however, the overall fear and anxiety may have been a reflection of the negative impact that the pandemic had on vulnerable populations such as the Latinx community. We believe it would be useful to examine KAP in larger populations during this time period and potentially use the data to inform public health approaches in Latinx communities amid the potential arrival of new pandemics.

Authors' Contributions

SNM led the project coordination, data analysis, and writing of the manuscript. SAMP and RSG also led the data analysis. ZCB, SNM, and TR led the proposal and protocol development. DOO, PKM, SBK, JK, and MM contributed to the clinical and logistical aspects of protocol development. All authors have approved the final manuscript and agreed to publication.

Conflicts of Interest

TR is a University of California, San Diego coinventor of a COVID-19 rapid test—patent pending. All other authors declared no additional conflicts of interest.

Multimedia Appendix 1

Additional knowledge, attitude, and practices survey results.

Abstract

Background: Sleep disturbance is a transdiagnostic risk factor that is so prevalent among young adults that it is considered a public health epidemic, which has been exacerbated by the COVID-19 pandemic. Sleep may contribute to mental health via affect dynamics. Prior literature on the contribution of sleep to affect is largely based on correlational studies or experiments that do not generalize to the daily lives of young adults. Furthermore, the literature examining the associations between sleep variability and affect dynamics remains scant.

Objective: In an ecologically valid context, using an intensive longitudinal design, we aimed to assess the daily and long-term associations between sleep patterns and affect dynamics among young adults during the COVID-19 pandemic.

Methods: College student participants (N=20; female: 13/20, 65%) wore an Oura ring (Oura Health Ltd) continuously for 3 months to measure sleep patterns, such as average and variability in total sleep time (TST), wake after sleep onset (WASO), sleep efficiency, and sleep onset latency (SOL), resulting in 1173 unique observations. We administered a daily ecological momentary assessment by using a mobile health app to evaluate positive affect (PA), negative affect (NA), and COVID-19 worry once per day.

Results: Participants with a higher sleep onset latency ($b=-1.09$, SE 0.36; $P=.006$) and TST ($b=-0.15$, SE 0.05; $P=.008$) on the prior day had lower PA on the next day. Further, higher average TST across the 3-month period predicted lower average PA ($b=-0.36$, SE 0.12; $P=.009$). TST variability predicted higher affect variability across all affect domains. Specifically, higher variability in TST was associated higher PA variability ($b=0.09$, SE 0.03; $P=.007$), higher negative affect variability ($b=0.12$, SE 0.05; $P=.03$), and higher COVID-19 worry variability ($b=0.16$, SE 0.07; $P=.04$).

Conclusions: Fluctuating sleep patterns are associated with affect dynamics at the daily and long-term scales. Low PA and affect variability may be potential pathways through which sleep has implications for mental health.

KEYWORDS

sleep; objective sleep outcomes; COVID-19; affect variability; affect dynamics

Introduction

Sleep is a robust and transdiagnostic risk factor for various physical and mental health problems, including mood disorders [1-3]. Indeed, sleep disorders, such as insomnia and circadian misalignment, contribute to the development or recurrence of mood disorders, particularly depression and anxiety [4]. Variability in sleep duration, as measured by day-to-day changes in nightly sleep, is as important a predictor for psychological well-being as the average total amount of sleep [5]. Sleep problems, such as chronic sleep restriction and irregular sleep patterns, are common among college students [6]. For emerging adults who are already at greater risk for psychopathology [7,8], the COVID-19 pandemic has disrupted daily routines [9,10], thereby potentially exacerbating variable sleep patterns and contributing to further insufficient sleep and greater variability in sleep duration. Given the prevalence of sleep disturbances as well as the impact of the pandemic on young adults, it may be important to examine the associations between sleep and affect in young adults during the COVID-19 pandemic.

Insufficient sleep and sleep variability may contribute to physical and mental health via affect dynamics. Positive affect (PA) and negative affect (NA)—broadband indices of emotion—are well-established predictors of well-being [11]. Blunted PA and increased NA are risk factors for and significant predictors of the development and recurrence of mental disorders, such as depression. COVID-19 worry, or concern over SARS-CoV-2 infection, is another relevant affect construct that has arisen during the pandemic [12,13]. COVID-19 worry has been discussed at length by psychologists during the COVID-19 pandemic [12-14] and is a distinct psychological factor that uniquely contributes to general anxiety and persistent pessimism [12]. Affect, however, is dynamic; the trajectory of emotional experiences often fluctuates across time [15]. Beyond average affect, daily affect dynamics, such as affect variability, may contribute to explaining individual differences in psychological functioning. Affect variability—a measure of the extent to which individuals experience frequent PA, NA, and COVID-19 worry fluctuations—is known to play a prominent role in psychopathologies, such as mood disturbances [16,17].

Prior literature has mainly focused on the negative consequences that sleep deprivation has for average PA and NA, finding that sleep duration significantly predicts dampened PA and elevated NA [18-22]. Experimental studies have also confirmed the similar effects of sleep loss on changes in PA and NA [23,24]. Specifically, 1 night of sleep deprivation and/or sleep restriction (ie, 4 hours of sleep), when compared to idealized sleep (ie, the opportunity of sleeping for 9.5-10 hours), decreases PAs such as vigor and increases NAs such as anger [23,24]. Yet, this knowledge is largely based on correlational studies or sleep deprivation experiments that do not generalize to the daily lives of young adults with chronic sleep restriction. Additional studies on the relation between affect and sleep problems in young adults that are conducted in a more ecologically valid context (eg, daily life) may help to elucidate these associations. Furthermore, to date, the literature examining the associations between daily sleep variability and affect dynamics remains scant. Daily sleep variability contributes to psychological

well-being [5,25], but more studies that use newer methods to examine objective sleep are needed. Studies with intensive longitudinal designs that are conducted over longer periods of time to assess both subjective and objective sleep outcomes are poised to accomplish these goals. Considering the important contribution of poor sleep to mood disorders, particularly depression and anxiety [4,19], it is important to examine the nuanced characterizations of the consequences that daily sleep disturbances have for affect dynamics. Examining the association between daily sleep and affect will allow for a better understanding of the development of comorbid sleep and mood disorders and how to design prevention programs for at-risk individuals.

The aim of this study was therefore to assess (1) the daily associations between sleep and affect and (2) the long-term associations between sleep patterns (ie, average and variability in total sleep time [TST], wake after sleep onset [WASO], sleep efficiency, sleep onset latency [SOL]) and affect dynamics (ie, mean levels of PA and NA, PA and NA variability, and COVID-19 worry) dynamics among young adults during the COVID-19 pandemic across a 3-month period. Examining these associations at the between- and within-person levels will allow for an improved understanding of the development of comorbid sleep and mood disorders and support the identification of early intervention windows for at-risk individuals. This study was designed to examine sleep among young adults in a 3-month period; however, the period of assessment varied from 1 month to 3 months due to retention. The majority of previous studies have assessed subjective and objective sleep outcomes in a 14-day period [5,25], meaning that our study examined a longer period of time. Further, multilevel modeling is a powerful analytic approach to analyzing intensive longitudinal data with missing values for both between-subject research questions and, especially, within-subject research questions.

Methods

Participants

College student participants (N=20; female: 13/20, 65%; age: mean 19.80, SD 1.0 years) were assessed daily across a 3-month period during the 2020 COVID-19 pandemic (June to November), resulting in 1173 unique observations. Participants were eligible if they met the following criteria: participants must be unmarried, be English speakers, be full-time undergraduate students aged between 18 and 22 years, and own a primary Android smartphone that is compatible with the ecological momentary assessment (EMA) phone-based survey apps and study wearable devices.

Ethics Approval

This study was part of a larger intensive longitudinal study for examining student mental health that included physiological assessments, sleep tracking, and daily emotional and behavioral reports. The procedures of this study were approved by the institutional review board (approval number: 2019-5153) at University of California, Irvine. All individuals provided written informed consent prior to participation.

Procedure

Herein, we describe the procedures that are relevant to the purposes of our investigation. Participants were first instructed on how to wear the noninvasive device (ie, Oura ring [Oura Health Ltd]) that continuously assessed sleep, activity, and physiology throughout the day and during sleep [26]. Participants completed daily surveys on affect by using a smartphone app. To maintain high adherence, participants received reminders via text message, email, or phone call if there were more than 2 days of inactivity.

Measures

Sleep

By using the Oura ring (specifications: 2 infrared light-emitting diode heart rate sensors, 2 negative thermal coefficient body temperature sensors, a 3-axis accelerometer, and a gyroscope), TST, WASO, sleep efficiency, and SOL were calculated through the detection and interpretation of physiological measures, including heart rate, heart rate variability, and pulse wave variability amplitude. Previous studies have compared the Oura ring to polysomnography—the gold standard of sleep measurement—and research-grade actigraphy (Philips Respironics). A study by Chee et al [27] shows that, based on an epoch-by-epoch analysis, the Oura ring yields sleep assessments that are comparable to those of actigraphy [27] but underestimates TST when compared to polysomnography. However, other studies, such as one by de Zambotti et al [28], have shown that summary variables for SOL, TST, and WASO are not different between the Oura ring and polysomnography. The validation study by de Zambotti et al [28] was conducted among healthy adolescents and young adults and showed that “the differences for TST and WASO between PSG and Oura are within the ≤ 30 min a-priori-set clinically satisfactory ranges for 87.8% and 85.4% of the sample, respectively.” Their study also showed that the Oura ring is able to categorize sleep, with an accuracy of $>81.3\%$, based on polysomnography-defined TST ranges (eg, <6 hours, 6-7 hour, and >7 hours). However, there are some concerns regarding detecting the stages of sleep (eg, light sleep, deep sleep, and rapid eye movement sleep); therefore, sleep stages were not included in this study.

Affect and COVID-19 Worry

As part of the EMA phone-based surveys, participants reported daily PA and NA by using the Positive and Negative Affect Schedule (PANAS) [29] each evening. On the PANAS, 10 positive (eg, inspired) items and 10 negative (eg, nervous) items were rated on a 0 to 100 scale (0=“Very Slightly”; 100=“Extremely”). Total scores for PA and NA were calculated by using the average across each 10-item subscale (PA: mean 45.27, SD 20.22; $\alpha=.85$; NA: mean 21.79, SD 12.28; $\alpha=.91$). As a separate item (“How worried were you about contracting COVID today?”), participants reported their COVID-19 worry on a 0 to 100 scale (mean 17.41, SD 19.15).

Sleep and Affect Variability

To determine the variability of each sleep and affect variable, we first created a series of successive differences by calculating the difference between 2 successive observations within the same subject (eg, night 2 – night 1; night 3 – night 2; etc). Next,

these values were squared. We used the square successive differences to compute a mean square successive difference score. Finally, we calculated the root mean square successive difference score for each participant. The root mean square successive difference is considered an index of variability that is similar to the intraindividual variance of a series of observations but is more sensitive to fluctuations across successive observations [30].

Data Analysis

We first examined variables for normality and heteroscedasticity. To examine the association between sleep (TST, sleep efficiency, and SOL) and affect variables (PA, NA, and COVID-19 worry), we first conducted multilevel models by using the restricted maximum likelihood approach. This approach improves estimates of variance components and fixed effect SE estimates in smaller samples by separating the estimates of the fixed effects from the variance components [31]. We predicted PA, NA, and COVID-19 worry as a function of the fixed effects of time and between- and within-subject sleep variables while controlling for previous-day affect. Next, we examined the association between sleep and affect variables by using multiple regression models. Previous studies have found that sex is linked with sleep outcomes [32-34]. Therefore, sex was included as a covariate in these regression models. Finally, we conducted hierarchical linear regressions to examine whether sleep variability variables contribute to affect dynamics above and beyond the average sleep variables.

Results

Descriptive Statistics

A total of 20 college students (female: 13/20, 65%) completed this study, providing 1623 (mean 43.49, SD 25.51 days/person) nights of usable Oura ring sleep data. Completion rates for EMA studies were high (83%).

Table S1 in [Multimedia Appendix 1](#) provides descriptive statistics and the bivariate correlations between the key variables. The averages for participants' TST and TST variability were 6.84 and 1.8 hours, respectively. Participants also experienced an average of 65.04 and 12.01 minutes of WASO and SOL, respectively, with a sleep efficiency of 86.52% across the study. Further, on average, participants reported low levels of NA (mean 21.79), moderate levels of PA (mean 45.27), and low levels of COVID-19 worry (mean 17.41) across the study. We assessed the bivariate correlations between the COVID-19 worry mean and PA and NA means (between-person level) and found no significant correlations between these constructs. Specifically, the correlation between the COVID-19 worry mean and PA mean was -0.19 ($P=.43$), and the correlation between the COVID-19 worry mean and NA mean was 0.43 ($P=.06$).

Daily Sleep and Daily Affect

The multilevel models of the relation between sleep and affect revealed that participants with a higher SOL ($b=-1.09$, SE 0.36; $P=.006$) and TST on the prior day ($b=-0.15$, SE 0.05; $P=.008$) had lower PA on the next day, while controlling for previous-day PA. No within-subject differences were observed in predictions

for next-day PA. No associations between daily sleep and NA and between daily sleep and COVID-19 worry were found. Table S2 in [Multimedia Appendix 2](#) shows more details.

Main Effects of Sleep on Average Affect

The regression model for predicting PA from average TST accounted for 34% of the variance in average PA (adjusted $R^2=0.26$; $F_{2,17}=4.24$; $P=.03$). Specifically, higher TST was associated with lower PA ($b=-0.36$, SE 0.12; $P=.009$). Other sleep variables were not associated with average PA. Sleep was not associated with average NA or COVID-19 worry. Table S3 in [Multimedia Appendix 3](#) shows more details.

Main Effects of Sleep on Affect Variability

Sleep Averages and Affect Variability

SOL and sleep efficiency predicted COVID-19 worry variability. The multiple regression model for predicting COVID-19 worry variability from the average SOL and sex accounted for 38% of the variance in COVID-19 worry variability (adjusted $R^2=0.31$; $F_{2,17}=5.29$; $P=.02$), and the model for predicting COVID-19 worry variability from average sleep efficiency and sex accounted for 38% of the variance in COVID-19 worry variability (adjusted $R^2=0.31$; $F_{2,17}=5.24$; $P=.02$). Specifically, higher average SOL predicted higher COVID-19 worry variability ($b=1.87$, SE 0.89; $P=.05$), and higher sleep efficiency predicted lower COVID-19 worry variability ($b=-2.02$, SE 0.97; $P=.05$). Table S4 in [Multimedia Appendix 4](#) shows more details.

Sleep Variability and Affect Variability

The multiple regression models for predicting affect variability from TST variability, while controlling for sex, accounted for 36% of the variance in PA variability (adjusted $R^2=0.29$; $F_{2,17}=4.82$; $P=.02$), 34% of the variance in NA variability (adjusted $R^2=0.27$; $F_{2,17}=4.44$; $P=.03$), and 40% of the variance in COVID-19 worry variability (adjusted $R^2=0.33$; $F_{2,17}=5.70$; $P=.01$). Specifically, higher variability in TST was associated with higher PA variability ($b=0.09$, SE 0.03; $P=.007$), higher NA variability ($b=0.12$, SE 0.05; $P=.03$), and higher COVID-19 worry variability ($b=0.16$, SE 0.07; $P=.04$). Table S4 in [Multimedia Appendix 4](#) shows more details.

The hierarchical regression models showed that TST variability predicted PA variability above and beyond the average TST (adjusted $R^2=0.26$; $F_{3,16}=3.20$; $P=.05$). However, the models for predicting NA variability and COVID-19 worry variability were not statistically significant after adding average TST to the models (adjusted $R^2=0.22$; $F_{3,16}=2.82$; $P=.07$ and adjusted $R^2=0.22$; $F_{3,16}=2.82$; $P=.07$, respectively).

Discussion

Principal Findings

Sleep patterns across the daily and long-term scales were associated with daily and average affect and affect variability, which were assessed over a 3-month period. These findings are

consistent with those of prior work suggesting that poor sleep confers a heightened risk for affective disturbances that are prevalent in mood disorders, such as depression [4]. The link between sleep variability and affect variability may provide a window into how such patterns develop over time.

Individuals with longer sleep times on the previous night experienced lower PA on the next day. Similarly, individuals with longer average TSTs over the study period reported lower PA. Previous studies however have suggested a positive association between sleep duration and greater PA (eg, a study by Galambos et al [25]). During the COVID-19 pandemic, young adults' lives have changed dramatically [35], and it is possible that they have been sleeping for longer than the recommended hours; therefore, there may be a curvilinear association between TST and PA. Future studies may benefit from examining this curvilinear association in a larger sample. Notably, consistent with prior studies [36], sleep did not predict NA. Low PA may be a potential pathway through which sleep duration has implications for mental health. Low PA is both a significant predictor of the onset of depression and a characteristic of depressive disorders. When low PA is directly treated, symptoms of anxiety and depression, as well as other disorders with anhedonic features, are known to improve [37]. Thus, improving daily sleep may be particularly important for preventing PA decline, thereby potentially interrupting the pathogenesis of illness states, such as mood disorders.

TST variability predicted higher affect variability across all affect domains (ie, PA, NA, COVID-19 worry); thus, it may be a proximal predictor of mood disturbances. Affect variability is prevalent in various mood-related disorders, such as depression, bipolar disorder, and anxiety disorders [38]. Our findings have important implications. First, interventions that support sleep stability may indirectly reduce affect variability and therefore prevent clinically significant mood disturbances. For example, in bipolar disorder, variable sleep and affect during euthymia predict worse long-term outcomes, including episodic relapses [39]. Second, our findings suggest that the stabilization of affect may be an early marker or predictor of the efficacy of transdiagnostic sleep interventions that target mood disorders with anhedonic features [39]. Future research may benefit from experimentally investigating the effect of regulating sleep time on affect dynamics in clinical populations.

Our findings also provide specific relevance to the COVID-19 context. Individuals with a higher SOL experienced higher COVID-19 worry variability, and individuals with a higher sleep efficiency reported lower COVID-19 worry variability. The specificity of the associations between SOL and sleep efficiency, and COVID-19 worry variability (ie, not NA in general) may suggest that the association between sleep and arousal-related affect is unique. Sleep disturbances may contribute to the lower capacity to adaptively overcome stress and therefore may be associated with higher stress-related sleep reactivity and cognitive presleep hyperarousal [40]. Future research may benefit from experimentally investigating the association between sleep and specific subtypes of affect.

Limitations

Our findings carry some limitations. First, whether sleep causally predicts affect remains unclear. Daily affect may also predict multiple sleep indices [36]. The bidirectional link between sleep and affect may result in a cyclical pattern of sleep disturbance impacting affect, which in turn may contribute to greater sleep disturbances. Second, the small sample size of this study was not diverse in terms of age, which limits the generalizability of our findings to other age groups. However, the peak prevalence of affect variability is among adolescents and young adults (ie, individuals aged 16-24 years) and gradually declines with age [38]. Considering the small sample size of this study, future studies may benefit from examining

the association between sleep patterns and affect dynamics in a larger sample.

Conclusion

Fluctuating sleep patterns are associated with affect dynamics, such as average PA and affect variability, across all affect domains (ie, PA, NA, COVID-19 worry) at the daily and long-term scales. Low PA and affect variability may be potential pathways through which sleep has implications for mental health. Interventions that target sleep stability may indirectly reduce affect variability and therefore prevent mood disorders. The stabilization of affect may be an early marker or predictor of the efficacy of transdiagnostic sleep interventions that target mood disorders with anhedonic features.

Abstract

Background: In-person directly observed therapy (DOT) is standard of care for tuberculosis (TB) treatment adherence monitoring in the US, with increasing use of video-DOT (vDOT). In Minneapolis, vDOT became available in 2019.

Objective: In this paper, we aimed to evaluate the use and effectiveness of vDOT in a program setting, including comparison of verified adherence among those receiving vDOT and in-person DOT. We also sought to understand the impact of COVID-19 on TB treatment adherence and technology adoption.

Methods: We abstracted routinely collected data on individuals receiving therapy for TB in Minneapolis, MN, between September 2019 and June 2021. Our primary outcomes were to assess vDOT use and treatment adherence, defined as the proportion of prescribed doses (7 days per week) verified by observation (in person versus video-DOT), and to compare individuals receiving therapy in the pre-COVID-19 (before March 2020), and post-COVID-19 (after March 2020) periods; within the post-COVID-19 period, we evaluated early COVID-19 (March-August 2020), and intra-COVID-19 (after August 2020) periods.

Results: Among 49 patients with TB (mean age 41, SD 19; n=27, 55% female and n=47, 96% non-US born), 18 (36.7%) received treatment during the post-COVID-19 period. Overall, verified adherence (proportion of observed doses) was significantly higher when using vDOT (mean 81%, SD 17.4) compared to in-person DOT (mean 54.5%, SD 10.9; $P=.001$). The adoption of vDOT increased significantly from 35% (11/31) of patients with TB in the pre-COVID-19 period to 67% (12/18) in the post-COVID-19 period ($P=.04$). Consequently, overall verified (ie, observed) adherence among all patients with TB in the clinic improved across the study periods (56%, 67%, and 79%, $P=.001$ for the pre-, early, and intra-COVID-19 periods, respectively).

Conclusions: vDOT use increased after the COVID-19 period, was more effective than in-person DOT at verifying ingestion of prescribed treatment, and led to overall increased verified adherence in the clinic despite the onset of the COVID-19 pandemic.

Introduction

Tuberculosis (TB) remains a leading cause of infectious disease death globally and a contributor to morbidity and mortality in the United States [1-3]. Adherence to a TB therapeutic regimen can be difficult, owing in part to its long treatment course over several months [1,4-6]. Incomplete treatment adherence can result in treatment failure, development of multidrug resistant strains, and poor clinical outcomes [7,8].

Directly observed therapy (DOT) has historically been regarded as the standard of care to document treatment adherence in most US public health TB clinics and involves a health care provider observing a patient take their TB medication [4,9-11]. It should be acknowledged that DOT is a multifaceted intervention that has heterogeneous implementation globally, with mixed data on effectiveness [12-14]. Nonetheless, in 2016, the US Centers for Disease Control and Prevention, American Thoracic Society, and Infectious Diseases Society of America guideline update suggested using DOT over self-administered therapy for routine treatment of TB [4].

While DOT offers the ability to document medication ingestion and couple adherence interventions (eg, psychological support and case management), implementation may carry substantial inconvenience, cost, or stigma for patients and service providers [15-17]. Furthermore, although current US and international guidance advocate for daily, 7-day TB treatment regimens, logistical constraints result in only partial documentation of adherence—DOT is commonly implemented only during weekdays, with self-report on weekends (ie, nearly one-third of all prescribed doses) [4,16]. New strategies to document TB treatment adherence using digital adherence technologies may allow more comprehensive ascertainment of adherence estimates in a more patient-centered manner [18-20].

Recent World Health Organization guidance has suggested that video directly observed therapy (vDOT) may replace DOT when video communication technology is available and can be appropriately administered, and its use has increased in US settings [9,16]. vDOT uses computer and other mobile devices to either synchronously (real time) or asynchronously (recorded) monitor a patient taking their TB medication and promote treatment adherence remotely [16,21,22]. Other benefits include facilitating adherence monitoring 7 days per week, being less resource intensive, and allowing flexibility in the timing of medication use for patients [16,20-23].

Previous studies, including randomized trials, demonstrated either noninferiority of vDOT to DOT for verifying scheduled weekday doses, or found that a greater proportion of prescribed doses can be verified using vDOT under study conditions [18,24-27]. Our group has previously assessed vDOT implementation under routine programmatic circumstances in a large urban clinic in the United States after an initial pilot period, and similarly found that vDOT led to higher proportions of verified prescribed doses than in person [20]. However, there are limited data on vDOT effectiveness and technology adoption in programs without prior experience with the technology.

We sought to evaluate vDOT use and effectiveness in a clinic with no prior vDOT experience and to understand patterns of technology adoption since the onset of the COVID-19 pandemic. In the Hennepin County Minnesota Public Health Department, the standard of care for TB treatment monitoring before Sept 2019 involved in-person DOT, Monday to Friday; vDOT technology was subsequently made available for routine use at the discretion of the TB clinic. We assessed the initial implementation of vDOT into the clinic and characterized technology effectiveness and adoption over time through a prospective pragmatic implementation study, beginning in 2019 when vDOT became available.

Methods

Overview

We conducted a pragmatic, prospective observational cohort study of TB treatment monitoring measured by self-report, in-person DOT, and asynchronous vDOT under routine conditions at the Hennepin County Public Health Clinic's Tuberculosis Program in Minneapolis Minnesota, a setting without prior vDOT use or experience [22].

Ethical Considerations

Patients with signed disclosures and authorization for release of records in accordance with the Minnesota Health Records Act were included. Protocols were approved by the ethics committees at Johns Hopkins University, with reliance agreements established with Hennepin Healthcare Research Institute (IRB00174219).

Study Population

We abstracted routinely collected clinical data from electronic medical records for patients receiving treatment for active TB, who had signed disclosures and authorization for release of records in accordance with the Minnesota Health Records Act, from Sept 2019 to March 2021, with treatment follow-up available until June 2021 [28]. We only included patients who were ≥ 18 years of age, as pediatric patients may have different considerations for using DOT and vDOT warranting a dedicated study [29]. In addition, we only included patients with ≥ 2 months of therapy remaining to ensure participants had sufficient follow-up time to measure adherence. vDOT (emocha Mobile health) became available for use within the Hennepin County Public Health Clinic TB program beginning Sept 2019 (Figure S1 in [Multimedia Appendix 1](#)).

Tuberculosis Care

As part of routine care, the TB program individualizes the modality of TB treatment monitoring (ie, self-report, vDOT, and in-person DOT) using locally developed protocols and in accordance with Hennepin County Public Health Clinic guidelines, following a shared decision-making paradigm with patients [30]. Local protocols excluded vDOT initiation in patients with current positive sputum acid-fast bacillus (AFB) smears; vDOT initiation was considered once patients were smear negative. There were no exclusion criteria for patients with drug-resistant TB or prior treatment adherence when determining modality for TB treatment monitoring. Providers

and patients are allowed to switch from treatment modalities as deemed necessary based on individual circumstances.

Most patients with active TB were treated with standard therapy (rifampin, isoniazid, pyrazinamide, and ethambutol) 7 days per week. Routine treatment monitoring for in-person DOT included a health care worker observing treatment ingestion at the patient's home or agreed location during weekdays (ie, Monday to Friday), with the exception of government holidays; other doses were self-administered, and adherence was determined by self-report.

Patients using vDOT were instructed to submit videos documenting ingestion of medications according to their prescribed schedule (ie, 7 days per week), and were given initial training into the vDOT software including demonstrations and instructions [31]. Patients received SMS reminders twice per day on days a video was expected, and the software allowed for secure chat between the patient and health care team in the case of questions or issues; the software was available in multiple languages. Videos were reviewed by either a nurse case manager or community health worker, typically the next business day. Patient inquiries were triaged and answered by either nurse case managers or community health workers during business hours.

Statistical Analysis

The “reach” or use of vDOT was defined as the proportion of patients in whom vDOT was used for treatment monitoring. We calculated effectiveness based on the *verified adherence*, defined as the proportion of total prescribed doses that were verified by in-person DOT or vDOT. Unobserved doses were considered either missed or “self-administered” if reported to be taken by the patient and documented as self-reported adherence in clinical charts (ie, doses during the weekend, holidays, or other occasions during a period of in-person DOT monitoring) [18,20,24]. We assessed observation time periods as “in-person” or “vDOT” based on the scheduled modality for treatment monitoring. We used 2-sample, 2-tailed *t* tests and chi-square tests to quantify the differences in clinical and demographic characteristics comparing in-person DOT and

vDOT, at an alpha of .05 to determine statistical significance. We assessed the association of potentially relevant clinical and demographic factors with the receipt of vDOT using a multivariable logistic regression; covariates were included in the model based on clinical relevance to the outcome of interest (age, sex, race, English proficiency, alcohol use, resistance, initial AFB smear status, site of TB, and COVID-19 period). To evaluate vDOT use over time due to increased experience with the tool and to assess the impact of COVID-19, we divided the observation period into approximately 6-month increments: September 2019-February 2020 (ie, pre-COVID-19 period), March 2020-August 2020 (early COVID-19 period), and September 2020-March 2021 (intra-COVID-19 period); periods after March 2020 were the considered post-COVID-19 period. All analyses were conducted in STATA 16 (StataCorp).

Results

Participant Characteristics

A total of 96 patients received treatment for active TB during the study period in the health department TB clinic, of which 49 (51%) signed disclosures allowing their charts to be abstracted for this study (n=31, 32% in the pre-COVID-19, n=11, 11% in the early COVID-19, and n=7, 7% in the intra-COVID-19 periods). Moreover, 96% (47/49) of the studied patients were non-US born, with the most commonly reported primary languages being English (28/49, 57%), Somali (11/49, 22%), Spanish (4/49, 8%), and Hmong (3/49, 6%; Table 1). Patients were classified as having pulmonary TB (n=20, 41%), extrapulmonary TB (n=22, 45%), or both (n=7, 14%; Table 1). Additionally, 7 (14%) patients had drug resistant disease, and 22 (45%) patients had AFB smear-positive disease at treatment onset (Table 1). The median treatment duration was 29.7 weeks (IQR 26-43), and it was longer in patients with exclusively pulmonary TB (median 38 weeks, IQR 29-66) compared to those with some extrapulmonary TB (median 27.5 weeks, IQR 26-39; $P=.02$). Additional patient characteristics are shown in Table 1.

Table 1. Patient characteristics.

^aThere were no significant differences in age, ethnicity, birth country, English proficiency, employment, homelessness, HIV, drug resistance, initial acid-fast bacillus smear status, or site of tuberculosis (TB) across the study periods. There were significantly more females with TB in the post-COVID-19 period (14/18, 78%) compared with the pre-COVID-19 period (13/31, 42%; $P=.02$).

^bvDOT: video directly observed therapy.

^cNo vDOT represents a combination of patients with self-administered and in-person directly observed therapy.

^dAge as of TB treatment start date.

^eTB: tuberculosis.

^fNo patients at the clinic were treated with injectable medications during the study period.

^gAFB: acid-fast bacillus.

^hPTB: pulmonary tuberculosis.

ⁱEPTB: extrapulmonary tuberculosis.

Reach of vDOT Compared to In-Person DOT

All patients had treatment monitored using in-person DOT, video-DOT, or some combination. vDOT was used for some portion of care in 47% (23/49) of patients, while the remainder (26/49, 53%) were monitored exclusively through in-person DOT (with self-administration during weekends, holidays, and per-clinic discretion; [Table 1](#)).

Overall, there was a trend toward increasing vDOT use when comparing each 6-month period, with 35% (11/31) using vDOT in the first 6 months after the technology became available (ie, pre-COVID-19), 64% (7/11) in the second 6 month (early COVID-19 period), and 71% (5/7) in the final

(intra-COVID-19) period (ie, 1 year after vDOT became available; $P=.10$; [Table 2](#)). When comparing the pre-COVID-19 period to after the onset of COVID-19 (ie, early and intra-COVID-19 periods combined), significantly more patients used vDOT in the post-COVID-19 period (12/18, 67%) compared to the pre-COVID-19 period (11/31, 35%; $P=.04$). Among individuals initiating therapy after vDOT was available, the median time to start vDOT relative to TB treatment initiation date was 7 days (IQR 0-78). In-person DOT was initiated at the same time as treatment in the clinic (median 0 days, IQR 0-26). There was no difference in the overall treatment duration among those receiving vDOT (median 29.7 weeks, IQR 26-39.4) and those who did not receive vDOT (median 31, IQR 26.1-52; $P=.67$).

Table 2. Primary outcomes by study period.

Variable	Overall (n=49)	Study period 1 ^a (n=31)	Study period 2 ^a (n=11)	Study period 3 ^a (n=7)	P value ^b
vDOT ^c use, n (%)	23 (47)	11 (35)	7 (64)	5 (71)	.10
Verified adherence (%), mean (SD)^d					
vDOT ^c	81 (17.4) ^f	76.1 (19.9)	81.9 (16.6)	90.7 (9.0)	.31
In-person DOT ^{e,g}	54.5 (10.9) ^f	54.6 (9.8)	47.7 (13.3)	65.4 (6.7)	.03
Overall (irrespective of monitoring modality)	61.7 (16.6)	56.1 (10.0)	66.6 (24.2)	79 (13.3)	.001
Self-administered therapy (%), mean (SD)^h					
During vDOT	10.8 (12.9)	15.6 (15.6)	6.6 (9.3)	6.1 (7.5)	.24
During in-person DOT	44.1 (10.9)	44.2 (10.1)	49.1 (14.0)	34.6 (6.7)	.11
Overall (irrespective of monitoring modality)	35.6 (17.2)	41.9 (10.2)	28.6 (24.5)	18.8 (14.9)	<.001

^aStudy period 1 is defined as the first 6 months of the study period from September 2019 to February 2020. Study period 2 is defined as the second 6 months of the study period from March 2020 to August 2020. Study period 3 is defined as the final study period from September 2020 to March 2021.

^bP values represent comparisons across study periods (by row).

^cvDOT: video directly observed therapy.

^dVerified adherence is defined as doses that were observed by either in-person or vDOT divided by the total number of prescribed doses.

^eComparing verified adherence between those receiving vDOT and in-person DOT, adherence was higher in all study periods when using vDOT ($P<.001$, $P=.001$, $P=.002$, for periods 1, 2, and 3, respectively).

^fThe overall verified adherence from vDOT (median 86%, IQR 71-99), was significantly greater than the overall verified adherence from in-person DOT (median 57%, IQR 47-63, $P=.001$).

^gDOT: directly observed therapy.

^hA greater proportion of doses was self-administered when using in-person DOT compared to vDOT overall and in each study period ($P<.001$ for all comparisons).

In univariate analysis ([Table 1](#)), mean age of individuals receiving vDOT was lower (35) compared to those not receiving vDOT (46; $P=.04$); a larger proportion of women (17/27, 63%)

received vDOT compared to men (6/22, 27%; $P=.01$; [Table 1](#)). However, in multivariate analysis adjusting for other covariates, the adjusted odds ratios (AORs) revealed that neither sex (AOR

0.23, 95% CI 0.29-1.83) nor age category (AOR 0.27, 95% CI 0.03-2.5; AOR 3.0, 95% CI 0.02-455; and AOR 0.06, 95% CI 0.01-2.4 for individuals 30-50, 50-65, and >65 years old compared to those <30 years old, respectively) was associated with vDOT use. There was a trend toward increased vDOT use after the onset of COVID-19 (AOR 10.1, 95% CI 0.57-176; $P=.11$), but it was not statistically significant; no other clinical or demographic features, including race, English proficiency, alcohol use, site of TB disease, initial smear status, or drug resistance, were found to be associated with vDOT use. All patients successfully completed treatment irrespective of adherence monitoring modality (or were censored at the end of the study period).

Effectiveness of vDOT Compared to In-Person DOT

Overall, the mean *verified adherence* (proportion of prescribed doses verified through observation) was significantly higher when using vDOT (mean 81%, SD 17.4; median 86%, IQR 71-99), compared to in-person DOT (mean 54.5%, SD 10.9; median 57%, IQR 47-63; $P=.001$; Table 2).

These findings were driven by the high proportion of “self-administered” doses when using in-person DOT (mean 44.1%, SD 10.9; median 41%, IQR 36-47) compared to periods when patients were using vDOT (mean 10.8%, SD 12.9; median 5%, IQR 0-16; $P<.001$). By contrast, few doses were documented as missed (median <1%, IQR 0-1.2) when using in-person DOT; overall, among prescribed doses (7 days per week), a median of 1% (IQR 0-11) was documented as missed when using vDOT ($P=.11$).

Effectiveness of vDOT Compared to In-Person DOT by Study Period

We found a trend toward greater verified adherence using vDOT over the time period of implementation, but it was not statistically significant (mean 76%, 82%, and 91%, in the pre-COVID-19, early COVID-19, and intra-COVID-19 study periods, respectively; $P=.31$; Table 2). In all time periods, adherence was higher when using vDOT compared to in-person DOT ($P<.01$ for each period; Table 2).

As a result of an increasing proportion of patients in whom vDOT was used for adherence monitoring, we found that overall adherence increased in the population across successive periods of observation (mean 56%, 67%, and 79% for each study period, respectively; $P=.001$; Table 2). We also found that the overall proportion of treatment doses documented as self-administered declined across study periods (42%, 29%, and 19%, respectively; $P<.001$; Table 2), which is attributable to the increasing vDOT use.

Discussion

Principal Results

Paradigms for documenting TB treatment adherence are evolving given the logistical constraints with in-person DOT since the onset of the COVID-19 pandemic and with the prioritization of daily TB therapy 7 days per week [4,9]. Several clinical trials have reported that video-observed therapy is effective at documenting TB treatment under study conditions,

but data to inform programmatic implementation are limited [25,27]. We previously reported that vDOT use was high under routine conditions in a clinic with established prior vDOT experience. In this prospective cohort study, at a vDOT naïve clinic (ie, no prior experience) in Minnesota, we found progressively increasing adoption of vDOT for patients with active TB disease [20]. Unsurprisingly, initial use of vDOT was slow ($n=11$, 35% of patients; Table 2); however, 1 year after vDOT availability, we found the TB program used vDOT preferentially in nearly three-quarters of patients. The shift toward monitoring treatment for all prescribed doses has clinical implications; vDOT was more effective than in-person DOT for verifying ingestion of prescribed TB treatment, allowing median documentation of adherence for 86% of the prescribed doses; by contrast, median in-person DOT verified adherence was 57%, owing to a large proportion of self-reported doses (Table 2). These data are consistent with findings in other study conditions [18,20,24,25]. With increasing vDOT use over time, we consequently found that the overall verified adherence among all patients in the clinic increased from 56% in the first 6 months of vDOT availability (pre-COVID-19 period) to 79% in the last 6 months of the study, despite programmatic disruptions and diminished staff during the COVID-19 pandemic (Table 2).

