mindfulness meditations (eg, practice length and frequency) as well as with the intervention; (2) assessing client experiences with mindfulness meditations during and after treatment; (3) measuring changes in measures of anxiety, depression, and PTSD to compare outcomes with previously published outcomes of the PSP Wellbeing Course [9]; and (4) assessing the relationship between mindfulness meditation use and outcome measures. We hypothesized that clients would actively participate in the mindfulness meditations, report positive experiences, and also identify areas for improvement in the mindfulness meditations. We also hypothesized that clients would report statistically significant improvements in symptoms of anxiety, depression, and PTSD and that greater mindfulness meditation use (ie, length and frequency) would predict less severe self-reported symptoms at posttreatment [23]. This feasibility study is the first step in assessing whether mindfulness meditations will be deemed usable and acceptable in iCBT for PSP.

Methods

Ethical Considerations

This study was approved by the Research Ethics Board of the University of Regina (2019-157). Clients were made aware of the details of the study and the potential risks and benefits of participating, and they provided informed consent before participation. Clients were given access to the PSP Wellbeing Course but were not otherwise offered incentives to encourage participation. Client data were stored on a secure server and deidentified before analyses.

Clients and Procedure

PSP were informed of the PSP Wellbeing Course offered by PSPNET through presentations, emails distributed through PSP organizations, social media, and word of mouth and encouraged to visit the PSPNET website [24]. PSPNET is a clinical research unit based at the University of Regina that develops, delivers, and conducts research on iCBT for PSP. In addition to offering a therapist-guided PSP Wellbeing Course, PSPNET also offers a therapist-guided PSP PTSD Course and a self-guided version of the PSP Wellbeing Course, all of which were available for PSP to select from at the time they visited the website. Prospective clients who were interested in the PSP Wellbeing Course read about the program and completed a consent form and a brief web-based screening questionnaire. Once they completed the web-based screening, they scheduled and completed a phone screening with a trained clinician. To be eligible for the intervention and thereby this study, clients needed to be current or past PSP (career or volunteer), be residing in an eligible Canadian province or territory (at the time of this study, this included Alberta, New Brunswick, Nova Scotia, Ontario, Prince Edward Island, Saskatchewan, and Nunavut), be aged at least 18 years, have access to an internet connection, and be willing to provide an emergency medical contact. Prospective clients were ineligible and referred to other services as appropriate if they reported a high suicide risk; reported a past-year suicide attempt or suicidality-related hospitalization; reported a primary problem with psychosis, mania, or substance use; or reported current involvement in another psychological treatment. The eligibility criteria were assessed during the web-based screening and the subsequent phone screening. Suicide risk was first assessed using item 9 from the Patient Health Questionnaire-9 (PHQ-9) [25], which inquires about suicidal ideation. Clinicians then conducted a clinical interview by phone to assess suicide risk, including asking about past-year attempts and hospitalizations. Severe alcohol or drug problems were assessed using validated questionnaires (ie, scored ≥20 on the Alcohol Use Disorder Identification Test [26] or ≥25 on the Drug Use Disorder Identification Test [27]). Psychosis and mania were assessed based on clinical history but were not reported by any client. Eligible clients were enrolled in the intervention and assigned to therapists who were either registered master’s-level social workers or registered psychologists. Therapists would email or call clients once or twice a week, depending on client preference. Therapist support was designed to help clients work on skills within the course, apply the skills to their lives, and troubleshoot difficulties. Clients were asked to complete regular symptom measures throughout the course on a weekly basis and at 8 weeks. At 10 weeks, the first 30 clients were invited to complete an interview assessing their perspectives on the mindfulness meditations and the course in general. There were 12 clients who agreed to participate in the interviews.

Materials

The iCBT Intervention

The PSP Wellbeing Course is a transdiagnostic iCBT course for PSP adapted from a previous Canadian iCBT course, the Wellbeing Course, which was initially developed at the Macquarie University in Australia and has been successful in treating a range of symptoms in Australia [28-31] and Canada [32-35]. More information on the origins of the intervention [25] and the adaptations of the intervention [29-32] can be found elsewhere. The course uses a theoretical, pragmatic approach to treatment that teaches clients skills that can be applied to various symptom presentations. The intervention specifically includes five core lessons: (1) introduction of CBT and identifying symptoms, (2) monitoring and challenging automatic thoughts, (3) management of physical symptoms, (4) graded exposure, and (5) goal setting and relapse prevention. Lessons are presented in a slideshow format and include text, diagrams, and case stories about PSP. Clients can download materials, homework assignments, and supplementary information on many topics (eg, panic, assertiveness, sleep, and grief). The intervention is designed to be completed in 8 weeks, but clients can have access to a therapist for up to 16 weeks and to the course materials for up to 1 year. Clients receive automated emails encouraging them to work through the materials during this period.

Mindfulness Meditations

Unlike the previous versions of the PSP Wellbeing Course, the version used in this study included a downloadable, guided, audio mindfulness meditation for each of the 5 lessons of the intervention and psychoeducational material on mindfulness meditations before the first meditation. Each lesson included a different type of mindfulness meditation designed to complement the CBT skills taught in that lesson and was based...
on evidence of successful implementation in other programs [22,36-39]:

- **Lesson 1: grounding** (eg, turning attention to physical sensations)
- **Lesson 2: loving kindness** (eg, cultivating feelings of love for self and others)
- **Lesson 3: awareness of breath** (eg, focusing on breathing slowly and deeply)
- **Lesson 4: awareness of the 5 senses** (eg, cultivating awareness of the environment through the 5 senses)
- **Lesson 5: body scan** (eg, focusing on the body for areas of tension)

Each mindfulness meditation was audio-recorded by a voice actor and was designed to be approximately 10 minutes long, consistent with previous recommendations [39-41]. Each mindfulness meditation was accompanied by a text script that clients could read in lieu of the audio. All clients who enrolled in the PSP Wellbeing Course were provided with access to the mindfulness meditations. Clients were encouraged to complete 10 minutes of mindfulness meditation practice per day while completing the intervention.

**Measures**

**Overview**

During eligibility screening, we administered a questionnaire to assess demographic and occupational characteristics. We also asked about pretreatment engagement in a mindfulness meditation practice. At both pretreatment and 8 weeks postenrollment, consistent with past research on the PSP Wellbeing Course, we administered the following measures: the PHQ-9 to measure symptoms of depression [25], the Generalized Anxiety Disorder-7 (GAD-7) to measure symptoms of generalized anxiety [42], and the Posttraumatic Stress Disorder Checklist for the DSM-5 (PCL-5) to measure symptoms of PTSD [43]. As anger and sleep problems are common among PSP [5,6], we also administered the Dimensions of Anger Reaction Scale-5 (DARS-5) to measure problems related to anger [44] and the Insomnia Severity Index (ISI) to measure sleep difficulties [45]. In an effort to help advance the growing research literature on resilience among PSP [46], we also administered the Brief Resilience Scale (BRS) to measure clients' resilience to life stressors [47]. Finally, the Five Facet Mindfulness Questionnaire (FFMQ-15) was administered to measure the degree to which clients engage in 5 aspects of mindfulness (ie, observing, describing, acting with awareness, nonjudging of inner experience, and nonreactivity to inner experience) [48].

**Patient Health Questionnaire-9**

The PHQ-9 is a 9-item self-report measure of the frequency of symptoms of depression in the past 2 weeks. Items are rated on a 4-point Likert-type scale ranging from 0 (not at all) to 3 (nearly every day). Higher scores are indicative of greater symptoms of depression. The PHQ-9 has demonstrated good sensitivity, specificity, and convergent validity [49,50]. Reliability was good to excellent for this study (range of before and after treatment, α=.78-.85; ω=.79-0.85).

**Generalized Anxiety Disorder-7**

The GAD-7 is a 7-item self-report measure of the frequency of anxiety symptoms in the past 2 weeks. Items are rated on a 4-point Likert-type scale ranging from 0 (not at all) to 3 (nearly every day). Higher scores are indicative of greater symptoms of anxiety. The GAD-7 has demonstrated good internal consistency (α=.89) and good test-retest reliability (r=.83) [42]. The reliability was good to excellent for this study (α=.87-.91; ω=.87-0.92).

**Posttraumatic Stress Disorder Checklist for the DSM-5**

The PCL-5 is a 20-item measure of each of the 4 clusters of PTSD (ie, intrusive thoughts, avoidance, negative alterations in mood, and alterations in arousal and reactivity). Items are rated on a 5-point Likert-type scale ranging from 0 (not at all) to 4 (extremely). Higher scores are indicative of greater symptoms of PTSD. The PCL-5 has demonstrated strong diagnostic utility within the general population [51] as well as strong test-retest reliability (r=.82) and high internal consistency (α=.94) [43]. Reliability was good to excellent for this study (α=.85-.95; ω=.94-0.95).

**Dimensions of Anger Reaction Scale-5**

The DAR-5 is a 5-item self-report measure of the dimensions of anger reactions, especially in stressful situations, over the past 4 weeks. Items are rated on a 5-point Likert-type scale ranging from 1 (none or almost none of the time) to 5 (all or almost all of the time). Higher scores are indicative of greater levels of distress. The DARS-5 has demonstrated convergent and discriminant validity [44,45] as well as high internal consistency (α=.95) [44]. Reliability was good to excellent for this study (α=.88; ω=.89-0.90).

**Insomnia Severity Index**

The ISI is a 7-item self-report measure designed to assess difficulties with sleep and insomnia [45]. Frequency items regarding how often someone experienced a problem in the last 2 weeks are rated on a 5-point Likert-type scale ranging from 0 (not at all) to 4 (very severe). Items regarding satisfaction with sleep, noticeability of sleep problems, worries about sleep, and interference with daily functioning are rated on a 5-point Likert-type scale, with higher scores indicating greater sleep difficulties. The ISI has demonstrated adequate concurrent validity and good internal consistency (α=.74 [45]).

**Brief Resilience Scale**

The BRS is a 6-item self-report measure of resilience. Items are rated on a 5-point Likert-type scale ranging from 1 (strongly disagree) to 5 (strongly agree). Higher scores are indicative of higher levels of resilience. The BRS has demonstrated good validity and good to excellent internal consistency (α=.80-.91) [47]. Reliability was good to excellent for this study (α=.87-.91; ω=.87-0.91).

**Five Facet Mindfulness Questionnaire**

The FFMQ-15 is a 15-item short-form self-report mindfulness measure designed to assess 5 facets of mindfulness using 5 subscales: observing, describing, acting with awareness, nonjudging of inner experience, and nonreactivity to inner
experience. Statements are rated on a 5-point Likert-type scale ranging from 1 (never or very rarely true) to 5 (very often or always true). Higher scores are indicative of higher levels of mindfulness. The FFMQ-15 has good convergent validity with the FFMQ-39 [48]. Reliability for the total scale was good for this study ($\alpha=.79-.85$; $\omega=0.80$). Subscale reliability for this study was also good ($\alpha=.77-.90$; $\omega=0.81-0.91$).

**Treatment Use and Satisfaction**

Each week during the course, clients were asked how much time they spent practicing mindfulness meditation throughout the week in minutes and how many days they practiced. At 8 weeks postenrollment, we administered a bespoke questionnaire assessing satisfaction with the mindfulness meditations and the intervention overall.

**Posttreatment Semistructured Interview**

After completing their 8-week measures, clients were invited to participate in semistructured telephone interviews to discuss their perspectives on the mindfulness meditations and the course in general. Invitations were extended upon completion of the course to ensure that clients had sufficient opportunities to review all course materials. Invitations continued until 12 interviews were conducted, which was deemed sufficient given the objectives and the exploratory nature of this study, and this is consistent with prior recommendations [53,54]. Interviews were conducted by a clinician and a research assistant and included questions such as “What parts of the course did you find to be the most helpful? Why?” and “Were there parts of the meditation that you did not like? Why?” Interviews ranged from 10 to 20 minutes and were recorded for later transcription and analysis. The clients were asked to provide both positive and negative constructive feedback on the mindfulness meditations. Informed consent was obtained before the commencement of each interview and confirmed verbally before each recording was initiated. Table 1 shows a summary of all measures used.

Analyses

Quantitative Analyses
SPSS (version 26; IBM Corp) was used to conduct the quantitative analyses. Data were deidentified before the analysis. Descriptive statistics were used to describe the sample’s demographic and clinical characteristics, engagement in mindfulness meditation practice, and satisfaction with the mindfulness meditations and the course in general. Completer analysis was used (ie, we did not impute missing data), as is common in pilot studies [55]. Paired sample t tests (2-tailed) were conducted to measure changes from baseline to posttreatment in the total scores on the GAD-7, PHQ-9, PCL-5, DAR-5, FFMQ-15, ISI, and BRS. Partial correlations were used to test for relationships between posttreatment measures (as measured by the GAD-7, PHQ-9, DAR-5, FFMQ-15, ISI, and BRS) and minutes spent meditating, when controlling for pretreatment measures.

Qualitative Analyses
Client interview data were deidentified and analyzed using NVivo 12 (Lumivero). The data were analyzed using a directed content analysis approach [56]. An initial codebook was developed by CAL to align with the questions posed during the semistructured interview. The data were then grouped into categories by CAL using a realist approach, whereby client data were treated as their descriptions of reality [57]. New codes were created by CAL when the data did not fit into the preexisting codes. The codebook and data were independently reviewed by JDB, a research associate with extensive experience in qualitative research. CAL and JDB convened to address conflicts in the codebook and continued discussions until a consensus was reached.

Results
Client Flow and Demographics
Figure 1 shows the flow of clients through this study, with 40 clients enrolling in and initiating the course and 32 (80%) clients completing the outcome measures. The mean age of the clients was 40.57 (SD 9.75) years. Most clients identified as White (37/40, 93%) and women (26/40, 65%) and reported currently residing in Saskatchewan (27/40, 68%). Most clients (22/40, 55%) reported that they were police, although other occupational groups were also represented (Table 2). In total, 30% (11/40) of the clients had scores above the clinical cut-off on the PHQ-9, 27% (11/40) above the cut-off on the GAD-7, 15% (6/40) above the cut-off on the PCL-5, and 45% (18/40) screened positive for at least 1 mental disorder. In terms of program completion at 8 weeks, 80% (32/40) of the clients had completed all lessons. On average, clients sent 5.42 (SD 3.57) messages to their therapists and received 9.48 (SD 3.18) messages. They also had 2.39 (SD 3.13) phone calls with therapists.

**Meditation Use**

No prospective clients reported participating in regular mindfulness practice at the time of their enrollment. Figure 1 shows that of the 40 clients, 28 (70%) viewed the grounding meditation in lesson 1, 28 (70%) viewed the loving kindness meditation in lesson 2, 18 (45%) viewed the meditation on awareness of breath in lesson 3, 21 (53%) viewed the meditation on awareness of the 5 senses in lesson 4, and 21 (53%) viewed the body scan meditation in lesson 5, as tracked through automatic computer system logs. Meditations were available for download; as such, some clients may have listened to the meditations more often than indicated by the system. Clients who completed the course tended to spend more time on the meditations overall, although this difference was not statistically significant (P>.16). Table 3 shows the mean number of text views and audio listens for each meditation and suggests that clients demonstrated a preference for reviewing the text over listening to the audio. Table 3 shows that the clients who completed the course accessed the written meditations an average of 4.91 (SD 2.91) times. Table 4 shows the self-reported number of times meditating and the number of minutes spent meditating and shows that those who meditated, meditated on average 5.67 times for a total of 28.48 minutes of meditation. As shown in Table 4, there was wide variability in days meditating (0-28 days) and minutes meditating (0-290 minutes) over the course. Of note, 9 clients opened meditation materials but reported that they did not use those materials.

Changes in Symptoms, Resilience, and Mindfulness

The 32 clients who completed the 8-week measures reported statistically significant reductions in total scores on the GAD-7, PHQ-9, PCL-5, and DAR-5 (all \( P < .001 \)) and a statistically significant increase in BRS total scores (\( P = .01 \)). No statistically significant change in ISI total scores was observed. Clients who completed the 8-week measures reported statistically significant increases in overall FFMQ-15 scores, with examination of the subscales revealing changes in mindfulness nonjudging and nonreactivity scores but not describing, acting with awareness, or observing. Time spent meditating was not associated with posttreatment measures while controlling for pretreatment measures (all \( P = .09-.67 \)). The details are presented in Table 5.

Treatment Satisfaction

The 32 clients who completed the 8-week measures generally reported feeling satisfied with the course. The 27 clients who accessed the mindfulness meditations also generally reported that they were satisfied with the mindfulness meditations. Most clients reported that they would recommend the intervention to a friend (32/32, 100%) and that they would recommend the mindfulness meditations to a friend (25/32, 93%). Table 6 provides details.

**Qualitative Results**

Overall, clients reported that the mindfulness meditations were beneficial (Table 7). Key themes from the qualitative analysis included clients liking the simplicity of following the mindfulness meditations, incorporating other strategies into the mindfulness meditations, and the variety of mindfulness meditations that were presented. Suggestions included providing videos alongside the mindfulness meditations for individuals who consider themselves to be more “visual,” providing distinct end points in the mindfulness meditations (eg, a bell chime to indicate when the meditation end), and providing shorter mindfulness meditations to start. Suggestions for technical or presentation changes, including creating an atmosphere for mindfulness meditations to be completed in a group setting, were also provided.

**Discussion**

**Principal Findings**

In this study, we explored the feasibility of adding mindfulness meditations to the PSP Wellbeing Course, as there is a gap in the literature with regard to the use of mindfulness meditations among PSP participating in iCBT. Overall, the study suggested that there was highly variable use of mindfulness meditations among PSP in the PSP Wellbeing Course, with 70% (28/40) of the clients reviewing the first 2 meditations and then about half of clients (ie, 18/40, 45% to 21/40, 53%) viewing the last 3 meditations. Client more often looked at the text of the meditations rather than the audio of the meditations. There was significant variability among clients in the use of the meditations, with some clients never using the meditations and others using the meditations 3 to 4 times a week. Similarly, in terms of practice, there was high variability observed, with clients on average practicing 23 minutes a week. The use data alone suggest that the incorporation of mindfulness within iCBT will not be universally used when offered. It is not fully known why some clients did not use the meditations. It is possible that the high amount of content in the PSP Wellbeing Course itself may be a factor in the lower use of mindfulness meditations by some clients (ie, some clients may not have had enough time or willingness to practice mindfulness meditation in addition to other skills taught in the course).