Several factors likely influenced our results and the observed “digital transformation” of health care. The adoption of vDOT in the Hennepin County Public Health Clinic TB program follows the “technology-push” paradigm, in which health care workers are in the process of implementing a tool foreign to them [32]. Commonly, the novelty of new tools and disruption to well-established routines often lead to lower initial use, as seen in our study [32]. Furthermore, health care providers’ perception of telemedicine may be negatively influenced by concerns surrounding telemedicine project funding, ease of use, and patient preferences [33].

The onset of the COVID-19 pandemic in March 2020 significantly impacted the TB clinic as well. The program staff of 4 full-time outreach Community Health Workers was reduced to 1.5 to 2 full-time equivalent workers at various times throughout the pandemic. Consequently, the reduction of in-person services caused by the COVID-19 pandemic likely accelerated the adoption of vDOT, along with growing comfort and experience with the technology. More generally, expansion of telemedicine and digitally enabled communication during the pandemic may also have contributed to greater acceptance of using digital adherence technologies among health care providers and patients [33,34].

In addition to these reasons, the continued use of vDOT technology over the course of the study period may also be partially due to the significantly larger proportion of prescribed doses that were verifiable using vDOT compared to in-person DOT. These findings are largely attributable to the reduction in the number of self-administered doses over weekends and holidays offered by vDOT compared to in-person DOT and is consistent with findings from other programmatic studies. Additionally, prior concerns within the Hennepin County TB program regarding costs and lost revenue associated with

reimbursements were mitigated by the program's ability to bill for vDOT visits based on local practices.

Limitations

Our study has several limitations. Due to local regulatory requirements, we were only able to abstract data from patients who had signed a disclosure and authorization for release of information; alternatively, this patient decision was independent of our specific study, and is unlikely to have led to significant selection biases as related to choice of treatment monitoring modality or adherence. We also were unable to differentiate the impact of COVID-19 (eg, staffing changes and lockdowns) and the natural process of technology adoption as staff became more familiar and comfortable with the platform. Our study setting implemented vDOT 7 days per week to allow the assessment of adherence to daily prescribed therapy; our study results may not be generalizable to clinics that prescribe treatment according to alternative dosing schedules (eg, 5 days per week or thrice weekly).

Comparison With Prior Works

While self-report or pill counts, in-person DOT, vDOT, and other digital technologies (eg, smart pill boxes) each provide a different level of certainty related to medication ingestion, they each broadly provide a measure of adherence. Our results add to the growing literature on the feasibility, acceptability, and effectiveness of video-DOT [18,20,24,25] for adherence measurements, but they also raise important considerations for the reevaluation of current paradigms in documenting TB treatment adherence. Recently, a large randomized trial found that electronic DOT was noninferior to in-person DOT at monitoring "scheduled" doses (Monday-Friday) but did not report adherence to all prescribed doses [27]. Our study highlights the limitations of this approach. Existing protocols for determining adherence used by many TB clinics offers incomplete assessments of true adherence by monitoring only a fraction of prescribed doses; for example, achieving 80%

documentation of Monday-Friday doses (with limited certainty of ingestion of prescribed weekend doses) represents documentation of only 57% of prescribed doses. We acknowledge that there are currently limited data on the optimal thresholds for determining the proportion of prescribed treatment that should be verified. Moreover, correlation of treatment verification and specifically added weekend treatment verification with clinical outcomes is also limited. Nonetheless, our results show that adoption of vDOT in a large urban clinic allowed verification of true adherence to above 80%, including weekend doses, and offered more comprehensive categorization of all treatment doses. Previously, we have also found that vDOT may reduce stigma and increase logistical convenience, while also allowing TB programs to reduce costs and reallocate resources more efficiently [18]. Notably, treatment adherence improved during the course of the study despite reductions in staff.

Conclusions

Our results should be interpreted in the context of individualized decision-making as is advocated by current guidelines. Some individuals continued to receive in-person DOT based on tailored individual considerations; while our prior work has suggested that older age may be associated with a lower likelihood of initiating vDOT in other settings, we did not find specific clinical or demographic factors associated with vDOT selection in this clinic [24]. We also note that provisions for adherence support (eg, psychological support, nursing support, and other incentives and enablers) were made in conjunction with decisions on deciding treatment modality for monitoring; in this manner, adherence support interventions should be viewed adjunctively and are not synonymous with DOT or vDOT. Other elements of adherence support built into the chosen vDOT system included electronic reminders, secure chat, and ability to document symptoms and side effects, which may have also impacted the results.

Abstract

Background: The COVID-19 disease results from infection by the SARS-CoV-2 virus to produce a range of mild to severe physical, neurological, and mental health symptoms. The COVID-19 pandemic has indirectly caused significant emotional distress, triggering the emergence of mental health symptoms in individuals who were not previously affected or exacerbating symptoms in those with existing mental health conditions. Emotional distress and certain mental health conditions can lead to violent ideation and disruptive behavior, including aggression, threatening acts, deliberate harm toward other people or animals, and inattention to or noncompliance with education or workplace rules. Of the many mental health conditions that can be associated with violent ideation and disruptive behavior, psychosis can evidence greater vulnerability to unpredictable changes and being at a greater risk for them. Individuals with psychosis can also be more susceptible to contracting COVID-19 disease.

Objective: This study aimed to investigate whether violent ideation, disruptive behavior, or psychotic symptoms were more prevalent in a population with COVID-19 and did not precede the pandemic.

Methods: In this preliminary study, we analyzed questionnaire responses from a population sample (N=366), received between the end of February 2021 and the start of March 2021 (1 year into the COVID-19 pandemic), regarding COVID-19 illness, violent ideation, disruptive behavior, and psychotic symptoms. Using the Wilcoxon rank sum test followed by multiple comparisons correction, we compared the self-reported frequency of these variables for 3 time windows related to the past 1 month, past 1 month to 1 year, and >1 year ago among the distributions of people who answered whether they tested positive or were diagnosed with COVID-19 by a clinician. We also used multivariable logistic regression with iterative resampling to investigate the relationship between these variables occurring >1 year ago (ie, before the pandemic) and the likelihood of contracting COVID-19.

Results: We observed a significantly higher frequency of self-reported violent ideation, disruptive behavior, and psychotic symptoms, for all 3 time windows of people who tested positive or were diagnosed with COVID-19 by a clinician. Using multivariable logistic regression, we observed 72% to 94% model accuracy for an increased incidence of COVID-19 in participants who reported violent ideation, disruptive behavior, or psychotic symptoms >1 year ago.

Conclusions: This preliminary study found that people who reported a test or clinician diagnosis of COVID-19 also reported higher frequencies of violent ideation, disruptive behavior, or psychotic symptoms across multiple time windows, indicating that they were not likely to be the result of COVID-19. In parallel, participants who reported these behaviors >1 year ago (ie, before

the pandemic) were more likely to be diagnosed with COVID-19, suggesting that violent ideation, disruptive behavior, in addition to psychotic symptoms, were associated with COVID-19 with an approximately 70% to 90% likelihood.

Introduction

Background

The COVID-19 disease results from infection by the single-stranded RNA virus SARS-CoV-2. Physically, COVID-19 can produce a range of mild symptoms, including fever, cough, shortness of breath, fatigue, muscle aches, headache, and new loss of taste or smell [1], to severe symptoms requiring ventilation in an intensive care unit because of respiratory failure, septic shock, and multiple organ dysfunction [1]. In the context of mental function, COVID-19 has been linked to significant cognitive and attention deficits, brain fog, anxiety, depression, and sleep problems [2,3]—all of which can affect mental health and well-being.

The COVID-19 pandemic has burdened the mental health of both those infected with SARS-CoV-2 and those who have been living through the pandemic without infection. The pandemic has indirectly caused worldwide emotional distress that has triggered the development of mental conditions in persons not previously affected and exacerbated symptoms in those with existing conditions [4-7]. Numerous COVID-19 research reviews have reported the adverse psychological effects brought on by pandemic-related stressors, including posttraumatic stress symptoms, confusion, and anger [8]. The management of behavioral symptoms in patients with COVID-19 (eg, agitation) has become a unique challenge for health care workers in emergency departments [9]. COVID-19 can be particularly distressing to individuals with pre-existing mental health conditions such as autism spectrum disorders and other neurodevelopmental disorders, leading to more intense and frequent behavior problems, including disruptive behavior [10] or increased externalizing and aggressive behavior [11].

Many mental health conditions can lead to violent ideation and disruptive behavior (VIDB), which is defined by aggression, threatening acts, or deliberate harm toward other people or animals, as well as inattention and noncompliance in education or workplace settings [12,13]. For instance, people with substance use disorders [14,15], mania [16,17], psychosis [18,19], and personality disorders [20,21] can all evidence VIDB or be at an increased risk for adverse psychosocial outcomes during pandemic-related periods of stress. Individuals with mild to severe symptoms of psychosis (eg, delusions, paranoia, and hallucinations) have been reported to be susceptible to pandemic-related emotional distress [18,19]. The 12-month prevalence of psychosis is 3.89 to 4.03 per 1000 individuals, and the median lifetime prevalence is 7.49 per 1000 individuals [22]. Prior research has shown that people with psychosis are less likely to take precautionary measures such as receiving vaccination or isolating during the influenza pandemic [23],

thereby increasing their potential risk for COVID-19 infection. As with autism spectrum disorder, individuals with psychosis can show greater vulnerability to unpredictable changes, such as COVID-19, and are thus at greater risk for VIDB [24,25].

Objective

In this preliminary study, we assessed potential relationships among COVID-19 infection, VIDB, and symptoms related to psychosis, which may increase the risk of infection and VIDB. Psychotic symptoms and VIDB increase the potential for engagement in riskier-than-average behaviors, potentially including nonadherence to COVID-19 precautions. Individuals exhibiting VIDB and psychotic symptoms could thus be at a greater risk of contracting and spreading the virus. Although these associations are not directional, any findings between VIDB and psychotic symptoms with COVID-19 would permit hypothesis framing for two scenarios: (1) COVID-19 infection increases the likelihood of psychosis and VIDB or (2) psychotic symptoms and VIDB increase the possibility of COVID-19 infections. Other viral infections, including influenza and HIV, have led to similar hypotheses [26-34]. To do this, we analyzed questionnaire responses regarding COVID-19 history along with historical questions regarding VIDB and psychotic symptoms over 3 time windows in a small but representative internet sample that followed the US Census (ie, 300 < n < 500). The questionnaire was distributed between the end of February 2021 and the start of March 2021 and was timed to overlap with the onset of the COVID-19 pandemic 1 year earlier. We assessed the frequency of self-reported VIDB and symptoms of psychosis from the past 1 month, 1 month to 1 year ago, and >1 year ago among participants with and without self-reported COVID-19. Given the existing case reports of an increased incidence of VIDB and psychotic symptoms during the pandemic, we hypothesized that participants with COVID-19 would exhibit an increase in VIDB and psychotic symptoms. We also investigated the relationship between these behaviors occurring >1 year ago and the likelihood of contracting SARS-CoV-2 with the hypothesis that people with these behaviors were more likely to experience COVID-19 infection. We used multivariable logistic regression (MVLRL) with iterative resampling to investigate how accurately VIDB and psychotic symptoms from before the pandemic discriminated between participants with and without self-reported COVID-19.

Altogether, the results of this study show that individuals with VIDB and psychotic symptoms have an increased risk for SARS-CoV-2, although long-term longitudinal data will be needed to assess causal relationships.

Methods

Participant Recruitment

Study participants were recruited by Gold Research Inc from multiple vendors. Gold Research vendors recruit the emails of willing participants in multiple ways. Some are recruited *by invitation only* from customer databases of large companies in revenue-sharing agreements, some are recruited from social media, some through direct mail, and others sign up voluntarily to participate in research studies in lieu of monetary or other incentives such as coupons for everyday household purchases. During recruitment, all survey respondents also go through a double opt-in process to indicate the types of research studies they would like to participate in, in addition to providing their profiles on different demographic attributes such as age, race, and sex. This information is then used to reflect representation against US Census metrics. In this process, respondents are also asked multiple test questions to screen out those providing random and illogical responses or showing flatline or speeder behavior. In addition to having cohort demographics balanced to meet the demographic criteria established by the US Census, Gold Research also oversampled 15% (7500/50,000) of the sample for mental health conditions. Gold Research reported that >50,000 respondents were contacted for questionnaire completion. They estimated that of the 50,000 participants, >37,500 (75%) either did not respond or said no. Of the remaining 25% (12,500/50,000) of participants who clicked on the survey link, >50% did not complete the questionnaire. Of the ≥6000 participants who completed the survey, those who did not clear the data integrity assessments were omitted to achieve the final number of completed surveys. Participants meeting quality assurance procedures (including completion of the survey) were studied, with a limit of 500-520 participants. All participants provided informed consent following oversight from the Northwestern University Institutional Review Board, and a double opt-in methodology was used for consenting (shown later in the following section).

This study assessed multiple mental health conditions, including psychotic symptoms, violent ideation, and disruptive behavior. For this paper, we focused only on psychotic symptoms, violent ideation, and disruptive behavior. All participants provided informed consent following oversight from the Northwestern University Institutional Review Board, which reviewed and approved the project procedures, including the use of a double opt-in methodology for consenting. Participants were guaranteed anonymity and confidentiality, and the researchers did not possess any protected health information. Questionnaire responses were collected between the end of February 2021 and the beginning of March 2021, approximately 1 year after the official pandemic declaration in the United States (March 11, 2020) [35] (Figure 1). Data integrity assessment (see the *Data Quality Assurance* section) reduced the final sample size to 366 participants.

Participants reported their age, sex, ethnicity, handedness, annual household income, employment status, level of education, and years of schooling. A total of 506 participants (mean age 47, SD 15 years) completed the study by Gold Research Inc. After quality assurance, participants were found to be 57.9% (212/366) female, 68% (249/366) White, 82% (300/366) right-handed, 42.6% (156/366) employed full-time, and 28.7% (105/366) with some college education (mean years of schooling 13, SD 5 years), approximating the national averages for these measures. A complete summary of the demographic variables is provided in Table 1.

Participants were asked questions related to COVID-19, as shown in Textbox 1. They were asked to report whether they had ever had a positive COVID-19 test (yes or no; *test+*), whether they were ever diagnosed with COVID-19 by a medical professional (yes or no; *diagnosis*), and whether a family member or close friend had experienced serious symptoms or died of COVID-19 (yes or no; *family*). Of the 366 participants, 36 (9.8%) reported a positive COVID-19 *test+*, and 34 (9.3%) reported a COVID-19 *diagnosis*; 26 (7.1%) participants answered *yes* to both the COVID-19 *test+* and *diagnosis*. Of the 366 participants, 95 (26%) reported that a family member or close friend had serious symptoms or had died of COVID-19.

Figure 1. Timeline for survey data collection.

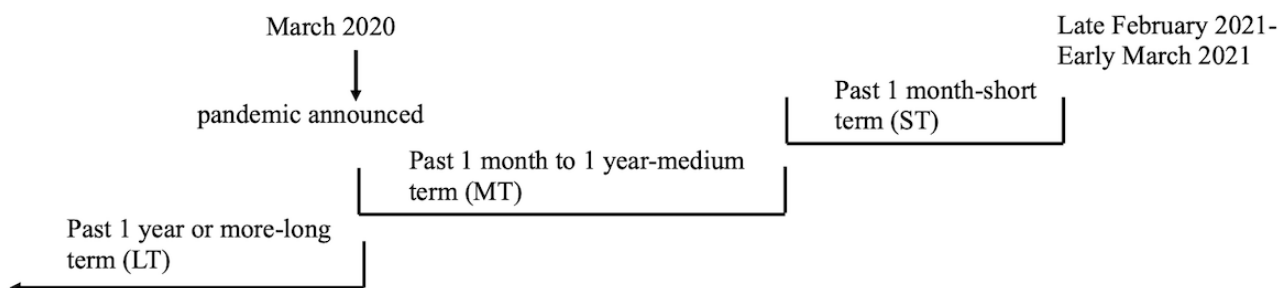

Table 1. Summary statistics of the demographic variables reported by the participants, including age, gender, ethnicity, handedness, annual household income, employment status, level of education, and years of schooling (N=366).

Variable	Values
Age (years)	
Participants, n (%)	366 (100)
Value, mean (SD; range)	46.67 (15.40; 18-70)
Years of schooling	
Participants, n (%)	366 (100)
Value, mean (SD; range)	13.29 (5.04; 1-30)
Sex, n (%)	
Male	153 (41.8)
Female	212 (57.9)
Other	1 (0.3)
Ethnicity, n (%)	
White	249 (68)
African American	48 (13.1)
Hispanic	29 (7.9)
Asian American or Pacific Islander	13 (3.6)
Native American or Alaskan Native	18 (4.9)
Mixed race	3 (0.8)
Other	3 (0.8)
Prefer not to answer	3 (0.8)
Handedness, n (%)	
Right	300 (82)
Left	52 (14.2)
Both	14 (3.8)
Level of education, n (%)	
Some high school	6 (1.6)
High school graduate	95 (26)
Some college	105 (28.7)
Bachelor degree	83 (22.7)
Some graduate school	12 (3.3)
Graduate degree	27 (7.4)
Postgraduate or doctorate	38 (10.4)
Employment status, n (%)	
Unemployed	58 (15.8)
Full-time	156 (42.6)
Part-time	41 (11.2)
Self-employed	24 (6.6)
>1 job	3 (0.8)
Retired	61 (16.7)
Other	23 (6.3)
Annual household income (US \$), n (%)	
<25,000	86 (23.5)

Variable	Values
25,000-50,000	92 (25.1)
50,000-75,000	70 (19.1)
75,000-100,000	47 (12.8)
100,000-150,000	37 (10.1)
150,000-300,000	26 (7.1)
>300,000	8 (2.2)

Textbox 1. COVID-19–related questions from the survey and their abbreviations used in this study.

Abbreviations used and COVID-19 questions (yes or no)

- Test+
 - Have you ever tested positive for COVID-19?
- Diagnosis
 - Have you ever been diagnosed with COVID-19 by a medical clinician?
- Family
 - Has anyone in your family or group of friends had serious symptoms or died of COVID-19?

Power analysis for a 2-sample Wilcoxon rank sum test revealed an estimated power of >0.80 for the experimental conditions based on *test+* (sample size for *test+* was 36 and sample size for no *test+* was 330; $\alpha=.05$) and an estimated power >0.9 for experimental conditions based on *diagnosis* (sample size for *diagnosis* was 34 and sample size for no *diagnosis* was 332; $\alpha=.05$). This power suggests that we had statistically adequate sample sizes for the analysis that follows.

For initial recruitment, participants received the following communication:

Gold Research Inc., a national market research firm and its client, Northwestern University, request your participation in this study of emotional health. We will be evaluating how different emotions and experiences are connected and may relate to our emotional health. The information you provide will be kept confidential, coded to be anonymous so it cannot be connected back to you and will be used only for research purposes. Researchers will not be able to contact you or restudy you after this survey. We will not share your information with any other third party. We will also not use your information to identify you individually or use your responses to market or sell other services or products to you. As part of this effort, you will not be asked to provide any personal identifiers such as your name, email, phone number, address or social media handles. A unique identifier will be generated for you and each survey participant to enhance privacy. As part of the survey process, we will be able to tell if you completed the survey, but we will not be able to tell which answers were yours. For this study, we are going to ask you some questions about yourself and how much

you like or dislike a set of pictures. You may discontinue this study at any time. We appreciate your help with this study, given the serious challenges facing many people regarding emotional health at this time. We thank you in advance.

1. Accept
2. Decline

If participants responded with “Accept,” they were sent a further communication with the following:

Thank you for participating in our survey. All responses during this survey are anonymous and confidential. We will be able to tell if you completed the survey, but we will not be able to tell which answers were yours. In this study, we aim to understand how different emotions and experiences relate to visual processing.

We are going to:

**Ask you some questions about yourself*

**Have you rate how much you like or dislike a set of pictures*

For this study, your identity is protected and your answers are anonymous and confidential. Press “Next” to proceed.

The survey would then begin if participants pressed “Next.”

Ethics Approval

Participants were offered notice that Gold Research administered an emotional health questionnaire on behalf of Northwestern University, with the following phrasing: “We will be evaluating how different emotions and experiences are connected and may relate to our emotional health.” The complete text related to the solicitation, study description, and opt-in procedures can be

found in the *Methods under Participant Recruitment*. All participants provided informed consent following oversight from the Northwestern University Institutional Review Board (approval number STU00213665), which reviewed and approved the project proposal. Participants were guaranteed anonymity and confidentiality, and the researchers did not possess any protected health information.

Survey Questions and Scoring

The survey comprised several blocks of questions from existing questionnaires on depression, anxiety, suicidality, addiction, psychosis, VIDB, and COVID-19 infection, in addition to demographic and historical diagnoses of mental health disorders. A picture-rating task was also administered; however, it is not the focus of this study. This study assessed the relationships among psychotic symptoms, VIDB, and COVID-19 infection. Questions about VIDB and 4 positive psychotic symptoms were taken from the behavioral neurology screening questions in the Massachusetts General Hospital Subjective Question (MGH SQ) Screener from the Phenotype Genotype Project in Addiction and Mood Disorder [36]. The MGH SQ has been used in several studies [37-43]. Of the 13 questions used here, 4 were related to positive psychotic symptoms (auditory and visual hallucinations, paranoia, and delusions), which had originally been adapted to the MGH SQ from a clinical textbook on emergency psychiatry (Textbox 2, Psych1-Psych4) [44]. A total

of 9 other questions were related to VIDB (eg, wanting to hurt others, prior attempts to hurt others or animals, wanting to start fires, being disruptive, or breaking rules) and were similarly adapted to the MGH SQ using the same clinical textbook on emergency psychiatry (Textbox 2, Disruption1-Disruption9) [44]. Participants rated the questions based on how often they experienced these behaviors as follows: (1) *past ≥1 year* (long term), (2) *past 1 month to 1 year* (medium term), and (3) *past 1 month* (short term; Figure 1 provides the timeline) on a 1 to 7 Likert scale (1=never; 2-3=rarely; 4-5=sometimes; 6=often; 7=always; Figure 2). The data were collected regarding psychotic symptoms and VIDB from the past 1 month (short term) and between 1 month and 1 year (medium term) to assess and relate these symptoms and behaviors during the recent past to COVID-19 infection. We chose a 1-month cutoff to obtain the most recent history, similar to what is done for timeline follow-back methods with substance use or menstrual cycle assessments. The data from >1 year ago (long term) were collected to assess these behaviors before the pandemic and to determine whether a history of psychosis and VIDB before the pandemic influenced a person's likelihood of COVID-19 infection. This would provide insight into the participants' current state and how COVID-19 infection or the pandemic, in general, has affected the general population. All 13 questions are listed in Textbox 2 as they appeared in the survey.

Textbox 2. The 13 questions from the larger survey related to psychosis and violent ideation and disruptive behavior that was used in this study for 3 time windows (long term, medium term, and short term) for which participants answered each question.

Questions and time windows

- Psych1-LT
 - Hallucinations/Hearing voices others cannot past ≥ 1 year
- Psych1-MT
 - Hallucinations/Hearing voices others cannot past 1 month to 1 year
- Psych1-ST
 - Hallucinations/Hearing voices others cannot past 1 month
- Psych2-LT
 - Hallucinations/Seeing things others cannot see past ≥ 1 year
- Psych 2-MT
 - Hallucinations/Seeing things others cannot see past 1 month to 1 year
- Psych2-ST
 - Hallucinations/Seeing things others cannot see past 1 month
- Psych3-LT
 - Worries that others are out to get you or to get people close to you (these might resemble paranoia) past ≥ 1 year
- Psych 3-MT
 - Worries that others are out to get you or to get people close to you (these might resemble paranoia) past 1 month to 1 year
- Psych3-ST
 - Worries that others are out to get you or to get people close to you (these might resemble paranoia) past 1 month
- Psych4-LT
 - Having one or more unique beliefs or impressions that are strong despite being contradicted by others (these might resemble delusions) past ≥ 1 year
- Psych 4-MT
 - Having one or more unique belief or impression that is strong despite being contradicted by others (these might resemble delusions) past 1 month to 1 year
- Psych4-ST
 - Having one or more unique belief or impression that is strong despite being contradicted by others (these might resemble delusions) past 1 month
- Disruption1-LT
 - Wanting to hurt others past ≥ 1 year
- Disruption 1-MT
 - Wanting to hurt others past 1 month to 1 year
- Disruption1-ST
 - Wanting to hurt others past 1 month
- Disruption2-LT
 - Prior attempts at hurting others past ≥ 1 year
- Disruption 2-MT

- Prior attempts at hurting others past 1 year to 1 month
- Disruption2-ST
 - Prior attempts at hurting others past 1 month
- Disruption3-LT
 - Having a plan for not hurting others when these feelings arise past ≥ 1 year
- Disruption3-MT
 - Having a plan for not hurting others when these feelings arise past 1 year to 1 month
- Disruption3-ST
 - Having a plan for not hurting others when these feelings arise past 1 month
- Disruption4-LT
 - Prior attempts at hurting insects or small animals past ≥ 1 year
- Disruption4-MT
 - Prior attempts at hurting insects or small animals past 1 year to 1 month
- Disruption4-ST
 - Prior attempts at hurting insects or small animals past 1 month
- Disruption5-LT
 - Intrusive thoughts that lead you to repetitive actions past ≥ 1 year
- Disruption5-MT
 - Intrusive thoughts that lead you to repetitive actions past 1 year to 1 month
- Disruption5-ST
 - Intrusive thoughts that lead you to repetitive actions past 1 month
- Disruption6-LT
 - Desire to start fires past ≥ 1 year
- Disruption6-MT
 - Desire to start fires past 1 year to 1 month
- Disruption6-ST
 - Desire to start fires past 1 month
- Disruption7-LT
 - Being disruptive in a social environment (eg, at school or elsewhere) past ≥ 1 year
- Disruption7-MT
 - Being disruptive in a social environment (eg, at school or elsewhere) past 1 year to 1 month
- Disruption7-ST
 - Being disruptive in a social environment (eg, at school or elsewhere) past 1 month
- Disruption8-LT
 - Attention problems past ≥ 1 year
- Disruption8-MT
 - Attention problems past 1 year to 1 month

- Disruption8-ST
 - Attention problems past 1 month
- Disruption9-LT
 - Breaking rules at school or elsewhere past ≥ 1 year
- Disruption9-MT
 - Breaking rules at school or elsewhere past 1 year to 1 month
- Disruption9-ST
 - Breaking rules at school or elsewhere past 1 month

Figure 2. The Likert scale on which participants rated the questions.

never	rarely		sometimes		often	always

Data Quality Assurance

Data quality used 4 exclusion criteria: (1) participants with the same responses throughout any section of the questionnaire (eg, “1” for all questions), (2) participants indicating they had been diagnosed by a clinician with ≥ 10 illnesses, (3) participants with minimal variance in a picture-rating task (all pictures were rated the same or varied only by 1 point; data not described here), (4) participants reporting inconsistent education level and years of education *and* participants who completed the questionnaire in < 500 seconds. From these procedures, 366 participants were cleared for statistical analysis.

Statistical Analyses

Analysis of Demographics and Survey Questions by Self-reported COVID-19 Infection

Demographic variables (Table 1) and survey question scores for all questions were divided into 2 distributions based on the *yes* and *no* responses from participants for each of the COVID-19 questions: *test+*, *diagnosis*, and *family*. Distributions of the demographic variables and survey question scores were assessed for differences using the Wilcoxon rank sum test [45]. Significant categorical demographic variables were further assessed for distribution equality using the Kolmogorov-Smirnov test ($\alpha=.05$) [46]. The resulting *P* values for the questions *Psych1-LT*, *Psych1-MT*, *Psych1-ST*, and *Psych2-LT* to *Psych4-ST* were corrected for multiple comparisons using the Benjamini-Hochberg procedure [47] (reported as *q*[FDR]) for each COVID-19 question. The same procedure was repeated for questions *Disruption1-LT* to *Disruption9-ST*. The normalized test statistic from the Wilcoxon rank sum test and *q*(FDR) are reported. Box plots were generated to display the *yes* or *no* distribution for all survey questions and are presented in the Multimedia Appendix 1.

MVLR and Iterative Resampling: Using Demographics and Survey Questions to Model COVID-19 Likelihood

MVLR was performed with the goal of modeling COVID-19 likelihood. The aim was to determine how psychotic symptoms and VIDB from before the pandemic made people more vulnerable to COVID-19 infection during the pandemic. The set of *past ≥ 1 year (long term)* survey responses for the psychotic symptoms and VIDB, which significantly differed (*q*[FDR]) between those responding *yes/no* to *test+*, *diagnosis*, and *family* questions for COVID-19, were used as *independent variables*. The demographic variables with significant differences across *yes* or *no* responses for COVID-19 *test+*, *diagnosis*, or *family* (*q*[FDR] < 0.05 ; Wilcoxon rank sum test) were used as *covariates* in the MVLR analyses. The COVID-19 question responses (*yes*=1 and *no*=0) were the binary *dependent variables*. However, the percentage of participants with a positive self-reported COVID-19 *test+* or *diagnosis* (*yes*=1; 9% to 10%) was much lower than the percentage of those without COVID-19 *test+* or *diagnosis* (*no*=0; approximately 90%), implying a class imbalance that could lead to model overfitting. To avoid overfitting the MVLR model to the majority class, data in the majority class (ie, participants in the COVID-19 *test+* *no* and *diagnosis* *no* groups) were randomly downsampled to match the sample size of those self-reporting COVID-19 (*yes*=0; 36/366, 9.8% for *test+* model, and 34/366, 9.3% for *diagnosis* model). Downsampling was iterated 1000 times, and MVLR was run at each iteration for the downsampled data to obtain the model accuracy, root mean square error (RMSE), and mean absolute error (MAE) of the model. The model accuracy was computed by comparing the number of times the model correctly determined the binary outcome divided by the size of the downsampled data. The average accuracy, SD of the accuracy, average RMSE, and average MAE across all iterations are reported.

Results

Overview

The demographic variables and the frequency of self-reported symptoms of psychosis and VIDB from the 3 time intervals were assessed for participants with and without self-reported COVID-19. For this assessment, we used a Wilcoxon rank sum test followed by multiple comparisons correction. The relationship between these behaviors occurring >1 year ago and the likelihood of contracting COVID-19 was investigated using MVLR with iterative resampling. Namely, we asked whether symptoms from >1 year ago could predict COVID-19 infection.

Demographic Variables and Survey Question Responses Varied by Self-reported COVID-19

In summary, of the 366 participants, 36 (9.8%) reported a positive COVID-19 *test+*, and 34 (9.3%) reported a COVID-19 *diagnosis*; 26 (7.1%) participants answered yes to both the COVID-19 *test+* and *diagnosis*. Of the 366 participants, 95 (26%) reported that a family member or close friend had serious COVID-19-related symptoms or died of COVID-19. We found that participants who self-reported yes to contracting COVID-19 were middle-aged and belonged to the higher-income and higher education groups. Participants who self-reported yes to contracting COVID-19 also reported a higher frequency of psychotic symptoms and VIDB across all 3 time windows of the past 1 month, 1 month to 1 year ago, >1 year ago.

Specifically, age and income significantly varied by *test+*, and age, income, and education level significantly varied by *diagnosis* (all $q[FDR] < 0.05$; Wilcoxon rank sum test; Table 2). Participants who responded yes to *test+* and *diagnosis* were, on average, younger than those who responded no (Table 3;

Figure 3A and 3B). Specifically, middle-aged adults more frequently reported yes to *test+* (IQR 25-47, median 37 years) and *diagnosis* (IQR 25-45, median 37.5 years) than those responding no (IQR 31-59, median 45). Participants responding no to *test+* or *diagnosis* showed a distribution with a higher percentage of low-income levels than those with COVID-19 ($P=.004$; $P=.001$; Kolmogorov-Smirnov test; Figure 3C and 3D). Participants responding yes to *test+* or *diagnosis* exhibited a bimodal distribution of education level, whereas the distribution for NO responses was skewed left ($P=.04$; $P=.01$; Kolmogorov-Smirnov test; Figure 3E and 3F) indicating a higher percentage of low education levels. None of the demographic variables exhibited significant differences based on *family* COVID-19 questions.

Furthermore, the survey questions for which responses significantly varied ($q[FDR] < 0.05$; Wilcoxon rank sum test) by COVID-19 status (*test+*, *diagnosis*, and *family*) have $q(FDR)$ highlighted in Tables 4 and 5. All 4 questions related to psychotic symptoms showed significant differences in medians across the yes and no distributions with respect to *test+* and *diagnosis* for COVID-19 across the three time windows: (1) *past ≥ 1 year (long term)*, (2) *past 1 month to 1 year (medium term)*, and (3) *past 1 month (short term)*; Table 4). All 9 questions related to VIDB also showed significantly different medians across the yes and no distributions with respect to *test+* and *diagnosis* for COVID-19 across the 3 time windows (Table 5). There were no significant response differences across the 13 psychotic symptoms and VIDB questions relative to the COVID-19 *family* questions. Box plots based on *test+* and *diagnosis* for yes distribution had higher scores than for those who answered no for all survey questions, as presented in the Multimedia Appendix 1.

MVLR: Using Demographics and Survey Questions to Model COVID-19 Likelihood

In brief, using MVLR with iterative resampling, we observed a model accuracy of 72% to 94% for an increased incidence of COVID-19 in participants with psychotic symptoms or VIDB >1 year ago (ie, before the pandemic).

Specifically, MVLR with iterative resampling focused on the responses from the time window of *past* ≥ 1 year (*long term*) for the 13 survey questions that significantly varied by COVID-19 status (Table 4 and Table 5). Responses to these 13 questions were used as *primary predictors* to model COVID-19 *test+* and *diagnosis* using MVLR. Given that no significant differences were observed in the survey question responses when split by responses to the COVID-19 *family* question, no attempt was made to model COVID-19 *family* using MVLR. The significant demographic variables of age, income, and education level were used as *covariates* in the model. To avoid overfitting of the model to the majority class (ie, participants in COVID-19 *test+* no and *diagnosis* no groups), the majority

class was iteratively downsampled 1000 times, and the MVLR model was run each time. The average accuracy, SD of the accuracy, average RMSE, and average MAE across all iterations are reported. The null model with only the survey questions regarding psychosis with responses from >1 year ago (ie, Psych1-LT, Psych2-LT, Psych3-LT, and Psych4-LT) had an average accuracy of 72.08% for *test+* and 76.75% for *diagnosis*. The model with 4 survey questions as predictors along with demographic variables as covariates had an average accuracy of 85.45% for model *test+* and 89.43% for model *diagnosis* (Table 6). Similarly, the null model for 9 survey questions regarding VIDB with responses from more than a year ago (Disruption1-LT, Disruption2-LT..., Disruption9-LT) had average accuracies of 81.32% and 87.53% for *test+* and *diagnosis*, respectively. The 9 survey questions, along with covariates, had an average accuracy of 90.35% for the model *test+* and 94.39% for the model *diagnosis* (Table 6). Additional measures, including the SD of the accuracy, average RMSE, and average MAE for these models are also reported in Table 6.

^cMAE: mean absolute error.

^dNo covariates were included in the model.

Discussion

Principal Findings

In a small population sample, we assessed the frequency of self-reported VIDB and psychotic symptoms among people with or proximate to someone with a COVID-19 diagnosis and further tested the potential for discriminating who might become infected by COVID-19 based on a preceding history of these behaviors. For all 3 time windows, we found that participants who answered yes to having COVID-19 (*test+* and *diagnosis*) experienced VIDB and psychotic symptoms more frequently than those who answered no. No significant differences were observed between the yes or no distributions for those who had a close friend or family contract COVID-19 (ie, *family*). Using MVLRL with iterative resampling to avoid model overfitting, we also found that participants who experienced psychotic symptoms and VIDB more frequently before the COVID-19 pandemic were more likely to subsequently contract COVID-19, suggesting that individuals experiencing psychotic symptoms and VIDB may (1) have comorbid conditions that increase their susceptibility to COVID-19 infection and (2) engage in

riskier-than-average behaviors, potentially including nonadherence to COVID-19 precautions and engaging with other people.

The 3 demographic variables (age, income, and educational level) were significantly different when divided into yes or no distributions for COVID-19. Regarding age, COVID-19 was more prevalent in middle-aged individuals, with *yes* distributions for both COVID-19 infection questions having a median age of 37 years. These results contrast with some reports of COVID-19 incidence, where it was reported that older adults were more likely to be hospitalized because of COVID-19 [48], but support the results of other studies, in which younger to middle-aged people were more likely to contract COVID-19 [49]. It should be noted that this study only asked about the diagnosis or testing positive for COVID-19, which is different from hospitalization.

Annual household income for participants who answered yes to COVID-19 questions was more equally distributed across all income levels, with a peak at higher-income households (>US \$75,000). In comparison, the income distribution of participants who answered no was skewed, with a higher concentration of

participants in lower-income households. However, the participants who answered yes were evenly distributed across all income levels. This demonstrates that people who answered no for COVID-19 *test+* and *diagnosis* were predominately from lower-income households and that people who answered yes to *test+* and *diagnosis* were evenly distributed across all household income levels. This suggests that COVID-19 occurred in people with a wide range of income levels and did not preferentially occur in those living in lower- or higher-income households. These findings are in line with those reported in the study by Alsan et al [49] but are in contrast with those in the study by Baena-Diéz et al [50]. This study [50] found that people belonging to lower-income level households had higher incidence rates of contracting COVID-19 infection in Barcelona, Spain. Education had bimodal distributions for participants who answered yes to COVID-19 questions, with a larger peak at higher education levels. For participants who responded no, the distribution was skewed to the left, suggesting that education level did not predispose individuals to COVID-19.

Responses to survey questions about VIDB and psychotic symptoms exhibited higher scores for participants who answered yes for COVID-19 than for people who responded no. This observation showed similar statistical effects regardless of the time window assessed (ie, in the past 1 month, 1 month to 1 year ago, and >1 year ago; Tables 4 and 5). Given these findings for all time windows in this specific study, including those before the pandemic, our observation of a higher frequency of psychotic episodes is less likely to be a direct consequence of COVID-19, which has been linked to cognitive and attention deficits, brain fog, and anxiety [2]. For the same reason, our findings are less likely to be because of higher doses of steroid treatment, which is known to complicate or trigger psychosis [51]. It should be noted that there have been multiple reports of subacute onset of psychotic episodes in healthy individuals with no prior history of mental illness after treatment for COVID-19 [52-55]. These psychotic episodes also led to aggressive, violent, and disruptive behavior and a preponderance of not following rules [53,55]. The psychological impacts of quarantine, temporary loss of employment, lack of livelihood, and financial insecurity have also been shown to trigger violent and disruptive behavior [8,56]. Owing to feelings of frustration and agitation associated with COVID-19, pandemic-related stressors may manifest as aggression and violence toward household members [57-59]. Fear surrounding the COVID-19 pandemic has also been associated with aggressive behavior on the web [60]. Although this is consistent with our results where participants who contracted SARS-CoV-2 reported higher incidences of psychotic symptoms and VIDB in the past 1 month and 1 month to 1 year, our observation of these symptoms, ideation, and behavior before the pandemic for these participants suggests that COVID-19 infection was not causal in the presentation of VIDB or psychotic symptoms. Our study did not find associations that were directional, namely, whether COVID-19 infection increases the likelihood of psychosis and VIDB or whether psychotic symptoms and VIDB increase the possibility of COVID-19 infection. Other viral infections, including influenza and HIV, have led to similar hypotheses [26-34]. Recently, a study by Douaud et al [61] observed a greater reduction in overall brain size, reduction in gray matter

thickness and tissue contrast in the orbitofrontal cortex and parahippocampal gyrus, and changes in markers of tissue damage in regions functionally connected to the primary olfactory cortex in people who tested positive for infection with SARS-CoV-2. Similar brain regions are known to be affected in the same way by psychosis and VIDB [62-66].

To assess whether self-reported VIDB or psychotic symptoms that occurred >1 year ago (ie, before the pandemic) modeled that individuals subsequently had COVID-19 infection, MVLR was performed with iterative downsampling of the majority class to reduce the possibility of model overfitting (Table 6). The demographic variables of age, income, and education level were used as covariates. The full model was not confounded by covariates as the highest accuracy without covariates (ie, null model) was 87.5%, whereas the highest accuracy for the full model was 94.4%. Across all the models, the accuracy of modeling COVID-19 by *diagnosis* was higher than that for *test+*. This might be because of the likelihood of false positives from COVID-19 testing and the fact that COVID-19 testing is an inherent component of clinical diagnosis, making clinical diagnosis more informed. There was also a lag at the beginning of the pandemic before testing was widely available. Overall, the highest accuracy for modeling COVID-19 infection from psychotic symptoms from >1 year ago was 89.4%, and for VIDB, it was 94.4%. These results may reflect comorbid conditions that increase susceptibility to COVID-19 infection or reflect engagement in riskier-than-average behaviors, potentially including nonadherence to COVID-19 precautions, as has been observed with other viral infections [30-32]. Conversely, there is another hypothesis that people with mental health conditions become more antisocial and are thus more distant from other people, potentially resulting in a reduced viral spread. Further work is needed to determine whether psychotic symptoms or VIDB increase the risk for, and the spread of, COVID-19.

This study has several limitations. First, this study involved a small sample size of participants responding yes to *test+* (36/366, 9.8%) and *diagnosis* (34/366, 9.3%) in our cohort. Although the percentage of studied participants infected with COVID-19 herein was consistent with the population estimates of COVID-19 in the United States at the time of data collection, future work needs to assess larger population samples. Another limitation is the bias arising from the false positives of self-reported COVID-19 test positives. It should be noted that the survey did not collect data when the respondents were infected with COVID-19 in the previous year; this is a limitation in estimating the precise time frame for an increase in behavioral symptoms associated with COVID-19. Recall bias is a well-known caveat for any study that uses survey methods [67]. Furthermore, it should also be noted that MVLR results do not represent true predictions, which would require adequately sized training and test sets, along with cross-validation of prediction outcomes. Future work will need to use larger sample sizes and perform better predictive analyses with more sophisticated machine learning algorithms. These caveats aside, it must be noted that this study used iterative resampling to overcome a major confounder that is common in current machine learning

papers with class imbalance in smaller data sets—model overfitting—supporting the generalizability of these results.

Conclusions

This preliminary study examined a population sample collected at the end of February 2021 and the beginning of March 2021 and found that people who reported a test and clinician diagnosis of COVID-19 also reported higher frequencies of VIDB or psychotic symptoms across multiple time windows (the past 1 month, 1 month to 1 year ago, and >1 year ago), including those before the pandemic started. We also found that participants

who experienced VIDB or psychotic symptoms >1 year ago (ie, before the pandemic) were more likely to contract SARS-CoV-2 or be diagnosed with COVID-19. A greater understanding of how COVID-19 may trigger these mental health issues is needed, given other literature on viral, carcinogenic, and toxic effects in changing mental status, including triggering psychotic symptoms and disruptive behavior [26-29,33,34,68-71]. It is also of utmost importance to understand which vulnerable populations are at a greater risk of contracting and spreading the virus to curb the viral spread, which includes vulnerable populations related to age, sex, and household income.

Acknowledgments

Funding for this work was provided by the Office of Naval Research (award N00014-21-1-2216) and the Warren Wright Adolescent Center at Northwestern University, Feinberg School of Medicine.

Authors' Contributions

SB, NLV, NM, AKK, and HCB took part in the study concept and design and acquisition of original data. SB performed the coding of statistical tools (with guidance from NLV, AKK, and HCB). SB and NLV performed the analysis of data (with guidance from HCB and AKK). Interpretation of data was conducted by SB, NLV, AKK, and HCB (with input from KS, SW, SL, LS, B-WK, and NM). SB performed the statistical assessment (with input from NLV, AKK, and HCB), authored the original draft (with input from HCB), and generated figures. All authors were involved in the revision of the manuscript for content. All authors approved the final version of this manuscript for submission. Coauthorship is as follows: SB and NLV are joint first authors; KS, SW, LS, LS, BWK, and NM are joint second authors; and HCB and AKK are cosenior authors.

Conflicts of Interest

None declared.

Abstract

Background: To reduce person-to-person contact, the COVID-19 pandemic has driven a massive shift to virtual care. Defined as the use of technology (synchronous or asynchronous) to support communication between health care providers and patients, rural-urban differences in virtual care are relatively unexplored.

Objective: The 2-fold purpose of this study was to examine rural and urban virtual care access, use, and satisfaction during the pandemic and to identify any unmet needs.

Methods: This study was a cross-sectional online survey exploring virtual care among rural and urban adults in summer 2021 using a combination of fixed and open-ended response options. Quantitative data were analyzed using both descriptive and inferential statistics, and qualitative data were analyzed using inductive thematic content analysis.

Results: Overall, 501 (373, 74.4% female; age range 19-86 years; 237, 47.3% rural-living) Western Canadians completed the survey. Virtual care use was high among both rural (171/237, 72.2%) and urban (188/264, 71.2%) participants, with over one-half (279/501, 55.7%) reporting having only started to use virtual care since the pandemic. The self-reported need for mental health programs and services increased during the pandemic, compared with prior for both rural and urban participants. Among virtual care users, interest in its continuation was high. Our analysis also shows that internet quality (all $P < .05$) and eHealth literacy (all $P < .001$) were positively associated with participants' perceptions of virtual care usefulness, ease of use, and satisfaction, with no rural-urban differences. Rural participants were less likely to have used video in communicating with doctors or health care providers, compared with urban participants ($P < .001$). When describing unmet needs, participants described a (1) lack of access to care, (2) limited health promotion and prevention options, and (3) lack of mental health service options.

Conclusions: The increased demand for and use of virtual care may reflect increased availability and a lack of alternatives due to limited in-person services during the COVID-19 pandemic, so a balance between virtual care and in-person care is important to consider postpandemic. Further, ensuring availability of high-speed internet and education to support patients will be important for providing accessible and effective virtual care, especially for rural residents.

KEYWORDS

virtual care; rural; urban; COVID-19; digital literacy; unmet needs

Introduction

The World Health Organization declared COVID-19 a pandemic and global health emergency on March 11, 2020 [1]. Respecting no geographic boundaries, the pandemic has impacted both rural and urban populations. However, the pandemic was superimposed on well known urban-rural health and health service disparities. Compared with their urban counterparts, rural dwellers experience poorer health and health behaviors, more chronic conditions, and shorter life expectancies and higher mortality rates [2]. These health inequities are systemic and avoidable differences in health that are caused by the unfair distribution of resources, wealth, and power in society [3] and reflect social and structural determinants of health, such as educational, financial, social, and geographical difficulties [4,5]. Moreover, rural communities have historically lacked access to health services and care, due to heightened health provider shortages, underdeveloped digital infrastructure, travel burdens, and costs [6,7].

Adding to the existing social-structural factors influencing rural health and health service use, the pandemic has contributed further to health care gaps [3]. The deferral of elective procedures and routine checkups [8,9] and patient avoidance of medical care for non-COVID-19 illness due to fear of contracting the virus [10] accounted for a massive global reduction in health care utilization (by one-third) during COVID-19 [8]. At the same time, a meta-analysis of 60 studies reported high levels of depression and anxiety worldwide [11], generating high demand for mental health services that have been disrupted by COVID-19 [12]. Few studies have considered the extent of unmet health and wellness needs as a result of these gaps and whether there are urban and rural differences. In their South Korean study [13], researchers found that demographics (eg, age, sex, educational level), chronic diseases, and stress and anxiety were associated with unmet care. To prevent or reduce exposure with the emergence of new variants coupled with the redirection of resources for COVID-19 patients, health care was drastically altered. COVID-19 catalyzed a massive shift to virtual care, with reported increases as much as 56-fold compared with prior to COVID-19 [14,15]. The term virtual care is often used interchangeably with telemedicine or telehealth; we are referring specifically to virtual care defined as the use of technology (synchronous or asynchronous) to support communication between health care providers and patients [16]. Virtual care technologies include video visits, email, text messaging, and telephone visits. In an online survey in summer 2020, 31% of rural adults reported using virtual care somewhat and far more often after March 2020 [17]. However, in a Canadian rural-urban comparison study using an administrative database, urban uptake of virtual care increased at a steeper rate than rural uptake at the start of the pandemic (220 vs 147 visits per 1000 patients) [18]. Similarly, 53% of US urban households, compared with 46% of rural households, used virtual care during the pandemic, though this difference was not statistically significant [19]. In their US study of rural

and urban living veterans, Hogan and colleagues [20] found higher use of virtual mental health care pre-COVID-19 among rural than among urban living veterans and increased use by both groups during the first 7 months into COVID-19 but with urban veterans surpassing rural veterans' usage. Researchers have suggested that barriers to a rapid transition to telehealth delivery may have affected rural areas more than urban areas particularly due to their lack of access to broadband internet, limited device ownership (smartphone, tablet, laptop), and lower digital literacy [20].

Despite lower uptake of virtual care, satisfaction with virtual care was high among rural-dwelling individuals both before [21] and during COVID-19 [22]. In a US study, virtual care satisfaction was higher in rural (88%) than in urban (84%) areas, though not significantly different [19]. Whether satisfaction translates into willingness to continue virtual care postpandemic deserves more research; however, in a recent COVID-19 study of 1059 US residents, 72% to 77% reported intentions to continue to use virtual care, at least for acute health conditions, with no rural-urban differences [23].

Another factor that impacts users' ability to use, and satisfaction with, virtual care is eHealth literacy, which is defined as the ability to find, use, and apply health information from electronic sources [24]. Although inextricably linked to rural challenges in access to high-speed internet, eHealth literacy is often reported to be lower among rural residents compared with their urban counterparts [25]. In a small US study (n=253), utilization of and satisfaction with virtual care were associated with higher eHealth literacy among rural-living adults [22]. Similarly, a significantly positive relationship was found between eHealth literacy and satisfaction with virtual care among people living peripherally to Israel [26].

Given the massive impact of COVID-19 on virtual care, a comprehensive examination of rural and urban virtual care access, use, satisfaction, and future intention to use, considering eHealth literacy and unmet needs, is needed. No such study has been conducted at the time of this study—a full year after COVID-19 was declared a pandemic [1]. The purpose of this study was to compare rural- and urban-living Canadian adults' access, use, satisfaction, and intentions to continue to use virtual care, as well as to explore unmet health and wellness needs 1 year after COVID-19 was declared a pandemic.

Methods**Study Design, Context, and Participant Recruitment**

This study employed a cross-sectional online survey open to adults (19 years or older) residing in urban, rural, and remote communities in a Western Canadian province where 18.44% live in rural communities [27]. The online survey was open to participants for a 6-week period (June 24, 2021, to August 9, 2021). During this time, the province was in a state of re-opening [28]. Step one of the provincial re-start plan began May 25, 2021; social restrictions were loosened, businesses re-opened,

and recreational activities resumed. Step two of the re-start (from June 15, 2021, to June 30, 2021) included additional lifting of travel restrictions and easing of restrictions for businesses and recreational activities (eg, liquor served until midnight, up to 50 spectators at outdoor sporting events allowed). The COVID-19 vaccine was available to everyone age 12 years and older during the time of this survey [29].

Recruitment efforts primarily involved Facebook posts targeting local community pages (n=35; eg, “What’s Up [community name]”) together totaling over 177,000 members as well as through 3 paid Facebook advertisements (“post boosts”) targeting adults living within a 25-mile radius of several rural and urban communities in the province. Email invitations with the survey link were also sent to rural-living participants who completed an online survey in 2020 [17] and consented to being contacted for a future survey. Advertisements were also posted on Twitter, Kijiji (Canadian Craigslist), Facebook, and rural websites and in the volunteer sections of classified web pages, as well as shared through targeted announcements in rural community association newsletters. Additionally, REACH BC, an online platform designed to connect individuals across British Columbia (BC) with research opportunities; Patient Voices Network, a partner platform of REACH BC; and a network aimed at engaging patients in their health care were used for advertisement and recruitment. Although we were unable to track how many potential respondents were reached in total, the 3 Facebook advertisements had a combined estimated audience reach of 5776 adults and engagement (link clicks) of 109 (1.9% response rate), and 56 of the 206 (27.2%) previous survey participants completed this survey. Due to more individuals residing in urban areas than in rural communities, it was anticipated that recruitment of urban participants would be more efficient. Accordingly, more recruitment efforts were focused on targeting participants in rural communities. To promote participation, 5 CAD \$100 (US \$77.61), 3 CAD \$200 (US \$155.22), and 1 CA \$400 (US \$310.43) draw prize incentives were advertised. The survey used a combination of fixed and open responses and an attention check question (“If you are a human reading this, please select strongly agree”) to detect survey bots and inattentive respondents [30,31].

Ethical Considerations

The study was conducted in accordance with the Declaration of Helsinki and with the Canadian Tri-Council Policy Statement. All participants provided informed consent online prior to completing the survey. Participants were provided a link to download the consent form and encouraged to keep a copy for their personal records. Consent was obtained by participants selecting “Yes” in response to the question “Do you consent to participate?” This study was reviewed and received ethics approval from the University of British Columbia—Okanagan Behavioural Research Ethics Board (H20-01166).

Measures

Rurality

Participants provided their community’s name, and based on the census subdivision of the community, a score was assigned from Statistics Canada’s Index of Remoteness [32]. Remoteness

index scores are based on population size and cost to travel to the nearest population center and range from 0 to 1, with scores closer to 1 indicating greater remoteness. Based on the manual method of classification into 5 categories of accessibility using predetermined cutoffs by Subedi et al [33], community scores categorized as easily accessible (<0.1500) or accessible (0.1500 to 0.2888) were classified as urban, and community scores categorized as less accessible (0.2889 to 0.3898), remote (0.3899 to 0.5532), or very remote (>0.5532) were classified as rural.

Demographic Characteristics of Participants

Demographic data collected from all participants included age in years (open response), gender (female, male, nonbinary, prefer not to answer, other), ethnicity/race (select all from options provided or enter under “other”), education (response options ranging from “some high school or less” to “university degree”), and occupation (working full-time, working part-time, going to school, retired, not employed, other).

General Health and Health Care Service Use

Participants were asked to rate their health on a scale ranging from poor (1) to excellent (5). They were also asked to indicate the frequency of contact with their doctor or health care provider in the last 12 months (never, once, 2-5 times, 6-11 times, or 12 or more times) and whether their communications with their doctor or health care provider during COVID-19 had included a series of video or nonvideo interfaces (select all that apply). Those who selected video alone or along with other modes of communication were grouped as having used video, and those who did not select video were grouped as having not used video.

Virtual Care Use and Satisfaction

Participants were provided with a definition of virtual care as using technology (including email, text messaging, video visits, and telephone visits) to communicate with clinicians. Participants were then asked about their engagement with virtual care, with the question “Have you used virtual care?” Response options included: “Yes, and I used virtual care prior to the COVID-19 pandemic,” “Yes, but I only began using virtual care since the COVID-19 pandemic began,” and “No.” Those who responded “Yes” were asked to complete modified 5-point (strongly disagree to strongly agree) subscales of the Telehealth Usability Questionnaire (TUQ) [34] related to Usefulness, Ease of use, and Satisfaction. The TUQ was modified to specifically refer to “virtual care” instead of “telehealth.” Mean subscale scores were calculated, with a higher score indicating greater usefulness, ease of use, and satisfaction with virtual care. The TUQ has strong content validity and good to excellent internal consistency [34]. In this study, Cronbach alphas were .82 for Usefulness, .84 for Ease of use, and .90 for Satisfaction subscales.

Intention to Use Virtual Care Postpandemic

The participants who reported using virtual care were also asked to answer a 4-item, 7-point (strongly disagree to strongly agree) scale about their intention to use virtual care postpandemic [23], modified to remove reference to “acute” conditions. Confirmatory factor analysis, internal reliability, and construct reliability have been reported [23]. In the present study, the

Cronbach alpha was .86 for the future intentions to use virtual care scale.

Health Service Need and Access

A series of questions asking participants about their health service needs and access both before and during COVID-19 were generated based on the expertise of the research team and a previous survey suggesting that mental health needs might be a focal area, given the impact of COVID-19 [35]. Health services included virtual care, online mental health programs, and video or phone mental health services (eg, connecting with someone). Participants were asked to indicate if they “needed and had access to,” “needed and did not have access to/not aware if available,” or “did not need” these services both before and during COVID-19. Responses were then grouped into “needed” versus “not needed” for comparison. In addition, an open-ended question, “Please describe any unmet health or wellness needs you have had since the start of the COVID-19 pandemic (March 2020),” explored unmet needs.

eHealth Literacy

Participants completed an 8-item, 5-point (strongly disagree to strongly agree; eg, “I know what health resources are available on the internet”) electronic Health Literacy Scale (eHEALS) [24] that measures “combined knowledge, comfort, and perceived skills at finding, evaluating, and applying electronic health information to health problems.” Summative scores range from 8 to 40. Previous research using the eHEALS has demonstrated moderate test-retest reliability, good internal consistency, and construct validity [24,35]. In this study, the Cronbach alpha was .92 for the eHEALS scale.

Internet Quality

Participants were asked to rate the adequacy of their internet access during their day-to-day life on a scale ranging from 1 to 7, where 1 represents poor/inadequate (minimal to no reliability and very poor quality) and 7 represents excellent/adequate (always reliable and high quality).

Analysis

Descriptive statistics (frequencies; means and SDs) were used to summarize the data. Chi-square tests were used to examine participant characteristics and virtual care use by rurality (rural or urban). Independent samples *t* tests were used to investigate differences in categorical variables (ie, rural vs urban and used video vs telephone only) on virtual care usefulness, ease of use, satisfaction, future use, eHealth literacy, and internet quality. Regression analyses were used to examine relationships between virtual care scale scores and age, general health, eHealth literacy, internet adequacy, and remoteness. Normality was examined using histograms and P-P plots. Internet adequacy and age were slightly skewed but considered acceptable given the large sample size. Multivariate outliers and influential cases were examined

using casewise diagnostics, Cooks distance, Mahalanobis distance, and leverage. Two cases consistently came up as outliers in each regression analysis; however, these were not consistently unusual on other variables, and regression results were the same with and without these cases, so they were retained. All regression analyses met assumptions of linearity, heteroscedasticity, and multicollinearity. Quantitative data were analyzed using SPSS version 27 (IBM Corp, Armonk, NY) [36]. Open-ended responses were analyzed by 2 research team members (CLS, KC), and inductive thematic analysis was used to code and determine central themes. Two research team members independently coded the responses. Once initial coding was completed, similar codes were clustered into derived themes using consensus. NVivo 12 (QSR International, Burlington, MA) was used to analyze the qualitative data.

Data Screening

Over the 6-week data collection period, 617 total responses were collected, 116 of which were excluded due to the participant selecting “under 19 years” or “not a resident of [Province]” in response to initial eligibility questions and exit survey (n=39), survey incompleteness beyond demographics (n=33), unidentified community name of residence (n=6), inattentive and inaccurate responses (n=8), or survey bots (n=30). An attention check question is a moderately effective strategy for survey bot detection, but other factors were considered (eg, repeating same response options across multiple questions, similar illogical responses to open-ended questions, unrealistic survey completion times) in determining the exclusion of potential survey bots [31]. After removing the exclusions, the final sample of 501 (373/501, 75.0% female) responses were retained for the current study and analyses.

Results

Participant Characteristics

In total, 237 (237/501, 47.3%) participants were classified as rural-living, and 264 (264/501, 52.7%) were urban-living. Characteristics of the sample are presented in Table 1. Urban participants (mean age 34.8 years) were, on average, younger than rural participants (mean age 48.8 years). Rural participants were more likely to have trades certification/diploma, while urban participants were more likely to be working or going to school and less likely to be retired or unemployed. Rural participants were more likely to be Indigenous or Caucasian (218/237, 92.0%), whereas urban participants were more likely to be Caucasian or Asian or mixed ethnicity (217/264, 82.2%). There were no rural/urban differences in general health or number of health care visits over the past year, though rural participants were less likely to have used video in communicating with health care providers, compared with urban participants.

Table 1. Characteristics of all (n=501), rural (n=237), and urban (n=264) participants.

Characteristics	All participants, n (%)	Rural, n (%)	Urban, n (%)	χ^2 (df)	P value ^a

^aChi-square tests comparing rural with urban participants.

^bChi-square for gender only compared men with women due to expected counts falling below 5 for the other categories.

Virtual Care

Virtual care use was high, with over one-half (279/501, 55.7%) of participants reporting having only started to use virtual care since the onset of the COVID-19 pandemic (see Table 2). The pattern of virtual care use was not different for rural versus urban participants ($\chi^2_2=1.03$, $P=.60$). There were more female users than male users of virtual care ($\chi^2_2=14.92$, $P=.002$). There were no age differences in virtual care use or nonuse.

The need for virtual health care and for mental health programs and services increased significantly during the COVID-19 pandemic compared with prior to COVID-19 (see Table 3). This pattern of increased need was similar in both rural and urban participants. A greater proportion of urban participants reported needing all mental health services both pre- and during COVID-19, though the only significant difference was that urban participants had a greater need for online mental health programming pre-COVID-19 ($\chi^2_1=5.08$, $P=.02$).

Table 2. Virtual care use among all (n=501), rural (n=237), and urban (n=264) participants.

Virtual care use	Total, n (%)	Rural, n (%)	Urban, n (%)
Has not used virtual care	142 (28.3)	66 (27.8)	76 (28.8)
Has used virtual care and used virtual care prior to COVID-19	80 (16.0)	42 (17.7)	38 (14.4)
Has used virtual care but only since the onset of COVID-19 (March 2020)	279 (55.7)	129 (54.4)	150 (56.8)

Table 3. Comparison of services needed versus not needed between rural (n=237) and urban (n=264) participants, pre-COVID-19 and post-COVID-19.

Services needed	Before COVID-19		During COVID-19		χ^2 (df)	<i>P</i> value ^a
	Rural, n (%)	Urban, n (%)	Rural, n (%)	Urban, n (%)

Missing	31 (13.1)	26 (9.8)	37 (15.6)	37 (14.0)		
Online mental health programs						
I needed	40 (16.9)	69 (26.1)	61 (25.8)	89 (33.8)	209.9 (1)	<.001
I did not need	163 (68.8)	169 (64.0)	134 (56.5)	138 (52.3)		
Missing	34 (14.3)	26 (9.8)	42 (17.7)	37 (14.0)		
Video or phone mental health services						
I needed	51 (21.3)	76 (28.9)	80 (33.7)	107 (40.5)	163.1 (1)	<.001
I did not need	154 (65.0)	162 (61.4)	115 (48.5)	118 (44.7)		
Missing	32 (13.5)	26 (9.8)	42 (17.7)	39 (14.8)		

^aChi-square tests comparing needed versus not needed before versus during COVID-19 (ie, collapsed across rural and urban participants).

Among those who “needed” virtual care, online mental health programs and phone or video mental health services, we also explored the proportion who either did not have access to the services or were not sure if the services were available (see Table 4). There were no differences in the pattern of results by rural versus urban, so combined data are presented for simplicity. Before COVID-19, for both rural and urban participants, there was a higher percentage who needed the services or programs and did not have access compared with those who needed them but did have access to all services or programs. Then, during COVID-19, the numbers evened out or

even reversed—where a significantly higher percentage needed and had access, compared with needed and did not have access, across both rural and urban participants.

There were no rural-urban differences in virtual care usefulness, ease of use, satisfaction, intention to use in future, or eHealth literacy; however, internet quality was reported to be significantly worse among rural participants than among urban participants (see Table 5). There were no gender differences on virtual care scale scores, eHealth literacy, or internet adequacy. Those who had used video had significantly higher scores for

virtual care usefulness, ease of use, satisfaction, intention to use in future, eHealth literacy, and internet adequacy scores compared with those who had not used video (see Table 6). There was a great deal of interest in continuing to use virtual care postpandemic (see Figure 1), with no significant rural-urban differences.

When controlling for age and general health, eHealth literacy and internet adequacy were positively associated with all virtual care usefulness, ease of use, and satisfaction scores (see Table 7). Only eHealth literacy individually contributed to future intentions to use virtual care when all predictors were entered in the model simultaneously.

Table 4. Comparison of access versus no access pre- to post-COVID-19 among those who needed virtual care, online mental health programs, and phone or video mental health services.

Services needed	Before COVID-19, n (%)	During COVID-19, n (%)	χ^2 (df)	P value ^a
Virtual care				
Needed and had access to	63 (12.6)	290 (57.9)	5.5 (1)	.03
Needed but did not have access or was unaware	87 (17.4)	27 (5.4)		
Online mental health programs				
Needed and had access to	31 (6.2)	71 (14.2)	25.0 (1)	<.001
Needed but did not have access or was unaware	78 (15.6)	79 (15.8)		
Video or phone mental health services				
Needed and had access to	55 (11.0)	136 (27.1)	28.9 (1)	<.001
Needed but did not have access or was unaware	72 (14.4)	51 (10.2)

Unmet Needs

Themes

Of the 501 participants, 294 (58.7%) responded to the unmet needs open-ended question. The proportion of the rural participants who responded to the question and reported “no unmet needs” (53/132, 40.2%) was similar to the proportion of the urban participants with “no unmet needs” (58/162, 35.8%). For the comments reporting unmet needs, thematic analysis was used to construct 3 inter-related main themes: (1) lack of access to desired care, (2) limited health promotion and prevention options, and (3) mental health impacts and service adequacy or options.

Lack of Access to Desired Care

Among those describing unmet health or wellness needs, both rural and urban participants described reduced or limited access to desired care due to restricted or delayed in-person care (appointments, services), lack of virtual communication options to accommodate disability, and care avoidance from personal fears of viral exposure. Underlying their desire for different care were participants’ concerns or anxieties about aspects of their care being missed. A 30-year-old rural participant described her response to delayed in-person care:

Being pregnant, I was unable to see a health care provider in person before 20 weeks. This led to a lot of anxiety and I felt I didn’t have proper prenatal care.

In some cases, participants reported serious consequences, such as a 51-year-old urban participant’s “ruptured appendix was undiagnosed and ended up in emergency; lucky to be alive.” Other participants were unwilling or afraid to access care (delaying care), as an urban participant described: “Visiting doctor or hospital involves risk of exposure to virus.”

Participants also expressed that new virtual care platforms did not address the needs of individuals with disabilities. One 48-year-old urban participant shared her challenges in using virtual care due to the temporary loss of her voice:

I lost my voice during the pandemic and have difficulty speaking, due to what we now know are post-acute Covid-19 syndrome neurologic issues. I needed access to texting, emailing, chatting communication options with medical providers because I could not speak, or be understood when calling. I literally could not call 911 for help because at times I could not communicate using speech. My primary care physician refuses to use virtual meetings, whereby I would have been able to at least use the chat function to communicate. This situation has caused me panic attacks, isolation from medical care, and other mental health issues rooted in hopelessness and fear.

Limited Health Promotion and Prevention Options

Participants also reported that less critical health promotion and prevention options had been greatly reduced, such as delays in routine health checking, cancer screenings, and dental appointments. A 58-year-old rural participant explained:

I have not been able to schedule my routine cancer screening exam (due every 3 years) with my physician. I also have not had a massage in over 18 months, and it was over a year before I went in to get my teeth cleaned.

The mandatory shutdown of health centers and gyms also impacted some urban participants’ exercise routines:

I’ve been less able to attend the gym facility [that] I used to use multiple times per week, especially with the most recent wave, and likely lost strength in my muscle groups. I’ve recently injured my knee and suspect this is the reason. As well, I’ve gained weight, likely in part for the same reason.

Mental Health Impacts and Service Adequacy

Finally, unmet mental health needs were indicated in response to this open-ended question. Participants described the negative socioemotional impacts of the pandemic, such as depression, anxiety, stress, and social isolation, and the corresponding lack of adequate mental health services to meet their needs. For example, one 59-year-old rural participant stated, “I have suffered from depression since the start of the pandemic,” whereas an urban participant expressed having “More anxiety and stress due to concerns about the pandemic. Especially safety of my loved ones.” Similarly, many participants expressed unmet social needs, restrictions on social gatherings, and the ever-changing COVID-19 safety protocols at work that had detrimental impacts on their mental health. One urban participant stated that “[their] mental health, specifically depression and anxiety, has deteriorated [gotten worse] since [their] ability to engage with others and make connections was limited to virtual options.”

Some participants also expressed unmet needs related to barriers to accessing mental health services, including affordable and ongoing versus crisis-oriented mental health services, and privacy concerns. One 24-year-old urban participant described her challenge with virtual privacy:

It is difficult to do online [mental health] sessions even from home when there are other people in the house (which is very often due to the pandemic).

Others felt like there were limited mental health services available, especially affordable options, as one 22-year-old urban participant explained:

Although there were mental health [services] available, I find that the majority of the free ones are crisis support, but not ongoing mental health support. I wish there were more low-cost or free ongoing counselling supports that were available, as I wasn’t necessarily always in crisis but I still needed help with my mental health.

One 27-year-old urban participant expressed that there is a need for more government-provided mental health programs:

My overall mental health took a decline with the increased expectations of my workplace and level of stress living in a small apartment with my partner. I wish that I could have more access to

government-provided mental health counselling with a human, either in-person or visually [virtually]

Discussion

Principal Findings and Comparison With Prior Work

The purpose of this study was to examine rural and urban virtual care access, use, and satisfaction during the COVID-19 pandemic, as well as to explore future intentions to use virtual care and understand participants' unmet health and wellness needs. Virtual care use, satisfaction, and future intentions to use were all high, with no rural-urban differences. Several unmet needs were identified.

Our finding that virtual care satisfaction was high among both rural and urban participants mirrors other research [19,22] and is consistent with participants' high levels of interest in continuing virtual care. However, it contrasts with participants in a peripheral/outlying area of Israel who had low levels of interest in continuing virtual sessions postpandemic in December 2020 [26], reflecting their low levels of satisfaction with virtual sessions (only 36%). Noteworthy were significantly higher future intentions to use virtual care among those study participants who had used video compared with those who had not. Prior to the pandemic, Ghaddar et al [37] found 78.9% of participants from an underserved Hispanic (Texas-Mexico) border community were somewhat or very likely to use telehealth services if offered. It may be that patients in underserved areas will continue to be willing to use virtual care, but the extent to which urban-dwelling patients and providers will be willing to continue virtual care may depend on the ongoing risk of exposure to the virus [38]. Yet, contrary to this notion, in a survey of South Korean urban virtual care users, fear of COVID-19 exposure was not associated with virtual care acceptance [39]. More research is needed on the role COVID-19 anxiety plays in willingness to use virtual care among both rural and urban adults.

Similar to our findings, higher use of and satisfaction with virtual care were associated with higher eHealth literacy among rural Virginians [22] and residents in peripheral areas of Israel [26]. Unlike other research that has found lower health literacy in rural populations [25], there were no rural and urban differences in eHealth literacy scores in our study population. However, the online survey was not available to those without internet or device access, and it is not clear if lack of access to internet or devices is associated with lower eHealth literacy levels. Indeed, our findings support the notion that challenges with internet quality, even among a connected sample, play a role in virtual care satisfaction in addition to eHealth literacy. Regular access to the internet was associated with higher satisfaction among rural US adults [22]. Virtual care used to its full capacity (eg, video) requires adequate broadband access [40], and more urban than rural participants in the present study reported using video virtual care. In a telephone survey of a nationally representative US sample, only 36% of rural US households without high-speed internet had used telehealth compared with 53% of households with it [19]. By including measures of not only eHealth literacy but also internet quality

and rurality, we were able to discern the unique contribution of each of these characteristics to virtual care satisfaction.

The need for virtual mental health programming and services increased among both rural and urban participants during the pandemic compared with before the pandemic, but encouragingly, a higher percentage of those who needed virtual mental health programs and services had access to these during the pandemic compared with before the pandemic. However, the need for online mental health programs and services in this study was higher among urban participants than among rural participants, with urban participants' needs significantly higher pre-COVID-19. This is consistent with pre-COVID-19 evidence indicating that risk for mental health problems was higher in urban than rural communities [41]. Urbanization and increased population density during a viral pandemic may exacerbate mental health needs and provoke greater anxiety; indeed, in a study from China, urban participants reported more severe anxiety and depression during the COVID-19 pandemic compared with rural participants [42]. It is also possible that urban participants were previously more reliant on in-person services that were less available to rural participants. Even so, mental health services and programs for special needs (eg, autism, youths, seniors, physical disabilities) are not accessible to many rural residents; therefore, it is crucial to ensure continuous mental health support to these populations. How rural and urban-dwelling adults access mental health services is a topic that requires continuing study.

Open-ended survey responses revealed that one-third or more of rural (79/237, 33.3%) and urban (104/264, 39.4%) participants in our study had a variety of unmet health and health service needs. Among these were lack of access to desired care (eg, obstetrics and gynecology visits, specialty care), delayed preventive care (eg, health checks, cancer screenings), limited health promotion and prevention options (eg, access to gyms), and lack of affordable and ongoing versus crisis-oriented mental health services. Similarly, Czeisler et al [43] found that, during the pandemic, 12% and 32% of US residents delayed or avoided urgent or ED care and routine care, respectively, because of concerns about COVID-19. Whether system- or patient-initiated, delayed care can have detrimental health consequences [44]. Additionally, a survey of 400,000 BC residents showed decreases in health-promoting behaviors (eg, exercise, healthy eating) and increases in alcohol and cannabis consumption during the pandemic [45], with likely longer-term negative population health impacts. Delayed access to care, including routine health checks and cancer screenings, has been documented. Furthermore, despite increased need for counselling, many BC residents reported an unwillingness to use virtual mental health services, viewing these as only for crisis situations [45], a notion that also surfaced in our findings. Although these themes relate to unmet needs specifically during COVID-19, a unique time of reduced service options, they provide valuable learnings for future virtual health delivery when service reductions are no longer a public health requirement.

Limitations and Future Research

The online nature of the survey and recruitment efforts excluded the perspectives of those without access to the internet. Despite this, we had participants from very remote locations, suggesting approximation of a representative sample with respect to rurality. Further, our results were consistent with comparative evidence from both online and telephone surveys [19]. Still, the primarily social media recruitment limits the generalizability of the results. The survey was conducted during the summer months when the province was in a state of re-opening (eg, recreational activities were resuming) when a vaccine was widely available and prior to announcements of a fourth wave (Delta variant) and vaccine passports and mandates, which may have influenced responses; yet, the timing of the survey during a phase of lower risk might mean that the finding that over two-thirds of participants were willing to continue virtual care use is a conservative estimate. It should also be noted, that during the time of the survey, significant climate hazard events in the province may have impacted participation and participant mental health; for example, during June 25, 2021, through July 1, 2021, a record-breaking heat wave swept the province [46], and the subsequent wildfire season was one of the worst on record [47].

More research is needed to explore why the pattern of access among those who needed virtual mental health services might

have changed; it is possible that increased programming and advertising has contributed to greater availability and awareness and perhaps less stigma. Furthermore, although this study explored virtual care access, satisfaction, and intentions, more research is needed to explore unmet in-person health care needs. The present results reinforce the notion that some things (eg, surgeries) cannot be done virtually. The trade-off between reducing exposure and delaying care will be important to consider for future research and care.

Conclusions

Overall, findings from this study suggest that eHealth literacy and internet quality play important roles in virtual care satisfaction and future intentions to use virtual care. Yet, despite high levels of satisfaction with virtual care among both rural and urban participants, open-ended responses highlighted many unmet needs, reinforcing the notion that virtual care can supplement, but not replace, in-person care. Understanding not only use of but also rural and urban patient satisfaction with virtual care and whether patient demand will continue post-COVID-19 are important considerations for providers and policy makers. If virtual care is to be incorporated into ongoing practice following COVID-19, it is important that equitable access is addressed.