In terms of improvements on measures over 8 weeks, clients in this course reported statistically significant improvements in symptoms of anger, anxiety, depression, PTSD, and insomnia. These findings are consistent with previous results regarding the PSP Wellbeing Course [9]. Although this was not a randomized controlled trial comparing iCBT alone with iCBT enhanced with mindfulness meditations, the results suggest that the addition of mindfulness did not have a marked positive or negative impact on the effectiveness of the course.
Other benefits observed in this study included improved resilience and improved mindfulness scores from pre- to posttreatment. In terms of mindfulness, the results suggested that the course was specifically associated with improvements in nonjudging and nonreactivity mindfulness scores. It appears that the course reduced the frequency with which clients labeled their thoughts and feelings as “good” or “bad” and enhanced client’s ability to detach from thoughts and feelings rather than getting caught up in their thoughts and feelings. The course was not associated with changes in observing (ie, noticing internal and external experiences), describing (ie, being able to express one’s experiences in words), or acting with awareness (ie, attending to present-moment experiences) mindfulness scores. The skills of observing, describing, and acting with awareness may be more specifically associated with the practice of mindfulness, and clients may not have participated in sufficient mindfulness meditations to experience these benefits.

As this was not a randomized controlled trial, we could not determine whether the changes in mindfulness were related to the mindfulness meditations or would have resulted from the PSP Wellbeing Course alone. In general, clients who participated in the interviews on mindfulness meditations reported a number of perceived benefits of mindfulness despite variable engagement with the mindfulness meditations. Most clients reported that mindfulness meditation helped reduce stress and improved relaxation and that mindfulness meditation can be beneficial with practice. Mindfulness has previously been associated with stress reduction and improved relaxation, among other benefits [16,58,59]. Clients also reported that they liked that other skills (eg, controlled breathing and emotion labeling) could be incorporated with the mindfulness meditations.

The interviews shed light on the challenges of offering mindfulness meditations to PSP as part of iCBT. A common challenge with the meditations that clients reported was the difficulty in sitting with their emotions. Clients also commonly reported difficulties with finding time or quiet space in which to complete the mindfulness meditations and reported that the mindfulness meditations were too lengthy. Beginning with shortened meditations that slowly increase in length may be better to help PSP to learn to cultivate mindfulness gradually. Future iterations of the intervention may benefit from including information on how mindfulness meditation can be practiced throughout the day in smaller timeframes to increase the accessibility of mindfulness meditation. A suggestion for improvement included providing shorter mindfulness meditations (eg, 2-3 min) to help people learning mindfulness meditation to work their way up to longer mindfulness meditations and gain increased comfort while sitting with their feelings.

Overall, the high degree of treatment satisfaction across the previous version of the PSP Wellbeing Course and this version enhanced with mindfulness meditation suggests that mindfulness meditations, at the very least, did not markedly decrease course satisfaction or negatively impact clients’ perceptions of the course. Of note, there was also no evidence to suggest that this version of the course impacted course completion. At 8 weeks, 80% (32/40) of the clients in this trial had completed all 5 lessons. Similarly, at 8 weeks, 77% of the clients in a prior study of the original PSP Wellbeing Course had completed the course [9]. In terms of therapist engagement, clients in this course sent an average of 5.24 emails and received 9.48 emails from their therapists. In the previous version of the course, on average, clients sent 4.98 (SD 5.53) messages to their therapists and received 9.80 (SD 4.71) messages [9]. Descriptively, treatment satisfaction was lower for mindfulness meditations than for other aspects of the course (ie, lesson material, meditations, and additional resources). The lower satisfaction with the mindfulness meditations may indicate that work is needed to improve the meditations and that some PSP are not open to practicing mindfulness.

Our sample of clients, who voluntarily enrolled in a therapist-guided iCBT course, may have been more interested in CBT skills than mindfulness skills. The large variation in the quality of publicly available mindfulness meditation programs means the clients in this study may have been justifiably skeptical of mindfulness meditation or unsure about the potential benefits of mindfulness meditation [60].

Of note, in this study, no statistically significant relationships were observed between time spent practicing mindfulness meditations and reductions in symptoms, which contrasts with previous evidence that increased time spent meditating is associated with increased symptom reduction [23]. This discrepancy may be a result of the small sample size and having inadequate power to detect effects. This discrepancy may also be explained by the finding that the intervention was already associated with significant reductions in symptoms, and the addition of mindfulness meditations could not meaningfully add to the results. Furthermore, previous studies on PSP and mindfulness appear to focus on the intervention as a whole (ie, the impact of the intervention and mindfulness combined) and have not considered the independent impact of mindfulness on outcomes. It should be noted that the extant research suggests that mindfulness can have positive effects when practiced for 10 minutes daily, but shorter periods can also be associated with benefits [39-41]. Evidence also suggests that the quality of mindfulness meditation may be more important than the amount of mindfulness meditation practiced [61]. Few studies have reported the actual time their clients reported practicing mindfulness [61]. In this study, it may have been preferable to assess the quality of practice rather than the minutes practiced.

Limitations
This study has important limitations that will help to inform future research. First, the sample size of the study was small; however, the detailed data collected allowed for an understanding of the usability and credibility of mindfulness meditation in a sample of PSP seeking treatment. The detailed data also allow for iterative improvements to the intervention, such as providing increased psychoeducation on mindfulness meditation and introducing ultrabrief meditations for clients who want to work for longer periods. Future studies on iCBT should be conducted using larger samples of PSP from diverse communities across Canada (and internationally), as this study is not generalizable cross-culturally. It should also be noted that the clients in this study overall had variable clinical symptoms. On average, the scores of this particular subsample suggested...
that clients had milder symptoms of depression, anxiety, anger, and PTSD, although 30% (11/40) of the clients had scores above the clinical cut-off on the PHQ-9, 27% (11/40) above the cut-off on the GAD-7, 15% (6/40) above the cut-off on the PCL-5, and 45% (18/40) screened positive for at least 1 of the aforementioned mental disorders. It is possible that the lower symptom severity overall in the sample may have impacted the relationship between minutes meditating and outcomes owing to floor effects. It is also notable that in this sample, there were more women than men, which may have affected the findings. Second, this study does not contain a randomized design and involves short-term follow-up; thus, it is descriptively compared with the previously published trial on the PSP Wellbeing Course. Future studies of the program could benefit from a randomized design and a larger sample size to evaluate potential differences in experiences between versions of the course. In addition, such studies could explore how the course compares with control conditions. Third, only a subsample of the clients was interviewed, and the experiences of those who did and did not consent to an interview could have differed (eg, clients with more favorable attitudes toward the mindfulness meditations may have been more likely to consent to an interview). Fourth, our ability to determine whether time spent meditating predicted outcome measure changes may have been limited by the low engagement from clients in the mindfulness meditations. Future studies should consider means to encourage mindfulness meditation use without clients feeling forced to complete the exercises.

Clinical Implications and Future Directions

This study has several important potential implications. First, results from this study replicated previous results regarding the PSP Wellbeing Course, indicating that the intervention is associated with statistically significant reductions in symptoms of anxiety, depression, PTSD, and anger with medium to large effect sizes [62]. Contributing to the literature on iCBT for PSP, the study showed that improvements were also observed in resilience and mindfulness with this version of the course.

Use data showed that a significant percentage of clients used the mindfulness meditations. The information gathered from the interviews indicated that clients enjoyed that the mindfulness meditations could be incorporated with other strategies. Therapists may be able to help support future clients in understanding what works for them and how to incorporate their existing strategies with mindfulness meditation to achieve increased benefits. Future programs may benefit from increasing psychoeducation regarding the potential discomfort associated with mindfulness meditation and encourage clients to consider practicing more to allow them to get used to experiencing emotions. Clients also made suggestions for improvement. The mindfulness meditations may be offered after the completion of the course as an additional resource for clients who may be interested in pursuing the meditations. Additional research is needed to identify who can benefit from mindfulness meditations and to ensure that those who do not benefit are not distracted from the rest of the course content in attempting to complete mindfulness activities. One potential solution is to include mindfulness meditations as an optional component, allowing interested individuals to use mindfulness within the course while not distracting individuals who are not interested in mindfulness.

Conclusions

To the best of our knowledge, this is the first study to assess web-based mindfulness meditations as an adjunct to a preexisting iCBT intervention among PSP. The incorporation of mindfulness meditation was largely acceptable to many clients enrolled in the intervention, although our findings were limited by variable client engagement with the mindfulness meditations. The mindfulness meditations were used by approximately half of the clients, and the clients who used them reported that they enjoyed the meditations. The addition of mindfulness meditations did not appear to remarkably affect the overall engagement, satisfaction, or outcomes of the course. Clients also expressed several challenges and suggestions for improvement, which represent opportunities to improve mindfulness meditations and iCBT for PSP in general. The presentation of shortened mindfulness meditations may serve as an important adjustment to allow PSP to experience the benefits of mindfulness while maintaining their busy schedules. The results of this study suggest that mindfulness meditations, when offered along with iCBT, may be an acceptable intervention for Canadian PSP. Future research is required to further explore how best to incorporate mindfulness into iCBT for PSP and the potential benefits of doing so now that we have demonstrated partial feasibility.

Acknowledgments

The authors would like to acknowledge the contributions of all public safety personnel (PSP) who participated and the members of the PSPNET team for their support with this project. The authors would also like to acknowledge the many stakeholders and organizations that assisted them in tailoring the PSP Wellbeing Course and distributing information about PSPNET to PSP. Acknowledgments are due to the Online Therapy Unit for their support in setting up PSPNET. The authors are indebted to Information Services at the University of Regina, especially Max Ivanov, for his pivotal role in developing the Online Therapy Unit platform that is used to host PSPNET. The authors would like to thank Dr Shadi Beshai, Dr Natasha Gallant, and Dr Jenn deLugt for providing valuable feedback on this study. The authors would also like to thank Ailesh Abrams and Isabelle Dene for helping complete the interviews and Peace Dukuye for her efforts. This manuscript is based on a published thesis defended by Caelleigh Landry [63]. This research was made possible by scholarship funding provided to CAL by the Canadian Institutes for Health Research, Mental Health Research Canada, and Saskatchewan Health Research Foundation. This study was also supported by PSPNET, which is funded by the Canadian Government’s Ministry of Public Safety and Emergency Preparedness. The funders had no involvement in the design of the study or in the collection, analysis, and interpretation of the data.
Data Availability

As part of the consent form, participants were informed that their data would only be shared with members of the research team. Therefore, we are unable to share data.

Conflicts of Interest

HDH is the director of PSPNET and executive director of the Online Therapy Unit. BD and NT are the authors and developers of the Wellbeing Course but do not derive any personal or financial benefit from it. The other authors have no conflicts of interest to declare.

Abstract

Background: Irritable bowel syndrome (IBS) is a disorder of the gut-brain interaction that is associated with abdominal pain, altered bowel patterns, and reduced quality of life. Up to 50\% of patients with IBS also report anxiety or depressive symptoms. Although effective self-management interventions exist for individuals with IBS, few have been effectively implemented, and most do not consider the unique needs of patients with comorbid IBS and anxiety or depression.

Objective: This study aimed to determine the anticipated acceptability, appropriateness, feasibility, and usability of a comprehensive self-management intervention using an implementation science and human-centered design approach among individuals with comorbid IBS and anxiety or depression and health care providers.

Methods: A convergent mixed methods design was used to elicit feedback on the comprehensive self-management intervention outline and content to identify refinement needs before testing. Patients with IBS and moderate to severe anxiety or depression and health care providers were purposefully sampled from primary care and gastroenterology settings. Participants completed semistructured interviews and surveys on anticipated acceptability, appropriateness, feasibility, and usability.

Results: Patient participants (n=12) were on average 36.8 (SD 12.2) years of age, and 42\% (5/12) were currently receiving psychological therapy. Health care providers (n=14) were from primary care (n=7) and gastroenterology (n=7) settings. The mean usability scores (out of 100) were 52.5 (SD 14.5) for patients and 45.6 (SD 11.6) for providers. For patients and providers, qualitative data expanded the quantitative findings for acceptability and appropriateness. Acceptability findings were the comprehensive nature of the intervention and discussion of the gut-brain interaction. For appropriateness, participants reported that the intervention provided structure, accountability, and support. Feasibility was confirmed for patients, but there was a divergence of findings between quantitative and qualitative measures for providers. Patients focused on intervention feasibility, while providers focused on implementation feasibility in the clinic. Identified usability issues to address before implementation included the intervention delivery format, length, and lack of integration into health care settings that, if not addressed, may limit the reach of the intervention.

Conclusions: Patients and health care providers found the intervention acceptable and appropriate. Several feasibility and usability issues were identified, including intervention delivery methods, length of intervention, and the best methods to implement in the clinic setting. The next steps are to refine the intervention to address the identified issues and test in a pilot study whether addressing usability issues leads to the anticipated improvements in implementation and uptake.

Introduction

Irritable bowel syndrome (IBS) is a disorder of gut-brain interaction that affects 6%-18% of individuals worldwide [1,2]. Many evidence-based practice interventions (EBPIs) have been developed to address symptoms of IBS, such as abdominal pain, and improve quality of life [3]. However, a gap exists in translating EBPIs into clinical practice settings. Clinical practice guidelines support the use of behavioral EBPIs for IBS [4,5], yet only a small proportion of patients actually receive such interventions [6]. Implementation science is a field that focuses on translating evidence-based practice into real-world settings [7]. Attending to implementation outcomes such as acceptability, feasibility, appropriateness, and usability can assist in identifying facilitators and barriers to successful intervention implementation and adoption within clinical practice settings [7-9].

When integrating EBPIs for IBS into real-world settings, an important consideration is the common comorbidities that exist among many individuals with IBS. Most notably, 30%-50% of patients diagnosed with IBS also have a diagnosis of anxiety or depression [10]. Psychological distress is linked to the onset and exacerbation of IBS symptoms, and reducing symptom severity and burden is a key component of behavioral approaches. With the publication of the consensus-driven Rome IV criteria [11], there is a growing appreciation that IBS is a disorder of gut-brain interaction. Although many studies have examined the effectiveness of interventions for IBS, including cognitive behavioral therapy and dietary interventions [6,12,13], few have focused specifically on interventions for individuals with IBS and comorbid anxiety or depression. Given the high prevalence of IBS in the United States, along with comorbid anxiety and depression, there is a significant need to implement effective therapeutic strategies to address both IBS and psychological distress [12,14].

One EBPI, the comprehensive self-management (CSM) intervention, has been shown in multiple randomized controlled trials to reduce abdominal pain symptoms and improve quality of life [15-17]. The intervention content has been published as a book, Master Your IBS [15-17]. Although initially developed for IBS symptoms, the intervention has elements of a transdiagnostic approach, reducing other common symptoms of anxiety, depression, extraintestinal pain, fatigue, and sleep disturbances [18,19]. The intervention consists of 8 1-hour sessions, which can be provided by a psychiatric nurse practitioner or similarly trained health professional. However, there is a gap in knowledge regarding how to implement the CSM intervention into clinical practice, specifically from the perspective of key stakeholders: individuals with IBS and comorbid anxiety or depression and health care providers.

Research has argued for applying human-centered design and usability principles to address the lack of intervention implementation by redesigning interventions to improve usability while retaining the effective components [20-22]. Although usability has been most often applied in technology-based applications, usability evaluation principles can also be used to assess other products and services, including interventions and implementation strategies [9,23,24]. Human-centered design approaches focus on developing usable interventions through stakeholder input [21]. By addressing design and content issues, interventions can have increased usability and acceptability to better integrate into clinical settings.

In this research, we sought to examine the usability and acceptability of the current, paper-based CSM intervention from the perspectives of patients with IBS and comorbid anxiety or depression and health care providers in primary care and gastroenterology settings. Our formative evaluation was intended to support (1) refining and adapting the CSM to a digital format and (2) the identification of implementation strategies to facilitate adoption in clinical practice settings. The initial impressions patients and health care providers form regarding the anticipated acceptability, feasibility, appropriateness, and usability of an intervention affect their likelihood of adopting it and help characterize their needs, and these impressions can inform intervention refinement or redesign as well as the selection of intervention strategies to plan for integration into clinical practice. Our research questions were as follows: (1) What are patient and provider perspectives on the acceptability, appropriateness, feasibility, and usability of the current CSM intervention? (2) What recommendations do patients and providers have for improving this intervention?

Methods

Design
We used a convergent mixed methods design to collect both quantitative (ie, surveys) and qualitative (ie, semistructured interviews) data [25] from patients with IBS and comorbid anxiety or depression, as well as primary care and gastroenterology health care providers. In this study, participants received the paper-based intervention content to review and critique, not the intervention directly. Each patient and health care provider participated in a semistructured interview to discuss the intervention content and structure and answer survey questions. Our interview and survey questions were guided by the discover, design, build, and test framework, which combines perspectives from implementation science and human-centered design [7,8,20]. To gain a comprehensive understanding of issues and recommended strategies, we designed our qualitative interview questions to align with the concepts addressed in the surveys [25]; these included acceptability, feasibility,
Sample

Individuals with IBS and self-identified comorbid anxiety or depression symptoms (referred to as patients) were recruited on the internet through 2 methods: the University of Washington Institute of Translational Health Sciences listservs and ResearchMatch, a national health volunteer registry supported by the US National Institutes of Health as part of the Clinical Translational Science Award program.

Patients were eligible if they met the following inclusion criteria: (1) aged between 18 and 70 years; (2) ROME IV IBS criteria of recurrent abdominal pain at least 1 day per week in the past 3 months that is associated with 2 or more of defecation, onset associated with a change in frequency of stool, or change in form of the stool; (3) have a diagnosis of IBS by a health care provider; (4) report moderate to severe anxiety or depression (Generalized Anxiety Disorder-7 [GAD-7] score of >10 [27]; Patient Health Questionnaire-9 [PHQ-9] score of >10 [28]); and (5) be able to read and write in English. Participants were excluded if they had a first-degree relative with colorectal cancer before the age of 60 years or had multiple “red flag” symptoms (ie, loss of 10 or more pounds without trying, blood in stool, or anemia). Patients completed a web-based screening questionnaire to assess their eligibility. All patients who expressed thoughts of hurting themselves were immediately directed to contact the National Suicide Prevention Lifeline.

Health care providers were recruited from primary care and gastroenterology clinics in Washington State. Individuals were eligible to participate if they self-reported caring for more than 3 patients with IBS per month. Health care providers from primary care clinics were recruited through the WWAMI (Washington, Wyoming, Alaska, Montana, and Idaho) region Practice and Research Network, a practice-based research network of primary care clinics and clinical organizations. Health care providers from Seattle gastroenterology clinics were recruited through purposeful convenience sampling. Health care providers received emails regarding the study and self-identified if they met the criteria of caring for at least 3 individuals with IBS per month.

Description of the CSM Intervention at the Start of the Study

The CSM intervention was developed as a comprehensive approach to improving quality of life and reducing abdominal pain among individuals with IBS [15-17]. The intervention is delivered in 8 individual sessions, with sessions lasting 60 minutes. Participants had up to 12 weeks to complete the 8 sessions, to allow for unexpected events. Participants can elect to complete the intervention in-person, over the telephone, or through a mixture of telephone and in-person sessions since there is no difference in intervention effectiveness between in-person and telephone modalities [16]. Each participant receives a paper-bound “IBS Managing Symptoms Workbook,” which includes information, worksheets, and homework assignments. Additionally, participants received CD audio recordings of the relaxation exercises. The CSM intervention includes content such as healthy thought patterns, problem-solving, healthy eating, and relaxation. Additionally, the intervention addresses practical topics such as sleep, travel, eating out, and physical intimacy. Participants receive verbal and written instructions regarding the use of the manual.

Measures

An overview of the measures by participant group (patients and health care providers) is presented in Table S1 in Multimedia Appendix 1.

Demographics

Age, sex, and race were assessed for patients and providers. For patients, the IBS subtype of constipation, diarrhea, or mixed was reported. Anxiety was measured using the GAD-7 questionnaire, which asks how often participants have been bothered by a list of 7 symptoms over the past 2 weeks [27]. Depression was measured with the PHQ-9, which asks participants how often they are bothered by 9 problems [28]. For both anxiety and depression measures, response options are on a 4-point scale, including “not at all,” “several days,” “more than half the days,” and “nearly every day.” Health care providers answered questions on the type of provider, years of working experience, and number of patients with IBS cared for per month.

Anticipated Acceptability, Appropriateness, and Feasibility

Anticipated acceptability, appropriateness, and feasibility were each measured with 4 items [26]. Participants responded on a 5-point Likert scale from 1 (completely disagree) to 5 completely agree. A higher score indicates greater agreement. Acceptability measures anticipate responsiveness to adopting a new implementation plan. Appropriateness measures the anticipated suitability of the intervention and the perceived fit of the intervention. Feasibility measures the anticipated likelihood of implementing the intervention.

Anticipated Usability

The anticipated usability of the CSM intervention was assessed using the Intervention Usability Scale, which has 10 items and was derived from the System Usability Scale [9,29]. Participants respond from “strongly disagree” to “strongly agree.” The scale ranges from 0 to 100. A score above 68 is considered average; a score below 68 is considered below-average usability.

Procedures

Institutional review board approval was obtained from the University of Washington (IRB# 00009463) before participant recruitment. All individuals were provided with a description of the risks and benefits of participating in the research study as well as an explanation that they could stop participating at any time. Individual interviews were conducted with patients and health care providers. For this study, participants provided feedback on the intervention content and format overall without participating in individual intervention sessions. The second phase of this study (data not reported in this manuscript) focused on obtaining feedback on the intervention redesign of the first 3 intervention sessions.
Patients and health care providers were asked questions using a semistructured interview guide. For example, introductory questions were asked about symptoms (patients) and the type of practice (health care providers). Next, both patients and health care providers were shown an outline of the current CSM content and completed a card sorting activity to categorize the intervention content into 3 categories (“most helpful,” “seems okay,” or “least helpful”). Additionally, the current CSM intervention format was described (eg, in-person and telephone-delivered intervention that included a paper-based workbook); we asked for patients’ and health care providers’ thoughts on the intervention content outline and format and how it could best be designed to integrate into their lives and promote adherence to the intervention. At the end of the interview, patients and health care providers were sent postinterview participatory design session questionnaires regarding the anticipated acceptability, appropriateness, feasibility, and usability of the intervention.

Data Analysis and Integration
Integration in quantitative and qualitative methods occurred through merging [25]. Quantitative and qualitative data were initially analyzed separately and brought together for analysis. For qualitative data, the interview recordings were transcribed. The 2 authors (KK and PLY) coded 2 transcripts from health care providers and 2 transcripts from patients to develop the coding scheme and reach a consensus using a framework approach [30]. The coding scheme was guided by the research questions to understand anticipated barriers and facilitators to acceptability, appropriateness, feasibility, and usability. Each coder then proceeded to code half of the interviews. Any discrepancies were discussed, and consensus was reached. The codes and results were presented to the entire team for further discussion. The mixed methods findings are presented within the text and highlight how the quantitative and qualitative findings align and show a confirmation of the findings, as well as those that are disparate and demonstrate discordance in findings [25]. By integrating the qualitative and quantitative data, we expanded our insights on which intervention components were acceptable and feasible and which needed modification. Mixed methods enabled us to gain new insights into the data, particularly by assessing numeric data to further explore themes from the qualitative interviews where usability or feasibility was lowest.

Ethical Considerations
This study was reviewed by the University of Washington Institutional Review Board (IRB# 00009463). All participants provided verbal consent before the interview. Data are presented as deidentified and do not include links to participant characteristics to protect the privacy and confidentiality of the research participants. Participants received a US $50 gift card for participating in the study.

Results

Demographics
A total of 12 patients completed the qualitative interview (Table 1). Patients had a mean age of 36.8 (SD 12.2) years and were predominantly female. Overall, 42% (n=5) were currently receiving psychological therapy for anxiety or depression. A total of 14 health care providers completed the interview; half (7/14) were primary care providers, and half (7/14) specialized in gastroenterology. Professional roles included 7 physicians, 1 physician’s assistant, and 6 nurse practitioners. One provider did not complete the questionnaires. Provider experience ranged from 4 to 26 years. On average, providers cared for 26 (SD 20; range 3-80) patients with IBS per month. Interviews lasted between 27 and 43 minutes for health care providers (mean 35, SD 5 minutes) and between 32 minutes and 1 hour and 11 minutes for patients (mean 47, SD 12 minutes).

Anticipated Acceptability, Appropriateness, and Feasibility

Acceptability
Mean acceptability was 4.0 (SD 0.8) out of 5 by patients and 4.4 (SD 0.5) out of 5 by providers, indicating that on average, the current CSM intervention content and format were acceptable (Table S2 in Multimedia Appendix 1 for individual acceptability items).

The qualitative results confirm the intervention was acceptable through its comprehensive nature, in which patients could try different components and see what works for them (Table 2 for...
Participants reported that, given the gut-brain interaction that exists, a comprehensive approach to management of both gastrointestinal and anxiety or depressive symptoms was an important component. Patients scored acceptability lower than health care providers, particularly for the item that asks if the intervention is appealing. Patients identified that several of the intervention topics were familiar, especially those who have struggled to manage their IBS for many years. Health care providers focused on individual intervention components such as access and literacy, cost or insurance coverage, and culture or race that could be potential barriers to patients engaging in a self-management intervention like the CSM. The card sorting activity identified content that was of higher priority to participants. Patients found content related to sleep, traveling, and trigger foods most helpful, whereas providers found content related to relaxation, introduction to IBS, sleep, and trigger foods most helpful.

<tbody>
<tr>
<td>Acceptability</td>
<td>• “I like the fact that there’s a wide variety of things; I feel confident that at least 1 or 2 of these things from the 7 kind of content weeks would be helpful.” [Patient 7]</td>
</tr>
<tr>
<td></td>
<td>• “I do think something like this could fit into my day-to-day life, because... it would give me some type of structure.” [Patient 8]</td>
</tr>
<tr>
<td></td>
<td>• “I really think this looks like a very comprehensive plan to address holistically what may be contributing to people who have irritable bowel syndrome.” [Provider 3]</td>
</tr>
<tr>
<td></td>
<td>• “I think improving accessibility, such that it’s one that I can give to [all] sort[s] of patients, regardless of their insurance status, regardless of where they live, or sort of their profession, would be good.” [Provider 8]</td>
</tr>
<tr>
<td>Appropriateness</td>
<td>• “I feel like it would keep me more accountable, and it would give me somebody I can talk through everything with instead of just trying to figure it out on my own.” [Patient 11]</td>
</tr>
<tr>
<td></td>
<td>• “I think just having that intentionality and having structure is really important if someone wants to make a change.” [Patient 4]</td>
</tr>
<tr>
<td></td>
<td>• “So, I’ve done that in my therapy with a psychologist, but my therapist doesn’t know very much about IBS, and my doctor that knows about IBS, I just see them like for 15 minutes every 3 months or something. So, it would be nice to have someone who is aware of the integration of those things.” [Patient 7]</td>
</tr>
<tr>
<td></td>
<td>• “When you’re doing something yourself and it doesn’t rely on a medication and this gives people a little bit of power. It gives them structure.” [Provider 12]</td>
</tr>
<tr>
<td></td>
<td>• “I think that it also gives some accountability in terms of, ‘Did you do these exercises?’ ‘Did you bring your record?’ and these kinds of things.” [Provider 8]</td>
</tr>
<tr>
<td></td>
<td>• “When you’re depressed or anxious and when your body feels like it’s turning against you, which is what a lot of people with IBS I hear being said to me, it gives you a facet of control. When you’re doing something yourself and it doesn’t rely on a medication and this gives people a little bit of power. It gives them structure.” [Provider 10]</td>
</tr>
<tr>
<td>Feasibility</td>
<td>• “I guess the part that might be difficult is just making sure someone actually does it, and sticking with it, which is the hard part.” [Patient 4]</td>
</tr>
<tr>
<td></td>
<td>• “I just think that somebody new to [IBS] would be more apt to get into this versus somebody who’s been through all this; they’d be like, ‘I’ve done all this stuff already.’” [Patient 5]</td>
</tr>
<tr>
<td></td>
<td>• “I’m curious, but also, I’m skeptical. I don’t know why. Just because I feel like I’ve tried so many things and I’m like, ‘Really? Fiber is going to be the thing?’ Maybe I just have more to learn.” [Patient 10]</td>
</tr>
<tr>
<td></td>
<td>• “I think the hard part is having a person that’s motivated enough to actually go through and do this on their own... unless there’s some accountability.” [Provider 12]</td>
</tr>
<tr>
<td></td>
<td>• “I think if they go in for counseling, they have more time to do CBT-type stuff. They have more time to talk to the patient about it. Whereas in primary care we don’t always have that kind of time... unless there’s some accountability.” [Provider 10]</td>
</tr>
<tr>
<td>Usability</td>
<td>• “I’d like it with an app, something that’s visual on the app as well as verbal. I’d like some types of video content to actually show me certain tasks for working through planning out certain things, as well as verbalized communication.” [Patient 8]</td>
</tr>
<tr>
<td></td>
<td>• “In an e-course-esque environment I think would be really helpful or an app, if that’s a possibility.” [Patient 10]</td>
</tr>
<tr>
<td></td>
<td>• “If you construct your own. Build your own. I don’t know, Amazon cart, I don’t like the bundle.” [Patient 1]</td>
</tr>
<tr>
<td></td>
<td>• “I’d rather do it by myself and if there was somebody after the fact that wanted to check up on me for 5 minutes and say, how did it go? Do you have any questions? Did you have any concerns? Did it work?” [Patient 2]</td>
</tr>
<tr>
<td></td>
<td>• “I have a very geriatric[ic] heavy panel, which certainly would not do well with an app and need kind of person kind of contacting them on a weekly basis in some shape or form phone call or something. Whereas I could definitely see my more hyper-focused, got a lot of stuff going on, needing it more as an app with an alert that pops up on their phone that says, ‘Hey, it’s time to work on your skill for today. Let’s set aside 15 minutes to do this,’ or whatever.” [Provider 1]</td>
</tr>
<tr>
<td></td>
<td>• “Just a very brief: Patient’s doing well. Patient does not seem to be progressing. Patient is not participating. They haven’t returned any of their journals.” [Provider 7]</td>
</tr>
<tr>
<td></td>
<td>• “Afterwards as a summary, was this overall sort of useful or which parts of it did you find use in? And, so then I know what are your residual symptoms that we can sort of work on and address because I think it’s also hard to see the clear benefit right away can sometimes take a while even with patients. Once it’s even kicked in, they have... for them to start suddenly realizing so many months down the road, ‘Actually my symptoms are doing a lot better. This used to be something I would think about all the time, and now it’s kind of rare.’” [Provider 8]</td>
</tr>
</tbody>
</table>

### Appropriateness

Mean appropriateness was rated by patients as 4.0 (SD 0.7) and by providers as 4.2 (SD 0.5) out of 5. The qualitative data confirmed the quantitative finding by indicating that the intervention was appropriate because it provided accountability, support, and structure. This was especially important, as many patients felt they had tried multiple other strategies on their own through a trial-and-error approach and viewed the addition of a support person as very helpful and important. Patients discussed accountability within the context of having someone help them navigate and talk through their experiences. Health
care providers also identified the importance of accountability, although they discussed accountability within the context of patients completing assignments and activities.

Patients and health care providers also addressed the appropriateness of the intervention in relation to patients with IBS who had comorbid anxiety or depression. Health care providers noted that structure was especially important as individuals with IBS and comorbid anxiety or depression often feel that a lot of things are out of their control. Even individuals who already received psychological therapy for anxiety or depression (n=5) saw the benefit of integrating IBS and mental health. The integration of an intervention that could address symptoms of IBS along with anxiety and depression was viewed positively by patients.

Feasibility
Mean feasibility was rated by patients as 3.9 (SD 0.7) and by providers as 3.9 (SD 0.7) out of 5. Among patients, the qualitative findings confirmed the quantitative findings. Patients identified specific situations that could influence feasibility, such as a lack of motivation to participate or “stick with” the intervention. Another factor affecting motivation is that many individuals with IBS and comorbid anxiety or depression have already tried multiple strategies to manage their symptoms. Several of the participants felt that components of the intervention were familiar and were perhaps better suited for newly diagnosed individuals. Due to having tried multiple previous strategies, some participants were skeptical that an intervention could truly help manage their symptoms. Yet, they were still interested in trying it due to experiencing symptoms. Patients primarily focused on the intervention feasibility.

Among health care providers, the quantitative and qualitative findings were discordant; the quantitative feasibility score was positive; however, the qualitative portion identified multiple barriers to implementation within a clinic setting. Similar to patients, health care providers also identified patient lack of motivation as a barrier to the intervention. Health care providers felt their clinic visits were so short that they did not have time to review the CSM self-management approaches. Health care providers’ comments regarding feasibility were focused on the feasibility of implementing the intervention in a health care clinic setting (see Perceived Usability section).

Perceived Usability
Overview
The mean score for the Intervention Usability Scale was 52.5 (SD 14.5) for patients and 45.6 (SD 11.6) for health care providers, which fell below the average usability cutoff of 68. Usability conversations provided confirmation that the intervention needed to be revised and focused on improving the delivery of the intervention, the time demands of the intervention, and integration into health care settings. Textbox 1 presents a summary of recommended changes.

Textbox 1. Summary of recommended changes.

- Patients were interested in moving through the intervention content at their own pace, but they still prefer a professional to check-in with for questions.
- Patients preferred the intervention content in a digital format.
- Reduce the face-to-face time required by providers to increase the likelihood that the intervention is adopted in clinical settings.
- Make the tracking (food, sleep, and symptoms) required by the intervention easier to do.
- Create content summarizing patient progress through the intervention to facilitate communication with their provider when they meet.

Delivery of Intervention
The original CSM was designed for in-person or telephone delivery with a paper workbook. Both patients and health care providers discussed the importance of continuing to have a person, either a health care provider or a peer, involved in the intervention. Patients, in particular, discussed the delivery of intervention content in online formats such as apps and e-courses where they could review content independently with weekly check-ins. All but 1 patient desired weekly check-ins. Some patients preferred web-based check-ins to be with an expert in IBS, whereas others noted that it may be helpful to have a peer mentor because they do not know many people with IBS. Regardless of who delivers the intervention (ie, health care provider or peer), the most important characteristic was someone who was skilled and knowledgeable in IBS. Health care providers said the delivery method depended on the age of the population. Some health care providers discussed the potential benefits of using videos to present information and demonstrate skills. However, most discussions with health care providers focused on in-person intervention delivery.

Intervention Time Demands
Patients had a variety of opinions regarding the length of the 8-week CSM intervention and the daily time commitment for practicing skills. Patients who preferred a shorter intervention typically identified content that was not applicable or of interest to them. For some, 8 weeks seemed reasonable, whereas others identified that 8 weeks may not be enough time to obtain results. Health care providers identified that the CSM, as originally designed, required more time to deliver the content than the providers were able to fit into their current practices. This creates an implementation barrier to incorporating the therapy into clinics.

Integration Into Health Care Settings
Health care providers thought the easiest integration into health care settings was for the providers to introduce the intervention to the patient and have another health care professional (eg, nurse or social worker) who was an expert in IBS deliver the intervention. Health care providers desired feedback on the patients’ progression through the intervention, such as a summary of symptoms, strategies that worked, and an overview.
of patient engagement. Most providers preferred a brief end-of-intervention update. Patients also preferred to learn about the intervention from their primary care provider or gastroenterologist.

Discussion

Overview

Overall, individuals with IBS and comorbid anxiety or depression, as well as health care providers, found the content and format of the CSM intervention acceptable and appropriate; however, challenges were identified related to anticipated feasibility and usability. The qualitative findings expanded the quantitative findings for acceptability and appropriateness. For feasibility, patient qualitative findings expanded the quantitative findings, whereas for providers, the qualitative findings indicated barriers to feasibility while the quantitative findings indicated feasibility. Overall, participants reported the intervention was comprehensive and provided structure, accountability, and support. However, participants warned that engagement in the intervention would be influenced by time, motivation, literacy, culture, and cost, in addition to a variety of usability issues (improving the delivery of the intervention, time demands of the intervention, and integration into health care settings). Addressing the anticipated acceptability, feasibility, appropriateness, and usability of the CSM intervention has the potential to influence key barriers to implementation and uptake among those with IBS and comorbid anxiety or depression.

Acceptability

Previous research has noted that patients with medically unexplained symptoms and comorbid anxiety or depression may have less favorable cognitive behavioral therapy outcomes [31]. Thus, our approach of human-centered design methods to elicit feedback from patients with IBS and comorbid anxiety or depression may serve as 1 method to create interventions to address the unique needs of this population. Specifically, patients with IBS and comorbid anxiety or depression discussed the importance of structure and support in completing the intervention. They also mentioned the importance of integrating IBS and mental health as previous health care encounters had focused independently on either IBS or mental health but did not take a holistic approach to symptoms. Recent evidence has highlighted the benefits of integrated care approaches, which include a team comprising gastroenterologists, nurses, dietitians, psychiatrists, hypnotherapists, and behavioral therapists. Individuals with IBS who were randomized to an integrative care arm had greater reductions in global symptoms as well as IBS symptom severity compared to those in the standard care group [32].