Acknowledgments

This research was supported by the University of British Columbia (UBC) Okanagan's Eminence Program (GR015968, 2019) and the UBC Okanagan Work Study program. The funders were not involved in the design, analysis, or write up of this research.

Authors' Contributions

All authors contributed to the conceptualization of the project and contributed to the study design. KC and NH contributed to the online questionnaire construction, participant recruitment, coding of open-ended data, and description of the methods. CLS oversaw the data collection and completed the data analyses. All authors contributed to manuscript drafts and reviewed the final manuscript.

Abstract

Background: The COVID-19 pandemic has led to an unprecedented increase in the delivery of virtual primary care. Adults with intellectual and developmental disabilities (IDDs) have complex health care needs, and little is known about the value and appropriateness of virtual care for this patient population.

Objective: The aim of this study was to explore the accessibility of virtual primary care for patients with IDDs during the pandemic.

Methods: We conducted semistructured interviews with 38 participants in Ontario, Canada between March and November 2021. A maximum variation sampling strategy was used to achieve a diverse sample including 11 adults with IDDs, 13 family caregivers, 5 IDD support staff members, and 9 primary care physicians. An iterative mixed inductive and deductive thematic analysis approach was used to code the data and synthesize higher-level themes. The analysis was informed by the Levesque Patient-Centered Access to Health Care Framework.

Results: We identified themes related to 4 of 5 access-to-care dimensions that highlighted both the benefits and challenges of virtual care for adults with IDDs. The benefits included saving time spent traveling and waiting; avoiding anxiety and challenging behavior for patients who struggle to attend in-person visits; allowing caregivers who live far away from their loved ones to participate; reducing illness transmission; and allowing health care providers to see patients in their home environments. The challenges included lack of access to necessary technology, lack of comfort or skill using technology, and lack of nonverbal communication; difficulty engaging and establishing rapport; patient exclusion from the health care encounter; and concerns about privacy and confidentiality. An overarching theme was that “one size does not fit all,” and the accessibility of virtual care was dependent on the interaction between the following 5 categories of factors: patient characteristics, patient context, caregiver characteristics, service context, and reason for a particular primary care visit. Though virtual care was not always appropriate, in some cases, it dramatically improved patients’ abilities to access necessary health care.

Conclusions: This study suggests that a flexible patient-centered system including multiple delivery modalities is needed to ensure all patients have access to primary care. Implementing this system will require improved virtual care platforms, access to technology for patients and caregivers, training for primary care providers, and appropriately aligned primary care funding models.

KEYWORDS

COVID-19; intellectual disability; developmental disability; qualitative; telemedicine; virtual care; primary care

Introduction

In March 2020, the COVID-19 pandemic led to an unprecedented increase in the delivery of virtual primary care in countries around the world [1-6]. In Ontario, Canada, virtual care increased 56-fold to comprise over 70% of primary care in the first 4 months of the pandemic [2]. Though virtual care is sometimes defined broadly to refer to any use of technology to improve health care, this study focuses on technology-supported interactions between health care providers and patients in different locations. This includes synchronous and asynchronous interactions using video, telephone, and text-based technologies [7]. The rapid expansion of virtual care during the pandemic has raised questions about the quality and accessibility of virtual care for different patient groups [8,9]. Primary care is often the first point of access to the health care system and plays an important role in improving health outcomes, reducing health inequities, and reducing health care costs [10]. Considering the ongoing role of virtual care, it is critical to ensure that primary care remains accessible for all patients.

Adults with intellectual and developmental disabilities (IDDs) are a group that may require additional consideration to ensure that the increased use of virtual modalities does not compromise their access to care. The term IDDs is an umbrella term that includes a wide range of conditions of childhood onset that impact cognitive and adaptive functioning across the lifespan [11]. The conditions include, for example, intellectual disabilities, autism, Down syndrome, and fetal alcohol spectrum disorders. People with IDDs are more likely to live in poverty [12] and may therefore have greater challenges accessing technology. Some adults with IDDs live in congregate settings where there is limited access to technology and limited private space to use that technology, and where support staff may have limited skills to support technology use [13,14]. Other adults with IDDs may be supported by older parents with limited technology skills [15,16]. Additionally, some people with IDDs rely on facial expressions, lip reading, sign language, or communication devices for effective communication, which may be more difficult to use in virtual interactions [17,18]. Conversely, some people with IDDs find travelling to the health care appointment and waiting in the waiting room to be extremely stressful [19-22], and the ability to access care from the comfort of their own home may improve accessibility.

There is currently limited research on the accessibility of virtual primary care for adults with IDDs. A recent scoping review [23] on virtual health care for adults with IDDs identified 12 studies on access to virtual care, none of which focused on primary care. The review found that study participants generally reported high acceptability of virtual care, though the studies conducted during the pandemic reported more mixed feedback. The main challenges reported were related to participant skill and comfort using technology, and poor internet quality. The review

concluded that the limited available literature suggests that virtual care can be accessible for adults with IDDs, but a better understanding is needed of when and for whom virtual care is appropriate. It is important to note that many of these studies were conducted prior to the pandemic. In these studies, patients typically opted for virtual care, care was usually provided by video, and access to technology was a requirement for participation. During the pandemic, virtual care was sometimes the only option, and it was much more likely to be delivered by telephone than video [24,25]. Additionally, in some studies, patients received virtual care in supported settings (eg, a telemedicine clinic) versus the typical experience during the pandemic where patients participated in virtual care from their homes.

We identified one study focused on video-based virtual primary care for autistic adults during the pandemic [26]. The study identified benefits to virtual care, including increased patient comfort and reduced risk of COVID exposure, and challenges, including technology issues, lack of a physical examination, and reduced patient engagement (eg, distracted and wandered away from the visit). Participants in this study reported that they found communication via virtual care to be the same or better than in-person communication, though the sample did not include individuals with intellectual disabilities. In contrast, other studies on virtual interactions for people with IDDs during COVID-19 found that effective virtual communication could be challenging [27,28].

The aim of this study was to explore the accessibility of virtual primary care for patients with IDDs. Our intention was to understand the experiences of virtual primary care in Ontario, Canada during the pandemic to help inform the potential ongoing role of virtual care within an accessible primary care system.

Methods

Access to Care Framework

We conceptualized access to care based on the Patient-Centered Access to Care Framework developed by Levesque et al [29]. In this framework, access is defined as the fit between the characteristics of the service and the needs and abilities of the individual. The Access to Care Framework identifies 5 dimensions of service accessibility with 5 corresponding dimensions reflecting the patient's ability to access the service as follows: (1) *approachability*, how easy the service is to identify or be aware of, and *ability to perceive*, the patient's awareness of their need for services; (2) *acceptability*, whether the service is perceived to meet patient needs, and *ability to seek*, the patient's capacity to seek care; (3) *availability and accommodation*, how, when, and where services are offered, and *ability to reach*, the patient's ability to use the service; (4) *affordability*, the cost of the service, and *ability to pay*, the patient's financial resources; and (5) *appropriateness*, the quality

of the service, and *ability to engage*, the patient's motivation to engage in care.

Methodology

Qualitative description methodology was used to guide the overall study design. Qualitative description focuses on describing and understanding participant experiences with the goal of achieving descriptive and interpretive validity [30-32]. This pragmatic participant-centered approach is recommended for applied health services research aimed at informing policy and practice [33] and for studies focused on addressing health disparities for vulnerable populations [34].

Sampling and Recruitment

This study included adults with IDD, caregivers (including family members and IDD support staff members), and primary care providers. The study was restricted to participants living in Ontario, Canada who had experience participating in at least one virtual primary care visit for an adult with an IDD over 18 years of age and had the capacity to provide informed consent. Adults with IDD were included if they self-identified as having an IDD. Given the limited prior research on this topic, we used a maximum variation sampling strategy to achieve a diverse study sample with the intention of capturing a wide range of experiences [35,36].

Efforts were made to recruit a demographically diverse set of participants based on age, gender, and geographic location across the province. Efforts were also made to recruit primary care providers from different practice models, as they may have different resources available to support virtual care, and adults with IDD living independently, with family, and in supported settings. To achieve these aims, we used broad recruitment strategies. A study flyer was developed and shared widely using existing health care provider networks (eg, the Alliance for Healthier Communities, the Association of Family Health Teams of Ontario, and Developmental Disabilities Primary Care Program), community agencies (eg, Vita Community Living Services, Community Living Ontario, and Surrey Place Centre), caregiver and self-advocate networks (eg, the Azrieli Adult Neurodevelopmental Centre self-advocate and caregiver advisories), social media, and other relevant newsletters (eg, Health Care Access Research and Developmental Disabilities newsletter and Developmental Services Ontario newsletter). All participants and recruitment contacts were encouraged to share the flyer widely. Additional targeted recruitment was conducted as needed to improve representation across participant groups.

Data Collection

Semistructured interviews were conducted with participants by phone or the Webex video conference platform (Cisco) according to participant preference. Participants also had the option of typing their responses through the chat function on the Webex platform. All interviews were conducted by the first author (AS) who has 10 years of qualitative research experience, including prior experience conducting interviews with adults with IDD.

Tailored interview guides were developed for each participant group informed by a previous scoping review of the literature [23] and the Levesque Access to Care Framework [29]. Questions focused on the experience of receiving, supporting, or delivering virtual care; preferences related to the future role of virtual care; and supports needed for successful virtual care. Virtual care was defined as including any care provided remotely including by phone, video, or written communication (eg, email). Demographic information on age, gender, disability, and geographic location was also collected. Interview questions for adults with IDD were developed recognizing the unique considerations in interviewing this population, including the need to adapt language based on individual capacity, potential difficulty with abstract concepts and recalling past events, and risk of suggestibility or acquiescence [37-39]. If helpful, interview questions were sent in advance. Patients with IDD had the option of being interviewed independently or with a support person. If both the patient with an IDD and their caregiver choose to participate in the study, dyadic interview techniques were used to elicit both the patient perspective, using caregiver-mediated communication if appropriate, and the caregiver's own perspective [40].

Interviews lasted approximately 20-60 minutes and were audio recorded and transcribed. Field notes were taken during and immediately following each interview to document interviewer impressions and nuances that may not be captured in the recording [41]. An honorarium was provided to all participants.

Interviews were conducted between March and November 2021. In Ontario, temporary billing codes were implemented in March 2020 to reimburse physicians for virtual health care, and physicians were encouraged to take a "virtual first" approach [42,43]. The proportion of care delivered virtually in Ontario has fluctuated throughout the pandemic in accordance with each wave of COVID, but early data suggest that it consistently accounted for a substantial proportion of patient visits throughout the study period [43,44]. A recent Ontario study using population-level administrative data found that about 62% of adults with IDD in Ontario used virtual care during the first year of the pandemic, similar to the proportion of adults without IDD [45].

Ethics Approval

This study received approval from the research ethics board at the Centre for Addiction and Mental Health (REB # 160/2020) and the University of Toronto (Protocol # 40483). All participants provided informed consent prior to participating in the study.

Analysis

A mixed inductive and deductive thematic analysis approach was used to guide the analysis [46-48]. Though the study was informed by a pre-existing Access to Care Framework [29], the framework was being applied in a novel context, and it was important that it should not restrict or limit initial coding. Therefore, initial coding was guided by the research question, but remained relatively open and data driven. The first author (AS) developed an initial codebook based on a review of all transcripts and field notes. A subset of transcripts from each

stakeholder group was reviewed and discussed with 2 additional authors (JD and YL) to identify key ideas and patterns of ideas, and to refine the initial codebook. The first author (AS) then coded all transcripts, iteratively updating and refining the codebook throughout the process. Coding was conducted using NVivo 12 software (QSR International).

A multi-stage process was used to synthesize the collated data and generate themes. First, an open data mapping exercise was conducted to explore relationships and patterns across all codes. Codes were then mapped onto the Access to Care Framework, considering fit with existing framework domains. These initial maps were reviewed and discussed by all the study authors, and key themes were identified. These initial themes were then reviewed, discussed, and refined with members of each stakeholder group (ie, self-advocates, caregivers, and primary care physicians) as part of a peer debriefing process [49]. Results are reported by access to care domain. Quotations are included to illustrate the findings.

Rigor

This study was conducted as part of the doctoral thesis of the first author and was supported by a team that included researchers working in both the health care and IDD sectors, including health services researchers, a psychologist, an occupational therapist, and family members of people with IDDs. Our team engaged in ongoing critically reflexive dialogues to reflect on our positionalities and assumptions in relation to this work and to consider how they shaped the study findings [49,50]. The collective experiences and perspectives of this team guided and informed the study design, analysis, and interpretation.

Several strategies were used to support trustworthiness in this study [32,49]. Credibility was supported by promoting an open and safe interview process, using clear and easy-to-understand interview questions, and conducting a peer debriefing process to support data interpretation. Dependability was supported through the use of an audit trail to clearly document each step of the analysis process, and through detailed and transparent reporting of the findings. Transferability was supported by providing detailed descriptions of the sample and the recruitment process, and contextualizing findings through thick descriptions so readers can gauge the applicability to different settings. Confirmability was supported through the use of field notes to

contextualize the data, an iterative coding process based on multiple re-readings of the data, and inclusion of quotations to illustrate the findings.

Results

Participants

In total, 38 individuals participated in this study, including 11 adults with IDDs, 13 family members, 5 IDD support staff members, and 9 primary care physicians. Participants included 25 women and 13 men (between 23 and 69 years old) living across the province (Greater Toronto Area, 19; Eastern Ontario, 9; Western Ontario, 8; Northern Ontario, 2). The study included adults with IDDs or the caregivers of adults with IDDs, who live with their family (n=18), independently (n=5), or in supported settings (n=6). Primary care physicians participated from all 4 primary care delivery models in Ontario: family health teams (n=3), community health centers (n=2), physician group practices (n=3), and solo practitioners (n=1). Seven of the nine physicians reported having practices with a particular focus on patients with IDDs. Participants had or supported people with a range of IDDs including autism, intellectual disabilities, and Down syndrome. Many of these individuals also had co-occurring health issues, including mental illness, vision and hearing impairments, physical disabilities, and chronic illnesses.

Main Findings

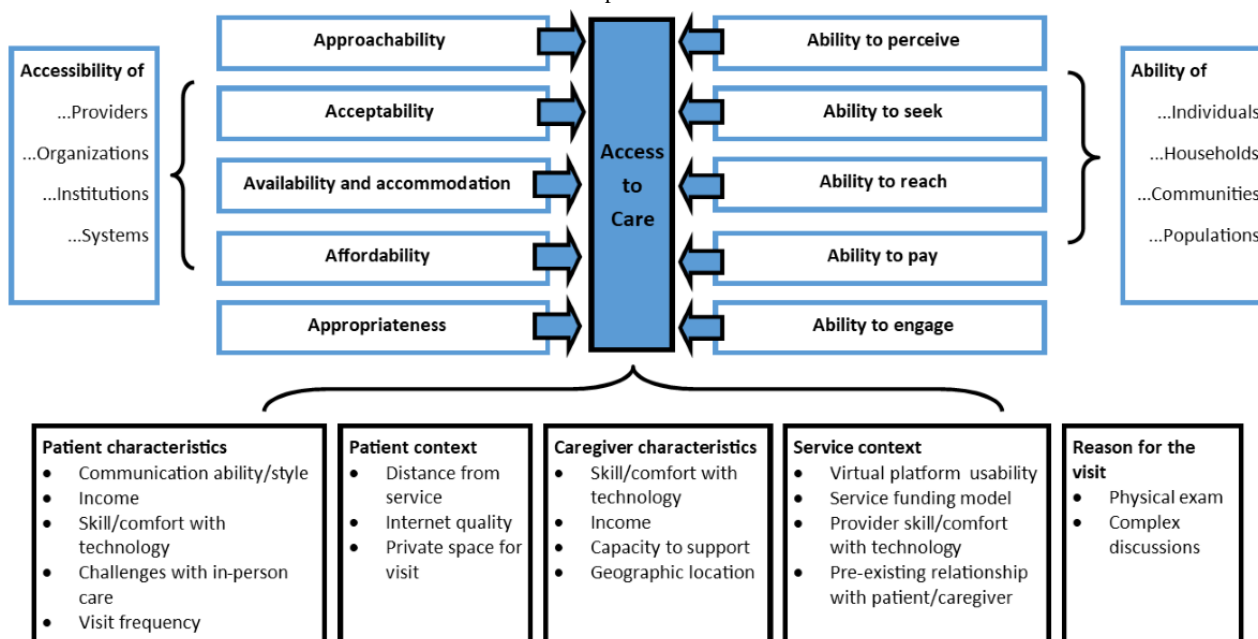

All study participants reported receiving or delivering synchronous virtual primary care by telephone or video. These synchronous appointments were sometimes supported by asynchronous communication by email or text message to schedule appointments; ask questions; and send documentation, photographs, and videos. Across the 38 interviews, we identified themes that aligned with each of the access-to-care dimensions, with the exception of approachability/ability to perceive (see [Table 1](#)). This is likely due to the data source used for this study. Interview participants could only speak about services they had used (ie, you do not know what you do not know). These themes were informed by mutable and immutable variables related to the patient's characteristics, the patient's context, the caregiver's characteristics, the service context, and the reason for a particular primary care visit (see [Figure 1](#)). Each of these themes is described in more detail below.

Table 1. Access to care dimensions and themes.

Dimensions and themes	Description
Acceptability/ability to seek (patient/caregiver comfort or satisfaction with the services)	
Convenience	<ul style="list-style-type: none"> Virtual care saved time and could be more convenient than in-person care. Phone was seen as quick and easy; video could be more difficult and time-consuming.
Change is hard	<ul style="list-style-type: none"> Virtual care was new, and change can be challenging.
Health care visits as a valuable outing	<ul style="list-style-type: none"> For some patients, in-person visits were enjoyable outings and important opportunities to practice social skills that were lost with virtual care. Some patients had important rituals or reward systems to facilitate health care visits that were disrupted by virtual care.
Caregiver distress	<ul style="list-style-type: none"> Virtual care sometimes put additional responsibility on the caregiver to negotiate health care interactions.
Availability and accommodation/ability to reach (patient/caregiver ability to use the service)	
Technology quality, access, and skill	<ul style="list-style-type: none"> Patients and caregivers did not always have access to necessary technology. Patients, caregivers, and primary care providers sometimes lacked skill and comfort using technology. Switching between multiple virtual platforms was confusing for some patients and caregivers.
Difficulty travelling and waiting	<ul style="list-style-type: none"> Virtual care facilitated access to care for patients unable or challenged to attend in-person visits.
Participation in the visit	<ul style="list-style-type: none"> Virtual care facilitated participation of multiple care providers and caregivers in the visit. Patients were less likely to be included in virtual visits, especially by phone.
Patient independence	<ul style="list-style-type: none"> Virtual care supported independence for patients unable to travel by themselves. However, it reduced independence for patients who could travel but required support to use technology.
Affordability/ability to pay (affordability of the service for patients/caregivers)	
Travel and parking costs	<ul style="list-style-type: none"> Virtual care saved costs related to travel and parking.
Staff time	<ul style="list-style-type: none"> Supported settings saved costs due to fewer staff required to accompany patients to their health care visits.
Technology costs	<ul style="list-style-type: none"> Costs were incurred to purchase high-speed internet and internet-enabled devices. Residential settings incurred costs for technical support staff.
Appropriateness/ability to engage (quality of care received by the patient)	
Communication and rapport	<ul style="list-style-type: none"> Nonverbal communication was lost in phone interactions and was more challenging in video interactions for patients, caregivers, and primary care providers. Communicating via phone could be more challenging for people with hearing impairments. It was sometimes difficult to manage conversations with multiple participants. The ability to use chat functions supported improved communication for some patients. Video was sometimes a better option to see facial expressions or read lips while masks were required for in-person visits. Some participants found it difficult to develop rapport virtually, especially with new primary care providers.
Seeing patients at home	<ul style="list-style-type: none"> Participating in visits from their home made some patients more comfortable and less anxious, leading to more effective visits. Video visits allowed primary care providers to see patients in their home environment.
Importance of physical examination	<ul style="list-style-type: none"> Physical examinations are sometimes a necessary component of care and were particularly important for some people with IDD^a who could not describe their symptoms.
Privacy/confidentiality	<ul style="list-style-type: none"> Patients did not always have a private space from which to participate in the visit. Some patients were concerned about cyber security. Some caregivers were concerned that people with IDDs may be more vulnerable to online scams and may disclose medical information inappropriately.
Safety	<ul style="list-style-type: none"> Virtual care reduced the transmission of COVID-19 and other illnesses. Some patients felt safer in-person when discussing potentially triggering topics.

^aIDD: intellectual and developmental disability.

Figure 1. Access to virtual care for adults with intellectual and developmental disabilities.

Acceptability/Ability to Seek

Acceptability of virtual care varied widely across participants. There were those who preferred their health care appointments to take place by phone, by video, or in-person and some who had no strong preferences. The following 4 themes related to acceptability/ability to perceive were identified: convenience, change is hard, health care visits as a valuable outing, and caregiver distress.

Convenience

Some patients and caregivers appreciated the convenience of participating in care from home. Virtual visits allowed them to avoid sometimes lengthy travel time to appointments, potentially requiring missed work or school. Instead of waiting in waiting rooms, they could go about their normal day until the primary care provider called. A 29-year-old autistic woman shared:

It's so convenient...I think it's great that they can kind of assess you on the phone and then say, "OK, well, I think you need to come in or you don't need to come in." [...] It saves so much time for everyone- getting ready to go, finding my stuff, getting it together, taking the subway, waiting in the waiting room.

This was particularly important in cases where the patient or caregiver lived far away from the provider, or if the caregiver had other responsibilities (eg, multiple care recipients). Phone visits were seen as particularly fast and easy, while video calls could be more complicated and time-consuming for patients, caregivers, and primary care providers.

Change is Hard

Some patients, caregivers, and primary care providers disliked virtual care because it was new and different. Participants also reported that change is always challenging, but can be particularly challenging for some people with IDD. A 48-year-old autistic man explained:

[Virtual care] is not something that I think should be encouraged for people on the spectrum because it's, yeah it's another change.

Participants noted that it is possible that some of the resistance or dislike of virtual care will change as people grow more accustomed to it.

Health Care Visits as a Valuable Outing

Some participants highlighted the experiences they or the person they support missed out on due to virtual care. Some people with IDDs enjoyed travelling for their health care visits and felt that virtual care deprived them of an enjoyable outing. For some people with IDDs, health care visits were an important opportunity to socialize and practice skills. A staff member at a group home in eastern Ontario explained:

Another big downfall [of virtual care] is just that so much of what we do here for these individuals is supporting that socialization and those social skills and it's one less opportunity for us to teach that in person. [...] So for these individuals, speaking with the receptionist and having that opportunity to practice with the nurse and then the doctor, it was a lot of opportunities for them to practice that social interaction.

There was also concern that some people with IDDs will find it very challenging to return to in-person visits, and it may require significant work to rebuild tolerance and comfort with health care settings.

Some people with IDDs had important rituals or reward systems surrounding the health care visit that served as motivation and positive reinforcement to support the health care visit, which were disrupted by the shift to virtual care. The mother of a 26-year-old autistic woman with multiple chronic health issues shared:

[My daughter] geared herself to these appointments by, you know, deciding what she's going to wear and

how she's going to get there. She's going to have a Starbucks latte afterwards or she's going to going into a special place after the appointment [...]. She makes it a special outing.

Without these rituals, some people with IDD were less motivated or willing to participate in the visit.

Caregiver Distress

Some caregivers felt that virtual care placed additional pressure on the caregiver to make medical decisions, conduct assessments, and communicate on behalf of the person they support. While the provider could conduct a physical examination during an in-person visit, virtual care required the caregiver to relay the relevant information to the provider to the best of their ability, and in some cases, they needed to conduct elements of the examination themselves (eg, monitoring blood pressure). This caused some caregivers a great deal of additional stress. The mother of a 28-year-old man with Down syndrome explained:

I have enough on my plate trying to parent him, trying to help him [...] manage every day, especially during COVID. To ask me to be the person that has to communicate all that to the medical person at the other end [...] can get to be extremely overwhelming. [...] For a family that has a child or an adult with intellectual disabilities who may or may not be able to communicate their needs, you're asking those parents to make even more decisions or communicate more things. And what if I mess up? What if I miss something?

Availability and Accommodation/Ability to Reach

This domain includes themes focused on the benefits or challenges of virtual care in facilitating the patient's and caregiver's abilities to attend a primary care visit. The following 4 themes were identified: technology quality, access, and skill; difficulty travelling and waiting; participation in the visit; and patient independence.

Technology Quality, Access, and Skill

A number of technology-related challenges were raised by participants as barriers to video-based care. Internet or technology failure (eg, internet cuts out or camera stops working) interrupted appointments. This was particularly challenging in more rural areas where internet quality is poor. Some patients, caregivers, and primary care providers also lacked skills or comfort using technology. This was further complicated by the fact that currently there are a number of approved secure video platforms used for health care in Ontario, which was confusing for some participants. The concern was also raised that not all patients and caregivers have access to internet-enabled devices or high-speed internet necessary to conduct video-based appointments. For these reasons, phone was sometimes preferred to video, which could appear to be too challenging and time-consuming to use. One physician shared:

I don't think the video worked very well at all. It was a challenge to set it up, you had to give a lot of

instructions on how to connect and turn it on. [...] And I found that even if I have a [video] visit, I still have to call them on the phone to see what was going on. 'Where are you?' 'Is it working?' So it's just frustrating. And then there were also technical glitches, screen freezes, no sound. [...] And also the quality, some people just don't have the Wi-Fi or Internet to have a great video quality so it's just a blurry picture. It's not helpful anyway.

Participants also shared, however, that they have become more skilled and comfortable using technology during the pandemic. In particular, it was noted that the pandemic has demonstrated that people with IDD are in many cases far more capable of using technology than was previously assumed. The mother of a 34-year-old woman with Down syndrome shared:

She is totally engaged [in virtual programs] and she's never done that before. She's never had the opportunity to try it this way. So this is a gift of COVID. All this came about because of COVID and people are seeing the benefits.

Difficulty Travelling and Waiting

There are some people with IDD for whom getting to an in-person visit or waiting in the waiting room is prohibitively difficult due to physical, mental, or behavioral challenges. Participants highlighted that for these individuals, virtual care is not only convenient, but also critical to enable them to access care. One physician shared:

It's not just that their needs are convenience, their needs are accessibility needs. It is very difficult to get a patient that requires, you know, an hour and a half of transitioning and then can't manage the sensory overload experience of the waiting room and, you know, other complex issues and is brought to the appointment by someone who isn't even their main caregiver and doesn't know them. Those aren't convenience issues, those are accessibility, accommodation needs.

Participation in the Visit

Participants noted that virtual care also impacted the extent to which patients, caregivers, and other health care providers can participate in the primary care visit. Virtual care allowed multiple caregivers, especially family members who live far away from the person they support, to all attend the visit, thus improving lines of communication and supporting appropriate decision-making. The brother of a 55-year-old man with Down syndrome described the benefits of everyone being in the same virtual room as follows:

Everything is transparent and there's no miscommunications. The group home staff are hearing the same thing that we are hearing.

Virtual care also supported case conferencing with multiple health care providers, improving care quality and coordination.

Patients, however, were less likely to be included in virtual primary care visits, particularly if they took place by phone. Sometimes it did not occur to the caregiver or provider that the

patient could or should be included. The mother of a 24-year-old autistic man explained:

Because it was a phone consult, I don't even think we thought of it to be honest.

Sometimes the patient was uninterested or harder to engage in the interaction. The sister of a 38-year-old autistic man shared:

He's not a part of it, no. He's nonverbal and he doesn't really communicate. We tried video [...] and he would sit down for maybe two minutes and then he just wants to bolt away. It doesn't keep his attention.

On the other hand, it was noted that a benefit of virtual care is that patients have the flexibility to come and go as they wish. A physician explained:

Even with the video calls, it's very rare that the patient will stay on the call the entire time. But I think that's OK, too. In some ways it's nice if I can see them and then the parents can give me the history and tell me more about what's been going on.

It was also suggested that it may be appropriate in some cases for the patient not to be included in the virtual visit. Examples were shared of successful hybrid approaches where an initial phone call with the caregiver was used to gather information, and then, a shorter in-person appointment was conducted with the patient, which was easier for them to tolerate.

Patient Independence

Participants appreciated that virtual care can support independence for some people with IDD who may need help with transportation but could participate in a virtual visit independently. A 30-year-old autistic man shared:

I don't drive, [my mom] drives. So it's basically on her to get me to the [clinic]. So it's better for me and her when I have an appointment and I don't have to physically go there.

Conversely, there were some people with IDD who could attend in-person appointments by themselves but required support for virtual encounters.

Affordability/Ability to Pay

This domain includes the following 3 themes related to the additional costs or costs saved due to virtual care: travel and parking costs, staff time, and technology costs. This domain received less focus in the interviews, potentially due to the challenges of isolating costs of virtual health care from the general increase in virtual interaction during the pandemic.

Travel and Parking Costs

Participants appreciated costs saved with virtual care due to avoided travel and parking costs. This is especially relevant for people who live further away from their primary care provider or in large urban centers with high parking costs.

Staff Time

Participants suggested that group homes or other supported settings may save costs due to fewer staff members needed to support in-person appointments.

Technology Costs

Participants reported that video appointments required increased spending on high-speed internet and internet-enabled devices and on information technology support in group home settings. However, it was noted that the increased spending on technology was not solely due to virtual health care. Some patients also incurred costs for medical equipment needed to support at-home monitoring (eg, blood pressure monitor, pulse oximeter, and scale).

Appropriateness/Ability to Engage

This domain includes findings related to service quality and effectiveness. The following 5 themes related to this domain were identified: communication and rapport, seeing patients at home, importance of the physical examination, privacy and confidentiality, and safety.

Communication and Rapport

In some cases, virtual care can be a barrier to effective communication. Some people with IDD were more reliant on nonverbal cues or body language for communication, which was lost entirely in phone interactions and was still sometimes challenging over video. The father of a 22-year-old autistic man explained:

Because of the autism, he doesn't pick up on the behavior cues as well virtually. [...] There's definitely a disconnect between what's... what he's able to process, and I don't think he gets as good cues. You need a full body to see what people are doing.

Similarly, physicians also missed important nonverbal information, such as lack of eye contact, repetitive movements, or hygiene issues, which may have impacted their ability to accurately diagnose and gauge patient comprehension. For those with hearing impairments, it was sometimes more difficult to understand the providers, especially if they had a heavy accent or if there was no visual component. Conversely, the chat function, if available, can offer a valuable alternative way to communicate for some individuals. Additionally, despite the limitations of video, it was sometimes a better option to see faces while mask requirements were in effect for in-person visits.

Despite the value of having multiple people participate in the visit, it sometimes made it more challenging to manage the conversation, especially by phone. One physician shared:

It's almost impossible on the phone to capture both voices. [...] Very, very difficult to really get that triadic relationship and back and forth on the speakerphone just because everyone struggles to know when to talk and [we] have no visual cues.

Participants also reported that it can be more difficult to develop rapport over virtual interactions, particularly when the visit is with a new primary care provider. People with IDD can have more difficulty engaging in virtual interactions and may be easily distracted when in their own homes. Without good communication and rapport, patients may be less interested in participating and less likely to disclose health issues, and important health issues may be missed.

Seeing Patients at Home

In-person visits can be an overwhelming and stressful experience for some people with IDD, causing distress for the individual and leading to a less effective appointment. Allowing the patient to participate from their home where they are calm and comfortable can improve the quality of the visit. One physician explained:

For my patients who don't enjoy coming into clinic, it's very stressful for them in terms of the sensory stimuli [and] in terms of the social interaction. I found that being on video, or just by phone even, I'm able to get a lot more history from them and a lot more engagement in that discussion than if they were in office because they're so overwhelmed and so just preoccupied with being in the office that there really isn't that much bandwidth to engage.

Participants shared that in some cases, virtual care allowed them to reduce or eliminate use of medications that were previously needed to get the patient to the appointment. Video visits have the additional benefit of allowing primary care providers to see how patients act in their home environments, which can be important to inform appropriate treatment.

Importance of the Physical Examination

Participants stressed that in-person physical examinations will always be a necessary component of care. It was suggested that for some adults with IDDs, the physical examination is even more important because they are unable to describe their symptoms. One physician shared:

I think what ended up happening was I just, I really wasn't trusting my virtual assessments in the same way that I might in someone in the general population. So I was often bringing them into clinic, just feeling like I had to do the clinical exam to complete my assessment and honestly, just to reassure myself of my virtual assessment.

There are some types of primary care visits that must be conducted in-person but others that may be possible to conduct virtually depending on a range of factors, including the capacity of the caregiver to support an examination or administer treatment, the feasibility of a quality video visit, the patient's level of insight into their physical health, and the patient's ability to communicate virtually.

Privacy and Confidentiality

Patients who lived with the family or in supported settings did not always have a private space from which to participate in the primary care visit. Primary care providers expressed concern that they did not always know who else was in the room or able to listen to the visit. There were also concerns about cyber security for medical information shared online. It was noted that this patient population may be particularly vulnerable to scams and may end up disclosing medical information to predators.

Safety

Participants highlighted that an important benefit of virtual care was infection control. This was critical during COVID-19 but

could also be an important ongoing benefit beyond the pandemic. This was also particularly relevant for some people with IDDs who could not tolerate wearing masks. There were some circumstances, however, when participants felt that in-person care was safer, such as when discussing topics that might trigger thoughts of self-harm. The father of a 22-year-old autistic man with complex mental health needs shared:

In person, there's the safety factor. If there's something that's been triggering for [my son], I think he feels safer if there's somebody else physically there.

Contextual Factors

Across the 4 access-to-care dimensions, we found that virtual care can be accessible for some individuals under certain circumstances. The success or appropriateness of a virtual care encounter is dependent on the interaction between 5 categories of factors. First, the characteristics of the individual patient, including their communication ability or style, income, skill and comfort using technology, difficulty attending in-person appointments, and visit frequency. Second, the patient's context, including their distance from the health care service, the local internet quality, and access to a private space to conduct the appointment. Third, the characteristics of the caregiver, including their skill and comfort using technology, income, distance from the patient, and other responsibilities (eg, multiple caregiving roles). Fourth, the service context, including the usability of the virtual platform, the provider reimbursement model, the provider's skill and comfort using technology, and whether the provider has a pre-existing relationship with the patient. Fifth, the specific reason for a particular health care visit, for example, if the visit requires a physical examination or a more complex or triggering discussion. Some of these variables are fixed, but many may change over time or per individual health care visit.

Discussion

Principal Findings

This qualitative study explored the accessibility of virtual primary care for patients with IDDs during the COVID-19 pandemic. A key finding was that one size does not fit all. We identified themes across 4 dimensions of accessibility that highlighted both the benefits and challenges of virtual care. For some patients, virtual delivery was critical to accessing necessary health care; for other patients, virtual delivery posed a barrier to accessing high-quality care. Whether virtual care was accessible was dependent on a combination of factors, including the characteristics of the patient, the patient's context, the characteristics of the caregiver, the service context, and the reason for the specific health care visit. Some of these variables may be relatively constant (eg, patient's communication style), some may change over time (eg, comfort with technology, distance from the provider, and private space), and some may change per appointment (eg, need for a physical examination).

Many of the themes identified in this study align with those identified in previous studies focused on the general patient population. Virtual care had many benefits, especially for simple issues or follow-up care. The benefits included greater

convenience for patients, lower risk of COVID-19 transmission, and the value of seeing patients in their home environment [1,6,44,51]. Virtual care was not appropriate for issues that required a physical examination, and while some issues could be diagnosed via photographs or video observations, this could be challenging due to technology failures, lack of nonverbal communication, privacy concerns, and difficulties establishing rapport with new patients [1,6,44,51].

This study showed, however, that these same issues may look different or require different accommodations for patients with IDD. One important difference for patients with IDD is that there is often a caregiver involved, leading to additional considerations for virtual care, such as the caregiver's comfort using technology, the value of facilitating the caregiver's participation if they live far away, and difficulties managing calls with multiple participants. Communication and rapport in virtual care may be challenging for many individuals but can be additionally challenging for individuals with IDD who are nonverbal, use communication devices, or have trouble engaging in virtual interactions. The physical examination is a critical component of care for all patients, but it can play a larger role in the care of people with IDD if they are unable to identify or articulate their symptoms. Privacy may be a concern for anyone participating in a health care visit from their home, but it can be a particular concern for people with IDD who live in congregate settings. Virtual care may be convenient for many patients, but for some people with IDD, it is a necessary accommodation to support access to care.

The fifth access dimension, approachability, was not identified in this study but is nonetheless important to consider in designing accessible primary care systems. There has been a great deal of inconsistency in how primary care has been delivered during COVID-19, and patients and caregivers are likely unaware that it is possible to receive care in different ways than offered by their primary care provider. Direct education is needed for patients and caregivers to ensure they know what is available, what they are entitled to, and how to advocate for it.

It is important to note that some of the challenges and benefits of virtual care identified in this study are specific to the current context and may be less relevant moving forward. Some of the benefits of virtual care are related to COVID-19, including reducing the risk of COVID-19 transmission and accommodating patients who cannot tolerate wearing masks. Additionally, some of the challenges are because virtual care was implemented abruptly, with little existing infrastructure to deliver it effectively, for patients with little experience participating in virtual care. In this study, some participants noted that at the time of their interview, at least 1 year into the pandemic, they already felt more comfortable and proficient using technology and participating in virtual care than they did at the start of the pandemic. People will likely continue to become more comfortable with virtual care as technology infrastructure improves and everyone becomes more accustomed to virtual interactions.

Implementing Accessible Virtual Care

It is clear from the study findings that the relevant question is not whether virtual care is accessible, but how it can be implemented in a way that will promote and not hinder health care accessibility. This study suggests that an optimal system should include multiple modalities depending on patient need and preference, including in-person, telephone, video, and written communication options. Achieving this type of flexible patient-centered system requires policies and supports considering both care delivery and use.