 Appropriateness

Patients and health care providers both identified the importance of support from a person throughout the intervention. It is unclear if the desire for a support person is unique to patients with comorbid IBS and mental health. For instance, a meta-analysis found that computer-assisted cognitive behavioral therapy for depression in primary care is effective if clinicians offer modest support (60-194 minutes) throughout the intervention (7-16 weeks) [33]. In this study, patients preferred to review the content and practice independently and have someone available to follow up with them. Additionally, health care providers indicated that in-person sessions would be preferred but acknowledged that, with the COVID-19 pandemic, telemedicine visits could also be useful. Although a review article highlighted the effectiveness of primary care provider–delivered self-management interventions, this study highlights the time limitations of clinicians in delivering such an intervention [34]. Even if primary care providers do not deliver the intervention, there is a need for integrated care approaches so that primary care providers can receive feedback on their patients’ progress through the intervention. Future research should examine innovative methods to integrate comprehensive interventions into primary care, gastroenterology, and other health care settings.

Feasibility

Patients indicated that the intervention may be best suited for newly diagnosed individuals to promote self-management earlier in the disease course. Thus, additional research is needed to understand if the intervention effects differ based on time since diagnosis or time since symptom onset. Health care providers had varied opinions regarding the feasibility of the intervention, specifically highlighting barriers to implementation. Yet few studies have focused on implementation strategies within the population of patients with IBS and anxiety or depression overlap. Implementation frameworks such as the Consolidated Framework for Implementation Research [35], the Practical, Robust Implementation, and Sustainability Model [36], and the Reach Effectiveness Adoption Implementation and Maintenance framework [37] can be used to guide such research.

Usability

Both patients and health care providers identified several ways to improve the usability of the intervention. Patients emphasized the benefits of accessing intervention content on the internet and being able to track and monitor symptoms. Health care providers identified age as a factor influencing intervention delivery methods, although this theme did not arise among the small sample of patients aged between 20 and 59 years. Previous research has indicated that older adults may avoid using technology due to fear of confirming negative stereotypes [38]. Thus, considerations should be made for understanding the specific technology needs of older adults with IBS and comorbid anxiety or depression and designing accessible systems that benefit all patients.

Patients had a variety of opinions regarding the length of the intervention. Patient differences such as disease severity, previous intervention experiences, or lifestyle may influence intervention length preferences. A previous study by Lackner et al [6] identified no statistically significant differences in the proportion of patients with IBS responding to a 10-week standard cognitive behavioral therapy (87.5%) compared to a brief 4-week cognitive behavioral therapy (80%, P = .55) [6]. Thus, there is a need to identify ways to tailor the intervention length based on the content participants are familiar with and their tolerance for intervention length.
Limitations

Strengths of the study include incorporating the perspectives of both patients and health care providers into the intervention evaluation. Using implementation science and a human-centered design approach provided an established framework to elicit feedback regarding the intervention. Yet, this study has several limitations. Patients and health care providers were recruited during the COVID-19 pandemic. Patients were recruited on the internet and therefore may have different characteristics than those typically obtained in primary care and gastroenterology settings, such as greater levels of computer literacy and comfort with technology-delivered interventions. Additionally, we did not have access to clinical records for patients. It is possible that selection bias may have occurred such that health care providers with a large number of patients with IBS were more likely to participate in the study and had different barriers than health care providers seeing fewer patients with IBS. Another limitation is that patients and providers did not complete the intervention but rather provided feedback on the overall content and intervention; therefore, additional implementation barriers may be found when using the intervention.

Conclusions

Patients and health care providers reported the CSM intervention was acceptable and appropriate but identified several potential feasibility and usability challenges. Thus, before applying the intervention among a population of individuals with IBS and comorbid anxiety or depression, there is a need to modify intervention delivery methods, consider the length of the intervention, and address the best methods of implementing in the clinic setting. Considerations should be made to improve the ease of tracking, allow participants to move through the intervention at their own pace, and provide a summary of patient progress through the intervention. Future work will assess whether addressing feasibility and usability leads to the anticipated improvements in implementation and adoption.

Abstract

Background: Conversational agents (CAs) are a promising solution to support people in improving physical activity (PA) behaviors. However, there is a lack of CAs targeted at adolescents that aim to provide support to overcome barriers to PA. This study reports the results of the co-design, development, and evaluation of a prototype CA called “Phyllis” to support adolescents in overcoming barriers to PA with the aim of improving PA behaviors. The study presents one of the first theory-driven CAs that use existing research, a theoretical framework, and a behavior change model.

Objective: The aim of the study is to use a mixed methods approach to investigate the potential of a CA to support adolescents in overcoming barriers to PA and enhance their confidence and motivation to engage in PA.

Methods: The methodology involved co-designing with 8 adolescents to create a relational and persuasive CA with a suitable persona and dialogue. The CA was evaluated to determine its acceptability, usability, and effectiveness, with 46 adolescents participating in the study via a web-based survey.

Results: The co-design participants were students aged 11 to 13 years, with a sex distribution of 56% (5/9) female and 44% (4/9) male, representing diverse ethnic backgrounds. Participants reported 37 specific barriers to PA, and the most common barriers included a “lack of confidence,” “fear of failure,” and a “lack of motivation.” The CA’s persona, named “Phyllis,” was co-designed with input from the students, reflecting their preferences for a friendly, understanding, and intelligent personality. Users engaged in 61 conversations with Phyllis and reported a positive user experience, and 73% of them expressed a definite intention to use the fully functional CA in the future, with a net promoter score indicating a high likelihood of recommendation. Phyllis also performed well, being able to recognize a range of different barriers to PA. The CA’s persuasive capacity was evaluated in modules focusing on confidence and motivation, with a significant increase in students’ agreement in feeling confident and motivated to engage in PA after interacting with Phyllis. Adolescents also expect to have a personalized experience and be able to personalize all aspects of the CA.

Conclusions: The results showed high acceptability and a positive user experience, indicating the CA’s potential. Promising outcomes were observed, with increasing confidence and motivation for PA. Further research and development are needed to create further interventions to address other barriers to PA and assess long-term behavior change. Addressing concerns regarding bias and privacy is crucial for achieving acceptability in the future. The CA’s potential extends to health care systems and multimodal support, providing valuable insights for designing digital health interventions including tackling global inactivity issues among adolescents.

Introduction

Background

There is indisputable evidence supporting the positive effects of regular physical activity (PA) on the physical and emotional well-being of adolescents [1], enhanced cognitive function [2], and improved educational attainment [3,4]. The UK government recommends that children and young people engage in 60 minutes of PA per day, with 30 minutes taking place at school and an additional 30 minutes outside of school hours. However, despite this guideline, only 57% of children participate in ≥30 minutes of PA outside of school, compared with 40% during school hours [5].

Inactivity is a global challenge, with a considerable number of adolescents worldwide failing to engage in sufficient PA [6]. It is crucial that adolescents maintain a consistent level of PA during adolescence as this may lead to healthy habits that extend into adulthood, lowering the risk of inactivity in later years and reducing the possibility of developing hypokinetic conditions [7-9]. There is a consensus that evidence-based approaches involving multicomponent interventions targeted at inactive adolescents are needed on a global scale [10-12].

Although schools provide equal opportunities for adolescents to participate in PA, making them valuable settings to focus resources [12], multiple barriers exist that prevent schools from allocating adequate time and resources to PA programs [13,14]. In addition, various barriers relating to physical, psychological, social, and environmental factors hinder PA participation in the adolescent population [15-17]. It is generally accepted that limited progress has been made in supporting adolescents to overcome these barriers, necessitating the development of innovative interventions [12]. This rationale underlies the launch of the Global Action Plan on PA in 2018 by the World Health Organization, aimed at promoting and supporting adolescents in achieving the recommended levels of PA [18]. As part of this plan, digital approaches were advocated, emphasizing that interventions should prioritize understanding and addressing barriers that prevent adolescents’ engagement in PA. By doing so, interventions can be effectively designed to facilitate sustainable changes in the PA habits and behaviors of adolescents [15-17].

Digital health interventions have emerged as a promising approach to promoting PA and overall well-being through digitally delivered support, providing PA education and motivational guidance [19]. However, the effectiveness of these interventions in promoting PA has yielded mixed results [20,21]. A systematic review focusing on digital interventions for PA among young people revealed positive changes in PA levels and attitudes toward PA [22]. These positive changes were attributed to numerous factors such as web-based education, goal setting, self-monitoring, parental involvement, and gamification and personalization [22]. In particular, personalization has emerged as a significant feature in engaging adolescents through digital health interventions [23]. Tailoring interventions to individual needs and preferences is crucial for promoting PA and overcoming barriers to participation. There is also some evidence of the positive engagement of young people in formal (eg, school) and informal (eg, home) settings to develop knowledge, skills, and behaviors related to PA [22]. This shows that locations, such as school and home, hold potential as promising venues for implementing such interventions.

Conversational agents (CAs) have emerged as promising tools for promoting PA, especially among adolescents, using popular digital platforms such as social media, web interfaces, and mobile apps [24-26]. These agents are accessible at any time of the day, are nonjudgmental, and can be accessed on an array of digital devices. CAs are the preferred choice for individuals seeking immediate web-based support and for those who are hesitant about seeking in-person assistance.

Systematic reviews have examined CA effectiveness in promoting PA, healthy eating, and weight loss [27,28]. Nevertheless, despite encouraging results, the efficacy of these interventions remains inconclusive owing to constraints in outcome measurement and reporting [28]. There is also a dearth of evidence regarding how such CAs have been used to help adolescents overcome barriers to PA, and there is a need for new conversational artificial intelligence (AI) approaches that draw insights from existing theories to ensure they are evidence based and effective [17,29].

To optimize CAs and maximize user engagement, previous studies have emphasized the importance of effective persona design and the integration of principles from user-centered design [30] and human-computer interaction [28,31]. However, previous research focusing on usability and feasibility has reported moderate results, highlighting challenges such as repetitive content, high attrition rates, technical difficulties, and concerns regarding safety and privacy [27]. Although rule-based approaches are commonly used, more successful outcomes have been achieved with unconstrained methods that allow for natural language input and personalized interaction. These methods offer opportunities for establishing relational and persuasive capacities [28] with adolescents, which are particularly important when delivering person-centered behavior change interventions.

Recent advancements in large language models (LLMs) as well as the advent of generative AI show promise in enhancing CAs by improving user engagement and satisfaction, potentially surpassing human performance [32]. Their ability to understand and generate natural language with complexity and accuracy allows for sophisticated conversations, including emotion detection, contextual understanding, and personalized responses [33,34]. LLMs offer automatic content generation, increasing scalability and cost-effectiveness [33,34]. All of these features
could potentially enhance CA quality and improve adherence in the future; however, concerns about bias, misinformation, privacy, and security need to be addressed before using them safely with adolescents [33,34]. In any health-related context, it is of paramount importance that the information delivered is not only accurate and trustworthy but also firmly rooted in evidence-based practices, curated in collaboration with domain experts. Consequently, as consideration focuses on the future applications of LLMs and generative AI in this sphere, it becomes imperative to place our faith in models that are not only trustworthy but also transparent, providing a clear and comprehensive audit trail for their decision-making processes. This ensures that the highest standards of quality and reliability are maintained, thereby safeguarding the integrity of health-related information and services.

**Summary**
This study introduces the co-design and evaluation of a pilot CA called “Phyllis” to evaluate its proof of concept. Its objective is to assist adolescents in overcoming 2 barriers to PA (ie, confidence and motivation) and offer an alternative digital solution to support students and promote PA. Building upon the findings of a previous study, which identified 52 barriers to adolescents’ PA participation, appropriate intervention functions and behavior change tools were identified to provide support for each barrier [17]. A theoretical framework designed for this study and the existing behavior change model also inform the CA [29] and both aim to aid the development of CAs in promoting PA.

The hypothesis for the study is that a CA can support adolescents to overcome barriers to PA and be perceived by adolescents as being a tool to help them increase their confidence and motivation to participate in PA. The objectives of the study are as follows:

- **Co-design a CA in collaboration with adolescents,** incorporating the model by Zhang et al [29] and a theoretical framework designed for this study to assess its proof of concept.
- **Demonstrate the CA’s ability to understand user input related to one of the 52 barriers to PA identified in the previous study [17].**
- **Evaluate the usability and acceptability of the CA among adolescents.**
- **Assess the perceived effectiveness of the solutions to barriers provided by the CA.**

**Methods**

**Overview**
In this section, we present a comprehensive and systematic methodology used for the co-design and evaluation of the CA. The methodology includes 3 key phases: phase 1 focuses on co-designing the CA with adolescents to ensure the agent’s relevance and user-centeredness. In phase 2, the development of the CA and its dialogue is presented, incorporating persuasive and relational capacity elements. To facilitate intelligent and contextual relevant interactions, a natural language understanding (NLU) model and knowledge model are integrated into the cognitive system. Finally, in phase 3, we detail the mixed methods evaluation used to comprehensively assess the CA’s effectiveness and user experience with adolescents.

**Co-Design of the CA**

**Phase 1: Understanding User Background and Designing CA Characteristics and Persona**
To participate in the co-design process, all students aged 11 to 13 years were required to apply through their school and meet the following selection criteria:

- Students perceived that they did not currently meet the UK government recommendations for participating in PA for 60 minutes per day over the course of a week.
- They were interested in participating in PA more often.
- In their application, they stated barriers to participation that had prevented them from being more physically active.

All interested students were given an information sheet and provided written consent to participate. The following is an example of an application from a student who participated in the co-design, highlighting the importance that students felt in participating in the research:

*Sir, I think I would be great for this role because I have always wanted to do sports and be more fit, but I have always stopped myself because I thought I wouldn’t be good enough. I would embarrass myself, just fail altogether or I would be too scared and think that it was too hard. I think that this opportunity would bring out the best in me and give me another chance to build a better me. I also stop myself from the joy of joining in because I have always thought people would judge me and I would always get scared that I wouldn’t be perfect. Now you might be thinking why should choose this girl she has only listed things that she is bad at and why but one thing that is that I love improving myself and with this once in a lifetime opportunity I could make a fresh start.*

The primary objective of phase 1 of the study was to gain insights into the user background of the co-design participants, including sociodemographic characteristics (eg, age and sex), behavior determinants (eg, attitude toward PA), and behavior habits (eg, PA and CA use) [29].

To accomplish this, a 2-hour workshop was conducted at Wickersley School and Sports College, located in Rotherham, South Yorkshire, where the students were based. During the workshop, the following co-design activities were conducted with the students, following the principles of user-centered design [30,35]:

- **Icebreaker activity:** this involved a demonstration of a robot and an introduction by the research team.
- **A 30-minute focus group discussion with the students, audio recorded, thematically analyzed [36], and covering the following topics:**
  - Participation in PA, barriers faced, and overall experiences related to PA

- **A 30-minute focus group discussion with the students, audio recorded, thematically analyzed [36], and covering the following topics:**
  - Participation in PA, barriers faced, and overall experiences related to PA
The theoretical framework played a pivotal role in informing how behaviors could be effectively delivered conversationally through a CA [17]. This process involved choosing behavior change tools that could be used to influence behaviors using the Behavior Change Technique Taxonomy [41]. The appropriate selection of evidence-based intervention factors influencing them. Furthermore, this approach ensured that the origins of adolescent behaviors and the factors influencing them. Furthermore, this approach ensured the appropriate selection of evidence-based intervention functions, policy factors, and behavior change tools for each behavior using the Behavior Change Technique Taxonomy [41]. This process involved choosing behavior change tools that could be effectively delivered conversationally through a CA [17]. The theoretical framework played a pivotal role in informing the cognitive system, including the knowledge model incorporating the study findings [17] and the conversational engine (ie, the NLU model) to accurately understand and respond to barriers input by adolescents.

The next step in the process was to evaluate the feasibility and usability of the approach and evaluate the changes resulting from the use of the CA. For this purpose, 2 CA modules were developed by the research team, specifically targeting the 2 primary barriers identified by the students: a lack of “confidence” and “motivation” to be physically active. The confidence module was designed based on the theory of planned behavior [42,43] and incorporated 3 evidence-based behavior change tools identified from a previous study [17], namely problem-solving, verbal persuasion about capability, and self-talk. These tools were developed based on 4 guiding principles:

- Setting goals: it is important to always have a goal and push oneself out of the comfort zone.
- Diverse goals: building confidence involves setting different types of goals to enhance overall confidence.
- Broad perspective: individuals with higher levels of self-efficacy can look at the bigger picture and go beyond short-term setbacks.
- Reframing setbacks: developing self-efficacy is a gradual process that may take years to reframe one’s mindset.

Failure is inevitable, but it should be viewed as unimportant. What matters is how one chooses to deal with failure and the lessons learned from it overall.

During the conversation, adolescents were prompted to answer the following questions. They were then given the opportunity to review their answers on the screen and receive a copy of their responses via email. This provided students with the opportunity to revisit and follow up on the actions they had stated.

- How confident are you when it comes to PA. Can you rate your answer from 1-10 with 1 being “very low,” 5 being “okay,” and 10 being “very confident.”
- When you feel confident where are you?
- Do you feel more confident being active with others or by yourself?
- And what motivates you more—being active with others or by yourself?
- When you feel most comfortable—what activity are you doing?
- If you think that activity is exercise related (eg, skipping) how could you do it more within your week? If that activity is not exercise related (eg, drawing) how could you add an element of exercise to it? (eg, standing whilst drawing, jumping on the spot every 10 min whilst drawing, etc).
- Based on what you know now, how can you bring activity into your weekly routine more?

The motivation module was developed using 2 behavior change tools: instructions on how to perform the desired behavior and behavior rehearsal or practice. Students were given a series of information on how to be more physically active and how to build small sessions (ie, 15 min) of PA into their day. These activities could be undertaken by any able-bodied person at no cost. Further information was given about how activity could be incorporated into your weekly routine more?

Phase 2: Developing Relational and Persuasive Conversational Capacity

Persuasive Capacity

To enhance the CA’s understanding of adolescents’ habits and behaviors and facilitate effective intervention design, it is crucial for all PA interventions to be grounded in existing evidence and theory. This phase of the study draws upon a theoretical framework that details a theory-based approach to designing CAs to support adolescents in overcoming barriers to PA. The framework used in this study is underpinned by the capability, opportunity, motivation, and behavior (COM-B) model and the Theoretical Domains Framework (TDF). Identified barriers were coded using the COM-B [39] model and TDF [40] to comprehend both the origins of adolescent behaviors and the factors influencing them. Furthermore, this approach ensured the appropriate selection of evidence-based intervention functions, policy factors, and behavior change tools for each behavior using the Behavior Change Technique Taxonomy [41]. This process involved choosing behavior change tools that could be effectively delivered conversationally through a CA [17].
be achieved despite educational pressure and time constraints and how PA can improve attainment. In addition, links to Sport England websites were provided to give young people further information on how to increase their PA levels in various environments, such as at home or outdoors. Useful information was provided on why PA is important and how often we should aim to engage in it.

**Relational Capacity**

To foster relational capacity, it is essential to design conversations that are evidence based, are expert led, and incorporate user feedback. However, there is a lack of empirical evidence regarding effective conversation design for CAs. To ensure that the CA is engaging and effective while adhering to the principles of conversation design, module design followed the happy and detailed conversation design process provided by the Conversation Design Institute [44]. This involved the inclusion of appropriate greetings, small talk, and module messaging that incorporated the elements of social dialogue, empathy, and humor. Sample dialogues were evaluated, and iterative refinements were performed using this process. Theoretical principles [17,29], along with the concepts of user-centered design [30] and human-computer interaction [31], were also considered.

To enable effective natural language interaction between humans and the CA, the researchers developed an NLU model [45]. They assigned at least one intent to each identified barrier from a previous study [17] to train the NLU model. For each intent, a minimum of 15 utterances were manually generated by the researchers and uploaded to Google Dialogflow’s NLU engine to train the data [46]. The training process involved providing the system with a diverse range of conversational data, allowing it to learn and comprehend various patterns, intents, and entities relevant to the specific domain. Through iterative training and refinement, the Dialogflow NLU model was optimized to accurately understand and interpret user input, forming a solid foundation for the subsequent phases of CA development and evaluation [47].

The NLU model represents a hybrid approach, falling between the spectrum of fully open-ended models, such as ChatGPT, and strictly closed branching–dialogue systems. Instead of strictly adhering to predetermined dialogue paths or being entirely unrestricted, the NLU model uses a nuanced methodology. It focuses on the interactions between the CA and students through several natural language processing techniques. Specifically, the NLU model is adept at comprehending and interpreting user inputs in natural language. It identifies the intent behind user queries and recognizes key entities mentioned in the text. Unlike rigid closed systems, the model does not follow a fixed script. Instead, it uses this understanding of user intent and entities to dynamically route the conversation. Although predefined dialogues are in place to guide the conversation, these paths are adaptable based on the context of the conversation and the user’s input. This flexibility ensures a more engaging and personalized interaction while still maintaining a degree of structure within the conversation flow.

**Figure 1** provides an example of an interaction between a student and the CA.

**Figure 1.** An example of an interaction between a student and the conversational agent.
To assess the accuracy of the model, the researchers used MindBehind, a software program that enabled the research team to input statements pertaining to each barrier and evaluate and refine the utterances used during the NLU model training. The performance of the CA was evaluated using an $F_1$-score, yielding a score of 80% [48]. MindBehind was then used to create a knowledge model and use its conversational engine, leveraging the NLU model and logic functions to route conversations based on the input of barriers and corresponding solutions. Following this, the researchers visually represented the conversational dialogue of the CA (ie, barriers and solutions) on a canvas and tested its accuracy to ensure its readiness to be deployed for testing.

**Phase 3: Evaluating Mechanisms and Outcomes**

During the final phase of the study, the CA was distributed to the students for testing via a test link. The students interacted with the CA through text messaging. The platform hosting the CA enabled the students to engage with it through various internet-enabled devices such as laptops, tablets, and smartphones. In addition, the students had the option to select appropriate responses from a predefined list of choices, which included options such as requesting help, ending the conversation, or seeking more support. This setup provided a user-friendly and versatile interface, accommodating different communication preferences and ensuring a seamless interaction experience for the participants. Initially, the adolescents were asked to engage in a conversation with the CA as users and to identify any barriers they faced that led them to seek assistance from the CA. Subsequently, they were requested to test the CA by inputting various barriers and assessing how the conversation was routed. Following this, participants were invited by each organization using convenience sampling to evaluate the CA from Wickersley School and Sports College (7 participants) and a community enterprise called Zest (31 participants), totaling 46 adolescents.

To evaluate the CA’s acceptability, usability, and perceived outcomes of using the modules, the students were invited to participate in a web-based survey using Key Survey, a specialized web-based survey platform. The survey also sought to gauge their perception of the CA’s effectiveness and user experience, encompassing 7 recommended themes for evaluating CAs, as outlined in a previous study [29]. Users were specifically encouraged to share both positive and negative aspects of their experience, offer suggestions for improvement, and report any observed malfunctions during their engagement. In addition, the survey included an adapted version of the AttrakDiff questionnaire, tailored specifically for young individuals, to measure usability [49].

**Analysis**

During phases 1 and 2, an analysis was conducted on both quantitative and qualitative data gathered from the participants. For the quantitative analysis, basic frequencies were used to examine data related to students’ age, sex, and levels of PA in phase 1 and to evaluate the user experience and efficacy of the CA in phase 2. This analysis provided an overview of the demographic characteristics and the distribution of PA levels among the participants, as well as an objective assessment of their experience and the outcomes of using the CA.

The qualitative data were subjected to thematic analysis [36] to identify and analyze recurring themes and patterns across several key aspects. These aspects included the persona and key characteristics that the CA should possess in phase 1, as well as user feedback on how the CA could be improved in phase 2.

**Ethical Considerations**

This study adheres to the established human subject research ethics guidelines and was granted institutional ethics approval (ER37229351) by the Sheffield Hallam University Research Ethics Committee.

Informed consent was obtained from participants’ legal guardians following a comprehensive explanation of the study’s purpose, procedures, risks, benefits, and the voluntary nature of their participation. The participants were explicitly informed that they had the right to withdraw from the study at any time without repercussions.

The privacy and confidentiality of all human subjects were rigorously safeguarded throughout the study. All the data collected were either anonymized or deidentified to protect the identities of the participants. The data were stored securely, and the data used in this study were not linked to any external databases or sources that could compromise the privacy of the participants. The participants were not offered an incentive to participate in the study.

**Results**

**Co-Design**

The following section presents the results of the co-design with adolescents and the evaluation of the performance of the CA and its efficacy.

**User Background**

The co-design of the CA involved 9 students aged between 11 and 13 years, in school years 7 to 9. The sex distribution among the students was 56% (5/9) female and 44% (4/9) male. In terms of ethnic background, 6 (67%) of the 9 students identified as White, 2 (22%) identified as Asian or Asian British, and 1 (11%) identified as Black.

All 9 students met the inclusion criteria and expressed their interest in exploring the use of a CA to support themselves and their peers to help overcome barriers to PA. Initially, the students were provided with a list of 52 barriers to PA and were asked to identify the specific barriers that they experienced. They highlighted 37 barriers, which accounted for 66% of the total barriers listed in the previous study [17].

Among the barriers identified, the most commonly highlighted included a “lack of confidence” (mentioned by 8 students), “fear of failure” (mentioned by 7 students), and a “lack of motivation” (mentioned by 5 students). When the adolescents were asked to elaborate on the barriers in their own words, they provided more specific insights, particularly concerning psychological barriers. For instance, 2 adolescents reported experiencing “anxiety” both before and during PA, especially at competitive levels.
events. Other students mentioned feeling self-conscious when being judged by others, lacking confidence in their abilities, feeling unmotivated because of excessive phone use, and harboring fears of getting injured. Given that these barriers were already included in the previously identified 52 barriers, they were all integrated into the programming of the NLU model for the CA.

The students were asked via the workbook to identify and express their emotions related to their experiences with PA. This information played a vital role in shaping the design of the modules and the conversational language used to establish relational capacity with the users. On average, the students reported experiencing 6 positive emotions and 9 negative emotions in relation to PA. A total of 21 distinct positive emotions were identified, with the most frequently mentioned being pride (mentioned by 5 students), optimism, and confidence (mentioned by 4 students each). In contrast, negative emotions were highlighted significantly more often (84 times), with the most frequently mentioned being humiliation, stress, insecurity (mentioned by 5 students each), and embarrassment (mentioned by 4 students).

Most students expressed an ardent desire to engage in more PA and recognized the numerous benefits associated with it. However, they also identified negative thoughts and emotions as significant barriers to their participation in PA. Notably, students mentioned using PA to enhance self-esteem, productivity, confidence, and feelings of empowerment and strength, in addition to its health benefits. This apparent paradox of wanting to be more active in improving confidence while simultaneously lacking the confidence to do so presents a unique global challenge that the proposed CA aims to address.

The students who participated in the study acknowledged the importance of receiving support to overcome the barriers they faced in engaging in PA. Despite having diverse experiences with CAs in the past, they demonstrated an interest in exploring the potential of using a CA for this purpose. It was evident that the students lacked access to adequate support systems to address their barriers, which highlights the innovative nature of the proposed approach. Despite this, the students displayed receptiveness and optimism toward using the CA to overcome these barriers. They also demonstrated a willingness to share personal information with the CA. However, it is worth noting that some students expressed concerns regarding privacy and data protection; as such, these concerns should be carefully considered and addressed during the future development and implementation of the CA to ensure user trust and data security.

### Relational and Persuasive Capacity

During the co-design process, the students were actively involved in expressing their preferences for the persona and characteristics of the CA. All co-design group members unanimously agreed that the CA should fall within the age range of 11 to 18 years, with the majority believing that a teenage persona would be most relevant and engaging for the target audience. When it came to gender, of the 9 students, 4 (44%) expressed a preference for a gender-neutral CA, whereas only 1 (11%) person advocated for a gender-specific CA. The remaining students (3/9, 33%) suggested that the CA’s gender should be customizable, allowing users to select their preferred option. In terms of appearance, most students felt that if the CA had an avatar, it should be customizable, with suggestions ranging from human-like features to animal-like or robot-like attributes.

Regarding the tone of the CA, approximately two-thirds of the group agreed that it should have a human-like and engaging tone, regardless of whether it was in the text or voice form. Of the 9 students, 2 (22%) students even proposed that the CA could mimic the tone of a coach or celebrity. Conversely, 1 (11%) person expressed a preference for the CA to have a robotic voice. However, 3 (33%) individuals indicated a preference for customizable voices, although it remained unclear whether these voices should be exclusively human-like.

During the design phase, the concept of customization and personalization emerged as a prominent theme, reflecting the students’ desire to have control over various aspects of the CA to meet their individual needs. This preference for customization poses several design challenges, as it necessitates the creation of multiple personas and the development of appropriate messages for each persona. However, it is a crucial consideration for the future development of CAs, as it allows for genuine personalization and enhances the overall user experience.

As part of the design process, students were also invited to suggest names for the CA. The name suggestions varied, highlighting different preferences and creative ideas. Some students proposed generic brand names with a playful twist related to PA, such as “Sporta” or “Phylo.” Others suggested human names such as Robert or Patricia, whereas some students preferred names that explicitly incorporated the terms “CA” or “robot,” such as “Charlie the CA” or “Sporty Bot.”

For the prototype, only 1 persona was created, and it was named “Phyllis.” This name remained unchanged throughout the final testing phase, as some students expressed a liking for the name, whereas others did not find the other suggested names suitable. The decision to choose Phyllis as the chosen name for the CA reflects the consideration of participant preferences and the desire for consistency during the testing phase.

During the co-design process, the students were asked to indicate their preferred personality characteristics for the CA using Leary’s Interpersonal Complex (Figure 2), which measures personality along 2 dimensions: dominance (horizontal) and agreeableness (vertical). As shown in Figure 2, the results revealed that students sought a balanced combination of dominance and agreeableness in the CA’s personality. They desired a friendly CA that exhibited both submissive and dominant behaviors and even opposing viewpoints at certain points in the conversation, potentially to challenge the user’s beliefs. These findings align with the broader characteristics that the students identified during the co-design process, emphasizing their need for personalization.
In total, the students selected 30 distinct characteristics that they believed the CA should possess, underscoring their desire for a personalized and tailored experience. Among the co-design participants, only 3 characteristics were mentioned more than once: understanding (mentioned 2 times), intelligence (mentioned 3 times), and kindness (mentioned 3 times). These repeated characteristics indicate the significance of empathy, intelligence, and kindness in the preferred personality traits of the CA.

Figure 2 illustrates students’ preferred personality characteristics using Leary’s Interpersonal Complex. The graph measures personality along 2 dimensions: dominance (horizontal) and agreeableness (vertical).

**Social Dialogue and Self-Disclosure**

Students were asked to provide dialogue examples that represented the personas they had chosen for the CA. All personas were of peer age for the students. The dialogue examples covered various scenarios, including greetings, providing assistance, encouraging positive actions, offering reassurance, giving praise, acknowledging mistakes, and saying goodbye.

The welcome messages displayed personalization, often addressing users by their first names and minimizing small talk. The style of the messages was similar across the personas. The “help” messages were typically direct and straightforward, presenting suggestions (eg, “I have a suggestion”). The “take positive action” messages were motivational, encouraging users to take specific actions (eg, “You can do it! How about you try this?”) Reassuring messages often began with an “okay” to acknowledge the user’s concerns before offering support. “Praise” messages consistently started with “well done” and then reiterated the user’s accomplishments. The “goodbye” messages usually included a supportive or hopeful closing message to conclude the conversation.

This approach to social dialogue and self-disclosure, characterized by personalization, motivational language, acknowledgment of concerns, and positive reinforcement, was preferred by the co-design participants. Their preferences were considered and integrated into the dialogue design of the CA persona.

**Content**

As part of the co-design process, students expressed their preferences regarding the content they wanted to be delivered through the CA, focusing on the barriers to PA they had previously identified. Most students preferred content that would help boost their confidence, overcome insecurities, address problems, and manage negative emotions related to PA. A student (1/9, 11%) suggested that the CA should provide advice on supporting others, whereas another (1/9, 11%) preferred a more proactive approach in which the CA would listen, understand their problems, and provide relevant answers.

Different preferences emerged regarding the approach the CA should adopt to engaging with adolescents and delivering content. A student (1/9, 11%) preferred a guiding approach, allowing the adolescents to find their own solutions while also offering assistance if they struggled with that approach. Practical solutions were also highlighted, such as suggestions for various sports activities, strategies to stay physically active, ways to improve performance in sports, and tips for eating healthier.

Furthermore, the students recommended including motivating quotes and information on accessing support through other organizations or websites.

**Media**

The students were provided with diverse options to choose from regarding the type of media they would like to use during the CA conversation. According to their preferences, the most favored options were pictures (7/9, 78%) and videos (7/9, 78%), followed by audio (6/9, 67%) and links to websites. Conversely, the least popular options were links to apps, social media (2/9, 22%) and documents (1/9, 11%). The CA being piloted incorporates pictures, animated pictures (GIFs), and links to websites and apps, whereas videos were not included owing to
the lack of appropriate content for adolescents, corresponding to the barriers identified. In the future, filming bespoke videos would be necessary to provide engaging content to adolescents via the CA.

**Dialogue Infrastructure**

Owing to the students’ age and unwillingness to disturb their schooling, the researchers were unable to spend extended periods with them and had to rely on the students’ prior experience with CAs. In the future, it is recommended that more time be spent with the students to fully understand all the key features of CA design and improve the co-design process.

**Implementation of Co-Design Phase Recommendations**

In this section, we summarize the implementation of the findings from the co-design process in the development of the prototype CA.

Textbox 1 presents the summarized findings from the co-design research with 8 adolescents to develop the prototype chatbot. It details the findings of user requirements and context, the content of the chatbot, and the chatbot’s persona.
Textbox 1. Summary of co-design findings.

Conversational agent (CA)
- Name: Phyllis
- Audience: Students aged 11-16
- Channel: A school website or social media

Use case
- Service and expertise
  - Identify barrier to physical activity (PA) from user input.
  - Provide solution to barriers including recommending activities they could participate in.
  - Prototype provides 2 modules on motivation and confidence.
  - Future version will have solutions to all 52 barriers as well as monitoring of PA.

- Purpose
  - Support for students in schools to overcome barriers to PA and to understand more about PA and gain information and guidance of how to be physically active.

- Media
  - CA mainly conversational but provides links to other website apps and resources.
  - Future iterations will include voice and video media.

User requirements and context
- User persona
  - Students aged 11-16 that want to be more active or support others to be active

- Motivations
  - Want to be more physically active but aware that there are barriers which prevent them from participating in PA and they want to overcome these

- Anxieties
  - That the CA can understand them
  - That the CA can help them

- Data protection

Content
- Behavioural modules
  - Improving confidence (5 min)
  - Improving fitness (4 min): General fitness
    - Balance with educational constraints
    - Links to Sport England content
    - Fitness tracking

- General content
  - Why it is important to be physically active
  - How long should adolescents be active for
  - Respond to input around 52 barriers to PA. Currently acknowledges and asks to confirm barrier before saying content is not yet available.

Bot persona
- Gender and age
• Age: 16
• Gender: Neutral
• Future designs may include a choice of personas

• Backstory
  • An understanding intelligent and kind young person with knowledge and experience of PA

• Role and style
  • Helpful peer who is supportive to other students of a similar age

• Personality
  • Humanoid
  • Helpful
  • Challenging
  • Understanding
  • Intelligent
  • Kind

• Can do
  • Have a conversation and identify barriers to PA
  • Suggest solutions to barrier and ways to be more active
  • Provide general information about PA

• Can’t do
  • Have a wider conversation than the stated use case
  • Advise on how to help others
  • Monitor PA

Standard vocabulary
• Typical things to say
  • Here are some ideas.
  • I have a suggestion.

• Introductions
  • Hi, my name is Phyllis how are you?
  • Hey, my name is Phyllis.
  • See you soon.

• Acknowledgement
  • Sure, I will do that.
  • Okay, I have a suggestion.

• Confirmations
  • Here you go ‘name’.
  • You can do it! How about you try this.

• Apologies
  • I am sorry I cannot help you with that.
  • Okay, I didn’t understand that. Can you try and tell me what stops you from being more physically active?
Following the co-design process, the CA was constructed based on the gathered findings and was internally evaluated with the research team. Subsequently, the CA was prepared for deployment to be tested with adolescents.

**Evaluation**
This section presents the findings of evaluating the prototype CA (referred to as “Phyllis”) with 46 students.