From an implementation lens, the largest hurdle seems to be supporting video-based care. The vast majority of virtual care in Ontario has been delivered by telephone, with only a relatively small proportion of virtual care delivered by video [24,25]. This study suggested that while telephone care can be very effective in some cases, it also has a number of limitations, including communication for individuals with hearing impairments or who are reliant on nonverbal communication, developing rapport between patients and providers, and managing conversations with multiple participants. These limitations can lead to health issues being missed and patients with IDD being less engaged or excluded entirely from the visit. While telephone and in-person options may be sufficient in many cases, this study suggests that video can play an important role in supporting accessible care and should be part of the basket of services available.

To support greater implementation of video-based care, it is important that patients and their caregivers have access to high-speed internet and video-enabled devices. During the pandemic, some health care organizations provided tablets and smartphones to low-income patients [52]. With appropriate funding, this is a practice that could be expanded across primary care practices. High-speed internet continues to be a challenge in parts of the province, and public investment is needed to build capacity [53]. Currently, multiple virtual platforms are used in the health care system, many of which are not user friendly. Ideally, a common virtual platform should be implemented across the system that is easy for patients, caregivers, and primary care providers to use; has built-in accessibility features (eg, chat box and captioning); and can be integrated into electronic medical record systems. Given that primary care providers may themselves struggle to use technology and do not have the time or expertise to provide technical support to patients and families, primary care practices would benefit from including a dedicated staff role to provide technical support [54,55]. This could include meeting patients at the beginning of the appointment to orient them to the platform and troubleshooting technical issues before the provider joins the session or even offering in-person practice sessions to teach patients and family members how to use the virtual platform.

Beyond building capacity for video-based care, we also need health care funding structures that facilitate and incentivize delivery of both in-person and virtual care options according to patient need and preference. There are unintended consequences with any reimbursement model, but it has been recommended that the best strategy to avoid incentivizing a

particular modality to the detriment of patients is shifting from a fee-for-service model to capitation or salary-based payment models [44].

Primary care providers also need training on how to deliver care virtually. Currently, most providers have received little if any training on when virtual care is appropriate, how to work with patients to determine the most appropriate type of care per visit, and how to effectively deliver care using virtual modalities [56]. There is starting to be more focus on the importance of this topic in medical education [57-59], and it is critical that these programs include considerations for different patient groups, including patients with IDD. It is important to also highlight that primary care providers generally receive little specific training on how to care for patients with IDDs [60-62]. Any virtual care-specific training should be situated within general competencies to provide high-quality care to patients with IDDs.

Efforts to support the implementation of high-quality accessible virtual care should be informed by the large body of literature on implementation and health technology. Frameworks, such as the nonadoption, abandonment, scale-up, spread, and sustainability (NASSS) framework developed by Greenhalgh et al [63], can help outline the many considerations, including but not limited to those identified above, required for successful adoption of virtual care.

Strengths and Limitations

This is one of the few studies we are aware of that looks at the accessibility of virtual primary care for adults with IDDs. A strength of the study is the inclusion of a diverse sample, including patients, family members, IDD support staff members, and physicians, to elicit perspectives from a range of different experiences. However, this study only collected limited demographic data on participants, and we cannot speak about the diversity of participants in terms of race or other important intersectional identities. This study was conducted in English, and it would be important for future work to look at the impact of virtual care for non-English speakers who may have different experiences. The study was limited to individuals who had participated in at least one virtual primary care visit. Therefore, individuals unable, unwilling, or lacking the opportunity to participate in virtual care were not included. Most participating physicians had practices that included a focus on patients with IDDs, and their perspectives may differ from the perspectives

of physicians less experienced in caring for this patient population.

The study was also limited to one Canadian province, and people in jurisdictions with different pandemic restrictions or different health care delivery systems may have had different experiences. This study reflects a single interview conducted with each participant during the second year of the pandemic. Though some participants described how their perspectives changed, we did not assess this directly. This study included perspectives from all members of the health care triad (patients, caregivers, and providers) but not related to the same encounter. It would be important for future studies to compare perspectives from the same encounter to understand how they may be similar or different.

All interviews were conducted virtually due to pandemic restrictions. Based on the interviewer's observations, good rapport was developed with participants, and they generally provided positive feedback on the interview experience. However, some interviews were disrupted due to technical challenges. In 6 cases, these challenges were severe enough to require the interview to be completed by phone. It is possible that these challenges or other issues not immediately apparent to the interviewer (eg, lack of rapport or participant discomfort) may have impacted the quality of the information gathered.

Conclusions

The COVID-19 pandemic has provided a unique opportunity to learn about the accessibility of virtual primary care for adults with IDDs. This study found that virtual care can increase the accessibility of primary care for some individuals with IDDs under some circumstances and decrease accessibility for others. To meet the needs of all patients, a flexible patient-centered approach is needed that includes in-person, phone, and video options. This system must be supported by the necessary infrastructure, resources, and supports to ensure that the potential benefits of virtual care can be fully realized. This includes training for patients, caregivers, and primary care providers; universal access to the technology necessary to participate in virtual care; implementation of accessible virtual care platforms; and a primary care funding structure that can facilitate and incentivize delivery of both in-person and virtual care. While virtual care is not appropriate or desirable for all patients, there is a subset of patients with IDDs for whom virtual care is not just convenient but can enable access to necessary health care.

Abstract

Background: The Data and Connectivity COVID-19 Vaccines Pharmacovigilance (DaC-VaP) UK-wide collaboration was created to monitor vaccine uptake and effectiveness and provide pharmacovigilance using routine clinical and administrative data. To monitor these, pooled analyses may be needed. However, variation in terminologies present a barrier as England uses the Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT), while the rest of the United Kingdom uses the Read v2 terminology in primary care. The availability of data sources is not uniform across the United Kingdom.

Objective: This study aims to use the concept mappings in the Observational Medical Outcomes Partnership (OMOP) common data model (CDM) to identify common concepts recorded and to report these in a repeated cross-sectional study. We planned to do this for vaccine coverage and 2 adverse events of interest (AEIs), cerebral venous sinus thrombosis (CVST) and anaphylaxis. We identified concept mappings to SNOMED CT, Read v2, the World Health Organization's *International Classification of Disease Tenth Revision* (ICD-10) terminology, and the UK Dictionary of Medicines and Devices (dm+d).

Methods: Exposures and outcomes of interest to DaC-VaP for pharmacovigilance studies were selected. Mappings of these variables to different terminologies used across the United Kingdom's devolved nations' health services were identified from the Observational Health Data Sciences and Informatics (OHDSI) Automated Terminology Harmonization, Extraction, and Normalization for Analytics (ATHENA) online browser. Lead analysts from each nation then confirmed or added to the mappings identified. These mappings were then used to report AEIs in a common format. We reported rates for windows of 0-2 and 3-28 days postvaccine every 28 days.

Results: We listed the mappings between Read v2, SNOMED CT, ICD-10, and dm+d. For vaccine exposure, we found clear mapping from OMOP to our clinical terminologies, though dm+d had codes not listed by OMOP at the time of searching. We

found a list of CVST and anaphylaxis codes. For CVST, we had to use a broader cerebral venous thrombosis conceptual approach to include Read v2. We identified 56 SNOMED CT codes, of which we selected 47 (84%), and 15 Read v2 codes. For anaphylaxis, our refined search identified 60 SNOMED CT codes and 9 Read v2 codes, of which we selected 10 (17%) and 4 (44%), respectively, to include in our repeated cross-sectional studies.

Conclusions: This approach enables the use of mappings to different terminologies within the OMOP CDM without the need to catalogue an entire database. However, Read v2 has less granular concepts than some terminologies, such as SNOMED CT. Additionally, the OMOP CDM cannot compensate for limitations in the clinical coding system. Neither Read v2 nor ICD-10 is sufficiently granular to enable CVST to be specifically flagged. Hence, any pooled analysis will have to be at the less specific level of cerebrovascular venous thrombosis. Overall, the mappings within this CDM are useful, and our method could be used for rapid collaborations where there are only a limited number of concepts to pool.

Introduction

COVID-19 vaccination is the best option for controlling the current pandemic, with data about uptake and pharmacovigilance (the science and activities relating to the detection, assessment, understanding, and prevention of any side effects of a vaccine or drug) therefore essential for monitoring its progress. Since COVID-19 was first identified in Wuhan, China, at the end of 2019, the virus has spread worldwide, with more than 190 million confirmed cases and over 5.9 million COVID-19-related deaths as of February 28, 2022 [1,2]. Worldwide, most health care systems have opted for a vaccination strategy to protect public health by reducing the incidence but, most importantly, serious outcomes leading to hospitalization and death. Five vaccines have been approved for use in the United Kingdom by the Medicines and Healthcare products Regulatory Agency (MHRA). The first 2, Pfizer-BioNTech and Oxford-AstraZeneca, have been used since December 2020 and January 2021, respectively [3,4]. Real-world data (RWD) suggest that these vaccines are effective [5,6] in preventing severe disease and death; RWD in medicine are data derived from any number of sources that are associated with outcomes in a heterogeneous patient population in real-world settings, such as patient surveys, clinical trials, and observational cohort studies. However, there has been concern about the risk of adverse effects, such as thrombotic thrombocytopenia and anaphylaxis [7,8]. It is important to be able to monitor these at scale to give power to detect potential associations with rare adverse events of interest (AEIs). AEIs are medical conditions arising after the administration of a vaccine, not necessarily causally linked.

Medical record systems enable information flow beyond organizational boundaries. General practices with their own information technology (IT) systems record millions of patient interactions daily. A challenge for this partnership is the heterogeneity of routine primary care data due to variation in the clinical terminologies used across the 4 UK nations. The Data and Connectivity COVID-19 Vaccines Pharmacovigilance (DaC-VaP) collaboration was formed to explore vaccine effectiveness, uptake, and safety across the United Kingdom.

England has transitioned to the Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT) and has not updated Read v2 since April 2016 [9]. Read v2 is a clinical terminology system (5-byte version) that was developed by Dr. James Read. However, the devolved nations (Scotland, Wales, and Northern Ireland) still use the Read terminology. In addition, the levels of granularity and hierarchy of the 2 are incompatible, making comparison of the results of any analysis a challenge. Primary care data have not been included in the Northern Ireland component of the study because systems to make anonymized primary care data available for research are under development.

The use of a common data model (CDM) could provide a solution faced by many looking to aggregate data from different sources [10,11]. CDMs use logic and semantics (in the case of the OMOP CDM, having 1 standard reference vocabulary per domain so that everyone is “speaking the same language”) to standardize data and enable data from different sources to be used in pooled analyses. The use of CDMs is common within clinical research, and at present, 3 are cited in many studies: (1) the Observational Medical Outcomes Partnership CDM (OMOP; used to be a partnership project but now only designates a type of a CDM for RWD/evidence in clinical research), (2) the US Food and Drug Administration (FDA) Sentinel CDM (the Sentinel Operations Center [SOC] coordinates the network of Sentinel data partners and leads the development of the Sentinel common data model [SCDM], a standard data structure that allows the data partners to quickly execute distributed programs against local data), and (3) the Patient-Centered Outcomes Research Institute (PCORI) CDM (PCORnet; facilitates the sharing of information across PCORI's wider network and is based on the mini-SCDM) [12]. The OMOP CDM, the most cited of the 3, enables the transformation of data from diverse observational databases into a common format using a standardized vocabulary [13]. The OMOP CDM includes different data domains required for observational studies, including demographics, vaccine exposure, and AEIs relevant to this study [14].

Other groups, including the National COVID Cohort Collaborative (N3C) in the United States, have faced challenges in how to achieve harmonization between data sources. Although

this was customized and drew together data from different sources and CDMs, the N3C also extensively used OMOP [15]. We carried out this study, therefore, to test the feasibility of using the OMOP CDM for comparisons of vaccine uptake and AEs across the 4 UK nations.

Our primary aim is to assess the feasibility of using the OMOP CDM to report the incidence of exemplar AEs following COVID-19 vaccination across the DaC-VaP collaboration and report these as repeated cross-sectional analyses. The objectives of the study include the following:

- To test the validity of the mappings within the OMOP Automated Terminology Harmonization, Extraction, and Normalization for Analytics (ATHENA) online browser to our exemplar AEs. ATHENA is a repository of all the latest OMOP CDM vocabularies and mappings are hosted and can be searched and downloaded.
- To report the vaccine uptake rate across the United Kingdom, stratified by age group, sex, vaccine type, and ethnicity, with the goal of reporting a UK-wide vaccination uptake rate. We differentiated people who have had their first and second doses.
- To report the rates for England, Scotland, Wales, and Northern Ireland and overall for the 2 exemplar AEs, cerebral venous sinus thrombosis (CVST) and anaphylaxis.

Methods

Overview

We used the OMOP ATHENA online browser to identify mappings to SNOMED CT, Read v2 terminology, and the *International Classification of Disease Tenth Revision* (ICD-10). We reported vaccine exposure using SNOMED CT for vaccine administration and *Dictionary of Medicines and Devices* (dm+d; National Health Service [NHS]) codes for vaccine prescriptions; dm+d is a dictionary of descriptions and codes which represent medicines and devices in use across the NHS. Each national team validated these mappings and any differences between the terms they would use to represent each concept discussed with a decision made by consensus. We then used to create monthly reports of vaccine coverage and AEs. We elected to use CVST and anaphylaxis as demonstration AEs [16].

Settings

The data were drawn from the data sources of the 4 DaC-VaP partners.

English Data

The data from England are from the Oxford Royal College of General Practitioners (RCGP) Research and Surveillance Centre (RSC), 1 of Europe's oldest surveillance networks. It is now in its 53rd season of operation, working alongside Public Health England (PHE) [17]. The RSC has been involved in monitoring studies of influenza vaccine safety. This network is active in COVID-19 research, including the PRINCIPLE (Platform Randomized Trial of Treatments in the Community for Epidemic and Pandemic Illnesses) trial [18]. The RSC is the surveillance platform of the Oxford RCGP Clinical Informatics Digital Hub (ORCHID, a secure data processing environment) [19,20].

Scottish Data

The EAVE II data of 5.4 million people registered in general practices in Scotland track COVID-19 within the Scottish population. This effort has led to impactful findings used by the Scottish and UK governments to respond to the COVID-19 pandemic.

Welsh Data

The Secure Anonymised Information Linkage (SAIL) databank is a trusted research environment (TRE), a Wales-wide research resource focused on improving health, well-being, and services, which includes primary care general practitioner (GP) records, secondary care hospital data, and emergency services data, along with a range of administrative, governmental, education, social care, and specialist audit, register, and services data. These data are also used by the National Institute for Health and Care Excellence (NICE) to shape policies that cover England and Wales. SAIL is powered by the Secure e-Research Platform (SeRP, a technology platform and service that enables the SAIL databank and other TREs and platforms in the United Kingdom and worldwide).

Northern Ireland Data

Data are accessed through the Business Services Organisation Honest Broker Service (HBS), which also uses SeRP. It has available GP registration (but not primary care clinical records), the enhanced prescribing database, emergency department attendances, hospital admissions, COVID-19 testing, and the vaccine management system.

Study Design

We performed repeated cross-sectional reports of the incidence of the AEs in the vaccinated population in a single time interval postvaccination.

Phase 1: Validating OMOP Mapping and Creating Searches for Distributed Analyses

We searched the OMOP CDM for the concepts of interest using the ATHENA online browser. These concepts were demographic details, COVID-19 vaccine uptake, and the AEs. The demographic and socioeconomic status (SES) data of interest were age and sex, and the SES was divided into quintiles (quintile 5 being the most deprived). We also collected data on obesity (defined as the latest BMI \geq 30 or coded as obesity; the BMI is a measure that uses your height and weight to work out whether your weight is healthy) and smoking status (current, ex-, or never smoked).

We compared the linkages flagged by the OMOP ATHENA online browser with those currently used across the 4 nations. We reported any differences and achieved a consensus as to which terms/codes will be used in each nation.

OMOP also maps to the *Medical Dictionary for Regulatory Activities* (MedDRA), and if the method in this protocol became established, considerations for enabling reporting of pharmacovigilance study findings mapped to MedDRA.

Each DaC-VaP partner nation will restrict its ATHENA search using the VOCAB (vocabulary) tool to SNOMED CT or Read v2, as relevant, and dm+d.

The medication dictionary dm+d is made up of a hierarchy of generic terms (termed “virtual”) and real prescribable items (termed “actual”). The dm+d use case for the COVID-19 vaccine is set out below:

- Virtual therapeutic moiety (VTM): top of the hierarchy (type of therapy indicator, eg, COVID-19 vaccine); in this use case, this is the COVID-19 vaccine.
- Virtual medicinal product (VMP): This is the next level of notional product and allows vaccine types (COVID-19 vaccine type: mRNA or vector); in our use case, messenger RNA (mRNA) vaccines and their manufacturers were to be distinguished from recombinant vaccines.
- Virtual medicinal product pack (VMPP): This is the notional product pack for the medical VMP, for example, a 6-dose multidose vial.
- Actual medicinal products (AMPs): These are the medicinal products prescribed to an individual; for example, vaccine brands (Pfizer-BioNTech, Moderna).
- Actual medicinal product packs (AMPPs): These are the distribution packs of medicinal products.

The analyst team from each nation reported whether they included all the terms identified from their search of OMOP for mapping to their terminology using ATHENA and whether they added others they routinely use.

Phase 2: Monthly Reports and Aggregation of Results

We ran these searches monthly to produce a monthly output of vaccine coverage by demographic group and reported the incidence of our AEs.

Vaccine uptake was reported as the percentage of adults vaccinated per nation and stratified by age, sex, smoking status, and obesity. We reported 2 exemplars of AEs following vaccination using 2 time windows (0-2 and 3-28 days).

Cross Sections, Exposures, and Outcomes

DaC-VaP partners ran cross-sectional studies for the previous 28 days.

The first search started on December 8, 2020 (first dose of the Pfizer vaccine given in the United Kingdom), and the second search on January 5, 2021. These ran in 28-day intervals (February 2, March 2, March 30, April 27-August 17, 2021).

The cross sections included all individuals registered with general practices on the date of vaccination and remained registered for 28 days. The outputs were reported in the following age bands: <16 years old, 16-39 years, 40-64 years, and 65 years and older. Mortality in the postvaccination period were also reported for those with AEs.

We reported by vaccine brand, including reporting unknown vaccines. We presumed that the unknown vaccine brand for December 2020 was Pfizer-BioNTech, as Oxford-AstraZeneca was unavailable until January 2021 and other vaccine types later.

We aimed to include statistical reporting and disproportional analysis metrics, a proportional reporting ratio (PRR), and a reporting odds ratio (ROR). We used a Bayesian method that provided a framework to combine prior information/knowledge

and data to account for conceptual transparency. Our aim was to use $IC = \log_2(\text{observed} + 1/2)/(\text{expected} + 1/2)$.

Ethical Considerations

The DaC-VaP collaborators had individual ethical control of their data. No data were reported that might risk identifying individuals. Where less than 5 individuals were in a group, this was reported as <5. This study aims to demonstrate the potential of the DaC-VaP collaboration to report outcomes of interest.

English Data

The University of Oxford complies with the General Data Protection Regulation and the NHS Digital Data Security and Protection Policy [21]. This study was approved by the Health Research Authority Research Ethics Committee (21/HRA/2786; (Integrated Research Application ID 301740). ORCHID meets the NHS Digital Data Security and Protection Toolkit requirements. [22].

Scottish Data

Ethical permission for this study was granted by the South-East Scotland Research Ethics Committee (#314 02; 12/SS/0201). The Public Benefit and Privacy Panel Committee of Public Health Scotland (#315) approved the linkage and analysis of the de-identified data sets for this project (#1920-0279).

Welsh Data

This study made use of anonymized data held in the SAIL databank. We used data provided by patients and collected by the NHS as part of their care and support. All research conducted was completed after the permission and approval of the SAIL independent Information Governance Review Panel (IGRP; project number 0911).

Northern Ireland Data

Northern Irish data were accessed from the Business Services Organization HBS, which provided de-identified linked data via SeRP. All research conducted was approved by the HBS Governance Board (HBSGB; project number 064).

Results

Study Concepts Within the OMOP CDM

We initially reported whether the data items or clinical concepts required for the study existed within the OMOP CDM and whether there were mappings to SNOMED CT, Read v2, or dm+d (Table 1).

We then reported the components by terminology (Table 2). Age did not map to the Read v2 terminology, but this is of no practical significance. We noted that the SES only exists as a generic concept in OMOP and that a custom mapping would be required. There was no mapping of vaccine dose (first or second) to Read v2. However, like age, this would not be practically important as these data are well ordered in the DaC-VaP collaborators' data sources.

Of most importance are the AEs. For CVST, the specific concept exists within OMOP, and it also exists in SNOMED CT: SNOMED concept IDs 95455008 and 19522900 from CVST

(concept ID 195229008). For anaphylaxis, SNOMED CT and the ATHENA online browser showed 130 and 161 items, respectively. SNOMED CT and OMOP had 16 and 15 items, respectively. Read v2 codes were generic for CVST and

anaphylaxis. Of these, those relevant to vaccination are shown in Tables 2, 3, 4, and 5 for England, Wales, Scotland, and Northern Ireland, respectively.

Table 1. Variables included in the CDM^a conceptual mapping exercise, with counts subsequently reported monthly.

Data item	OMOP ^b (Y=yes, N=no)	Data source
Demographics		
Gender	Y	Standardized sex (gender) codes are used in OMOP CDM mapping. Date of birth and age concepts also exist.
Age band	Y	Date of birth and age concepts exist in OMOP.
SES^c quintile		
The Index of Multiple Deprivation (IMD, a set of relative measures of deprivation for small areas [lower-layer super-output areas] across England, based on 7 domains of deprivation), in England, the Scottish Index of Multiple Deprivation (SIMD), the Welsh Index of Multiple Deprivation (WIMD), and the Northern Ireland Multiple Deprivation Measure (NIMDM)	N	Does not exist in the OMOP CDM. It can be introduced as a custom mapping in all UK databases within OMOP. It is to be harmonized across the DaC-VaP ^d data partners (quintile 5 most deprived, quintile 1 least deprived).
Other characteristics		
BMI>30/obesity	Y	Will be found in the measurement table or from a diagnosis of obesity.
Smoking status	Y	Will be found in the observation table.
Vaccination		
Vaccine type	Y	Will be found in the drug, procedure, and event tables. For England, the source codes are dm+d ^e or SNOMED CT ^f .
Vaccine dose	Y	In vaccine administration.
Vaccination date	Y	Date of event when the event is COVID-19 vaccination.
Exemplar AEs^g		
CVST ^h	Y	Will be found in the condition table. It is mapped to SNOMED CT or Read v2. We did not include medications in this feasibility study.
Anaphylaxis	Y	Will be found in the condition table. It is mapped to SNOMED CT or Read v2. We did not include medications in this feasibility study.

Vaccine Exposure

COVID-19 vaccine exposure was well recorded with dm+d and SNOMED CT. The vaccine unsurprisingly was listed as a VTM at the top of the drug dictionary hierarchy, with VMPs created for each vaccine type. There were virtual and actual packs and

products to match the vaccines available. Additional administration and vaccine-type clinical terms were also within SNOMED CT (Table 6). Finally, we found a small number of vaccine administration codes within dm+d that were not mapped to OMOP.

Table 6. COVID-19 vaccine concepts.

Discussion

Principle Findings

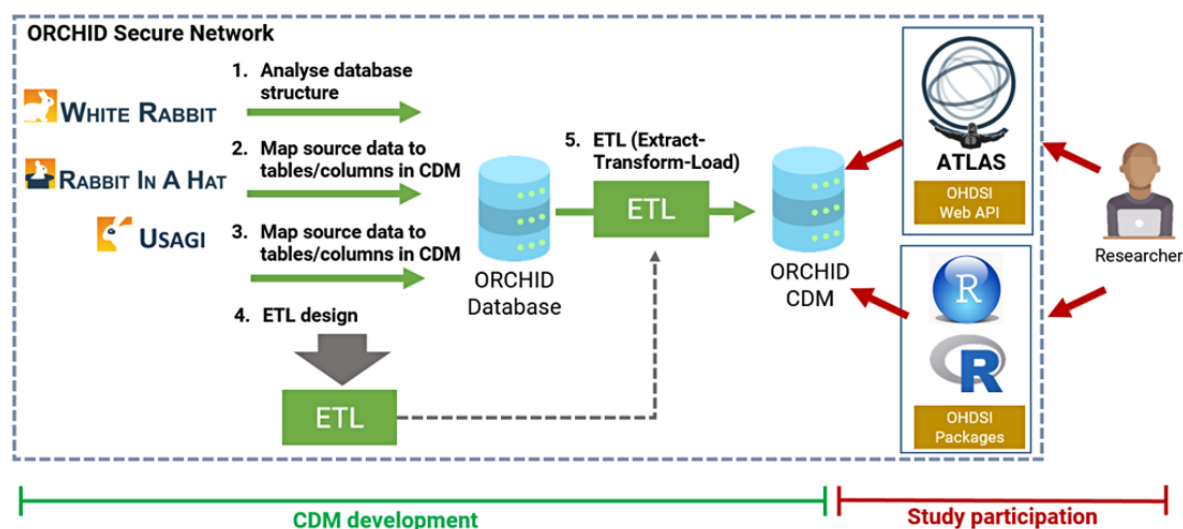

This study shows a mapping method to identify codes relevant to CVST and anaphylaxis using the OMOP CDM to link common concepts required for COVID-19 vaccine pharmacovigilance to different terminologies relevant to the United Kingdom. All our predefined concepts were represented in the OMOP CDM. However, some, such as SES, did not have specific mappings and, thus, custom mappings would need development. We noted that local codes and curation of variables may be used to enable specificity where the concepts are less granular, especially for CVST.

Comparison With Prior Work

The OMOP CDM may be suboptimal to overcome the limitation in the granularity of the coding systems used for AEs. As well as being less granular, the Read v2 terminology has not been updated formally since April 2016, so local adaptations have been undertaken in the developed UK nations to enable new conditions and treatments, such as COVID-19 and vaccination, to be recorded.

Conventionally, CDMs, such as OMOP, are used by each database, mapping data and querying them using the script created by 1 of the teams. The cataloguing is carried out using applications such as White Rabbit and Rabbit in a Hat (Figure 1).

Figure 1. Formal mapping of a database (in this case ORCHID) to the OMOP CDM. We used 3 steps to develop the extract, transform, and load (ETL) design. We tested this specifically in relation to the SQL environment of the ORCHID database. CDM: common data model; OHDSI: Observational Health Data Sciences and Informatics; OMOP: Observational Medical Outcomes Partnership; ORCHID: Oxford RCGP Clinical Informatics Digital Hub.

Limitations

The OMOP CDM provides a framework for capturing patient demographic and socioeconomic characteristics, varying vaccine exposure [23], and AEI data. Although others could replicate our approach, avoiding the need to map whole databases, initial findings reflect the relative size of the terminologies we use, and their granularity needs improvement. Therefore, to conduct future research, concepts will require localization to evaluate COVID-19 vaccination associated with CVST and anaphylaxis. We selected dm+d rather than the better-known British National Formulary (BNF), although the latter is mapped to SNOMED CT. Its limitations are that it only lists prescribable drugs. Its chapter headings change from time to time, and it is not mapped to the ATHENA OMOP hierarchy. We considered MedDRA with clinically validated medical terminologies for clinical conditions, medical devices, and medicines that is commonly used to share AEIs mainly with regulators. MedDRA is primarily

used to report pharmacovigilance using acute care and clinical trial data. This approach cannot be directly used within primary care but will be considered for future studies.

Conclusion

Concept mapping to a large number of terminologies, such as within OMOP and its ATHENA online browser, are usable and valuable for those conducting studies that draw together heterogeneous data to perform pooled analyses. Comprehensive mappings have to set a level of granularity that may be more or less specific than the terminologies they map to. Clinical variable curation at a local database level would prove useful to address issues around granularity. This would allow local expert refinement of the mappings that could be used by others looking to do a limited pooled analysis of a small number of clinical concepts. The interconnectivity of the pooled analysis may also support the MHRA's Spontaneous Report System used for optimizing patient safety.

Acknowledgments

We thank patients registered with practice members of the Oxford Royal College of General Practitioners (RCGP) Research and Surveillance Centre (RSC) who allowed their pseudonymized data to be shared for this research. We also thank EMIS (Education Management Information System), TPP (The Phoenix Partnership), InPractice Systems, and Wellbeing for cooperation to facilitate data extraction. The RSC is principally funded by the UK Health Security Agency.

We would also like to acknowledge all data providers who made anonymized data available for research. We wish to acknowledge the collaborative partnership that enabled acquisition and access to the de-identified data, which led to this output. The collaboration was led by the Swansea University Health Data Research UK team under the direction of the Welsh Government Technical Advisory Cell (TAC) and includes the following groups and organizations: the Secure Anonymised Information Linkage (SAIL) databank, Administrative Data Research (ADR) Wales, Digital Health and Care Wales (DHCW), Public Health Wales, the National Health Service (NHS) Shared Services Partnership (NWSSP), and the Welsh Ambulance Service Trust (WAST).

Authors' Contributions

SdeL conceived the approach in collaboration with FDRH and A Sheikh. SdeL, GD, and A Stipanac drafted versions of the protocol, with input from all authors who have read and approved the paper.

Conflicts of Interest

SdeL reports that through his university, he has had grants from AstraZeneca, GSK, Sanofi, Seqirus, and Takeda for vaccine-related research and membership of advisory boards for AstraZeneca, Sanofi, and Seqirus. FDRH acknowledges part support as director of the National Institute for Health and Care Research (NIHR) Applied Research Collaboration (ARC) Oxford Thames Valley, and theme lead of the NIHR Oxford University Hospitals (OUH) Biomedical Research Centre (BRC). FDRH also received occasional fees or expenses for speaking or consultancy from AstraZeneca, Boehringer Ingelheim (BI), Bayer, Bristol Myers Squibb (BMS)/Pfizer, and Novartis. A Sheikh serves as an adviser to the UK and the Scottish Governments. He is also a member of Astra-Zeneca's Thrombotic Thrombocytopenic TaskForce. All these roles are unremunerated. RO is a member of the National Institute for Health and Care Excellence (NICE) Technology Appraisal Committee, member of the NICE Decision Support Unit (DSU), and associate member of the NICE Technical Support Unit (TSU). She has served as a paid consultant to the pharmaceutical industry, providing unrelated methodological advice. She reports teaching fees from the Association of British Pharmaceutical Industry (ABPI) and the University of Bristol. RAL is an unremunerated member of the Welsh Government COVID-19 Technical Advisory Group. All other authors declare no conflicts of interest.

Abstract

Background: Screen time (ST) drastically increased during the COVID-19 pandemic, but there is little research on the specific type of ST use, degree of change from before COVID-19, and possible associations with other factors. Young adults are a particular interest since previous studies have shown the detriment ST has on a young person's health. With the combination of a life-changing pandemic, there are unreached depths regarding ST and young adults. This study aims to provide insight into these unknowns.

Objective: This study aims to assess ST in 3 domains (entertainment, social media [SM], and educational/professional) in young adults early in the COVID-19 pandemic; identify trends; and identify any correlations with demographics, mental health, substance abuse, and overall wellness.

Methods: An online, cross-sectional observational study was performed from September 2020 to January 2021 with 183 eligible respondents. Data were collected on ST, trauma from COVID-19, anxiety, depression, substance use, BMI, and sleep.

Results: The average total ST during COVID-19 was 23.26 hours/week, entertainment ST was 7.98 hours/week, SM ST was 6.79 hours/week, and ST for educational or professional purposes was 8.49 hours/week. For all categories, the average ST during COVID-19 was higher than before COVID-19 ($P < .001$). We found ST differences between genders, student status, and continent of location. Increased well-being scores during COVID-19 were correlated with greater change in total ST ($P = .01$). Poorer sleep quality ($P = .01$) and longer sleep duration ($P = .03$) were associated with a greater change in entertainment ST ($P = .01$). More severe depression and more severe anxiety was associated with the amount of entertainment ST ($P = .047$, $P = .03$, respectively) and greater percent change in SM ($P = .007$, $P = .002$, respectively). Greater stress from COVID-19 was associated with the amount of ST for educational/professional purposes ($P = .05$), change in total ST ($P = .006$), change in entertainment ST ($P = .01$), and change in ST for educational/professional purposes ($P = .02$). Higher Alcohol, Smoking, and Substance Involvement Screening Test (ASSIST) tobacco scores were associated with greater change in total ST ($P = .004$), and higher pack-years were associated with greater change in SM ST ($P = .003$). Higher alcohol scores ($P = .004$) and servings of alcohol per week ($P = .003$) were associated with greater change in entertainment ST. Quarantining did not negatively impact these variables.

Conclusions: There is no doubt ST and worsening mental health increased during COVID-19 in young adults. However, these findings indicate there are many significant associations between ST use and mental health. These associations are more complex than originally thought, especially since we found quarantining is not associated with mental health. Although other factors need to be further investigated, this study emphasizes different types of ST and degree of change in ST affect various groups of people in discrete ways. Acknowledging these findings can help young adults optimize their mental health during pandemics.

Introduction

Background

COVID-19, a novel disease, wreaked havoc on the world and caused an international public health emergency. Thus, quarantine and social distancing measures were implemented to decrease viral transmission and, in turn, resulted in dire consequences, including posttraumatic stress, fear, and anger [1,2]. These self-isolation measures caused work and education to move online, naturally increasing screen time (ST) use among groups [3]. Because ST was a controversial and well-studied topic prior to the pandemic, the interest revolving around ST and ST behaviors and the correlations they may have with various wellness variables became a popular target for mental health and public health researchers. Since the inception of the worldwide pandemic, many studies have demonstrated the harmful effects of ST on different population groups, particularly from mental and physical health perspectives [3]. Increased ST use during the pandemic has been linked to addictive behaviors, like alcohol, smoking, and sugar intake in adults [4].

It is obvious that ST use during the pandemic and the relationship to mental health are quite complex and multifactorial. For example, researchers have found shocking findings regarding ST in adolescents, pinpointing various demographic disparities and acknowledging mixed findings of ST depending upon modalities (ie, smartphone vs television), signifying that device ST may be an important factor to consider [5]. These findings indicate that the focus on ST should not solely be on time spent doing a particular activity on the screen, but it is important to further quantify activities in a way that might be meaningful to a person's overall wellness. For instance, there has been a significant increase in online gaming during the pandemic associated with the need for individuals to socially connect due to stay-at-home mandates, which can either be beneficial or detrimental to a person's well-being [6]. Understanding these complex associations can not only help improve future generations but also provide insight on novel treatment systems to potentially help others in the future during similar situations.

ST use during the COVID-19 pandemic largely focuses on its effects in children and adolescents, and there is little research on the young adult population (ages 18-30 years), which is of particular interest as this is the age of people attending college or university, developing their careers, and connecting with peers. Furthermore, specific ST use (ie, ST for studying vs ST for social media [SM] use) has not been looked at during the COVID-19 pandemic, and most of the focus is on total ST, as opposed to evaluating ST spent on specific activities without focusing on modality. Lastly, there is little analysis comparing the current use of ST to before the COVID-19 pandemic, as the degree of change could potentially hold vital insights and add

information upon the complex relationship with ST and psychological state.

Aim of This Study

Due to the emergence of the impact of specified ST use during the COVID-19 pandemic on declining mental health in younger generations around the world, this study originally aimed to collect information on ST patterns in young adults ages 18 years to 28 years, as well as additional wellness measures, like mental health, substance use, and overall well-being. The study not only collected data on 3 different ST uses (entertainment, SM, and educational or professional uses) but also aimed to assess ST changes between the pre-COVID-19 era and ongoing COVID-19 pandemic to expand the literature on ST patterns amid the pandemic.

Methods

Study Design and Sample Size

Data were collected via an online, international, cross-sectional, observational study that was conducted using the SurveyMonkey online survey platform (SurveyMonkey, San Mateo, CA) from September 2020 to January 2021. The research utilized convenience sampling to recruit participants in the targeted age range of 18 years to 28 years from the group's medical institution in Saint Vincent and the Grenadines via word of mouth and school-wide emails. The study was publicized on popular SM websites (ie, Facebook, Twitter, LinkedIn) and research platforms (ie, SurveyCircle and SurveySwap) to collect additional responses on an international scale. The collection of responses was generated positively by the local campus (11/174, 6.3%), SM (55/174, 31.6%), and online research participant platforms (108/174, 62.1%).

A total of 294 respondents completed the questionnaire. Inclusion and exclusion criteria were added to validate all collected responses due to the structure of the research study. The inclusion criteria required all participants to be between the ages of 18 years and 28 years at the time of survey administration, which was verified by birth date. If a participant was outside of this age group, they were excluded from data analysis. Three validated questions were implemented within the survey to minimize random selection of choices. Respondents who incorrectly answered questions such as "Click to continue the survey" and "Please select agree/disagree for this answer" were excluded from data analysis. A total of 183 responses were validated, where 35 respondents were ineligible because they were out of the age range (ie, less than 18 years of age or greater than 28 years of age) and 76 respondents did not correctly answer the validation questions.

Ethics Approval

An online consent form was presented to every participant to confirm their voluntary participation, allowing them to withdraw

at any point or skip or refuse any questions they felt uncomfortable answering. All participants included in the study participated in the informed consent process with an additional informed consent for all individual participants for whom identifying information is included in this article. Participants did not receive any risks or reimbursements for their participation except the benefit of allowing this research group to gain more information on how mass pandemics can affect an individual's mental health, which might help public health expand mental health options in the future. For the mental health section, we included an international mental health number and website the participant could go to should they experience distress from answering any of the questions. The research was approved by the Institutional Research Committee of the Saint James School of Medicine Saint Vincent and the Grenadines campus (Research Study #119). All procedures performed in studies involving human participants were per the ethical standards of the institutional or national research committee and with the 1964 Helsinki declaration and its later amendments or comparable ethical standards.