**Use Patterns**
During the evaluation phase, 62 conversations were conducted with the CA. Among these conversations, 15 students concluded one conversation and then initiated a new conversation with Phyllis. Overall, the users sent 1512 messages to Phyllis, resulting in an average of 33 messages per person. Phyllis responded by sending 2806 messages to the users, averaging 61 messages per conversation. Only a small portion (n=77, 5.09%) of the messages sent per person could not be successfully matched with a corresponding intent. This was because the students sent unintelligible messages or misspelled words while discussing barriers to PA participation. The most frequently matched intents included “lack of confidence,” “lack of time,” and “lack of motivation,” which aligns with the barriers identified during the co-design focus groups.

**User Experiences**
The users generally had positive experiences with the CA, rating its conversational capacity as good, clear, simple, and straightforward to use on a comparative scale (Figure 3). Qualitative feedback indicated that the users found the CA clear and easy to use, with good options for obtaining information and interesting websites to access from the CA.

Concerning acceptability, a sizable portion of the students (34/46, 73%) expressed their definite intention to use a fully functional CA in the future. The remaining students stated that they might consider using it in the future. When asked to rate Phyllis, 65% (30/46) of respondents considered it “good,” whereas 20% (9/46) rated it as “very good.” The remaining 15% (7/46) rated Phyllis as “average.” The CA received a positive net promoter score of 13, indicating a favorable likelihood of recommendation. This suggests that not only would most students use Phyllis themselves but also they would recommend it to their friends.

On the basis of user feedback, it was suggested that Phyllis should reduce the amount of text in each message to enhance readability and recommended slowing down the speed of message delivery to assist with user recognition and comprehension. Furthermore, 2 users specifically requested that the CA offer direct answers to various questions about fitness and exercise without necessitating the initial mention of barriers. They also suggested incorporating more videos, diagrams, and real-life scenarios depicting PA. As anticipated, users expressed an interest in customizing the CA further by having the option to choose a different avatar, name, and personality.

**Relational Capacity**
The students assessed the CA’s relational capacity and reported finding the bot to be “likable” and “motivating.” However, the scores for the persona of the CA being either “human” or “robotic” and “creative or unimaginative” were neutral, warranting further investigation. Qualitative feedback revealed that certain students appreciated the bot’s personality; humor; and use of emojis, icons, and GIFs. They found Phyllis to be helpful, informative, and reassuring, particularly highlighting Phyllis’s use of open-ended questions. A participant (1/46, 2%) even expressed gratitude for Phyllis being a peer, stating, “students like us” during the conversation. However, some students felt that Phyllis could offer more support and advice, particularly within the fitness module. Rather than receiving a list of websites, they expressed a preference for conversational and diverse guidance on engaging in PA.

**Persuasive Capacity**
A total of 2 modules, focusing on the behaviors of “confidence in user ability to engage in PA” and “motivation to be physically active,” were evaluated. Users were asked to rate their agreement...
level with 3 statements, both before (pre) and after (post) the use of Phyllis. A total of 80% (37/46) of students reported being “confident in their ability to engage in PA or play sports,” indicating a 50% increase from the initial preresponse rate of 53%. The findings for motivation were even more notable, with 73% (34/46) of users reporting an enhanced motivation to engage in PA following the intervention. This represents a significant 120% increase in agreement with the statement from 33% (15/46) pre-to 73% (34/46) postintervention. Furthermore, students were asked about their ability to overcome challenges related to PA or sports. Over half of the respondents (24/46, 52%) agreed that they could overcome these challenges, which increased to 67% (31/46) after engaging with Phyllis. However, it is worth noting that this outcome may have been less substantial owing to the current limitations of the CA, as it is unable to provide solutions or modules for all 52 identified barriers. Overall, 67% (31/46) of respondents felt more motivated to participate in PA or sports since using Phyllis, and an overwhelming 93% (43/46) of them expressed a desire to be more active throughout the day. In addition, 73% (34/46) of respondents indicated that Phyllis helped them contemplate ways to increase their PA levels during the day.

Overall, there was no significant difference reported between the adolescents who were part of the co-design and those who were not. This was the same for users when comparing users from Wickersley School and Sports College and Zest.

Discussion

Principal Findings

The study involved co-designing and evaluating a pilot CA named Phyllis to test its proof of concept. The primary objective was to support adolescents in overcoming barriers to PA [15-17], to realize the associated benefits [1,2,4,50], and to provide an alternative digital solution to combat global inactivity [6]. Furthermore, it aims to promote the development of healthy behaviors during adolescence [7,8,51], thereby fostering continued participation in adulthood. The hypothesis guiding the study was that a CA could assist adolescents and that they would perceive Phyllis as a valuable tool for boosting their confidence and motivation to engage in PA. The study’s objectives were to co-design the CA in collaboration with adolescents, demonstrating the CA’s capacity to understand user input related to the identified barriers. It also aimed to evaluate the CA’s usability and acceptability among adolescents and assess the perceived effectiveness of the solutions offered by the CA to address these barriers. Overall, adolescents reported high acceptability and positive user experiences when using Phyllis, whereas the modules and personas designed to increase motivation and confidence achieved positive outcomes. This evidence positions Phyllis as a promising digital tool to alleviate global inactivity and aligns with the goals of the World Health Organization’s Global Action Plan on PA [18].

The research builds upon prior studies of PA interventions [24,25,27,28,52,53] and adolescent barriers to PA [15,16,51] and is informed by a behavior change model and theoretical framework [29]. This approach is unique as it draws upon relevant research, engages in co-design with adolescents and applies relevant theories [30,35,38,54] to design a CA targeted at adolescents. It is a novel approach in this domain targeted at this population, as indicated by prior research [27,28], which has identified a lack of CAs tailored specifically for adolescents. This innovation in design, using the COM-B model and TDF for intervention development, promises to pave the way for more impactful interventions in the future.

The co-design process engaged 8 adolescents, which represented the broader population’s sex distribution and a higher representation of “Asian” and “Black” ethnic groups who are more likely to be inactive [17]. The process yielded significant findings that support the rationale for the study. First, it highlighted the inadequate access that adolescents have to support systems for addressing barriers to PA and provided further evidence of the array of barriers faced by adolescents [15-17]. Co-design participants were able to identify 37 barriers to engaging in PA, reporting an average of 9 barriers per person. This accounts for approximately 66% of the barriers that the CA will aim to support, based on a study that served as the foundation for the current research [17]. These findings highlight the significance of developing multicomponent interventions that can effectively address multiple barriers, as advocated in the existing literature [12]. Notably, a lack of confidence and motivation emerged as significant barriers to this cohort, which is consistent with previous studies [15,16,51]. Moreover, adolescents reported experiencing 4 times as many negative feelings as positive feelings when describing the emotional impact of PA, highlighting potential reasons for limited engagement in PA. An unintended outcome of the study was the revelation of a paradox, as some adolescents reported that PA may exacerbate psychological effects such as anxiety, while perceiving it as a means of improving these conditions. Subsequent iterations of Phyllis will consider these limiting beliefs, aiming to help individuals become more self-aware of such conflicting thoughts.

For the CA to effectively address barriers to PA, it must be perceived as an acceptable tool for support by adolescents. The co-design participants expressed high levels of acceptability toward the CA and demonstrated a willingness to share personal information with it. However, some students voiced concerns regarding privacy and data protection, aligning with the findings of other studies [27]. Previous studies have highlighted the significance of personalization [23], and this study further underscores adolescents’ specific requirements. Although a consensus favored a gender-neutral teenage persona with a human-like tone, the ideal scenario would involve fully customizable features such as persona, avatar, and tone of voice. The adolescents’ diverse preferences were also reflected in their choice of the CA’s personality and characteristics, representing a range of personalities. Although challenging for designers, this evidence is valuable for guiding the future design of CAs and for advancing research in this domain. Overall, the feedback emphasized the importance of empathy, intelligence, and kindness in the CA’s approach, characterized by motivational language, acknowledgment of concerns, and positive reinforcement through both submissive and dominant behaviors at specific points of interaction. For example, some adolescents appear willing and would even encourage the CA to challenge
their beliefs and offer alternative views and solutions. Similarly, there was variation in the preferred approach to delivering content using different media; yet, it was clear that adolescents desired more complex interactions with content delivered and explained conversationally rather than being signposted to external websites or apps. This perception strengthens the case for CAs to be used for this purpose, with interventions delivered conversationally. All this knowledge provides much-needed insight into the design of effective CAs targeted at this population.

The second objective was to build a CA that, although informed by the co-design, had a specific purpose of recognizing input from adolescents around the 52 barriers [17] and providing a relevant solution to overcome each barrier. This is a novel approach that has not been applied in the design of previous CAs. In terms of recognition, an $F_1$-score was used to assess the performance of the model, which scored 80%. All relevant and negligible utterances were matched accurately during the pilot, and adolescents who typed utterances related to “a lack of confidence” or “fitness” were accurately matched to the solution. Further testing will be required when all solutions are developed, including training data, to help improve recognition further. Importantly, the model can recognize a range of input from adolescents, thereby improving the potential viability of this approach to support adolescents.

Once the prototype CA was designed and developed, the objective was to validate it as a proof of concept by assessing its acceptability, usability, and effectiveness in supporting adolescents to overcome barriers to PA. Most adolescents expressed positive acceptability toward the CA, with 73% (34/46) of students indicating they would “definitely use” a fully operational Phyllis and 85% (39/46) rating the CA as either “good” or “very good.” In addition, Phyllis received a “good” net promoter score, indicating that adolescents would also recommend it to their friends [55]. Qualitative data analysis revealed positive scores in terms of user experience, whereas qualitative feedback highlighted students’ appreciation for the CA’s personality; humor; and the use of emojis, icons, and GIFs.

The evaluation also provided valuable feedback to enhance Phyllis in the short term (eg, delivering fitness activities conversationally) and long term (eg, enabling deeper personalization and reducing message text). Students found Phyllis helpful, informative, likable, and motivating and appreciated its ability to ask open-ended questions, demonstrating the importance of unconstrained conversation [28] and the ability to provide reassurance. These results indicate that adolescents had a positive user experience and would be willing to use a CA such as Phyllis in the future, further strengthening the evidence for these tools to be used to support adolescents. Such features developed from the co-design process will help alleviate concerns expressed in the literature around usability challenges [27] faced by users and further reinforce the importance of integrating the principles of user-centered design [30] and human–computer interaction [31] with the aim of establishing relational and persuasive capacity [28] with users. These findings could also be used to inform the development of other CAs in this and other domains, serving as useful insights for designers and developers of digital health interventions.

The primary goal of the CA is to augment PA behaviors, and the prototype included 2 modules developed for this purpose. Following an interaction with the CA, 80% (37/46) of the students reported improved confidence in their ability to participate in PA or sports. This represents a 50% increase compared with the initial response. In addition, there was a significant 120% increase in the proportion of students who agreed with the statement expressing their motivation to engage in PA after engaging with the CA. This serves as a positive indicator of the CA’s efficacy. Most students (34/46, 73%) also indicated that the CA would assist them in exploring ways to incorporate more PA into their daily routines. These findings demonstrate the potential of the CA as an effective tool in helping students overcome barriers to PA, further validating the CA’s potential. However, further research is necessary to determine if these improvements translate into increased levels of PA and to identify an appropriate measurement method so that PA can be monitored via the CA.

It is important to consider the implications of these findings in the context of recent developments in LLMs and generative AI, as they have the potential to enhance the effectiveness of the CA as they can comprehend and generate natural language with heightened complexity and accuracy [33,34]. These advancements can also expedite the development process, elevate the quality of interaction, and expand their knowledge base by providing a more comprehensive conversational experience that meets the specific needs of users. In health-related fields, it is imperative that CAs provide accurate, trustworthy, and evidence-based information and address concerns related to bias, misinformation, privacy, and security that may arise from the use of LLMs.

The approach advocated in this study has the potential to bridge the gap between sophisticated LLMs and trusted, evidence-based content. To illustrate this further, interventions should continue to be co-designed and expert led, grounded in evidence-based content. This content can then serve as the foundation for the development of domain-specific models, which in turn are used to provide data to inform intervention delivery. The critical aspect of intervention delivery depends on the use of prompt engineering or the application of a cognitive system that guides the model on how and when to deliver an intervention. The process of delivering interventions may necessitate extremely precise prompting to ensure the accuracy of behavior change tools, intervention content, language, and persona. This precision may require the use of an LLM working in combination with a traditional intent-based approach to allow for predefined responses to guarantee the accuracy and quality of the expert-designed intervention content. Adhering to these principles can effectively mitigate concerns and establish an audit trail for the content provided, ultimately promoting greater transparency. This transparent and comprehensive audit trail serves not only to foster trust but also to strengthen accountability and facilitate the identification of potential biases or inaccuracies.
The limitations of the study findings lie in their reliance on a single interaction with the CA, which does not provide insight into long-term adherence or sustained behavior change resulting from CA use. Nonetheless, the results show promise in terms of children’s willingness to engage and to self-report positive attitude changes after a brief period of interacting with the CA. The evidence also demonstrates why this population perceives CAs as a potentially valuable solution. Further research is necessary to address each of the 52 identified barriers, identify the commonalities among them, enhance the algorithm, and ensure greater efficacy.

Overall, the results demonstrate that Phyllis has the potential to be a cost-effective, resource-efficient solution that organizations can offer to support adolescents and address the multifaceted barriers to PA [15-17]. With further development, the tool could serve as a self-help resource for students, with teachers administering it to inactive students to enhance their levels of PA. Positive evidence of digital interventions being used in both formal and informal settings exists to support their potential use in this setting [22]. As this research highlights, schools lack the time, resources, and capacity to adequately support adolescents [14], making the CA an effective tool to augment existing support. Data from CA interactions could also be shared with schools to identify more serious barriers such as mental and physical health issues or to highlight prevalent barriers within the student population, thereby improving support within the CA and informing policy or intervention approaches within schools. Moreover, the data could offer greater insight into adolescent needs and barriers, informing policy in this field.

The implementation of digital technology in schools, which ensures transparency, safety, and trust, can be achieved with minimal demands on school staff and teachers while also being cost-effective. The findings reinforce the importance of evidence-based self-help tools, which can be accessed by adolescents in schools at a low cost. Moreover, these tools can be supervised by trusted adults, ensuring personalized support for adolescents without overwhelming the capacity of teachers or the school. The CA and its design also have the potential for broader deployment within health care systems as part of the PA referral pathway to enhance adherence to programs or social prescribing services that aim to enhance PA levels among adolescents with long-term conditions or hypokinetic diseases. The design could also be enhanced to provide multimodal support by using robotics and be adapted and used within other populations, such as with older adults.

Conclusions
The study aimed to co-design, develop, and evaluate a prototype CA as a proof of concept to assist adolescents in overcoming barriers to PA. It presents one of the first theory-driven approaches to designing a CA. Drawing from prior studies, theoretical approaches, and insights into adolescent barriers, the research focused on achieving relational and persuasive capacity with adolescents using the CA. Highlighting inadequate access to support systems, 37 barriers were identified, with 66% aligning with previous research. The emphasis was placed on the acceptability and personalization of the CA to address privacy and data protection concerns. The results demonstrated very high acceptability and positive user experiences, highlighting the potential of the CA. The modules designed for the CA showed promising outcomes, fostering increased confidence and motivation for PA. Phyllis also performed well, recognizing a range of different barriers to PA. However, further research is needed to develop other modules to overcome other barriers and explore long-term adherence and the effectiveness of interventions for sustaining behavior change. Adolescents also expect to have a personalized experience and be able to personalize all aspects of the chatbot. Phyllis holds potential as a cost-effective solution for schools to support adolescents and tackle barriers to PA. The integration of LLMs can significantly enhance the CA’s capabilities, facilitating sophisticated conversations and automated content generation with this study providing knowledge of how they can be designed to incorporate evidence-based approaches to ensure trust and transparency. The CA’s potential extends to health care systems, social prescribing services, and multimodal support, including robotics. This study provides valuable insights for designing and developing digital health interventions in other domains as well as contributing to the improvement of PA levels among adolescents and addressing global inactivity concerns.

Abstract

Background: Young people today are exhibiting increasing rates of disordered eating behaviors, as well as eating disorders (EDs), alongside other mental and behavioral problems such as anxiety and depression. However, limited access to mental health care means that EDs, disordered eating behaviors, and comorbid mental health problems are often underdiagnosed and undertreated. Digital mental health interventions (DMHIs) offer accessible and scalable alternatives to traditional treatment modalities, but their effectiveness has not been well established among adolescents with EDs and disordered eating behaviors.

Objective: This study uses data from a collaborative care pediatric DMHI to determine whether participation in a DMHI is associated with a reduction in adolescents’ disordered eating behaviors.

Methods: Adolescent members in care with Bend Health Inc completed the SCOFF questionnaire at baseline (before the start of care) and approximately every month during care to assess disordered eating behaviors. They also completed assessments of mental health symptoms at baseline. Member characteristics, mental health symptoms, and disordered eating behaviors of adolescents with elevated SCOFF scores at baseline (before the start of care) were compared to those of adolescents with nonelevated SCOFF scores at baseline. Members participated in web-based coaching or therapy sessions throughout the duration of mental health care.

Results: Compared to adolescents with nonelevated SCOFF scores (n=520), adolescents with elevated SCOFF scores (n=169) were predominantly female and exhibited higher rates of elevated anxiety and depressive symptoms. SCOFF scores decreased over time in care with the DMHI for 61.4% (n=70) of adolescents with elevated SCOFF scores, and each additional month of participation was associated with greater improvements in disordered eating behaviors ($F_{1,233}=72.82; P<.001$).

Conclusions: Our findings offer promising preliminary evidence that participation in mental health care with a collaborative care DMHI may be beneficial in the reduction of disordered eating symptoms in adolescents, including those who are experiencing comorbid anxiety and depressive symptoms.

Introduction

Eating disorders (EDs) and associated disordered eating behaviors impact approximately 10% of the US population [1]. The peak age of onset of EDs such as anorexia nervosa, bulimia nervosa, avoidant or restrictive food intake disorder, and binge ED is between 13 and 18 years, making them particularly relevant during adolescence. Estimates of EDs in adolescence range from 1.2% among males to 5.7% in females and 9% among sexual and gender nonconforming youths [2-5]. Disordered eating behaviors (eg, obsessing over food intake and excessive worry about weight) are even more common, impacting nearly 1 in 4 children and adolescents [6]. EDs and disordered eating behaviors disrupt critical periods of physical and socioemotional development that occur during childhood and adolescence [7]. Youths with EDs experience compromised physical functioning such as malnutrition, disrupted pubertal development, and delayed menarche, as well as worsened psychosocial functioning. EDs are highly comorbid with, and often preceded by, other mental health problems such as anxiety or anxiety disorders, depression, and obsessive-compulsive disorder [8].