Research Instruments

The pre-COVID-19 period was from October 2019 to December 2019, while the current COVID-19 period was from March 2020 to the day the participant participated in the survey. All questionnaires were tailored to specify assessment during the COVID-19 pandemic.

Social Demographics

The first section of the questionnaire collected general demographic information, like gender, age in 2020, ethnicity, race, employment status, country of residency in the past 6 months, income, and student status. Those who were students and not employed selected "unemployed, not looking for work." Due to low sample sizes, the country of residence was categorized into continents during data analysis.

COVID-19-Related Questions

Participants were also asked a series of COVID-19 medically related questions. They answered questions ("Yes," "No," "Don't know/unsure," or "Refuse to answer") regarding whether they had been tested for the virus and whether they were infected by SARS-CoV-2. Participants also answered questions regarding whether they quarantined and, if they quarantined, to specify if the quarantine time was past or current. Lastly, if they did quarantine (past or present), they were required to include the number of days they quarantined.

Screen Time Data

A validated questionnaire quantified the use of ST but was modified by asking participants for average ST use (hours/week) in the past 7 days during the COVID-19 pandemic for a particular category (entertainment, SM, and educational or professional purposes) [7]. "Thinking of an average week BEFORE the COVID-19 pandemic (October 2019-December 2019) and DURING (March 2020-Present Day), how much time do you spend using each of the following types of screens as the primary activity?" ST for the pre-COVID-19 era was retrospectively collected. Each category had examples listed. Entertainment included streaming websites, television, movies,

music, and video games. SM included all major SM networks (ie, Facebook, Twitter, Snapchat) and related activities (eg, chatting, sharing information or pictures). Educational and professional ST included online lectures, webinars, business meetings, and video tutorials. If no time was spent, respondents were instructed to use "0" as their answer.

Mental Health (Depression, Anxiety, Psychological Impact of COVID-19, Substance Use, and Fear of COVID-19)

We used the Patient Health Questionnaire (PHQ-9) to assess depression, scoring each of the 9 DSM-IV criteria on a 4-point Likert-scale ranging from "not at all" (0), "several days" (1), "more than half the days" (2), and "nearly every day" (3), with a total sum ranging from 0 to 27 and scores equal to or greater than 10 indicating possible depression [8-10].

We used the Generalized Anxiety Disorder 7-item (GAD-7) to assess anxiety on a 4-point Likert scale from "not at all" (0) to "nearly every day" (3), where anxiety symptoms are classified as minimum (0-4), mild to moderate (5-14), and severe (15-21) [11,12].

The Impact of Events Scale-Revised (IES-R) is a 22-item measure, where scores over 24 indicate potential posttraumatic stress disorder (PTSD) [13-16]. The assessment for COVID-19 distress required calculating the overall IES-R scores, consisting of 22 items that include 7 items for intrusion, 8 for avoidance, and 7 for hyperarousal. The amount of difficulty experienced for each item is scaled as not at all "0," a little bit "1," moderately "2," quite a bit "3," and extremely "4." Overall scores can point to a potential diagnosis of PTSD based on the range. A score from 24 to 32 indicates partial PTSD symptoms, a score from 33 to 38 indicates a probable diagnosis of PTSD, and a score above 39 suggests suppression of the immune system's functioning. The means of each subset (intrusion, avoidance, hyperarousal) were also computed and used in the data analysis.

Illicit substance use was assessed using the World Health Organization's (WHO's) Alcohol, Smoking, and Substance Involvement Screening Test (ASSIST V3.0), which was modified to focus only on tobacco, alcohol, cannabis, amphetamine, and opioid use. The responses to each question are rated on a 5-point scale that ranges from "never," "once or twice," "monthly," "weekly," to "daily or almost daily." Substance scores under 3 indicate no treatment needed, scores from 4 to 26 require brief treatment, and scores of 27 and higher require intensive treatment [17]. Additional questions evaluated pack-years and the average amount of alcohol consumed per week, with a guideline for serving size of alcohol (1 can/glass of beer = 1 glass of wine = 1 shot of liquor [eg, rum, tequila, vodka]). Due to low sample sizes, cocaine, amphetamine, and opioid ASSIST scores were dropped from the data analysis.

We used the Fear of COVID-19 Scale (FCV-19S) to assess an individual's stress, anxiety, and fear over the virus. The questionnaire uses the Likert scale, ranging from 1 (strongly disagree) to 5 (strongly agree), to calculate the total score, with an overall sum score from 7 to 35: the higher the score, the greater the level of fear of COVID-19 [18].

Overall Well-being

The WHO's Five Well-Being Index (WHO-5) was used to measure subjective well-being, where 0 signifies the lowest quality of well-being and 100 indicates the highest quality of well-being [19]. Like the ST questions, these questions were asked twice—before and during the COVID-19 pandemic.

BMI

Each respondent was asked for their current height and their specific weight before and during the pandemic, along with dates of the weight recordings. The survey accepted each respondent's weight and height depending on whether they chose the US measurement system (pounds and feet/inches) or the universal metric system (kilograms and centimeters).

Sleep Quality

The Pittsburgh Sleep Quality Index (PSQI) was used to assess sleep quality in the past month (ie, during the COVID-19 pandemic) [20]. The sum score for each of the 7 subareas (subjective quality, sleep latency, sleep duration, habitual sleep efficiency, sleep disturbances, sleep medication use, and daytime dysfunction) yields a total score, which can be used to categorize sleep quality. Scores less than 5 indicate “good” sleep quality, whereas scores 5 or more indicate “poor” sleep quality.

Data Analysis

Data analysis was conducted at the 95% significance level with SPSS version 25.0 (IBM Corp, Armonk, NY). Data analysis included paired and independent *t* tests, Levene test for equality

of variances, Pearson correlation, chi-square tests, ANOVA tests, and Tukey post-hoc tests. Missing data and those who answered with “don't know” or “refuse to answer” were removed, as were small sample size numbers ($n < 15$), like in the case of ASSIST cocaine, amphetamine, and opioid scores. If a participant had missing data for a scored section (ie, GAD-7, IES-R), that participant did not receive a score.

The dependent variables for analysis included demographic information (age in 2020, gender, ethnicity, race, student status, employment status, and continent of residence), alcohol weekly servings, pack-years, FCV-19S scores, past and current WHO-5 scores, past and current BMI, change in BMI, sleep duration, PSQI scores, PHQ-9 scores, GAD-7 scores, IES-R total, IES-R intrusion, IES-R avoidance, IES-R hyperarousal scores, and ASSIST scores for tobacco, alcohol, and cannabis.

Most participants were female ($n=128$), White ($n=142$), not Hispanic/Latinx ($n=128$), and from Europe ($n=124$). The average age in 2020 for all 183 participants was 23.43 (SD 2.54) years. Of the participants, 58.2% (106/183) were unemployed, and most participants were students (162/183, 88.5%). Over 70% (98/136, 72.1%) reported an income of less than US \$50,000. Income was not associated with any of the dependent variables.

Results

Demographic Information

A comprehensive summary of demographics is in [Table 1](#).

Table 1. Summary of demographic characteristics (n=183).

Individual-level variables	Results
Age in 2020 (years), mean (SD)	23.43 (2.54)
Gender, n (%)	
Male	52 (28.9)
Female	128 (69.9)
Race, n (%)	
Caucasian/White	142 (77.6)
Black/African American	3 (1.6)
Asian	25 (13.7)
American Indian	1 (0.5)
Mixed	7 (3.8)
Ethnicity, n (%)	
Hispanic/Latinx	52 (28.9)
Not Hispanic/Latinx	128 (71.1)
Continent, n (%)	
Europe	124 (67.8)
North America	42 (23.0)
Asia	11 (6.0)
Africa	4 (2.2)
Australia	2 (1.1)
Employment status, n (%)	
Full-time	24 (13.2)
Part-time	47 (25.8)
Currently unemployed/student	106 (58.2)
Other	5 (2.7)
Income (US \$), n (%)	
<50,000	98 (72.1)
50,000-99,999	22 (16.2)
100,000-149,999	8 (5.9)
≥150,000	8 (5.9)
Student status, n (%)	
Current student	162 (89.0)
Not a student	20 (11.0)

COVID-19–Specific Statistics and Associations

A breakdown of statistics on COVID-19 testing, diagnosis, and quarantine is provided in [Table 2](#).

Only 40.3% (74/183) of the sample took a COVID-19 test, which was not associated with any of dependent variables. Of the participants, 6.7% (12/183) were diagnosed with a COVID-19 infection, which was only associated with ASSIST cannabis scores ($t_{33}=2.299$, $P=.004$), 9.3% (17/183) were currently quarantining with an average quarantine time of 15.18

(SD 23.50) days, and 33.9% (62/183) quarantined in the past with an average quarantine time of 20.07 (SD 20.87) days. The Student t test analysis did not detect differences between groups quarantining or not quarantining for any of the dependent variables. The Pearson correlation analysis did not detect significant correlations between length of past quarantine and the dependent variables. However, the Pearson correlation did detect a positive correlation between length of current quarantine and current WHO-5 well-being scores ($r_{17}=0.531$, $P=.03$) and past WHO-5 well-being scores ($r_{17}=0.626$, $P=.007$).

Table 2. Summary of COVID-19 statistics (n=183).

Category	Results
Took a COVID-19 test ^a , n (%)	74 (40.4)
Had COVID-19 ^b , n (%)	12 (6.7)
Currently in quarantine ^a , n (%)	17 (9.3)
Length of current quarantine (days) ^c , mean (SD)	15.18 (23.50)
Quarantined in the past ^a , n (%)	62 (33.9)
Length of quarantine in the past (days) ^d , mean (SD)	20.07 (20.87)

Summary of ST Statistics

The average use of ST before and during COVID-19 for all domains is provided in [Table 3](#).

Table 3. Comparison of screen time (ST) before and during the COVID-19 pandemic.

Type of ST	Before the COVID-19 pandemic	During the COVID-19 pandemic	<i>t</i> statistic (<i>df</i>)	<i>P</i> value
Total ST (hours/week), mean (SD)	14.26 (11.24)	23.26 (16.19)	-12.08 (178)	<.001
Entertainment ST (hours/week), mean (SD)	5.08 (4.85)	7.98 (6.45)	-10.11 (179)	<.001
Social media ST (hours/week), mean (SD)	4.49 (4.47)	6.79 (6.41)	-8.14 (179)	<.001
ST for educational or professional purposes (hours/week), mean (SD)	4.69 (5.54)	8.49 (7.05)	-8.63 (178)	<.001

Before and During COVID-19 ST Comparisons

The paired *t* tests indicated that the mean ST for all domains significantly increased ($P<.001$; [Table 3](#)).

Categorical Analysis of ST

For total ST during COVID-19, 20.7% (37/183) of participants used ST 0 hours to 10 hours per week, 38.0% (68/138) used ST 10 hours to 20 hours per week, and 41.3% (74/183) used ST at least 20 hours per week. There was a significant association with student status ($P=.002$; [Table 4](#)).

For entertainment ST during COVID-19, most participants (108/183, 60.0%) used ST 0 hours to 7 hours per week ([Table](#)

[5](#)). There was a significant association with student status ($P=.02$; [Table 4](#)), as well as between groups for PHQ-9 scores ($P=.047$; [Table 6](#)).

For SM ST during COVID-19, 70.0% (126/183) of participants used ST 0 hours to 7 hours per week ([Table 5](#)).

Regarding ST for educational or professional purposes during COVID-19, 54.7% (98/183) of participants used ST 0 hours to 7 hours per week, and 45.3% (81/183) used ST more than 7 hours per week ([Table 5](#)). There was a significant difference between groups for total IES-R scores ($P=.05$) and for IES-R intrusion scores ($P=.004$; [Table 6](#)).

Table 4. Significant associations between screen time (ST) data and demographic information.

Average Change in ST

The calculation for the average ST change was the difference between the ST during and the ST before the COVID-19 pandemic.

For total ST, the average change in ST was 9.00 hours per week (SD 9.97, *n*=179; [Table 7](#)). There was a significant difference in student status (*P*=.002; [Table 4](#)). There were also correlations with WHO-5 scores before COVID-19 (*P*=.04), IES-R total (*P*=.006) and intrusion scores (*P*=.003), and tobacco scores (*P*=.03; [Table 8](#)).

For entertainment, the average change in ST (*n*=180) was 2.90 (SD 3.85) hours per week ([Table 7](#)). Students were significantly different from nonstudents (*P*<.001; [Table 4](#)). There were associations with WHO-5 scores before COVID-19 (*P*=.045); GAD-7 scores (*P*=.03); IES-R total (*P*=.01), intrusion (*P*=.02), and hyperarousal scores (*P*=.045); sleep duration (*P*=.03); PSQI

scores (*P*=.01); alcohol servings per week (*P*=.004); and alcohol scores (*P*=.003; [Table 8](#)).

For SM, the average change in ST (*n*=180) was 2.29 (SD 3.78) hours per week ([Table 7](#)). There was a significant difference between groups for student status (*P*=.001) and employment status (*P*=.046; [Table 4](#)). The Tukey post-hoc analysis showed full-time employees (mean 0.22, SD 1.95; *n*=23) were significantly different than part-time employees (mean 2.68, SD 3.19; *n*=47; *P*=.05; 95% CI -4.93 to 0.0005) and unemployed individuals (mean 2.56, SD 4.20; *n*=104; *P*=.04; 95% CI -4.57 to -0.11). There was also a correlation with pack years (*P*=.007; [Table 8](#)).

For educational or professional uses, the average change in ST (*n*=179) was 3.80 (SD 5.89) hours per week ([Table 7](#)). There were correlations with IES-R total (*P*=.02) and intrusion (*P*=.02) scores ([Table 8](#)).

Average Percent Change in ST

The average percent change in ST was calculated by dividing the change number by the amount of ST before COVID-19 and multiplying it by 100.

The average percent change in total ST (n=178) was 88.28% (SD 166.79%; Table 7). Students had statistically significant higher percent changes in total ST than nonstudents ($P=.04$; Table 4). There were also correlations with WHO-5 past and current scores ($P=.004$ and $P=.001$, respectively; Table 9).

For entertainment, the average percent change in ST (n=169) was 93.29% (SD 159.10%; Table 7). There is a positive correlation with alcohol weekly servings ($P<.001$; Table 9).

The average percent change in SM ST (n=175) was 56.94% (SD 83.08%; Table 7). Students had statistically significant higher percent changes in SM ST than nonstudents ($P=.005$; Table 4). There was a significant difference between groups for

employment status ($P=.03$; Table 4). The Tukey post-hoc analysis showed full-time employees were statistically significant from unemployed individuals ($P=.049$; 95% CI -97.85 to -0.20). There are correlations with GAD-7 scores ($P=.007$), PHQ-9 scores ($P=.002$), and IES-R intrusion scores ($P=.02$; Table 9).

For educational or professional uses, the average percent change in ST (n=144) was 150.14% (SD 268.59%; Table 7). Students had statistically significant higher percent changes in educational or professional ST than nonstudents ($P=.045$; Table 4). In addition, there was a significant difference between groups for continent of residence ($F_{4,139}=3.634$, $P=.008$; Table 4). The Tukey post-hoc analysis showed those who lived in Europe (mean 154.35, SD 236.61; n=100; $P=.01$; 95% CI -794.30 to -63.67) and North America (mean 68.52, SD 183.52; n=30; $P=.003$; 95% CI -896.16 to -133.45) had less change than those in Africa (mean 583.33, SD 141.42; n=4).

Categorical Analysis of Percent Change in ST

For the percent change in total ST, less than one-quarter of participants (27/178, 15.2%) decreased ST use, but more than three-quarters (151/178, 84.0%) increased it (Table 10). There was a significant association with student status ($P=.002$; Table 4). There was a significant difference between groups for total IES-R scores ($P=.01$) and IES-R intrusion ($P=.03$; Table 11).

For percent change in entertainment, more than one-quarter of participants (44/169, 26.0%) decreased ST use, and almost three-quarters (125/169, 74.0%) increased it (Table 10). There was a significant association with gender ($P=.02$; Table 4). There was a significant difference between groups for WHO-5 scores during the pandemic ($P=.01$), GAD-7 scores ($P=.047$), IES-R total scores ($P=.03$), IES-R intrusion scores ($P=.01$), and IES-R hyperarousal scores ($P=.01$; Table 12).

For percent change in SM ST, 29.7% (52/175) of participants decreased SM use, but over 70% (123/175, 70.3%) increased it (Table 10). There was a significant association with gender ($P=.04$), student status ($P=.03$), and average age in 2020 ($P=.03$; Table 4). For average age, the Tukey post-hoc analysis found the mean value for the -200% to 0% category (mean 23.01, SD 2.49 years; n=97) was significantly different from the mean value for the 0% to 100% category (mean 23.38, SD 2.16 years; n=26; $P=.02$; 95% CI -2.20 to -0.16). There was a significant difference between groups for PHQ-9 scores ($P=.03$) and IES-R total ($P=.006$), intrusion ($P=.001$), and avoidance ($P=.02$) scores (Table 13).

For percent change in ST for educational or professional purposes, 41.0% (59/183) of participants decreased ST for educational or professional purposes, and over one-half (124/183, 59.0%) increased (Table 10). There was a significant difference between groups for BMI during COVID-19 ($P=.03$; Table 14).

Discussion

Main Findings

Overall, our findings corroborate with those of other studies indicating that ST increased significantly during COVID-19 in all domains compared with before COVID-19 (all $P < .001$; Table 2) [3,5,21]. Since most of our sample consisted of students, it is expected that the change and percent change in ST for educational and professional purposes had the greatest increase (Table 7). Yet, we found the percent change in ST for SM increased by around 57% compared with entertainment, at 93% (Table 7), indicating our sample drastically increased their time spent on entertainment and only somewhat increased time spent on SM. Higher ST levels for SM were associated with higher social connectedness in high school students, which would be expected during quarantine situations in students, as they might use SM networks to keep in touch with friends during remote schooling [22]. Discovering that entertainment had a higher increase in ST sheds light onto the patterns of young adults who are primarily students during the pandemic and how this population sought more time on entertainment and less on social networking. Even evaluating categorical breakdowns, more participants spent ≥ 7 hours per week (72/180, 40.0%) on entertainment than SM (54/180, 30.0%; Table 5), and more

participants increased their ST time $\geq 100\%$ for entertainment compared with before the pandemic (39/169, 23.1%) than for SM (26/175, 14.9%; Table 10). This could potentially be explained by the fact that researchers are now finding that playing video games, which was included as an example of entertainment ST, is now a new form of social contact for people during COVID-19 and could even have a positive impact on people, which may indicate why quarantine was not associated with negative mental health findings [23].

The differences between SM and entertainment ST variables are stark and emphasize discrete characteristics. For one, we found that there were no significant findings for the dependent variables and SM ST between the 0-7 hours/week and ≥ 7 hours/week groups, but there were differences between the groups for entertainment ST and depression scores ($P = .047$; Table 6). Furthermore, greater change in SM ST compared with before the pandemic was only associated with higher pack-years ($P = .007$), but greater changes in entertainment were associated with higher well-being scores ($P = .045$), poorer sleep quality ($P = .01$), longer sleep duration ($P = .03$), more severe anxiety ($P = .03$), greater stress from the pandemic ($P = .02$), higher levels of alcohol abuse ($P = .004$), and more servings of alcohol per week ($P = .003$; Table 8). However, the greater degree of change compared with before the pandemic is critical, as the greater

the percent change in SM has associations with more severe depression ($P=.007$), more severe anxiety ($P=.002$), and more stress from the pandemic ($P=.02$), whereas a greater degree of change in entertainment ST was only associated with higher servings of alcohol per week ($P<.001$; [Table 9](#)). Once these degrees of change are broken down into decreased percent change, mild to moderate percent change (0%-100% compared with before), and extreme percent change ($\geq 100\%$ compared with before), more correlations become apparent and reiterate that degree of change compared with before does play a role in areas of well-being, anxiety, depression, and stress from the pandemic ([Tables 12 and 13](#)). These findings suggest a complex relationship between type of ST and increase compared with before, especially since this study found that total ST did not have any associations with the dependent variables outside of gender.

Current research emphasizes that quarantine affects a person's mental health, yet we did not find that in our sample size [24]. However, a recent meta-analysis did suggest that quarantine affects varying groups of people differently, and our population might possess a quality or multiple qualities that affects them less than others [25]. A study in Ecuador did mention that, although students express discontent in self-isolation, many students are happy with remote learning, and only 16% have clinical depression [26]. Since our sample is primarily students, this also might be a reason for these findings, especially since we found that, if people were quarantining at the time of taking the survey, longer time spent quarantining was associated with higher well-being scores ($P=.03$). Another reason behind this could be due to increased levels of entertainment ST, and despite finding associations with negative mental health consequences, gaming can be a positive impact. Future studies need to assess ST, entertainment ST, gaming-specific ST, and types of games played with these factors to provide more concrete explanations [23]. In addition, although a COVID-19 diagnosis was not found to be associated with mental health or wellness in this sample, we did find that there was an association with ASSIST cannabis scores ($P=.004$), potentially indicating an association between COVID-19 diagnosis and cannabis use, which could be explained by the fact that researchers postulate that regular cannabis users may be more vulnerable to COVID-19 infections [27].

Although our study did show some demographic differences, the most significant demographic grouping difference was seen between students and nonstudents. There were significant differences ($P<.05$) for all but 2 ST characteristics—percent change in total ST and categorical analysis percent change for entertainment ST ([Table 4](#)). Although it is well-known that students have increased ST during the pandemic due to remote learning [28], a noteworthy finding is that students were more likely to have a higher degree of percent change for entertainment and SM ST compared with nonstudents. This further reiterates the point that total ST only provides minimal information and detailing the type of ST and the amount spent will provide greater insights into ST behaviors and patterns. Aside from students, we also found that full-time employees were less likely to have a drastic change in ST for SM and average percent change in SM than part-time employees or

unemployed individuals ($P=.046$ and $P=.03$, respectively; [Table 4](#)), indicating employment may play a role in the amount of SM usage during a pandemic. A similar finding was recently found, associating it with increased sedentary time [29]. Furthermore, percent change in SM ST may have a generational link, as those who had a general percent decrease in SM were younger than those who had an increase ($P=.03$; [Table 4](#)). Although we did not find any differences between races in our sample, we did find differences between ethnicities for change in entertainment ST ($P=.01$) and percent change in entertainment ST ($P=.02$; [Table 4](#)), which has been postulated to be due to structural and systemic racism-driven factors proposed by a recently published study [5]. These discrepancies encourage race and ethnicity-specific studies to learn more about these patterns to help benefit these minority populations who have largely struggled during the COVID-19 pandemic. Lastly, one of the more unique findings is the difference between groups for the continent of residence for the average percent change in ST for educational and professional purposes ($P=.001$; [Table 4](#)). On average, those who lived in Africa had a more remarkable change than the participants who lived in Europe or North America. This finding implies participants who live in Africa drastically increased their time devoted to education and profession during the pandemic than before the pandemic. This discrepancy can be due to multiple factors, from cultural to structural ones.

There was substantial evidence linking ST to multiple adverse wellness factors, especially with psychological distress from the pandemic. IES-R total scores were more significant for those who spent ≥ 7 hours per week on ST for educational or professional reasons ($P=.05$; [Table 6](#)) but not for other ST variables. This unique finding suggests a correlation between educational or professional ST and psychological distress. Furthermore, like studies before, we found an association between depression and entertainment ST ($P=.047$; [Table 6](#)) [30], not to mention the various post-hoc tests for percent change and IES-R indicate how the IES-R scores were notably increased when the percent change in ST increased; this was seen for all but educational or professional ST. It is critical to note depression scores were not correlated with total ST use, indicating certain types of ST do not influence depression, but others, like entertainment, might. In addition, we found associations with anxiety and average change in entertainment ST ($P=.03$; [Table 8](#)), something sparse in current literature. This finding is novel because, like depression, it is not linked with total ST but rather a specific type of ST.

Since the literature is lacking in information about substance use and ST, our findings add insight into multiple substances. For one, we reiterated the link between increased entertainment ST and alcohol drinking during COVID-19 [4]. We also found ASSIST tobacco scores increased with greater change in total ST use, similar to other studies' scores ($P=.03$; [Table 8](#)) [31]. This could be due to stress, as increased academic stressors can increase smoking behaviors [32]. Our research also found links between the number of pack-years and change in SM ST ($P=.007$; [Table 8](#)), the first mentioned in current literature.

We did not find many associations between sleep quality and ST despite literature indicating otherwise [33,34]. Physiotherapy

students with excessive ST had poor sleep quality, yet our data suggest this is only the case for a significant change in ST for entertainment ($P=.01$; [Table 8](#)) [33]. We also expected to find significant associations with ST and BMI [35] but found those who decreased their ST had a significantly higher BMI than those who increased their ST ($P=.03$; [Table 14](#)). Aside from this association, there were no significant findings regarding BMI, indicating ST was not an impactful factor on BMI scores during COVID-19 in our sample.

Limitations

This study has multiple limitations. Some variables had small sample sizes and needed to be removed from the data analysis. The study was conducted online, and participants were recruited online, thus providing an amount of bias in reporting since these participants may have more ST than others. We were unable to stratify by country due to low sample sizes; thus, we grouped participants into continents, which generalizes and takes away from the discrete culture within one country. For one, we did not collect information on psychiatric history. In addition, calculating ST was focused on hours per week and did not scientifically measure time spent on each device, nor did we

collect information on modalities. Furthermore, the inability to recall could influence and provide a degree of bias in the pre-COVID-19 variables. Lastly, our population did not properly mimic the overall young adult population, as most were White, students, and female.

Conclusion

This study is the first in the current literature to focus on ST behaviors and patterns during the COVID-19 pandemic in young adults and to identify various correlations in ST and demographics, mental health, substance use, and wellness factors. Our findings show that total ST alone is not enough to predict mental health of young adults during the pandemic and that certain types of ST, in particular for entertainment and SM, provide more insight into psychological health and other wellness factors. Furthermore, the amount and degree of change of ST compared with before the pandemic are more telling of psychological impact and wellness. These insights provide a baseline for future researchers to continue to explore these untouched depths in hopes to find personalized solutions to benefit young adults and their mental health and wellness in the future with similar pandemics.

Acknowledgments

The authors would like to acknowledge the valuable contributions of Sreenivas Sappati-Biyyani and Alexis Sotomayor, all young adult participants who participated in the international survey, and support from the faculty of Saint James School of Medicine in the conduct of the study.

Data Availability

The raw data presented in this study are not publicly available, but senior author MTW can provide additional statistical analysis in response to a reasonable request. Participants received assurance that all responses would remain confidential within the research team with limited access to databases except for the listed co-authors.

Abstract

Background: The emergence of COVID-19 exacerbated the existing epidemic of opioid use disorder (OUD) across the United States due to the disruption of in-person treatment and support services. Increased use of technology including telehealth and the development of new partnerships may facilitate coordinated treatment interventions that comprehensively address the health and well-being of individuals with OUD.

Objective: The analysis of this pilot program aimed to determine the feasibility of delivering a COVID-19 telehealth care management program using SMS text messages for patients receiving OUD treatment.

Methods: Eligible individuals were identified from a statewide opioid treatment program (OTP) network. Those who screened positive for COVID-19 symptoms were invited to connect to care management through a secure SMS text message that was compliant with Health Insurance Portability and Accountability Act standards. Care management monitoring for COVID-19 was provided for a period of up to 14 days. Monitoring services consisted of daily SMS text messages from the care manager inquiring about the participant's physical health in relation to COVID-19 symptoms by confirming their temperature, if the participant was feeling worse since the prior day, and if the participant was experiencing symptoms such as coughing or shortness of breath. If COVID-19 symptoms worsened during this observation period, the care manager was instructed to refer participants to the hospital for acute care services. The feasibility of the telehealth care management intervention was assessed by the rates of adoption in terms of program enrollment, engagement as measured by the number of SMS text message responses per participant, and retention in terms of the number of days participants remained in the program.

Results: Between January and April 2021, OTP staff members referred 21 patients with COVID-19 symptoms, and 18 (82%) agreed to be contacted by a care manager. Participants ranged in age from 27 to 65 years and primarily identified as female (n=12, 67%) and White (n=15, 83%). The majority of participants were Medicaid recipients (n=14, 78%). There were no statistically significant differences in the demographic characteristics between those enrolled and not enrolled in the program. A total of 12 (67%) patients were enrolled in the program, with 2 (11%) opting out of SMS text message communication and choosing instead to speak with a care manager verbally by telephone. The remaining 10 participants answered a median of 7 (IQR 4-10) SMS text messages and were enrolled in the program for a median of 9 (IQR 7.5-12) days. No participants were referred for acute care services or hospitalized during program enrollment.

Conclusions: These results demonstrate the feasibility of a novel telehealth intervention to monitor COVID-19 symptoms among OTP patients in treatment for OUD. Further research is needed to determine the applicability of this intervention to monitor patients with comorbid chronic conditions in addition to the acceptability among patients and providers using the SMS text messaging modality.

Introduction

When the COVID-19 *pandemic* began in the United States, it collided with a multidecade opioid *epidemic*. Following the emergence of the pandemic in March 2020, drug overdoses spiked by 28.5% between April 2020 and April 2021 [1]. Provisional data reported that approximately 75% of drug overdose deaths in 2020 were due to opioids including potent synthetic opioids such as fentanyl [2].

As overdose deaths continue to increase, improving access to evidence-based treatment for opioid use disorder (OUD) is a key tertiary prevention strategy [3]. This necessitates coordinating efforts with treatment settings including opioid treatment programs (OTPs). However, patients face challenges in meeting recovery and other health goals while adhering to COVID-19 safety precautions. Specifically, calls for increased social distancing to reduce disease spread may impede access to OUD treatment services [4]. Thus, there are concerns that the COVID-19 pandemic may exacerbate the current opioid crisis [5]. People with OUD may also be at higher risk for contracting COVID-19 and experiencing more severe outcomes in terms of mortality and morbidity [4,6-9].

To address these concerns, experts recommend increased use of technology, including telehealth, and the development of new partnerships to facilitate coordinated treatment interventions that comprehensively address individual health and well-being [10,11]. While this could help manage the needs associated with co-occurring OUD and COVID-19, there is limited evidence on how to best engage and retain patients with OUD in telehealth care management services. This retrospective study aimed to determine the feasibility of a COVID-19 telehealth care management program using a standardized protocol of SMS text messaging for patients receiving OUD treatment in a statewide OTP network.

Methods

Pilot Program Setting and Participants

An OTP network based in the state of Delaware recruited patients to participate in this telehealth care management program where eligible patients are invited to connect with a care manager to monitor their COVID-19 symptoms through daily SMS text messaging communications. The overall COVID-19 telehealth care management program has been in place since the beginning of the pandemic and provides COVID-19 resources and support to businesses and their employees. It consists of 10 care managers who are all licensed registered nurses. This study focuses on the feasibility of enrolling patients with OUD into this established telehealth program.

OTP staff conducted universal COVID-19 symptom screenings for their patients during OTP appointments and referred patients with symptoms to community sites for a COVID-19 test to confirm diagnosis. The Delaware Department of Public Health reviewed and verified diagnostic test samples, and notified the testing facility if patients were positive for COVID-19.

Eligible patients who screened positive for COVID-19 symptoms were invited by OTP staff to participate in the telehealth care management program. Eligibility criteria included patients 18 years or older; with confirmed COVID-19 symptoms; currently receiving OUD treatment; who owned a cell phone with SMS text messaging capabilities; and able to understand, speak, and read English.

Program Procedures

Beginning January 2021, OTP staff invited patients who met eligibility criteria to receive a SMS text message from a care manager using Twistle software [12]. This enabled a 2-way communication between the care managers and program participants that was compliant with Health Insurance Portability and Accountability Act standards. Program monitoring services consist of a standardized protocol for daily SMS text messages sent from care managers to patient participants inquiring about the following: the participant's physical health status in relation to COVID-19 symptoms by confirming their current temperature, if the participant is feeling worse since the prior day, and if the participant is experiencing symptoms such as coughing or shortness of breath. Individuals with OUD participating in the pilot program were monitored up to 14 days while continuing OUD treatment at the OTP. The length of the monitoring period during this pilot program was based on the Centers for Disease Control and Prevention (CDC) COVID-19 quarantine and isolation guidelines that were in place for the general population as of January 2021. These guidelines were later updated by the CDC in December 2021 [13]. If any participants reported worsening COVID-19 symptoms during this monitoring period, the care manager would conduct a standardized assessment to obtain additional details about their symptoms. This assessment included a brief survey asking participants to select their current temperature in terms of Fahrenheit degree categories: 103 °F (39.4 °C) or greater, 101.6 °F to 102.9 °F (38.7 °C to 39.4 °C), 100.4 °F to 101.5 °F (38 °C to 38.6 °C), 97 °F to 100.3 °F (36.1 °C to 37.9 °C), or less than 97 °F (36.1 °C). Participants were also asked to confirm if they were experiencing any coughing or shortness of breath. Care managers would use this clinical information to help determine when patients needed a referral to a local health care provider for acute care services or hospitalization.

Data Sources and Measures

This pilot program was conducted between January 11 and April 30, 2021. We assessed the feasibility of the program intervention

by focusing on three process measures: (1) adoption, which was measured by the number of patients who were invited versus the number who agreed to participate and enrolled in the program; (2) engagement, as measured by the overall number of SMS text messages sent by participants; and (3) program retention, as measured by the number of days participants remained active in the program by continuing to respond to the daily SMS text messages. OTP staff provided a count of patients screened for COVID-19 symptoms and program referrals. The lead care manager tallied the number of patients who screened positive for COVID-19, received a SMS text message program invitation, were lost to follow-up or declined participation, and were enrolled in the program. They also reported the number of days participants were monitored and if any were referred for acute care services during the program. The Twistle data provided the number of messages sent by participants to care managers. Demographic data including age, sex, race, and insurance type were obtained from the electronic health record (EHR). An EHR review confirmed if participants were locally hospitalized while in the program.

Analysis

Descriptive statistics summarized the characteristics of patients approached to participate in the telehealth care management

pilot program and process metrics for program enrollment. Mann-Whitney *U* and Fisher exact tests calculated differences in the demographic characteristics for age, sex, race, and insurance type between those enrolled and not enrolled in the program. Data were analyzed using Stata/SE version 16.1 (StataCorp).

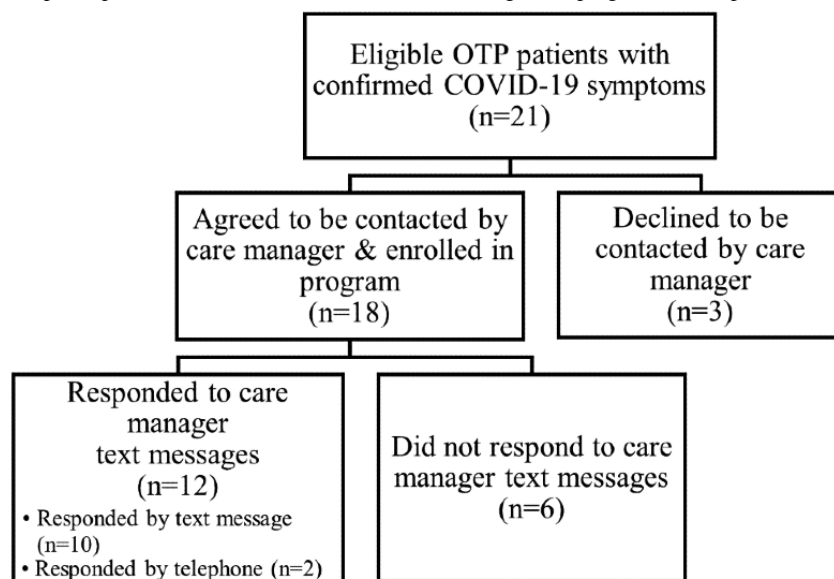

Ethics Approval

We received approval from the ChristianaCare Institutional Review Board (IRB00000480) to evaluate the feasibility of this program.

Results

Figure 1 provides a flow diagram of the participation of OTP patients in the COVID-19 telehealth care management program. Of the 21 eligible patients with COVID-19 symptoms, 18 (82%) agreed to be contacted by a care manager. Of those, 6 (33%) did not enroll in the program, including 4 not responding to care manager messages, 1 opting out, and 1 being withdrawn after confirming a negative COVID-19 diagnostic test. This left 12 (67%) individuals who participated in the telehealth care management program.

Figure 1. Flow diagram of OTP participants in the COVID-19 telehealth care management program. OTP: opioid treatment program.

Characteristics of patients enrolled in the program (n=12) and those not enrolled (n=6) are shown in Table 1. Overall, participants ranged in age from 27 to 65 years and primarily identified as female (n=12, 67%) and White (n=15, 83%). The majority of participants were Medicaid recipients (n=14, 78%) with the remaining participants enrolled in either a Medicare, private, or dual Medicaid/Medicare plan (n=3, 17%). There were no statistically significant differences in demographic characteristics between those enrolled and not enrolled in the program (Table 1).

Of the 12 individuals enrolled, 2 opted-out of SMS text message communication and instead spoke with the care manager verbally by telephone. The remaining 10 participants answered a median of 7 (IQR 4-10) messages. The median time in the program was 9 (IQR 7.5-12) days. Of the 12 participants, 10 were monitored for less than 14 days because of improvement in COVID-19 symptoms, and 2 were monitored for the maximum 14-day period. No participants were referred for acute care services or hospitalized while being monitored by the care manager.

Table 1. Characteristics of opioid treatment program patients enrolled and not enrolled in the COVID-19 telehealth care management program.