During the COVID-19 pandemic, the prevalence of EDs more than doubled among adolescents, exacerbating an already pressing public health issue [9,10]. Indeed, EDs confer a significant economic burden for families and hospitals, with an estimated annual disease burden of US $70 billion [11,12]. However, more than 75% of those with EDs or risk for EDs do not receive the necessary treatment [13]. Several issues underlie this gap between ED diagnosis and treatment. ED treatments are often difficult to access, especially for young people, who often experience financial, geographic, and transportation constraints as well as increased stigma [14]. Additionally, in-person services, such as inpatient and outpatient care and face-to-face therapy, are severely limited in their accessibility, largely due to shortages of trained personnel and long waitlists [14].

In recent years, digital mental health interventions (DMHIs) such as self-guided applications and web-based therapy have emerged as accessible and scalable alternatives to traditional mental health treatments. Several systematic reviews and meta-analyses suggest the potential for DMHIs in ED treatment, although results remain heterogeneous and inconclusive [15]. Moreover, few studies of DMHIs for EDs have been conducted among adolescents, despite the pressing need for accessible child and adolescent ED treatments. As argued by Loucas et al [16], most pediatric DMHIs for EDs are more similar to web-based self-help programs than therapeutic interventions, given their lack of personalized and interactive components [17-19]. However, recent advances in pediatric DMHIs using family-based therapy for ED treatment have yielded promising results, suggesting that digital ED treatments for youths are most effective when administered in the context of a holistic care team [20-22].

The collaborative care model is a team-based framework for mental health care that has been used by DMHIs with promising results. In the collaborative care model, primary care providers collaborate with behavioral care managers (BCM) and other providers to implement measurement-based mental health care. Collaboration between providers reduces the burden on primary care providers while ensuring optimal, evidence-based care via regular symptom assessments. As a result, interventions that use collaborative care models are particularly effective for the treatment of mental health problems in both youths and adults [23-26]. However, no studies to date have evaluated whether participation in collaborative care DMHIs may improve disordered eating behaviors among adolescents. As such, the purpose of this study was to use retrospective analyses of data collected from adolescents participating in care with a collaborative care DMHI to determine whether participation in a pediatric collaborative care DMHI is associated with a reduction in disordered eating behaviors. Considering established demographic and clinical correlates of disordered eating behaviors we also explored associations between potential confounds (age, sex, and anxiety and depressive symptoms) and disordered eating behaviors among those receiving care with the DMHI.

Methods

Design and Participants

All adolescents (ages 13-17 years) who met the following inclusion criteria were eligible for inclusion in the study (N=689): (1) started mental health care (first synchronous event) with Bend Health Inc between January 1, 2023, and October 1, 2023 (9 months); (2) had at least 1 synchronous session with a Bend Health Inc coach or therapist during the study time frame; and (3) completed the assessment of eating behaviors before the start of care (baseline).

Treatment

Bend Health Inc is a DMHI that provides behavioral care for adolescents (aged 13-17 years), using a whole-family approach (ie, caregivers are closely involved in care), via a web-based platform. Bend Health Inc’s behavioral care has been described elsewhere [24,25]. Members enroll via referral from a health care provider, or they use insurance, employer benefits, or self-pay. Members are assigned a BCM, who conducts an initial evaluation of the member’s mental health concerns and circumstances, and they continue to monitor the member’s care while they are enrolled in the program. BCMs assign members a coach, and also a therapist in some cases, based on their mental health symptoms (eg, type and acuity), goals for treatment, and insurance coverage; therapists tend to be assigned only to members with more severe symptoms and conditions, whereas nearly all members are assigned a coach. Members with higher symptom acuity or a psychiatric referral may also be assigned a prescribing psychiatric practitioner (eg, a medical doctor or psychiatric nurse practitioner). In synchronous video-based coaching and therapy sessions, Bend Health Inc’s practitioners guide members and their caregivers through structured care programs. These care programs are designed to deliver evidence-based tools and techniques that target common mental and behavioral health issues such as anxiety, depression, and body image. Most care programs are designed to be completed in approximately 3 months, and some care programs (eg, the
body image program) are designed to be completed in a shorter amount of time. Once a month, caregivers and adolescent members are asked to complete validated web-based assessments of the adolescent’s mental health symptoms (see Measures section). Caregivers are required to be in the same general location for their adolescents’ synchronous sessions with a coach or therapist for safety purposes.

Measures
Demographic and health information of adolescent participants is gathered during enrollment with Bend Health Inc. Caregivers respond to basic demographic questions, providing their adolescent member’s date of birth, sex at birth (male, female, or others), gender identity (male, female, transgender, nonbinary, or others), and race or ethnicity. Details on the race or ethnicity response options are included in Multimedia Appendix 1.

In addition, at enrollment, caregivers and adolescent members complete a series of symptom screening questions and validated assessments to identify common mental and behavioral health concerns. To assess eating behaviors, all adolescent members complete the SCOFF (Cronbach α=.48) [27,28]. The SCOFF is a validated questionnaire, in which the member responds “yes” or “no” to 5 items about disordered eating behaviors that they might have. The 5 items, each correspond with a letter of the SCOFF name, are as follows: (1) Do you make yourself sick because you feel uncomfortably full? (2) Do you worry that you have lost control over how much you eat? (3) Have you recently lost more than one stone (14 lb) in a 3-month period? (4) Do you believe yourself to be fat when others say you are too thin? and (5) Would you say that food dominates your life?

To identify members with elevated anxiety and depressive symptoms, caregivers of adolescent members respond to 5 screening questions drawn from the Diagnostic and Statistical Manual of Mental Disorder, Fifth Edition, Text Revision (DSM-5-TR) Cross-Cutting Symptom Measure [29]. For anxiety, the caregivers and adolescents together respond to the following questions: Over the last 2 weeks, how often have you been bothered by any of the following problems? (1) Feeling nervous, anxious, or on edge? and (2) Not being able to stop or control worrying? For depressive symptoms, caregivers and teens responded to the items: Over the last 2 weeks, how often have you been bothered by any of the following problems? (1) Had less fun doing things than you used to? and (2) Felt sad or depressed for several hours? Best-fit responses are selected from a 4-item Likert-type scale, with responses ranging from “not at all” (item score=0) to “nearly every day” (item score=3). Screener scores are calculated by aggregating all item scores for each screener.

Members who have an anxiety screener score of 2 or more are prompted to complete the Generalized Anxiety Disorder-7 (GAD-7) assessment (Cronbach α=.91) [30,31], and members who have a depressive screener score of 2 or more are prompted to take the Patient Health Questionnaire-9 for Adolescents (PHQ-9A; Cronbach α=.85) [32,33]. The GAD-7 has 7 questions regarding symptoms of anxiety in the prior 2 weeks with the same Likert-type scale as used in the screener questions (“not at all” to “nearly every day”). The PHQ-9A is a modified version of the PHQ-9 for adolescents aged 11-17 years. The original measure has 9 questions, but we omit a question regarding suicide and self-harm (ie, the PHQ-9A here includes 8 questions). The PHQ-9A asks adolescents about depressive symptoms in the prior week using the same Likert-type scale as in the GAD-7 and screener questions. Adolescents are asked to report their own symptoms for both GAD-7 and PHQ-9A.

Statistical Analysis
Outcome Calculations
The last assessment before the start of care (baseline) and all assessments after the start of care were considered for analysis. SCOFF scores were calculated by aggregating the number of “yes” responses, with scores ranging from 0 to 5. As has been used previously [27], members with a SCOFF score of 2 or more on their baseline assessment (ie, the last assessment before the start of care) were included in the “elevated SCOFF score” group, and members with a score of less than 2 were included in the “non-elevated SCOFF score group.” GAD-7 scores were calculated by aggregating the individual item scores. PHQ-9A scores were calculated by aggregating the individual item scores, and then, dividing by 8 and multiplying by 9 (to account for the omitted item). Members with moderate or greater severity anxiety or depressive symptoms, as determined by established criteria for the GAD-7 and PHQ-9A [29,30], were flagged as having elevated anxiety or depressive symptoms, respectively.

Baseline Characteristics: Eating Behaviors and Member Characteristics
SCOFF scores at baseline were characterized for all members, including total score and responses to individual SCOFF items. Then, member characteristics, anxiety and depressive symptom severity (elevated or nonelevated), and care participation characteristics were reported for each group and compared between groups to identify any differences. Member characteristics included age at baseline, sex (female, male, and nonbinary), gender-sex conformity (conforming and nonconforming), race or ethnicity (Asian, Black or African American, Hispanic or Latino, White, and other or multiracial), mental health condition (anxiety disorder diagnosis and depressive disorder diagnosis), and elevated mental health symptoms (anxiety and depression). The care participation metrics included the number of months in care (time between first session and last session), rates of members in coaching and therapy, and rates of members participating in the anxiety, depression, and body image care programs. Member demographics were reported by caregivers (described earlier), mental health conditions were identified from electronic health records, mental health symptoms were characterized based on symptom severity at baseline, and care participation characteristics were assessed using data from electronic health records. Age in years and months in care were compared between groups using Wilcoxon signed rank tests. All other between-group comparisons for member characteristics were performed using chi-square tests.

Change in Eating Behaviors
The number of total SCOFF assessments (ie, with baseline as the first assessment) was quantified for members in both groups.
Only data from members with at least 2 assessments (baseline and at least 1 assessment after care) were included in the analyses of change in SCOFF scores (n=233 members excluded). For members in both groups, SCOFF scores at baseline and the last assessment, as well as the change in score from baseline to last assessment, were quantified. Change scores were compared to 0 using Wilcoxon signed rank test to determine whether SCOFF scores changed significantly over the course of care. The rates of members with a decrease and an increase in SCOFF score were reported for both groups to quantify rates of symptom improvement and symptom worsening, respectively. To identify which items contributed to a change in SCOFF score, “yes” responses to each item at the last assessment were reported for members who responded “yes” to the item at baseline.

Finally, a linear mixed effects model was used to test whether SCOFF scores decreased over months in care and to test whether mental health symptom severity (at baseline) and demographic factors predicted SCOFF scores. Only members with a baseline assessment within 1 month or less of the start of care were included in the linear mixed effects model (n=10 members excluded). The basic model included a fixed effect of months in care (at the time of SCOFF assessment) and a random effect of subject (member ID) on the intercept. Alternative models including one of the following predictors were tested for fit against the basic model using likelihood ratio tests: elevated anxiety symptoms at baseline (yes or no), elevated depressive symptoms at baseline (yes or no), sex at birth (female or nonfemale), age at baseline (in years), and participation in therapy (yes or no). When a likelihood ratio test was statistically significant, the predictor variable was included in the final model as a fixed effect.

Throughout, standard descriptive statistics (eg, percentages, mean and SD, and median and IQR) were used to describe the data, as appropriate. IQR values are reported as the range: 25th-75th percentile. An α level of .05 was used as the threshold of statistical significance for all analyses. Tests of normality (Kolmogorov-Smirnov and Jarque-Bera) were performed to determine appropriate statistical tests and descriptive statistics. P values were corrected for multiple tests using the Bonferroni Hoc correction statistical tests performed on baseline characteristics and change in SCOFF scores (2 sets of corrections).

Ethical Considerations
At enrollment with Bend Health Inc, all study participants provided informed consent for primary data collection (required for participation in care) and use of their data in further analyses.

Given the retrospective observational nature of the study, participants were not compensated for their participation in the study. Procedures for this study were approved by the Biomedical Research Alliance of New York (Study 23-12-034-1374; approved on June 5, 2023). To ensure the privacy and confidentiality of the human participants in this study, all data (eg, from electronic health records) were deidentified prior to analysis.

Results

Baseline Characteristics: Eating Behaviors and Member Characteristics
The distribution of baseline SCOFF scores is reported in Table 1. Ultimately, 75.5% (n=520) had nonelevated SCOFF scores, and 24.5% (n=169) had elevated SCOFF scores. For members with nonelevated SCOFF scores, 13.7% (n=71) of members responded “yes” to the item about control (item 2), and 9.2% (n=48) responded “yes” to the item about believing you are fat (item 4; Table 2). For members with elevated SCOFF scores, the most commonly reported items were loss of control (item 2: n=151, 89.3%), believing you are fat (item 4: n=113, 66.9%), and food dominating life (item 5: n=92, 54.4%).

Compared to the nonelevated SCOFF score group, the elevated SCOFF score group was more predominantly female (χ²=24.2; P<.001) and also had a higher rate of diagnoses with depressive disorders (χ²=9.5; P=.005; Table 3). Rates of elevated anxiety and depressive symptoms were higher for members with elevated SCOFF scores than members with nonelevated SCOFF scores (anxiety: χ²=31.9; P<.001 and depression: χ²=63.2; P<.001). Age, gender-sex conformity, race or ethnicity, and rates of anxiety disorder diagnoses did not differ between groups.

Members were in care for a median of 2.60 (IQR 1.27-4.23) months. In terms of participation in behavioral care, 98.8% (n=681) of all members were in coaching, and 39.8% (n=274) of all members were in therapy. Rates of participation in coaching and therapy, as well as months in care, did not differ between groups. Approximately 1 in 2 members participated in the anxiety care program, and this was similar between groups. However, participation in the depression and body image care programs was higher for members with elevated SCOFF scores versus members with nonelevated SCOFF scores (depression: χ²=15.0; P<.001).

\(^c\)Between-group comparison was performed using a Wilcoxon signed rank test (z=-1.46).
Change in Eating Behaviors

SCOFF assessment counts during the study time frame are reported for each group in Table 4. For all members with a baseline and postcare assessment (ie, 2 or more total assessments), baseline assessments were completed at a median of 0.27 (IQR 0.5-0.13) months before the start of care, and the last assessments were completed at a median of 2.23 (IQR 1.1-3.6) months after the start of care. The timing of baseline and last assessments did not differ between groups (baseline: \(z=0.70; P=0.70\) and last assessment: \(z=-0.38; P=0.70\)).

For members in the nonelevated SCOFF score group, 16.4% (n=56) had a decrease in SCOFF score from baseline to their last assessment, 13.7% (n=47) had an increase in SCOFF score, and 69.9% (n=239) had no change (Table 5). For members in the elevated SCOFF score group, on the other hand, 61.4% (n=70) had a decrease in SCOFF score from baseline to their last assessment, 16.7% (n=19) had an increase, and 21.1% (n=25) had no change. While SCOFF scores remained stable for the nonelevated SCOFF score group (\(z=-0.47; P=0.70\)), median SCOFF scores decreased from 2 (IQR 2-3) at baseline to 1 (IQR 0-3) at the last assessment for the elevated SCOFF score group (\(z=-6.39; P<0.001\)). Individual item responses at the last assessment for members who responded “yes” to the item at baseline are reported in Table 6.

In the linear mixed effects model of SCOFF score over time in care for members with elevated SCOFF scores, the following predictors were included in the final model: elevated anxiety symptoms at baseline (\(\chi^2_1=7.6; P=0.006\)), elevated depressive symptoms at baseline (\(\chi^2_1=8.6; P=0.003\)), and participation in therapy (\(\chi^2_1=4.4; P=0.03\)). SCOFF score decreased by 0.26 points for each month in care (\(F_{1,233}=72.82; P<0.001\;\text{Figure 1}\)). Members with elevated anxiety symptoms at baseline had SCOFF scores 0.40 points higher than those with nonelevated anxiety symptoms (\(F_{1,101}=9.87; P=0.005\)). Similarly, members with elevated depressive symptoms at baseline had SCOFF scores 0.43 points higher than those with nonelevated depressive symptoms (\(F_{1,101}=5.40; P=0.044\)). Participation in therapy did not relate to SCOFF score (\(F_{1,101}=2.87; P=0.16\)).

Discussion

Principal Results

Using retrospective analyses of data collected from adolescents participating in care with Bend Health Inc, the purpose of this study was to determine whether mental health care with a collaborative care DMHI is associated with a reduction in disordered eating behaviors while also accounting for demographic and mental health symptom covariates. Disordered eating scores decreased throughout care with the DMHI for 61.4% (n=70) of adolescents with elevated disordered eating scores at baseline, and longer participation was associated with greater reductions in scores. Elevated disordered eating behaviors at baseline were associated with female sex and elevated mental health symptoms. This study provides preliminary evidence that mental health care with a DMHI may positively affect disordered eating behaviors.

Over the course of care with the DMHI, 61.4% (n=70) of adolescents with disordered eating behaviors exhibited fewer problematic eating behaviors throughout participation. Further, each additional month in care was associated with larger improvements in disordered eating behaviors, even while controlling for elevated mental health symptoms. These findings, which suggest the effectiveness of a pediatric DMHI in mitigating symptoms of disordered eating, are especially timely, as many youths with EDs and disordered eating symptoms are unable to access adequate care via in-person modalities—a lingering effect of the COVID-19 pandemic and current mental health crisis in youths [34,35]. Moreover, these results suggest that collaborative care DMHIs may mitigate disordered eating.
behaviors in a relatively short time frame, with the change in disordered eating behaviors assessed within this study sample after just 2.23 (IQR 1.1-3.6) months in care. Given the complex and chronic nature of disordered eating behaviors and EDs, it is understandable that health care professionals prefer team-based, integrated behavioral care (eg, the collaborative care model used by the DMHI in this study) for the identification and treatment of EDs [36-39].

Compared to those without disordered eating behaviors, adolescent members with disordered eating behaviors were more likely to be female than male. Extant literature suggests a similar trend, namely, that females tend to report more disordered eating behaviors and higher rates of ED diagnosis than their male peers [40,41]. However, this does not mean that disordered eating is not a problem among males. In this study, 19.5% (n=33) of adolescents flagged with problematic eating behaviors were male. Disordered eating behaviors may go underreported and unrecognized in males due to stigma [42], and ED diagnostic criteria may not accurately capture disordered eating behaviors that are more prevalent in males than females, such as preoccupation with gaining muscle mass and fear of losing weight [43,44]. Mental health providers and practitioners in both traditional and web-based modalities should continue to screen for disordered eating behaviors among all clients, regardless of sex and gender, while paying particular attention to muscle dysmorphia and excessive exercise [41].