	All patients (N=18)	Enrolled (n=12)	Not enrolled ^a (n=6)	P value
Age (years), mean (SD)	41.47 (11.43) ^b	43.0 (11.60)	37.80 (11.34) ^b	.41
Sex, n (%)				.10
Female	12 (67)	7 (58)	5 (83)	
Male	5 (28)	5 (42)	0 (0)	
Unknown, not reported	1 (6)	0 (0)	1 (17)	
Race, n (%)				.25
White	15 (83)	11 (92)	4 (67)	
Other ^c	2 (11)	1 (8)	1 (17)	
Unknown, not reported	1 (6)	0 (0)	1 (17)	
Insurance type, n (%)				.19
Medicaid	14 (78)	9 (75)	5 (83)	
Other ^d	3 (17)	3 (25)	0 (0)	
Unknown, not reported	1 (6)	0 (0)	1 (17)	

^aPatients that were not enrolled either declined participation or were lost to follow-up after agreeing to be contacted by a telehealth care manager.

^bAge for 1 participant not reported.

^cOther race: due to the small sample size, participants with race identified as “Black/African American” or “Other” were combined into one category.

^dOther insurance type: due to the small sample size, participants with insurance type identified as “Medicare,” “Private” plan, or “dual Medicaid/Medicare” plan were combined into one category.

Discussion

Principal Results

In this study, we assessed the feasibility of using SMS text messaging to manage COVID-19 symptoms of OTP patients receiving treatment for OUD. We evaluated the feasibility using three criteria: adoption measured by the ratio of enrolled participants over eligible patients, engagement measured by the number of participant responses to the care managers, and retention measured by the days participants remained in the program. Although a small number of individuals were eligible, the majority of those approached about the program agreed to be contacted and monitored by a care manager via SMS text message. Only a few then opted for verbal telephone communication as opposed to SMS text message communication. Our findings are consistent with the literature documenting the acceptability of SMS text message interventions among individuals seeking OUD treatment following emergency department discharge [14]. Adherence with our SMS text message protocol was high, with the majority of participants responding multiple times to the care manager messages during the monitoring period.

Telehealth is considered safe and effective for a variety of conditions, and research has demonstrated its ability to manage health care needs while maintaining social distancing to reduce infectious disease transmission [15-17]. Current research involving individuals with substance use disorders (SUDs), including OUD, primarily address the provision of telehealth services for SUD treatment including medication management and counseling [18-20]. Little is known about telehealth’s ability to manage co-occurring medical concerns while receiving SUD

treatment. The convenience of offering telehealth-based care management for COVID-19 could ease the burden of managing multiple conditions and potentially improve retention in SUD treatment programs.

Telehealth care management through secure SMS text messaging is a promising tool that offers a convenient, private, and low-maintenance approach to promote patient engagement. SMS text messaging does not require broadband internet access, a smartphone data plan, or downloading a smartphone app, thereby avoiding barriers that exist for many individuals including those in rural areas [21]. Though care management delivered through SMS text messaging is acknowledged to be cost-effective and a relatively simple telehealth modality, few studies have explored its application among individuals receiving treatment for SUDs including OUD [20].

Our study shows that OTP patients may be comfortable communicating through SMS text messages. Though 2 participants preferred to communicate verbally by phone, we believe SMS text messaging remains a feasible telehealth modality. Further research is needed to explore telehealth preferences including concerns related to privacy, security, and other potential barriers. This is consistent with a recent review identifying that only a limited number of studies to date have explored telehealth *acceptability* among patients and providers [22]. Consequently, more participatory research on telehealth use is necessary to better address patient engagement needs and ensure sustained telehealth use among patients and providers [22,23].

Limitations

The small sample size of this pilot study limits the generalizability of our findings to the broader population of OTP patients. Because of the small sample size, we could not assess other feasibility criteria such as estimating the appropriate workload for the care manager or the referral rate to acute care. The program focused on patients from a single OTP network within Delaware, which restricts the validity of our findings to this local region. The feasibility of this program may vary depending on contextual factors such as geography. Fortunately, our OTP network included multiple community-based sites in urban, suburban, and rural settings throughout the state.

Conclusions

This study identified the feasibility of a novel telehealth program intervention delivering COVID-19 care management services for OTP patients. Further research is needed to determine the impact of this intervention on managing other comorbid chronic conditions within this patient population, the association between telehealth outcomes and use of health care services, and telehealth acceptability among patients treated for OUD and providers to ensure engagement and sustainability of services through this evolving modality using SMS text messaging for telehealth purposes.

Abstract

Background: Mass asymptomatic testing for COVID-19 was piloted for the first time in the United Kingdom in Liverpool in November 2020. There is limited evidence on uptake of mass testing, and previously where surge testing has been deployed, uptake has been low.

Objective: There was an urgent need to rapidly evaluate acceptance of asymptomatic testing, specifically identifying barriers and facilitators to taking part.

Methods: As part of the wider evaluation, we conducted a rapid thematic analysis of local community narratives on social media to provide insights from people unlikely to engage in testing or other standard evaluation techniques, such as surveys or interviews. We identified 3 publicly available data sources: the comments section of a local online newspaper, the city council Facebook page, and Twitter. Data were collected between November 2, 2020, and November 8, 2020, to cover the period between announcement of mass testing in Liverpool and the first week of testing. Overall, 1096 comments were sampled: 219 newspaper comments, 472 Facebook comments, and 405 tweets. Data were analyzed using an inductive thematic approach.

Results: Key barriers were accessibility, including site access and concerns over queuing. Queues were also highlighted as a concern due to risk of transmission. Consequences of testing, including an increase in cases leading to further restrictions and financial impact of the requirement for self-isolation, were also identified as barriers. In addition, a lack of trust in authorities and the test (including test accuracy and purpose of testing) was identified. Comments coded as indicative of lack of trust were coded in some cases as indicative of strong collective identity with the city of Liverpool and marginalization due to feeling like test subjects. However, other comments coded as identification with Liverpool were coded as indicative of motivation to engage in testing and encourage others to do so; for this group, being part of a pilot was seen as a positive experience and an opportunity to demonstrate the city could successfully manage the virus.

Conclusions: Our analysis highlights the importance of promoting honest and open communication to encourage and harness existing community identities to enhance the legitimacy of asymptomatic testing as a policy. In addition, adequate and accessible financial support needs to be in place prior to the implementation of community asymptomatic testing to mitigate any concerns surrounding financial hardship. Rapid thematic analysis of social media is a pragmatic method to gather insights from communities around acceptability of public health interventions, such as mass testing or vaccination uptake.

Introduction

As part of the United Kingdom's response to COVID-19, in September 2020, the government announced a large-scale expansion of the national testing program, with the intention of regular testing of the entire UK population on a weekly basis, regardless of symptoms [1]. This strategy was known as "Operation Moonshot" and involved using lateral flow antigen tests, which aim to provide results within 30 minutes.

To pilot the operationalization and effectiveness of mass testing, on November 2, 2020, it was announced that Liverpool City would be offered asymptomatic testing for everyone who lived or worked in the city, before the rest of the country. The pilot was a collaboration between the National Health Service (NHS) Test & Trace, Liverpool City Council (LCC), NHS Liverpool Clinical Commissioning Group, the Army (8 Engineer Brigade), Cheshire & Merseyside Health & Care Partnership, and Liverpool Charity and Voluntary Services.

A similar mass asymptomatic testing pilot in Slovakia resulted in extremely high uptake of testing, with 97% of eligible people taking part in the mass testing pilot, resulting in 38,000 new cases being identified within 2 days [2]. In the United Kingdom, research suggests that, although intentions to take a test if asymptomatic were quite high at the time [3], actual engagement with mass asymptomatic testing during the Liverpool pilot was much lower (25%) [4]. There was an urgent need to rapidly gather local insights in the Liverpool city community, to understand barriers and facilitators to engaging with mass asymptomatic testing and to inform ongoing engagement and communication strategies to increase uptake of mass asymptomatic testing. To address this and to supplement self-report survey data, we carried out rapid thematic analysis of local narratives from local community media and social media sites in Liverpool. This work was part of a wider evaluation of the Liverpool mass testing pilot, known as MAST (mass, asymptomatic, serial testing), that was led by The University of Liverpool with NHS Test and Trace, Public Health England (PHE), the Joint Biosecurity Centre, and Office for National Statistics [4]. The pilot resulted in 25% of residents taking part in testing using lateral flow tests and the identification of 897 COVID-19 cases. The aim of this study was to identify barriers and facilitators to engaging in mass asymptomatic testing and to generate recommendations for improving uptake of mass asymptomatic testing in future.

Methods

Aim

As part of the wider evaluation work undertaken by the Evaluation Steering Group, we conducted a rapid thematic analysis of local narratives from local community media and social media sites in Liverpool. The aims of this analysis were to provide insights into local narratives surrounding MAST, particularly from people who may not engage in testing or other standard evaluation techniques such as surveys and interviews; to inform a broader understanding of public test-seeking behaviors, including facilitators and barriers to accessing testing;

and to optimize management of mass testing as part of the national COVID-19 response.

Population

Liverpool is a city in the northwest of England, with a population of around 500,000. The average age of the population is 37.6 years [5], and in 2019, it was ranked the third most deprived local authority area in England based on the overall Indices of Multiple Deprivation score [6]. In week 41 2020 (October 5 to October 11), just before the end of a national lockdown and prior to the implementation of a new tiering system for COVID-19 restrictions, Liverpool had one of the highest rates of COVID-19 in England (659 per 100,000) [7] and was the first area of England to be placed under very high alert (Tier 3) restrictions on October 14, 2020. A strong sense of identity and belonging exists in Liverpool communities, reinforced by experiences with racism, stigma, and marginalization [8,9].

Ethics Approval

In line with British Psychological Society guidelines [10] for conducting internet-mediated research, this research did not require ethical approval because only publicly available data (comments posted in response to public Facebook posts, Twitter posts, or comments posted in relation to online media articles) were used. The PHE Research Ethics and Governance Group was consulted and confirmed that ethical approval was not required for this research.

Sampling

Data were collected from publicly accessible sources of community narratives, including social and online media sites. These included online comments sections from the local online newspaper for Liverpool City, which has a large circulation, the LCC Facebook page, and Twitter. Sampling captured comments posted from November 2, 2020 (when Liverpool was announced as the city to pilot mass testing) to November 8, 2020, to cover the period before and during the first week of the pilot. All publicly accessible comments on identified posts or articles were copied and pasted to text documents for coding.

Articles from the local online newspaper about the mass testing pilot were identified using the search terms "testing" and "mass testing" between November 2, 2020, and November 8, 2020. The searches resulted in the identification of 11 articles, and all comments from these articles were sampled for analysis.

All posts made by the council on the LCC Facebook page related to the mass testing pilot were identified between November 2, 2020, and November 8, 2020. Overall, 16 posts were identified, and all comments from other Facebook users on these posts were sampled for analysis.

The following search string was used to search Twitter to identify tweets with the hashtags #liverpooltesting and/or #masstesting between November 2, 2020, and November 8, 2020, sent in the Liverpool area: *near:liverpool (#liverpooltesting OR #masstesting) until:2020-11-08 since:2020-11-02*.

The search included replies to tweets (which may not necessarily have originated in or near Liverpool) and tweets containing links. In addition to the hashtag search outlined in the previous paragraph, all replies to 2 tweets announcing the mass testing pilot (1 from the local newspaper and 1 from LCC) before 00:00 on November 8, 2020, were collected. Replies to tweets from official accounts (eg, LCC and news media sources) were included in Twitter data collection, but the original tweets were excluded from analysis as they reflected official, organizational perspectives, rather than lay, public perspectives.

Overall, 1096 comments were sampled: 219 newspaper comments, 472 Facebook comments, and 405 tweets.

Analysis

Data were depersonalized by removing any identifiable data (including names and locations) and divided and analyzed separately by 2 authors in NVivo or Microsoft Word. An inductive approach using open coding [11] identified key themes

of interest and was used to develop the initial coding framework. During this stage, meetings were held to discuss coding and reach consensus. Through this process, the authors developed a final coding framework using the framework approach, a type of thematic analysis that is commonly used in research that has implications for policy [12]. This coding framework was then applied to the remaining data. Data were categorized into 2 broad themes of interest (facilitators to testing and barriers to testing), each of which was then divided into relevant subthemes.

Results

Facilitators to Getting Tested

For those motivated to get tested, key drivers were a desire to protect the community, a belief that mass testing could help the city return to normality, and a belief that testing would be (or experience that testing was) convenient and efficient. Some example quotes are included in the following sections, and further examples are shown in [Table 1](#).

Table 1. Facilitator and barriers to engagement with mass asymptomatic testing in Liverpool (2020)—results of the thematic analysis of social media.

Theme	Example quote	Source	Date
Facilitator: protecting the community			
	“No symptoms just want to do my bit!”	Facebook	November 7, 2020
	“Get in and get it done. Save a life maybe?”	Online newspaper	November 6, 2020
	“I actually got tested so I can be sure I’m not a carrier infecting others! It’s a bit insulting to assume every person from Liverpool is just getting tested so they don’t have to work.”	Facebook	November 7, 2020
	“If it saves lives and gets this city back to some semblance of normality then I am all for it.”	Online newspaper	November 3, 2020
	“I think it’s perfectly reasonable to be careful in Liverpool when 1 in 250 people currently have the virus (many of whom will not know about it) and the risks for vulnerable people are much greater. Why wouldn’t you follow the advice from people who’ve dedicated careers to this?”	Twitter	November 3, 2020
	“I will be taking part in #MassTesting #Liverpool to break the chain of transmission and protect the people I love.”	Twitter	November 7, 2020
	“Protecting or vulnerable is most important. With regular testing, we can get tested on a Friday after work, if negative go see, spend time with vulnerable loved ones, and then return to work and school etc, repeat until necessary.”	Facebook	November 5, 2020
Facilitator: return to normality			
	“It’s important we get this testing and tracing working effectively so that we can go back to ‘normal’ life. People need to recognise their own responsibility though and self-isolate when appropriate.”	Facebook	November 6, 2020
	“The more tests, the more people that will be diagnosed, the quicker we can put a cap on it in LIVERPOOL, the more likely WE (not London, not the Tories) but WE, will get out before [Christmas].”	Online newspaper	November 3, 2020
	“If everyone gets tested 2 or 3 times a week we’d potentially have very very few cases in a matter of weeks.”	Online newspaper	November 5, 2020
	“Just get yourself tested, and then we can all start to think about getting back to normal. You can’t be anti-lockdown and anti-testing.”	Twitter	November 2, 2020
Facilitator: positive experience			
	“Hand it in, results back in 40 mins #covid #Liverpooltesting”	Twitter	November 6, 2020
	“Arrived at the test centre, got tested, and received results through all within one hour. Well done to all the Army and NHS staff involved”	Twitter	November 7, 2020
	“...once I had the test it took under an hour for the result to come through ...so this test could be a game changer ...test wait and if negative fly or entry to a theatre etc”	Facebook	November 6, 2020
Facilitator: shared social identity with others in Liverpool and with authorities			
	“Let’s support them. What I have always loved about Liverpool is the community spirit, warmth and the way we pull together in a crisis...If it works it will have positive effects not just in Liverpool but across the whole country. All eyes are on us. Let’s show the country that Liverpool can beat covid 19, and they can too.”	Online newspaper	November 3, 2020
	“Really great to see such a huge positive response to this - together we will do this. Well done Liverpool [thumbs up emoji].”	Facebook	November 6, 2020
	“Absolutely, come on Liverpool we have got this!”	Twitter	November 4, 2020
	“We are the test bunnies, but this isn’t a negative thing, in fact, if we get this sorted, we’ll be the first back to normal.”	Online newspaper	November 3, 2020
Barriers: practical barriers			
	“I wouldn’t bother booking, having a time slot doesn’t make any difference, you have to queue up with everyone else, it’s a joke. [In response] Might not bother at all then if it’s not organized.”	Facebook	November 6, 2020

Theme	Example quote	Source	Date
	"3 1/2 hour wait at [<i>location</i>] even though I booked! Didn't bother waiting, won't bother again! [angry face emoji]."	Facebook	November 6, 2020
	"I am in a family of 6, can only order 4 home tests. Why?"	Facebook	November 6, 2020
	"Tried to book a test, via http://gov.uk link but only allowing me to go for a test in [<i>location</i>]? As a key worker in Liverpool this doesn't make sense... not sure this system is ready to be rolled out yet..."	Twitter	November 6, 2020
	"...they will never help us all. I won't be getting tested unless I'm unwell as I don't get paid for being off and not entitled to those payments. I am sure lots won't. Hopefully mass testing certain groups will. Pin point the problem anyway [thumbs up emoji]"	Facebook	November 4, 2020
	"...Not just the self employed. I don't earn enough to qualify for sick pay but my wages are needed to keep us afloat. And because we don't claim benefits, we can't get that payment from the council. I've already had to isolate through track and trace and lost 2 weeks wages. Like you, no help available anywhere. I want to participate because I believe testing is the only way out of this hole but, yet again, it's the people who actually work who lose out."	Facebook	November 4, 2020
	"Well I went wrong one. Still had test but the normal one. I have to make sure I do the right one next time [eye roll, laughing face emoji]."	Facebook	November 6, 2020
	"Queues for booked appointments at [<i>location</i>] are hours long. There is no signage there are people leaving the queue having waited over 2 hours."	Facebook	November 6, 2020
Barrier: risk of transmission			
	"How do we know these test centers aren't spreading 'it'?"	Facebook	November 2, 2020
	"I just wouldn't do that wait in a queue like that it's pathetic and more to the point riskier"	Facebook	November 6, 2020
	"It infuriates me that the PM positively encouraged these awful tests where you are more likely to get pneumonia stood in a queue, in the cold, without a mask"	Facebook	November 6, 2020
	"Being at the testing site today it would seem that there are two 'sites' in the same car park (one for invited people with symptoms and one for asymptomatic people who booked a test) and I was in a single queue of both groups mixed because of no direction from staff or signs"	Twitter	November 6, 2020
	"What a shambles! Wouldn't let me book a drive in test so I booked a walk in test for 1pm. The que [sic] is absolutely huge, nobody knows what's going on. No managers just car park assistants to ask. Why give so many people the same time? No social distancing. I've walked away" "More chance of me getting covid with that system. Please look at the numbers you are allowing to book in the half hour slots #farcical"	Twitter	November 6, 2020
Barrier: perceived ineffectiveness of testing			
	"Don't see the point you could get tested today and all clear and then catch it tomorrow."	Online newspaper	November 6, 2020
	"How does a Covid test help you get better from the virus? We are in Lockdown so we are all isolating anyway."	Online newspaper	November 6, 2020
	"What's the point? They can't cure it!!!"	Online newspaper	November 3, 2020
Barrier: lack of trust			
	"The tests are not accurate & not fit for purpose, giving up to 85% false positives, they do not isolate Covid, so what's the point in getting tested, just doesn't make sense to me?"	Online newspaper	November 6, 2020
	"I won't be getting tested or using the so-called NHS app whilst Serco are involved."	Twitter	November 2, 2020
	"Forced tests today, forced vaccines tomorrow."	Twitter	November 2, 2020
	"Not a chance in hell would I get one of these tests.... corrupt government!"	Twitter	November 2, 2020

Theme	Example quote	Source	Date
	“Precisely that...every dog on the street know the tests are wholly unreliable, and the possibility of false negatives high, and yet everything that even meekly questions the narrative is a conspiracy theory!! Dismal!!”	Twitter	November 3, 2020
	“I wonder if that will increase the so-called number of cases They can use those false cases to justify their lockdown #WakeUp”	Twitter	November 2, 2020
	“Liverpool are being played for mugs. The disease rate is falling by itself. They are going to find a lot of “cases” to justify the lockdown.”	Twitter	November 2, 2020
	“More tests = More False Positives More false positives = More False ‘cases’ More cases = More lockdown restrictions More lockdowns = More power to the government More government power = Less rights & less liberty for the UK people STOP GETTING TESTED”	Twitter	November 3, 2020
	“Don’t get tested. Dodgy test = false positives = further lockdown”	Twitter	November 6, 2020
	“The will make the R rate rise and we won’t get out of lockdown”	Facebook	November 5, 2020
	“Imagine how many old criminal cases that will be solved with the mass DNA harvest.”	Twitter	November 3, 2020
	“Can Liverpool City Council explain why they are taking peoples DNA. That’s what the test is isn’t it?”	Facebook	November 7, 2020
Barrier: shared social identity with others in Liverpool but not with authorities			
	“Surprise Surprise, we are just one big test case.”	Online newspaper	November 7, 2020
	“Mass testing should be in London, not Liverpool. The Greater Manchester mayor said no to our area being treated like a canary in a coal mine.”	Facebook	November 6, 2020
	“The guinea pigs are staying in their cages”	Twitter	November 6, 2020
	“Why not do this in London first.”	Twitter	November 2, 2020
	“We are the Guinea Pigs for everything”	Twitter	November 2, 2020
	“Operation Scouse Guinea pigs is a go.”	Twitter	November 2, 2020
	“Do you really think they want Liverpool out of tier 3?? If they wanted anyone out of tier 3 Liverpool would be bottom of the pile.”	Facebook	November 6, 2020
	“There’s an agenda behind this and obviously us being the guinea pigs isn’t a coincidence. That toffee nosed slob hates Liverpool and would love to bring the city to its knees. If he’d moved his backside in before March and locked down sooner, maybe we wouldn’t be at this point- unless this was all by design, I don’t know anymore.”	Online newspaper	November 3, 2020
	“There [sic] blaggin ya eds [your heads] big time, look if you do what we say we can save [Christmas] for you!!!”	Online newspaper	November 2, 2020
	“Don’t comply, we’re being scapegoated again, you will gain nothing by being tested apart from losing your jobs and having your kids barred from school, it’s just another money spinner for the old school tie network of the Eton set”	Online newspaper	November 3, 2020
	“Obedient biodrones’ couldn’t agree more.”	Online newspaper	November 6, 2020
	“People who don’t question what’s going on just play into the hands of the greedy politicians and snearing [sic] middle classes. The problem is the rest of us are left to protest and fight for their rights as well. Come on people, please wake up.”	Online newspaper	November 5, 2020
	“Won’t be testing me anytime soon, I’m no government clone, bring them swabs anywhere near me and they’ll be inserted where the sun don’t shine”	Twitter	November 2, 2020
	“The car park was full of SERCO workers who told me they had been drafted from London and the South and knew nothing about local details. Couldn’t you get local Test & Trace workers?”	Facebook	November 6, 2020

Protecting the Community

Wanting to protect their community was a key motivator for those who engaged with the testing program. This included a motivation to protect their loved ones, which in turn would have wider implications for public health:

I will be taking part in #MassTesting #Liverpool to break the chain of transmission and protect the people I love. [Twitter, November 7, 2020]

There was also a wider understanding of community, beyond immediate family and friends. For example, people wanted to protect vulnerable people, both within their family and elsewhere. Within this, they fulfilled a sense of duty and felt, by engaging with the asymptomatic testing, they were contributing to saving lives:

Get in and get it done. Save a life maybe? [Online newspaper, November 6, 2020]

Return to Normality

Tied in with wanting to protect the community was the anticipation of being able to return to “normal”:

If it saves lives and gets this city back to some semblance of normality then I am all for it. [Online newspaper, November 3, 2020]

There was an understanding that pulling together as a community would not only help protect others and save lives but would also help the city recover quicker, specifically reducing the number of cases and entering a lower tier following the national lockdown:

The more tests, the more people that will be diagnosed, the quicker we can put a cap on it in LIVERPOOL, the more likely WE (not London, not the Tories) but WE, will get out before [Christmas]. [Online newspaper, November 3, 2020]

Positive Experience

Among commenters who did get tested, some discussed positive experiences of the testing process itself. These positive experiences were noted throughout the testing process, including ordering tests or booking test slots. Positive experiences were also shared for the time spent at the test site, specifically how organized the process was:

Arrived at the test centre, got tested, and received results through all within one hour. Well done to all the Army and NHS staff involved. [Twitter, November 7, 2020]

In addition, the kindness of the staff working at the test centers was noted as part of their positive experience of the end-to-end test experience.

Shared Social Identity With Others in Liverpool and With Authorities

There is a strong sense of social identity associated with the city of Liverpool; the city is who people are and where they belong. Where people identified with others in the city, as well as with authorities managing the response, shared identity

operated not only as an individual motivator to get tested but also to encourage others to do the same:

Absolutely, come on Liverpool we have got this! [Twitter, November 4, 2020]

There was a sense of wanting to come together as a community, to help not only the city but also the rest of the country. Rather than seeing this as a sacrifice on behalf of the rest of the country, it was seen as an opportunity to demonstrate that Liverpool can successfully manage the virus, setting an example for everyone else:

Let's support them. What I have always loved about Liverpool is the community spirit, warmth and the way we pull together in a crisis...If it works it will have positive effects not just in Liverpool but across the whole country. All eyes are on us. Let's show the country that Liverpool can beat covid 19, and they can too. [Online newspaper, November 3, 2020]

Rather than being chosen as the city to pilot test being viewed as negative, the feeling of social identity and an emotional connection with the city helped people understand the pilot as an opportunity and privilege for the city, for example being the first place out of lockdown or into a lower tier following the end of the national lockdown.

Barriers to Getting Tested

Analysis of the data highlighted several barriers to people getting tested. The key barriers identified were practical barriers to testing, concern over the risk of transmission at the testing sites, and lack of trust in the mass testing program and in the government.

Practical Barriers

A key practical barrier to getting tested was inconvenience associated with attending testing sites. Various factors associated with inconvenience were identified, including long queues at testing sites and poor organization of the testing process:

3 1/2 hour wait at [location] even though I booked! Didn't bother waiting, won't bother again! [angry face emoji]. [Facebook, November 6, 2020]

In addition, there was frustration that the booking system did not help to reduce queue length on attending the testing site—those who experienced long queues despite advanced booking were less motivated to try again. In some cases, people shared their negative experiences on social media, for example around queues, disorganization, or delays in getting results; this may have influenced others' decisions in regard to getting a test.

The uncertainty surrounding the pilot, particularly in the first few days of launch, led to questions being raised in local narratives. These were predominantly related to access to testing, how to book, where the test sites were, whether there were separate sites for asymptomatic testing, and who would be conducting the tests. Uncertainty around how to access testing sometimes resulted in people attending the wrong test centers and having the wrong test or being unable to book tests at all:

Well I went wrong one. Still had test but the normal one. I have to make sure I do the right one next time [eye roll, laughing face emoji]. [Facebook, November 6, 2020]

Another practical barrier to getting tested related to concerns about the consequences of someone testing positive. For example, some individuals raised lack of compensation if required to self-isolate following a positive test as a reason for not getting tested.

Risk of Transmission

As well as long queues being a barrier to accessing testing because of the inconvenience, they also contributed to concerns over the risk of transmission. For some, the risk of catching COVID-19 while queuing was cited as a reason for not wanting to get tested:

I just wouldn't do that wait in a queue like that it's pathetic and more to the point riskier. [Facebook, November 6, 2020]

In some cases, commenters who had participated in testing reported lack of distancing at test sites, with symptomatic people having to queue alongside asymptomatic people.

Perceived Ineffectiveness of Testing

There was also confusion surrounding the purpose of mass testing and how it would help the overall COVID-19 response. In addition, there was the perception that there was no practical purpose for getting tested because there would be no individual benefit to knowing your disease status, particularly if asymptomatic:

What's the point? They can't cure it!!! [Online newspaper, November 3, 2020]

Lack of Trust

In addition to the more passive barriers outlined in the previous sections, there was a motivation to actively avoid participation in mass testing, sometimes expressed alongside discouragement to others or criticism of fellow residents who had been or were planning to get tested. A key factor motivating people to not get tested was lack of trust. This included lack of trust in the accuracy of the test and lack of trust in stakeholders involved in the delivery of mass testing, such as national and local government, scientists, and Test and Trace:

Not a chance in hell would I get one of these tests.... corrupt government! [Twitter, November 2, 2020]

Those who displayed low trust in the mass testing process, and in government response generally, raised potential illegitimate bases on which testing was implemented or highlighted potential adverse consequences of mass testing for Liverpool. These potential consequences focused on 2 main concerns: coercion by the state during mass testing and further restrictions following mass testing due to the rise in the number of known cases. The latter concern was related to the aforementioned lack of trust in the accuracy of the test, with commentators predicting an anticipated high number of false positive cases (sometimes referred to as a “casedemic”) that would lead to further restrictions in Liverpool only, including a prolonged lockdown:

More tests = More False Positives. More false positives = More False “cases”. More cases = More lockdown restrictions. More lockdowns = More power to the government. [Twitter, November 3, 2020]

Other drivers for not getting tested were concern about the use of mass testing for surveillance or DNA gathering:

Can Liverpool City Council explain why they are taking peoples DNA. That's what the test is isn't it?” [Facebook, November 7, 2020]

Shared Social Identity With Others in Liverpool But Not With Authorities

Analysis highlighted how social identity can have a dual role in understanding responses to testing. For those who identified with authorities managing the response, as well as with others in the city, this operated as a facilitator to getting tested (as described in the previous sections). However, for those who did not trust the government response and for whom there was no shared identity with authorities, shared identity with others in the city contributed to motivations not to get tested. In this instance, people felt that mass testing was something being imposed on them rather than something they could engage with as a community:

Surprise Surprise, we are just one big test case. [Online newspaper, November 7, 2020]

This led to a sense of marginalization; local communities felt disconnected from those making the decisions, particularly central government. Feeling disenfranchised from local and central government resulted in discussions around ulterior motives, highlighting a breakdown in trust between the local community in Liverpool and those in power:

Do you really think they want Liverpool out of tier 3?? If they wanted anyone out of tier 3 Liverpool would be bottom of the pile. [Facebook, November 6, 2020]

In addition, the role of social identity in local narratives around testing resulted in some members of the community not wanting to conform with what others were doing. For this group, people who were participating in testing were viewed negatively; they had lost their identity and become “other” and therefore outsiders in the local community, which resulted in criticism for “conforming”:

‘Obedient biodrones’ couldn't agree more. [Online newspaper, November 6, 2020]

Social identity also played a part in concern over “outsiders” coming to the city to deliver the testing program and highlighted a lack of trust in central government.

Discussion

Principal Findings

Findings from this study have implications for the management of mass testing in the future, both in terms of practical management of setting up and running testing sites and communication with members of communities in which mass testing will be provided. Our analysis identified that facilitators

for engaging in mass asymptomatic testing included a sense of community, a desire to return to normality, positive experiences of others, and having a shared identity with Liverpool authorities. Barriers included practical barriers (access to test sites, long queues), concern over risk of transmission, perceived ineffectiveness of testing, lack of trust, and a shared social identity with the Liverpool community but not those in authority.

Findings showed that one of the key motivators to engaging with the pilot in Liverpool was a strong sense of community identity and belonging, both with city residents and local authorities. However, when a strong sense of identity was not shared with authorities (for example, where local and central governments were not seen as trusted organizations), community identity acted as a barrier to engagement with testing. Furthermore, it actively motivated people to disengage from the pilot. To ensure that shared community identity acts as a facilitator rather than a barrier, it is important that members of the community identify with the authorities managing the testing, as well as identifying with each other. This is in line with previous research that emphasized that shared identity is a crucial part of promoting community resilience in response to mass disasters and emergencies [13] and can provide a basis for understanding of the relationship between communities and authorities [14]. Harnessing and working with existing shared identities, such as the identity shared by Liverpool city residents, can help build and maintain trust in authorities and the information they provide [14]. Authorities should communicate openly and honestly and demonstrate respect for public needs in order to enhance legitimacy of the response and facilitate the development of shared identity between communities and authorities, subsequently promoting increased adherence to recommended behaviors, for example mass testing [15,16].

Identity also plays a role in the sense of responsibility duty that was frequently cited by Liverpool residents for reasons why they were engaging in testing. This response is not unique to Liverpool residents; in a recent survey of university students taking part in asymptomatic testing, the majority of students stated they took part in testing because they wanted to protect others (91%) and because it was the right thing to do (82%). A smaller proportion (63%) also stated they took part to help fight the virus [17]. Return to normality was also identified as a key motivator to engage in testing. This has also been identified elsewhere; for example, in the pilot in Slovakia, a relaxation of restrictions was offered as an incentive to participate and increased willingness to take part in the pilot.

However, it is not enough that people are willing to take part in mass testing; they must also be able to do so. Our analysis of local narratives in Liverpool identified several structural barriers, which made it more challenging to access testing, even for those willing to engage in the pilot. These were primarily access to testing sites and queues, for example not wanting to spend time traveling to a test site or waiting in a queue. Clear guidance about how to access testing and test sites would help negate concerns over access, for example dedicated websites or booking systems for asymptomatic testing where applicable; maps of where testing sites are located, including directions for how to access them (for example bus routes, nearest available public car park); and clear signage at the site.

In addition to being identified as an access barrier, queues were also cited as a barrier due to concern over risk of transmission. This was particularly early on in the pilot, where there was confusion between how to access asymptomatic testing opposed to the symptomatic testing to which the community had become accustomed. Requesting people to queue in proximity to others is contra to the basic public health guidance on protective behaviors that has become the pervasive narrative throughout the pandemic response: social distancing. To address concerns about being unable to social distance while waiting for testing, communicating what measures have been put in place to ensure safe queuing is an essential part of the communications for asymptomatic testing.

Financial concerns around the requirement to self-isolate if a test was positive were also highlighted as a barrier to testing. Several people stated that they would be reluctant to take a test because they would not receive any financial support and would therefore struggle to self-isolate if they received a positive result. It is essential that everyone required to self-isolate has the financial support to do so without encountering financial hardship, in order to improve adherence both to self-isolation [18,19] and to related behaviors (eg, testing) and to mitigate against adverse effects on mental health [20]. It is essential that people are aware of support available to them if they are self-isolating (eg, financial support scheme for people required to self-isolate), as this will remove some of the financial barriers associated with undergoing mass testing.

It is currently unclear the extent to which mass asymptomatic testing had an impact on cases or hospitalizations in Liverpool. As of December 9, 2020, one-quarter of the city's residents engaged in the pilot and took a lateral flow test. During this time, nearly 900 people were identified as positive [4]. Interestingly, the uptake of testing in Liverpool was considerably lower than a similar pilot in Slovakia, where nearly all eligible people engaged in testing [2]. This highlights the importance of evaluating acceptance of asymptomatic testing, specifically identifying barriers and motivators to undergoing mass testing. The work presented here could therefore provide valuable insights into barriers and facilitators to mass testing that could be used to inform the way in which these processes are managed in future and could potentially increase uptake with mass testing programs.

Recommendations

Based on the findings presented here, we suggest that, in order to promote good uptake of mass testing, authorities should communicate openly and honestly with communities, particularly about the nature and purpose of mass testing; provide clear instructions around practical aspects of testing (eg, details of site locations, how to access testing); provide financial support for self-isolation; listen to and address public concerns; engage with communities in order to understand their experiences; and ensure that communities know that their views are being taken into account (eg, where community engagement is taking place and being used to inform the response, this should be communicated).

Limitations

Although analysis of social media data and other online media can facilitate access to the perspectives of those who do not necessarily choose to participate in other types of research, there is the potential that the demographic composition of digital media users may differ from that of the wider population [21]. The first limitation of this study is therefore that we only collected the perspectives of people who opted to publish their thoughts online; consequently, the sample may not be representative of the wider population.

The pragmatic thematic analysis of a targeted sample of social and online media sites presented in this paper was carried out to provide rapid insights into public perceptions of mass testing. A second limitation of the study is therefore that the rapid nature of the research meant that there was no time to carry out checks of interrater reliability. We recommend that future studies employ web scraping tools to capture a greater quantity of data and that checks of interrater reliability are carried out wherever possible. While every effort was taken to increase the likelihood that comments collected in the data set were all expressed by Liverpool residents, there is no guarantee that the data set was entirely limited to Liverpool residents.

Conclusion

This study has highlighted several key barriers and facilitators to engaging in asymptomatic testing in residents in Liverpool city, including concerns over access, risk of transmission, and financial hardship. These structural barriers are amenable to mitigation and should be considered when rolling out similar testing programs elsewhere. We also identified psychosocial barriers, including lack of trust in authorities, which was associated with a sense of marginalization and disengagement with the testing program. This emphasizes the importance of recognizing and engaging with local community identity when implementing asymptomatic testing programs. We suggest that future implementation of mass testing programs should include honest and open communication to encourage and harness existing community identities, thereby enhancing the legitimacy of asymptomatic testing as a policy. In addition, adequate and accessible financial support needs to be in place prior to the implementation of community asymptomatic testing to mitigate any concerns surrounding financial hardship. Rapid thematic analysis of digital media is a pragmatic method to gather insights from communities around acceptability of public health interventions, such as mass testing or vaccination uptake. This methodological approach can complement other, more established approaches to ascertaining insights, such as surveys, interviews, and focus group discussions.

Acknowledgments

The authors would like to acknowledge all those involved in the evaluation of the asymptomatic testing pilot in Liverpool including colleagues at the University of Liverpool, Department of Health and Social Care, National Health Service (NHS) Test and Trace, Joint Biosecurity Centre, Cabinet Office, and Office of National Statistics. We would also like to extend our gratitude to Liverpool City Council and residents in the Liverpool City Region.

Abstract

Background: Effective suicide risk assessments and interventions are vital for suicide prevention. Although assessing such risks is best done by health care professionals, people experiencing suicidal ideation may not seek help. Hence, machine learning (ML) and computational linguistics can provide analytical tools for understanding and analyzing risks. This, therefore, facilitates suicide intervention and prevention.

Objective: This study aims to explore, using statistical analyses and ML, whether computerized language analysis could be applied to assess and better understand a person's suicide risk on social media.

Methods: We used the University of Maryland Suicidality Dataset comprising text posts written by users (N=866) of mental health-related forums on Reddit. Each user was classified with a suicide risk rating (no, low, moderate, or severe) by either medical experts or crowdsourced annotators, denoting their estimated likelihood of dying by suicide. In language analysis, the Linguistic Inquiry and Word Count lexicon assessed sentiment, thinking styles, and part of speech, whereas readability was explored using the *TextStat* library. The Mann-Whitney *U* test identified differences between at-risk (low, moderate, and severe risk) and no-risk users. Meanwhile, the Kruskal-Wallis test and Spearman correlation coefficient were used for granular analysis between risk levels and to identify redundancy, respectively. In the ML experiments, gradient boost, random forest, and support vector machine models were trained using 10-fold cross validation. The area under the receiver operator curve and F_1 -score were the primary measures. Finally, permutation importance uncovered the features that contributed the most to each model's decision-making.

Results: Statistically significant differences ($P<.05$) were identified between the at-risk (671/866, 77.5%) and no-risk groups (195/866, 22.5%). This was true for both the crowd- and expert-annotated samples. Overall, at-risk users had higher median values for most variables (*authenticity*, *first-person pronouns*, and *negation*), with a notable exception of *clout*, which indicated that at-risk users were less likely to engage in social posturing. A high positive correlation ($\rho>0.84$) was present between the part of speech variables, which implied redundancy and demonstrated the utility of aggregate features. All ML models performed similarly in their area under the curve (0.66-0.68); however, the random forest and gradient boost models were noticeably better in their F_1 -score (0.65 and 0.62) than the support vector machine (0.52). The features that contributed the most to the ML models were *authenticity*, *clout*, and *negative emotions*.

Conclusions: In summary, our statistical analyses found linguistic features associated with suicide risk, such as social posturing (eg, *authenticity* and *clout*), *first-person singular pronouns*, and *negation*. This increased our understanding of the behavioral and thought patterns of social media users and provided insights into the mechanisms behind ML models. We also demonstrated the applicative potential of ML in assisting health care professionals to assess and manage individuals experiencing suicide risk.

Introduction

Background

Suicide is one of the leading causes of death worldwide [1] and is an international public health problem. The World Health Organization estimates that approximately 800,000 people die because of suicide every year, and global targets to reduce suicide mortality are unlikely to be met [2].

Effective suicide risk assessment screening methods are key to reducing this preventable cause of death [3,4]. Traditional approaches to suicide risk assessment include a comprehensive clinical evaluation and the use of self-reported measures, including the Columbia Suicide Severity Rating Scale, Patient Health Questionnaire, and other measures that screen for depression and psychological distress [1,5,6]. Although these approaches provide the best practice for suicide risk assessment, not all people experiencing thoughts of suicide or suicidal ideation disclose their risk or have access to health care professionals.

In addition, people experiencing suicide risk may not seek mental health support [7,8], and for those who do, the demand for clinicians often exceeds the supply, especially in remote areas where access to health care professionals is limited [9]. Therefore, an automated risk detection tool, or a deeper understanding of the linguistic features associated with suicide risk, could allow individuals to assess their own risk of suicide. This may prompt them to seek support and, in turn, increase suicide prevention.

Social Media and Suicide Risk Detection

Suicidal ideation has been widely documented on social media [10]. As these platforms provide individuals with an outlet to express their innermost thoughts [10], social media data offer new ways of understanding and assessing suicide risk. Hence, this creates novel possibilities for suicide assessment, intervention, and prevention [11].

Reddit, a web-based forum with >52 million daily users, offers particularly rich data. This is because of several reasons. First, it has a high character limit of 40,000 per post, which is a notable increase from other social media sites such as Twitter (280 characters), allowing users to write linguistically richer posts. Second, the website has the potential to be anonymous. Users can make *throwaway* accounts—temporary identities separate from their main accounts—to uninhibitedly discuss sensitive topics and emotions. This feature has been proven to promote open conversations and emotionally engaging feedback [12], thus making it ideal for suicide risk detection studies. Finally, Reddit's structure is advantageous. The website is made up of subforums (subreddits) that are topic specific. This allows researchers to preselect data from mental health-related

subreddits, identifying users who potentially express suicide risk.

Machine Learning for Mental Health

In recent years, there has been increased interest in using machine learning (ML) to detect mental health conditions, including depression [13]. However, such studies often focus primarily on the performance of the classifier rather than on processes that underpin or explain its classification decisions [14].

This raises a key problem. ML models are often opaque, with *black box* models such as neural networks being largely uninterpretable [15]. This highlights a clear need for increased interpretability and understanding of the features themselves. Model-agnostic methods for understanding the feature importance include permutation importance [16] and Shapley Additive Explanations [17]. Such techniques are beneficial as they help us understand not only the outcomes but also the mechanisms behind the models themselves.

Research Objectives

This study aimed to examine the relationship between linguistic features and indicators of users' suicide risk on Reddit, thereby increasing interpretability. In addition to identifying statistically significant relationships, this study explored the contributions of the features to classifications by constructing ML models and permutation importance analysis.

Our main contributions are as follows: (1) we conducted nonparametric statistical analysis to identify linguistic features significantly associated with suicide risk; (2) we performed correlation analysis to identify relationships between significant features, thus identifying redundancies; (3) we built several ML models using linguistic features, highlighting the potential for future application; and (4) we measured the features that contributed the most to each model's decision-making through permutation importance analysis.

Methods

Data Selection and Access

In this work, we used the existing University of Maryland Suicidality Dataset [9,18]. This comprised social media posts annotated by mental health experts and crowdsourced annotators with respect to the author's suicide risk.

We chose this source for the following 3 main reasons.

First, it was extracted from the web-based Reddit forum. As stated earlier, Reddit has a generous character limit that allows greater linguistic complexity. Thus, it would be ideal to explore our first research question.

Second, another benefit of this data set was its high-quality annotations. A prevalent problem with social media data is the

reliability of ground truth labels; it is difficult to determine whether a web user is actually at risk in real life. Annotators are often inaccurate, even when label definitions are shown [19]. The Maryland data set alleviated this issue in several ways. To begin with, the researchers preselected at-risk (low-, moderate-, and severe-risk) users by identifying people who posted on mental health-related forums (eg, SuicideWatch). Furthermore, the annotation process was completed by mental health experts and crowdsourced annotators. Consensus mechanisms (eg, multiple annotators for each user) were also used.

Ethics Approval

The University of Maryland Suicidality Dataset [9,18] was approved for use by the Australian National University Human Research Ethics Committee (protocol number 2021/047). This was followed by obtaining proper permission to access and use it for the purposes of this study from the University of Maryland.

Data Overview

Reddit is a web-based forum designed to help people “detach from their real-world identities” [20]. The Maryland data set comprises text posts written by 934 unique users of this website—specifically, posts published on the SuicideWatch subforum from January 1, 2008, to August 31, 2015. It includes posts from both SuicideWatch and users’ other non-mental health-related posts. In addition, users who did not post on any mental health-related forum [21] were included as a control group.

Although Reddit is intended to be anonymous, users may provide personal identifying information. Thus, this data set was further anonymized by replacing each username with a token, as well as by replacing all URLs [9,18].

Annotation Process

The Maryland researchers annotated the data set as follows. First, posts written by a given user were temporally organized and split into annotation units. These contained up to 5 posts each. Each unit was then annotated with a suicide risk rating by either medical experts or crowdsourced contributors. Experts were given *short* instructions asking them to follow their formal training in assessing patients at risk of suicide. Meanwhile, the crowdsourced annotators were given *long* instructions that asked

them to focus on risk factors such as thoughts (eg, suicide ideation and feeling like a burden), thought patterns (eg, sense of agitation), logistics (eg, talking about methods of attempting suicide), and context (eg, previous attempts and isolation from family and friends) [9,18].

Ratings were on a 4-point risk scale as follows [9]: (1) no risk (“I don’t see evidence that this person is at risk for suicide”), (2) low risk (“There may be some factors here that could suggest risk, but I don’t really think this person is at much risk of suicide”), (3) moderate risk (“I see indications that there could be a genuine risk of this person making a suicide attempt”), and (4) severe risk (“I believe this person is at high risk of attempting suicide in the near future”).

Users with <10 posts and users whose posts had <3 annotators were eliminated from the data set by the Maryland researchers. This resulted in a final sample size of 866 unique users who posted on SuicideWatch, which is described by Reddit as a peer support forum for anyone struggling with suicidal thoughts. There was also an equal number of unannotated control users (n=866). Of the 866 annotated users, 245 (28.3%) were labeled by experts, whereas 621 (71.7%) were disjointly labeled by crowdsourced contributors.

The expert annotators included multiple mental health professionals. These included a cochair of the National Suicide Prevention Lifelines Standards, Training and Practices Sub-Committee, and a clinician in the Department of Emergency Psychiatry at Boston Children’s Hospital [9,18]. To generate user-level annotations, maximum likelihood estimation was used [22,23]. Overall, the average Krippendorff interannotator agreeability α was .812.

In contrast, the crowdsourced task was completed on the web-based platform, CrowdFlower. The website’s inbuilt consensus mechanism was used to resolve disagreements among crowdsourced annotations [18]. Each user was assigned a *trust score*, which indicated their reliability. Annotations were then weighted by this trust score and aggregated into a *confidence score* for each label. The label with the highest confidence score was chosen. This resulted in a Krippendorff α of .554.

An example of a typical post is presented in (Table 1). To preserve user privacy, the post body was an aggregate of several existing posts, and the subreddit was randomly chosen.

Table 1. Example of a typical Reddit post from the data set and the suicide rating.

Features	Value
Post ID	1a2b3c
User ID	45678
Time stamp (Unix epoch)	1.4E+09
Subreddit	r/self-harm
Post body	“I’ve been feeling depressed for a while. I don’t know how to deal with it anymore...”
Label	Severe risk

Data Preprocessing and Linguistic Feature Engineering

In our research, we randomly split the data into an 80:20 training-test ratio following the Pareto principle [24]. This was

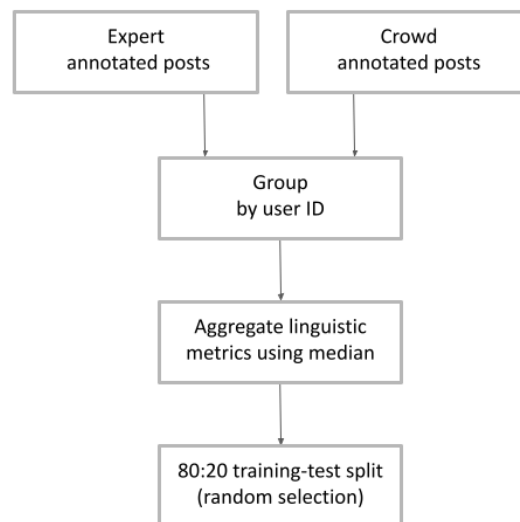

achieved by randomly selecting 80% of the user IDs from both the crowd- and expert-annotated data sets. All posts associated with the users were then retrieved. In addition, unannotated

control users and posts without any text were discarded. For the ML models, expert- and crowd-annotated users were combined into singular training and test sets to maximize the available data. Meanwhile, the statistical analysis was performed on the expert and crowd data sets separately to compare the distributions of the different groups.

Linguistic features for users were aggregated by taking the average of all the posts (Figure 1). The median rating was used instead of the mean rating to reduce the influence of outliers. Overall, we chose to group according to users to reflect the annotation process, as ratings were attached to a user rather than an individual post.

Linguistic Inquiry and Word Count (LIWC) 2015 and the *TextStat* Python library were used to extract linguistic features from posts. All the LIWC and *TextStat* features are listed in Multimedia Appendix 1 and Multimedia Appendix 2, respectively.

Figure 1. Flowchart detailing the data preprocessing stages.

Statistical and Correlation Analyses

Statistical and correlation analyses were designed and reported in consultation with the Australian National University Statistical Consultation Unit.

Statistical errors because of the assumption of normality are common in quantitative studies [33]. To mitigate this, we used the Shapiro-Wilk test [34] from *scipy.stats*. The analysis revealed that none of the features were normally distributed. Hence, nonparametric tests were used to compare the distributions of different risk groups.

First, a 2-sided Mann-Whitney *U* test was used to compare at-risk and no-risk users. This test was chosen because of its nonparametric nature and previous applications in medical studies [35]. To form this binary grouping, users who received either a severe-, moderate-, or low-risk rating were considered at risk. Meanwhile, users who received a no-risk rating formed their own group.

To supplement these results, we used the Kruskal-Wallis test. This compared the distribution of features within different risk

LIWC is a lexicon [25] that groups words into psychologically meaningful categories. Aside from aggregate features such as *authenticity*, the scores for most features were the percentage of total words in a text that belonged to a specific category. Prior studies have demonstrated the capacity of LIWC to detect emotionality [26,27], thinking styles [28], and individual differences [29,30]. Moreover, it has been used to detect self-reported symptoms of depression and other mental health conditions [31,32]. In this study, all the categories were used to ensure comprehensive coverage.

In juxtaposition, *TextStat* is a computerized analysis tool that measures linguistic complexity. This package was selected because it contains both simple features such as word count and widely used linguistic readability metrics such as the Gunning Fog Index, Simple Measure of Gobbledygook, and Flesch-Kincaid scores.

levels. This analysis allowed us to determine whether the severe-, moderate-, and low-risk groups behaved differently.

For both tests, we used an α value of $P < .05$. To correct for multiple comparisons, we applied the Benjamini-Hochberg procedure [36] to the *P* values. We calculated 95% CIs to estimate the difference between medians using the Mann-Whitney *U* test. In addition, although post hoc methods (eg, Dunn test) for the Kruskal-Wallis test can be calculated to determine which specific medians are different, these were not computed in this work, as this was largely observed through the use of comparative box plots. Python (*scipy.stats* and *scipy.statsmodels*) and R (*wilcox* and *kruskal*) libraries were used for the implementation.

To reach a consensus between the expert- and crowd-annotated data sets, the features needed to have *P* values of $< .05$ and the same directionality to be labeled as *significant* in the Mann-Whitney *U* and Kruskal-Wallis tests. In addition, features with 95% CIs that included 0 were eliminated. This was because of 2 main reasons.

First, crowdsourced annotators were less reliable than experts. As they had less training, they had a lower macro F_1 -score, with

a tendency to misclassify lower-risk users as having higher risk [9].

Second, the distribution of features could be different because of random variation. Although this does not necessarily mean that features that are only significant in one data set are not significant overall, it does suggest that the distributions are noticeably different. Therefore, it would be inappropriate to compare them.

A correlation analysis was also used to identify redundancies. This was because, in a practical context, having too many features limits interpretability and increases the computational complexity. For instance, if there are thousands of features, even if we know the weighted contribution of each feature, it is still extremely difficult to fully understand ML models and their classifications [37]. Hence, we identified relationships between significant features to determine potential proxies on both the expert- and crowd-annotated data sets, with P values corrected using the Benjamini-Hochberg procedure. We selected the Spearman correlation coefficient because of its nonparametric nature [38] and established use in medical research [39].

ML Models, Their Performance Evaluation, and Feature Importance Analysis

To determine whether the features would prove useful for risk assessment, we constructed several preliminary ML models that classified whether a user was at risk or had no risk. For this project, we used random forest (RF) [40], gradient boost (GB) [41], and support vector machines (SVMs) [42]. These techniques were selected because of their application in mental health research [43]. All LIWC and *TextStat* features were used to train the models.

An SVM is a supervised ML algorithm. It classifies data by representing each data point as a vector and fitting a hyperplane that separates the different classes [42]. In a 2D context, this is equivalent to fitting a dividing line through the data. Intuitively, an optimal hyperplane in such a fitting should be approximately at the center of the 2 classes. For SVMs, this is determined by calculating the distance between the hyperplane and the closest data points from each class. The hyperplane that maximizes this distance, or the maximum-margin hyperplane, is selected [42]. As not all data are linearly separable [44], SVMs use a kernel function in classification problems, a mathematical operation that performs the equivalent of mapping a lower-dimensional space to a higher dimension [45]. Ideally, this higher-dimensional projection should help make the data separable and, therefore, classifiable.

Decision trees are nonparametric and supervised learning methods. They work by splitting the root node, which represents the entire data set, into branch-like segments based on the values of their features. This continues until all the data are matched to a leaf node, which represents a class label [46]. Splitting is determined by the *purity* of the split, which is measured by metrics such as the information gain, gini index, and gain ratio [47].

Fundamentally, the algorithm tries to split the data so that the data points in each branch belong to the same class. However,

a problem with decision trees is that they are prone to overfitting [48]. Hence, a common way of addressing this problem is through ensemble methods that combine multiple smaller classifiers into a single classifier [49].

The RF method is a prime example of an ensemble method. It works by drawing k random subsamples of the data and fitting decision trees to each subsample. When presented with a new data point, each of the k decision trees casts a vote for the class label. The final label is determined by the results of the majority vote [40].

GB is another decision tree-based ensemble method. However, in contrast to RF, GB functions in an additive manner [50]. Fundamentally, this implies that each of the k decision trees is iteratively trained. The first decision tree is fitted to the training data, and the error is calculated. Following this, data points that were incorrectly classified will be given a higher weight, so that the following model can address the deficiencies of the previous model [41]. After all the weak learners have been trained, the final class label is determined by a weighted majority vote, with votes from more successful learners being more important.

As noted above, an 80:20 training-test split was used. The class distribution was as follows. In the training set, there were 63% (546/866) at-risk and 16.4% (142/866) no-risk users. A similar distribution was observed in the test set, with 14.4% (125/866) at-risk and 6.1% (53/866) no-risk users. To find the optimal hyperparameters and reduce overfitting [51], we used 10-fold cross validation [52] on the training set. The area under the receiving operator curve (AUC) was used as the primary scoring metric for validation because of increased discrimination and consistency [53,54]. To evaluate the performance on the test set, a more diverse range of metrics, including the AUC and accuracy, as well as the precision, recall, and F_1 -score, were used to balance the trade-off between sensitivity and specificity [55]. Finally, confusion matrices [56] provided visualizations of true and false positives, as well as negatives on the test set.

Although univariate statistical tests can uncover relationships between linguistic variables and suicide risk, they might not indicate the importance of features in a given ML model. Hence, to better understand our models' decision-making process, we analyzed the permutation importance of each feature [16]. This examined the decrease in an existing model's score over a given number of iterations when the values of a single feature were randomly reordered. We implemented this using the Python *sklearn* library.

Features were considered important for a given model if a large decrease was observed and vice versa. For the purposes of this research, we calculated the permutation importance over 100 iterations on a holdout test set and used AUC, precision, and recall as the scoring mechanisms. Only variables with mean permutation importance values >1 SD away from 0 were considered significant.

Results

Mann-Whitney U Test

At-risk (low-, moderate-, and severe-risk) users had, on average, a greater use of *authenticity*, *first-person singular pronouns*, and *negation* (Multimedia Appendices 3 and 4). They also had lower *clout* (Tables 2 and 3). This suggests that, overall, they were more authentic in their expression and engaged less in

social posturing (*authenticity* and *clout*). For brevity, all tables show only statistically significant values ($P < .05$) after applying the Benjamini-Hochberg correction, with the mean and CIs rounded to 4 significant figures.

This observation was also reflected visually. The box plots, which show that the overall distributions, in addition to the central measures such as the mean and median, were skewed further left for the at-risk users (Figures 2 and 3). Again, the inverse was observed for *clout* (Figures 4 and 5).

Table 2. Mann-Whitney U test results for expert-annotated users.

Feature	Examples	At-risk, mean (SD)	No-risk, mean (SD)	P value	95% CIs for differences between medians
Clout	N/A ^a	36.81 (16.62)	48.21 (11.48)	.005	-17.83 to -6.590
Authenticity	N/A	64.82 (21.31)	47.35 (20.86)	.005	10.04 to 27.09
First-person singular pronouns	I, my, and mine	7.105 (2.979)	5.419 (2.194)	.04	0.6900 to 2.840
Negation	Not, no, and never	1.391 (0.8524)	0.7924 (0.6987)	.01	0.2250 to 0.9650

Kruskal-Wallis Test

When comparing the severe-, moderate-, low-, and no-risk groups (Multimedia Appendices 5 and 6), no LIWC or *TextStat* features were significant ($P < .05$) for both the expert- and crowd-annotated data sets after correction. This indicates that although certain linguistic variables are associated with at-risk versus no-risk groups, there are no significant differences within the at-risk groups themselves.

Correlation Analysis

Using the Spearman correlation coefficient (Multimedia Appendices 7-10), we found the following.

For LIWC, various parts of speech (eg, *function words* and *pronouns*; $\rho > 0.74$ and 0.84 [unless otherwise specified, the first ρ is the correlation coefficient on the crowd-annotated data set, whereas the second is for the expert-annotated data set; all

figures have been rounded to 2 significant figures]) were highly correlated with each other, indicating redundancy.

In addition, many parts of speech also had moderate correlations with variables measuring post length, such as syllable count (eg, *comparatives*; $\rho > 0.50$ and 0.63) and word count (eg, *focus on the future*; $\rho > 0.59$ and 0.67). This suggests that they could be proxies of length. Intuitively, this association was understandable, as the longer the post, the more parts of speech it will have.

Some features such as *clout* and *authenticity* appeared to be aggregate features, combining other variables, as shown through moderate positive correlations with other variables (eg, *authenticity* and *function words*; $\rho > 0.47$ and 0.59). This was in line with the LIWC manual [57] and suggested that overall, aggregate features could be an efficient way of condensing information. Visual and statistical evidence provided additional support for this conclusion. When examining the box plots (Figures 2-5), we found that the aggregate measures were generally more discernible than individual categories. Furthermore, the P values tended to be smaller ($P < .01$), and the distance between medians also tended to be greater (Tables 2 and 3).

Table 4. Summary of classification results of various machine learning models^a.

Models	AUC ^b	Accuracy	Precision	Recall	F_1 -score
Gradient boost	0.67	0.62	0.61	0.67	0.62
Random forest	0.66	0.75	0.65	0.66	0.65
Support vector machine	0.68	0.53	0.64	0.68	0.52

^aThe precision, recall, and F_1 -scores are the macroaverage of the different classes.

^bAUC: area under the receiving operator curve.

Permutation Importance

A noticeable overlap was present in the features that had higher permutation importance for the GB and RF models (Table 5), with *authenticity*, *negative emotion*, and *clout* contributing to higher precision and AUC (*authenticity* and *negative emotion* only) for both models. Meanwhile, the SVM yielded different results, having no common significant features with other

Model Performance

Overall, all models showed great promise in identifying suicide risk and achieved a similar performance (Table 3; Multimedia Appendices 11 and 12). Most errors lay in a tendency to overassign to the at-risk category. As type II errors are preferable to their type I counterparts in the medical domain, this demonstrated that LIWC and *TextStat* features are effective for building ML risk assessment models.

The performances of all models were largely comparable, with the AUCs for the GB, RF, and SVM models being 0.67, 0.66, and 0.68, respectively. Furthermore, when looking at performance evaluation outcomes (Table 4; Multimedia Appendices 11 and 12), all models were better at classifying at-risk users, with the RF model having the highest performance (F_1 -score of 0.83) for this class. This was most likely because of the imbalanced nature of the data, with more users being at risk than not because of the selection process. It should be noted that the SVM, in particular, performed worse on the no-risk class, as indicated by its noticeably lower F_1 -score (0.52). This implies that it is less useful in practice.

models. However, as noted earlier, the SVM model had a notably lower performance (F_1 -score) than the other 2 models. The permutation importance only measures the importance of a feature for a given model. Hence, if a model did not perform well, its permutation importance analysis results were not necessarily reliable. Thus, rather than showing that the aforementioned features were not important, this disparity could be an indicator of model quality.

Table 5. Permutation importance results for AUC^a, precision, and recall.

Features	Gradient boost, mean (SD)	Random forest, mean (SD)	Support vector machine, mean (SD)

Discussion

Principal Findings and Prior Work

A key finding was that linguistic features were significantly ($P < .05$, 95% CIs) associated with suicide risk on social media. This was achieved using nonparametric statistical analysis. Significant variables included social (*authenticity* and *clout*) and grammatical (*first-person singular pronouns* and *negation*) features (Tables 2 and 3). This confirmed prior studies linking suicide risk and depression to the increased use of first-person pronouns [31,58,59].

In addition to complementing prior work [31,58,59], our contribution provided novelty by examining the directionality and distribution of features at a finer granularity. We found that at-risk users tended to be more authentic and less concerned about social posturing (Tables 2 and 3). Overall, at-risk users had a larger median value than no-risk users for most features. However, there was no real difference between the distributions of the significant variables for low-, moderate-, and severe-risk users.

Another notable finding was the identification of redundant features such as various parts of speech. Although numerous studies have examined the relationship between linguistic features and adverse mental health [58,59], few statistically

examined the correlation between the significant features themselves. Moreover, although there are mathematical methods [17,60] for determining feature importance, these techniques are not widely used in the health sciences. Hence, established methods such as the Spearman correlation coefficient may be easier for clinicians to interpret.

Through correlation analysis, we found moderate positive relationships between readability metrics (eg, *Gunning Fog Index*; $\rho > 0.77$ and 0.76), parts of speech (eg, *comparatives*; $\rho > 0.50$ and 0.63), and post length (eg, *syllable*, *word*, and *sentence count*). This indicates that the underlying feature, length, could potentially be used in favor of its proxies. Moreover, using aggregate variables such as *clout* and *authenticity* may further increase computational efficiency. Not only do they combine more detailed categories, but they may also be better at discerning risk levels because of the increased differences between medians.

Another contribution was the demonstration that linguistic features alone could be used to create effective ML models (GB, RF, and SVMs). After hyperparameter tuning, the models achieved commendable AUCs ranging from 0.66 to 0.68 and F_1 -scores ranging from 0.52 to 0.65. This received at par, if not better, performance than other lexical feature-based models whose AUC and F_1 -scores ranged from 0.51 to 0.75 [61] and from 0.20 to 0.32 [62], respectively. In addition, all models had

a markedly better F_1 -score for the at-risk group (Multimedia Appendices 11 and 12). As failing to identify a person with high suicide risk could lead to loss of life, a more conservative model is advantageous for suicide prevention.

Finally, we used permutation importance to identify the features that contributed the most to each model's decision-making. Through this analysis, we found that *authenticity* and *negative emotion* contributed to higher AUC and precision scores for both the GB and RF models, whereas *clout* contributed to a higher precision for the models. This indicated that such features could potentially be important indicators of suicide risk.

Reproducibility

As we are not the data set owners, we will not be able to provide it upon request. Thus, all applications for data access should be directed at the University of Maryland, following their formal request protocol.

By nature, ML for mental health is a sensitive research area. Hence, the source code for our experiments and the parameters of the classifiers will be made available upon reasonable request, with a justification for the intended use. All code distribution will be under the Massachusetts Institute of Technology license.

Limitations

Our study had 4 primary limitations. First, the observational nature of the study should be noted. Owing to privacy concerns, the University of Maryland Suicidality Dataset does not have ground truth labels, and we were unable to confirm whether users labeled as at risk were in fact experiencing suicidal ideation. In addition, it should be acknowledged that a person experiencing suicidal ideation may not be at risk of suicide, and people on the SuicideWatch forum may be affected by suicide through a family member or friend and not be experiencing suicide risk themselves. However, these confounds are likely to have been mitigated by expert annotation and consensus mechanisms.

Second, another limitation was the granularity of the annotations. Annotations were attached to each user and not to each post. Hence, we did not know which posts were more important and used aggregated features to train the models. Therefore, the performance could have potentially been further improved with finer-grained annotations.

Our third main limitation was the use of only linguistic features to train the models. As demonstrated by prior work, behavioral and relational analyses may further improve automated screening for suicide risk [35,63]. However, having a production-ready model was not the aim of this study. Instead, we aimed to determine whether simpler interpretable models could be used to screen for suicide risk. This was done to ensure that the models were accessible to health care professionals. Hence, *black box* ML methods such as deep learning and nonlexical features were not considered.

Our final limitation was the use of permutation importance to indicate the feature importance. As previously stated, permutation importance indicates only the importance of a feature for a particular model. Hence, it is arguably limited by the effectiveness of the models.

Future Work

This study focused on highlighting the usefulness of linguistic features in constructing ML models. Hence, only lexical features were used. However, prior studies [35,63] indicate that features based on behavioral data and metadata can be used to enhance performance. Therefore, before deploying our model for production, the inclusion of a more varied range of features could be investigated. It would also be interesting to explore deep learning as this would help us evaluate whether latent variables could further increase performance.

The usefulness of our findings in practice and how they relate to suicide assessment, intervention, and prevention could also be examined. This can be done in two ways: (1) exploring the use of ML-based models to support risk assessment on social media sites themselves and (2) investigating the integration of our work into clinical practice.

With regard to existing interventions on social media, in March 2020, Reddit developed *Reddit Care Resources*—an initiative aimed at providing mental health resources to users at risk of suicide or self-harm [64–66]. This method operates in 2 ways. First, if a user searches for certain keywords (eg, “suicide” and “kill myself”), the first result displayed is a post indicating where to find mental health support (Figure 6). Second, users can confidentially report other users who they believe are at risk of suicide or self-harm, which then connects them to trained crisis counselors [64,65].

Although these changes mark an increasing awareness of mental health and suicide risk, these measures could still be improved. For instance, the list of keywords that triggers *Reddit Care Resources* is limited, with searches for “depression,” “self-harm,” or “anorexia” not prompting this intervention (Figure 7).

ML models, such as those used in this study, could help alleviate this problem. For example, Reddit could run such models on searches and posts, prompting *Reddit Care Resources* to pop up if a certain risk threshold is met. This would eliminate the need to constantly expand the mental health–related keyword list, as internet slang and neologisms (eg, “proana” for “pro-anorexia”) can make it difficult to record every word related to mental health.

Examining how our work can be integrated into clinical practice would also be meaningful. Social media can offer an outlet for people to express opinions and thoughts that they may find difficult to express face to face [12]. Hence, analysis of such posts by a health care professional may allow for a deeper understanding of their clients if informed consent is granted. However, a problem is that directly reading such posts may result in an unintentional breach of confidentiality [67]. For instance, if a client shares web-based posts with a health care professional that includes self-harm or abuse, they may be required to report this as part of their duty of care and mandatory reporting obligations [67].

Using a combination of ML and linguistic features (eg, LIWC and *TextStat*), as demonstrated in this work, could help address this problem. Being very time poor, health care professionals do not have time to read through social media posts. Instead,

with consent, automated methods could provide a report that summarizes suicide risk and other clinically relevant information, including the affective (eg, *emotional tone*), cognitive (eg, *discrepancy* and *certainty*), and social aspects (eg, *clout* and *authenticity*) of posts. This preserves client privacy while using ML to extract important clinical information that can potentially enhance client engagement and care. Furthermore, coproduction approaches with mental health experts and people with lived experience of suicide risk would help identify user and system requirements. This, in turn, would facilitate the development of future software apps (eg, desktop and mobile).

A final future development would be to diversify the annotated data sets. The University of Maryland Suicidality Dataset was

unique because of its expert annotation and heightened levels of reliability; however, it has some limitations. For example, the demographics of Reddit tend to skew toward young and male [68-70], which is not representative of the world's population. Hence, gathering a wider and more varied data set would increase the generalizability of our work. Moreover, it may be helpful to further increase the granularity of annotations. There are 2 main reasons for this. First, it would help us understand which text posts contributed the most to an annotator's decision. Second, it would allow us to examine the fluctuation of risk within an individual, as a person identified as at risk may no longer be at risk at another point in time. These additions would likely allow us to achieve more informed results.

Figure 6. Screenshot of Reddit Care Resources.

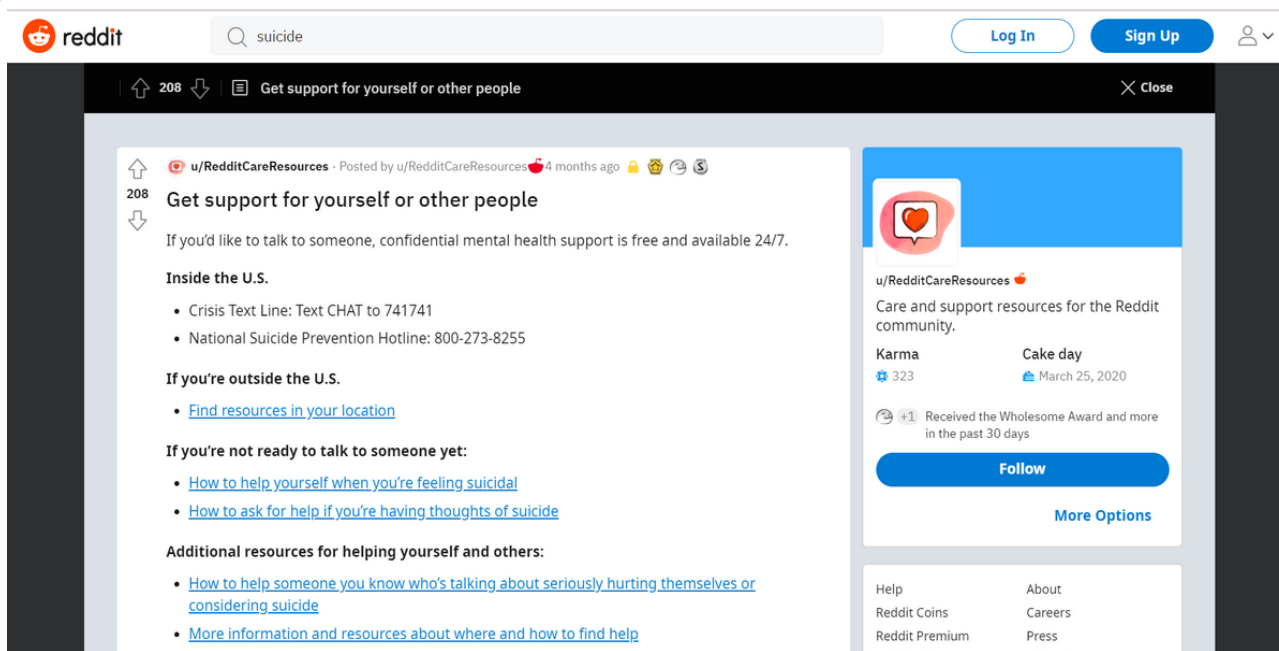

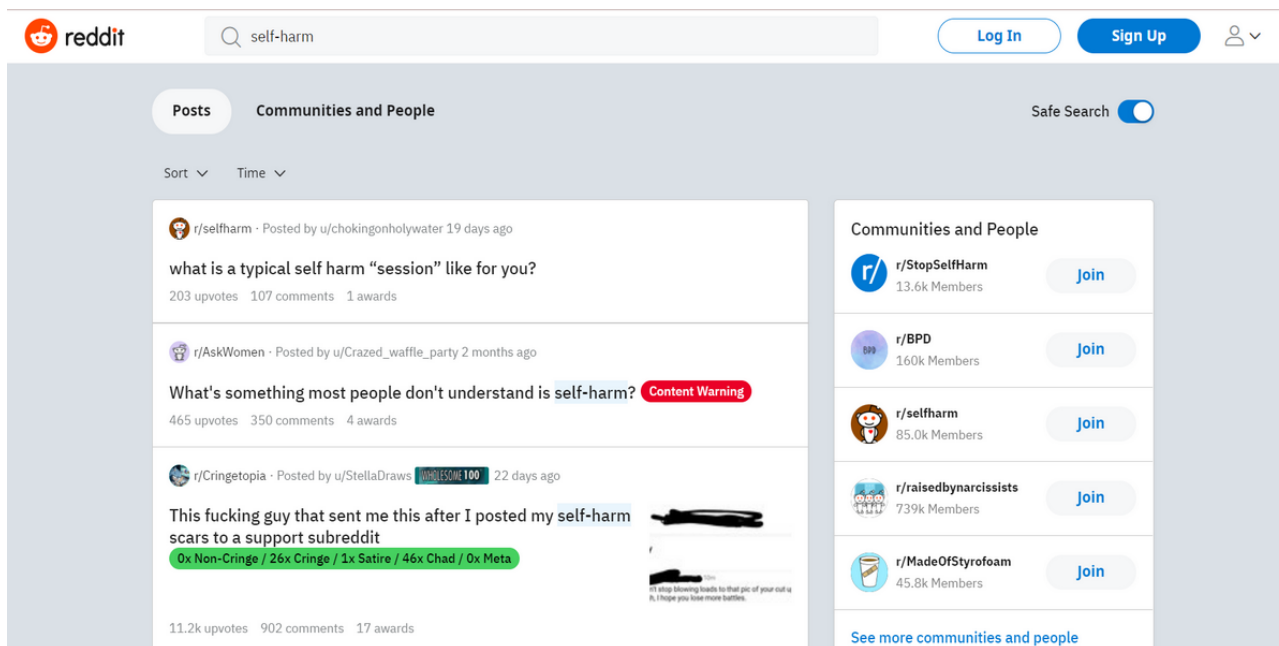

Figure 7. Screenshot of search results for “self-harm”.

Conclusions

In this study, we demonstrated the potency of linguistic features in supporting suicide risk assessment through social media posts. Through statistical and permutation analyses, we were able to determine features significantly related to suicide risk, features

that contributed the most to risk classifications, and redundancy through feature relationships. Finally, the commendable performances of the SVM, GB, and RF models highlight the utility of lexical features alone. This suggests that with future development, these models could be highly useful tools to help enhance clinical care.

Acknowledgments

The authors would like to thank Associate Professor Alice Richardson from the Australian National University Statistical Consultation Unit for her statistical insights and expertise, which greatly assisted in this research. The authors would also like to thank the University of Maryland Institute for Advanced Computer Studies for allowing us to use the data set for research purposes. In particular, the authors would like to thank Professor Philip Resnik for his cooperation and kind words of encouragement. Finally, the authors would like to thank Dr Sumithra Velupillai from the Institute of Psychiatry, Psychology, and Neuroscience at King's College London for her insightful comments on an earlier version of this paper. This research was funded by and delivered in partnership with Our Health in Our Hands. Our Health in Our Hands is a strategic initiative of the Australian National University, which aims to transform health care by developing new personalized health technologies and solutions in collaboration with patients, clinicians, and health care providers.

Abbreviations

AUC: area under the receiving operator curve

GB: gradient boost

LIWC: Linguistic Inquiry and Word Count

ML: machine learning

RF: random forest

SVM: support vector machine