We also found that adolescents with disordered eating behaviors also had higher rates of elevated anxiety and depressive symptoms than their peers who were not flagged with disordered eating behaviors. Moreover, having elevated anxiety and depressive symptoms at baseline was a significant predictor of more severe disordered eating behaviors among youths flagged with disordered eating behaviors. In children, adolescents, and adults, internalizing disorders such as anxiety and depression frequently co-occur with disordered eating behaviors and EDs [45-47]. This study sample exhibited higher rates of anxiety and depressive symptom comorbidity than previously reported. This is to be expected, given that all children and adolescents in this study were treatment-seeking, whereas previous estimates have included both treatment- and nontreatment-seeking individuals [45,46]. Notably, 95.9% (n=162) of members flagged with disordered eating behaviors participated in care programs other than the body image care program (namely, the anxiety and depression programs), and this group exhibited improvements in disordered eating behaviors, nonetheless. This finding adds to the body of literature suggesting that the overlap between disordered eating behaviors and internalizing problems such as anxiety and depression may have similar underlying constructs and thus may warrant similar treatment [45,48]. Further research is necessary to study the effectiveness of DMHIs in directly addressing disordered eating behaviors as well as treating comorbid EDs and internalizing problems among young people.

Limitations and Future Directions

While our findings provide compelling evidence that participation in a collaborative care DMHI may be associated with improvements in disordered eating behaviors, there are several limitations. The SCOFF assessment has attracted criticism for lack of sensitivity and accuracy and other questionnaires. The Eating Attitudes Test [49], for instance, may indeed allow for more fine-grained assessment and diagnosis of eating behaviors. However, the SCOFF has been used and validated extensively as a screener and assessment of common EDs among adolescents [27,50,51]. Moreover, the SCOFF has a high correlation with other validated disordered eating surveys [52] and has also shown acceptable convergent validity when compared to clinical interviews [53].

It should be noted that the SCOFF questionnaire includes an item that may not be appropriate for adolescents. Adolescence is a time of puberty and rapid growth, and therefore, losing 14 pounds may indicate extreme weight loss and a significant health issue (more so than the other SCOFF items). Further, if an adolescent responds “yes” to this item at one time point, it is unlikely that they will respond “yes” in the next several months. Therefore, we investigated whether our findings were driven or altered by the inclusion of this potentially problematic item. We found that few participants in the study sample responded “yes” to this item (n=44, 7.3% at baseline), and follow-up analyses revealed that our longitudinal results did not substantively change when this item was removed from the calculation of SCOFF scores (Multimedia Appendix 2). Thus, the inclusion of this item did not confound the primary findings reported here.

Although we evaluated cross-sectional associations between improvements in disordered eating behaviors and internalizing problems at baseline, future research should explore longitudinal and bidirectional associations between disordered eating symptoms and changes in mental health symptoms among youths involved in collaborative care DMHIs. Extant research regarding causal associations between disordered eating behaviors and other psychiatric symptoms among those engaged in treatment has yielded heterogeneous results [54-56], but no relevant studies to date have been conducted among youths involved in a collaborative care DMHI.

Concluding Remarks

Young people today are exhibiting increasing rates of disordered eating behaviors and EDs alongside other mental and behavioral problems such as anxiety and depression. Collaborative care DMHIs have the capacity to mitigate the growing mental health crisis by providing holistic and evidence-based care that is more accessible and scalable than traditional modalities. The findings from this study suggest that participation with a collaborative care DMHI such as Bend Health Inc may be beneficial in the reduction of disordered eating symptoms in adolescents. Future studies, particularly those bolstered by improved measurement of eating behaviors over time and with a larger and more diverse cohort of youths, are paramount to establishing the effectiveness of collaborative care DMHIs as an evidence-based provider of care for those with problematic eating behaviors and EDs.
Data Availability
The data sets generated and analyzed during this study are not publicly available because this would violate Bend Health Inc’s privacy. However, aggregated and anonymized data are available from the corresponding author on reasonable request.

Authors’ Contributions
LGH wrote the first draft of the paper and led further editing and paper refinement. DL-S performed formal data analysis and generated tables and figures for the paper. ABB wrote the first draft of the paper. JH supervised all paper writing and data analysis. All authors were involved in study conceptualization, development of methodology, and reviewing and editing the paper.

Conflicts of Interest
All authors are employed by, contracted with, or volunteering for Bend Health Inc, which delivered the treatment used in this retrospective study. However, authors’ employment status, salary, and any associated compensation are not dependent upon the results of their research.

Abstract

Background: Clinical decision-making is a complex cognitive process that relies on the interpretation of a large variety of data from different sources and involves the use of knowledge bases and scientific recommendations. The representation of clinical data plays a key role in the speed and efficiency of its interpretation. In addition, the increasing use of clinical decision support systems (CDSSs) provides assistance to clinicians in their practice, allowing them to improve patient outcomes. In the pediatric intensive care unit (PICU), clinicians must process high volumes of data and deal with ever-growing workloads. As they use multiple systems daily to assess patients’ status and to adjust the health care plan, including electronic health records (EHR), clinical systems (eg, laboratory, imaging and pharmacy), and connected devices (eg, bedside monitors, mechanical ventilators, intravenous pumps, and syringes), clinicians rely mostly on their judgment and ability to trace relevant data for decision-making. In these circumstances, the lack of optimal data structure and adapted visual representation hinder clinician’s cognitive processes and clinical decision-making skills.

Objective: In this study, we designed a prototype to optimize the representation of clinical data collected from existing sources (eg, EHR, clinical systems, and devices) via a structure that supports the integration of a home-developed CDSS in the PICU. This study was based on analyzing end user needs and their clinical workflow.

Methods: First, we observed clinical activities in a PICU to secure a better understanding of the workflow in terms of staff tasks and their use of EHR on a typical work shift. Second, we conducted interviews with 11 clinicians from different staff categories (eg, intensivists, fellows, nurses, and nurse practitioners) to compile their needs for decision support. Third, we structured the data to design a prototype that illustrates the proposed representation. We used a brain injury care scenario to validate the relevance of integrated data and the utility of main functionalities in a clinical context. Fourth, we held design meetings with 5 clinicians to present, revise, and adapt the prototype to meet their needs.

Results: We created a structure with 3 levels of abstraction—unit level, patient level, and system level—to optimize clinical data representation and display for efficient patient assessment and to provide a flexible platform to host the internally developed CDSS. Subsequently, we designed a preliminary prototype based on this structure.

Conclusions: The data representation structure allows prioritizing patients via criticality indicators, assessing their conditions using a personalized dashboard, and monitoring their courses based on the evolution of clinical values. Further research is required to define and model the concepts of criticality, problem recognition, and evolution. Furthermore, feasibility tests will be conducted to ensure user satisfaction.

Introduction

Background

In the pediatric intensive care unit (PICU), clinicians are required to make clinical decisions daily regarding inpatients’ health conditions. In critical care, data access accuracy and speed are crucial for optimizing the decision-making process. However, the following are some factors that can limit the effectiveness of this decision-making process: (1) clinicians must deal with a high volume of clinical data from several sources, such as physiological monitors, laboratory systems, and caregiver notes on the electronic health record (EHR) [1], which can lead to delays in processing data and reaching a decision; (2) decisions made in intensive care units rely on clinical judgment based on the clinician’s knowledge and experience, which are variable [2]; (3) clinical uncertainty in critical care and the variability of cases may lead to inconclusive decisions [3]; and (4) clinician’s stress, lack of sleep, and multiple stimuli can interfere with decision-making.

To gather relevant information, clinicians have to go through several systems, browsing through different sections of an EHR, laboratory systems, and imaging systems. They must sort and analyze all this information based on their personal expertise and available scientific evidence before making any decision regarding patient care.

For the last few decades, the emergence of clinical decision support systems (CDSSs) has assisted clinicians in their cognitive process by combining scientific knowledge bases with patient data for personalized and adapted management [4]. The design of the CDSS can take different forms depending on the clinical needs [5]. These systems focus on specific problems in the environment where they are to be implemented and often rely on existing systems and organizational contexts [6]. Therefore, understanding the workflow of existing systems is essential for supporting the adoption and optimal use of a new system. This understanding of the existing systems helps to determine when and how CDSS will be used [7].

To develop decision support mechanisms, participative approaches have been used to optimize the representation of clinical data. Faiola et al [8] adopted a human-centered approach to design a decision support tool, which has been shown to be effective in reducing the cognitive overload experienced by users [8]. More design and integration approaches have been developed based on domain-specific characteristics and matching users’ cognitive processes [9,10]. Clinical data display optimization, including EHRs focused on patient-centered care [11] and dedicated clinical decision support tools that depend on specialized knowledge bases [12], has attracted the interest of other researchers.

End user involvement is essential to ensure optimal data representation, which can be achieved through observation of clinical activities, individual interviews, and focus groups [13].

Data visualization must be validated by clinicians to ensure that it is understandable, relevant, useful, and readily available [14,15].

In this study, we aimed to adapt the data representation structure to the clinical processes in the PICU and allow its application in various clinical care scenarios. Although most decision support research in the literature focuses on specific clinical needs, the objective of our study is to facilitate the integration of multiple CDSSs developed for specific problems and the use of such systems for specific patients while ensuring harmonized monitoring and adequate evaluation for all hospitalized patients.

Our approach involved the end users throughout the data representation implementation process, including needs identification and prototype design, to illustrate the targeted structure.

Literature Review

Clinical Decision-Making

The clinical decision-making process is based on 2 main approaches: an intuitive heuristic approach, which is triggered in uncertain or critical situations requiring rapid intervention, and an analytical approach that involves gathering and processing information before reaching a conclusive decision. In clinical practice, the decision-making process varies with the clinician’s experience, their developed cognitive model, and processed information [16]. Furthermore, to refine clinical decisions and reduce the risk of errors, clinicians rely on knowledge bases and scientific evidence to process patient-specific data [17]. This adds complexity to the cognitive process in terms of time and effort invested.

In critical care, clinical teams typically discuss patients’ status and care during handoff meetings and medical rounds. Decision-making at these times depends on the relevance and accuracy of the data presented [18]. Decision support mechanisms are increasingly integrated into clinical processes to reduce the information gap by making relevant knowledge and data readily available through computerized systems.

Use of CDSSs

CDSSs are computer-based solutions that support clinicians and health care professionals in making clinical decisions [19] by providing them with person- or population-specific knowledge and information. This information is filtered and presented in a convenient timeframe to improve the health care of individuals and promote better population health [20].

Historically, CDSSs have been used for preventive, diagnostic, and therapeutic purposes, with the primary goal of improving the quality, safety, and efficiency of patient care [21]. Depending on the context of use, these systems may include best-practice guidelines for specific conditions or suggestions based on patient clinical data [22].
A CDSS is usually supported by an inference engine that incorporates clinical practice guidelines with patient-specific data to generate tailored suggestions [4]. However, other models are increasingly used, and artificial intelligence is used to predict condition changes or deterioration [23]. Computerized systems encompass 5 common types of decision support methods for knowledge sharing to reduce the risk of error among clinicians: order sets, information buttons, data documentation forms and templates, alerts and reminders, and relevant data representation [24].

The synthetic representation of patient data is a major challenge, mainly because of variability in data sources and format, along with the integration of medical knowledge in data processing. To implement such a representation, researchers have developed integration and structure design approaches that rely on the specificities of the work domain and adapt to users’ cognitive processes [9,10].

Improved visual representation facilitates timely information access, which has a positive impact on clinicians’ performance and cognitive processes [25,26]. Therefore, selecting adequate, reliable, and relevant content and using simple and understandable messages is highly recommended. Furthermore, clinicians’ time must be optimized by providing accurate and timely information and avoiding double entries by ensuring interoperability with EHR [27]. Finally, incorporating these systems into the users’ workflow is key to optimizing their implementation [28].

Wright et al [29] developed a taxonomy of clinical decision support tools to help categorize and compare their capabilities (eg, guidelines, notification, and order edition) in both commercially available and internally developed systems [28,29]. They found that a home-developed CDSS is more likely to achieve its goals as it focuses on local needs. Few studies have been conducted on implementing CDS components in commercial EHRs [30]. A review of 9 commercial systems found variability in decision support capabilities, which shows a significant gap between vendors [31]. Most EHRs focus on patient care and limit the scope of integrated CDS components to medication safety and managing lists of patients with common characteristics. However, standalone CDSSs are continuously evolving [32]. Recent work has demonstrated the feasibility of developing a flexible platform for hosting CDSS outside a specific EHR. The authors estimated that an EHR-agnostic approach facilitated the modification and development of new features because it implies fewer technical challenges [33].

The implementation of new technologies in the PICU settings should be performed carefully. This applies to CDSSs as their potential to improve clinical outcomes depends on how they are implemented in terms of integration into clinical workflow; process fluidity; interoperability and communication with the existing clinical systems; and data collection, analysis, and display. A previous study reported that commercial EHRs lacked features required in pediatric settings and that CDSSs were mostly integrated using home-developed tools in the unit [34].

At Sainte-Justine Hospital, several research initiatives have been undertaken in the PICU to develop CDSSs for specific needs, such as assistance in the automated diagnosis of acute respiratory distress syndrome in children based on various physiological and radiological criteria [35,36], assessment of the quality of head injury care in adherence to clinical practice guidelines [37], early detection of ventilator-associated pneumonia [38], and hypoxemia diagnosis and management [39]. Unlike the commercially available CDSSs, these tools developed at the Sainte-Justine Hospital were based on local clinical needs, adapted to patient characteristics in the PICU, and developed in harmony with the existing infrastructure, including devices, data availability, and access. Using additional tools to address individual problems can cause an excessive burden on clinicians. The integration of these initiatives into a unified structure will benefit both the clinical workflow through centralized information and the patient’s overall care, as each CDSS improves accuracy by targeting specific criteria.

Research Objective

The purpose of this study was to collect and analyze clinicians’ needs in an academic hospital PICU in support of clinical decision-making and establish a data representation structure for easy and quick access to relevant information required for clinical care, depending on patients’ care trajectory. Our goal was to provide a customizable visual tool allowing an overview of the patient’s data depending on their health condition (eg, diagnosis, current problem, and deterioration of the human body system) to reduce information processing time and mental overload for clinicians. This tool serves as a platform for integrating CDSSs in the PICU in response to patients’ specific needs while ensuring that the clinical flow is respected. This was the first step in implementing multimodal real-time CDSSs.

This study was not intended to replace existing clinical tools (eg, EHR, laboratory systems, bedside monitors, and ventilators) because these tools remain essential sources for acquired data and form integral parts of the intensive care unit environment. The EHR represents the core of this technological ecosystem, as it covers the patient’s trajectory from admission until being transferred or discharged. During this time, clinicians (eg, intensivists, nurses, external specialists, pharmacists, and health professionals) use the EHR’s functionalities for different purposes (eg, notes, prescriptions, reports, consultations, patient assessment, and monitoring) and have access to some decision support features, such as alerts for abnormal clinical values, task reminders, prescription aid, and events notification. Although these features help clinicians in their daily work, they do not provide further assistance in specific situations or for variable diagnoses.

In addition, we believe that an independent decision support tool allows for continuous improvement and adjustment while considering local needs. To this end, we encouraged the clinicians’ involvement throughout the study.

Methods

Overview

In our approach to implementing the new CDSS structure, we opted for the standard process of implementing computerized systems, which starts with identifying end users’ needs before beginning the modeling and prototyping phase and then
continues with performing tests to finally allow its integration into the clinical flow [40].

Our work focuses specifically on the first 2 phases of the process: identifying requirements through observation activities and interviews, followed by modeling and prototyping using design meetings. User testing will be covered in future work.

Needs Identification
To identify clinicians’ needs in terms of decision support, we first participated in a day of routine clinical activities at the Sainte-Justine Hospital PICU to understand the general workflow by observing interactions between team members and how they used clinical systems.

Following our observations, we planned interviews with PICU clinicians to understand their workflow and collect data on their needs. We approached the main categories of clinical staff in the unit, including intensivists, fellows, residents, nurses, and nurse practitioners. To achieve the target sample level (>10 participants), we used different communication channels for recruitment, namely email invitations, announcements in weekly journals, and direct contact in the unit.

We enrolled 11 clinicians, including 5 intensivists, 1 fellow, 4 nurses, and 1 nurse practitioner. Semistructured interviews lasting between 30 and 60 minutes were conducted face-to-face or remotely via a videoconferencing platform based on the participants’ preferences and availability. The interviews were recorded and transcribed by the research team. The interview guide was designed to provide an understanding of the use of existing work systems, evaluate participants’ knowledge and familiarity with decision support systems, and identify their needs and expectations regarding CDSS implementation.

Modeling and Prototyping
On the basis of data collected from the observation activities and interviews, we defined a 3-level data representation structure (ie, unit, patient, and system). This provided us with a basis for designing the first prototype. To validate the understanding of this first prototype and the relevance of the integrated functions, we held design meetings with the enrolled participants via videoconferencing. Before these meetings, the participants received a short video explanation with an evaluation survey and interviews, followed by modeling and prototyping using design meetings. User testing will be covered in future work.

needs. We approached the main categories of clinical staff in the unit, including intensivists, fellows, residents, nurses, and nurse practitioners. To achieve the target sample level (>10 participants), we used different communication channels for recruitment, namely email invitations, announcements in weekly journals, and direct contact in the unit.

We enrolled 11 clinicians, including 5 intensivists, 1 fellow, 4 nurses, and 1 nurse practitioner. Semistructured interviews lasting between 30 and 60 minutes were conducted face-to-face or remotely via a videoconferencing platform based on the participants’ preferences and availability. The interviews were recorded and transcribed by the research team. The interview guide was designed to provide an understanding of the use of existing work systems, evaluate participants’ knowledge and familiarity with decision support systems, and identify their needs and expectations regarding CDSS implementation.

Modeling and Prototyping
On the basis of data collected from the observation activities and interviews, we defined a 3-level data representation structure (ie, unit, patient, and system). This provided us with a basis for designing the first prototype. To validate the understanding of this first prototype and the relevance of the integrated functions, we held design meetings with the enrolled participants via videoconferencing. Before these meetings, the participants received a short video explanation with an evaluation survey to introduce the general functioning of the prototype and obtain their initial feedback. Our goal was to engage in interactive discussions with participants during the design meetings. To this end, we used a clinical scenario involving a patient with a severe head injury, and then we asked the participants to perform some tasks, such as sorting the patient list and assessing the patient’s health condition based on the presented data, to use the functionalities available on the prototype and to describe their understanding. Simultaneously, the participants were given the opportunity to suggest improvements for adding, removing, or correcting the represented data. A total of 5 intensivists participated in these design meetings. Depending on their availability, 3 physicians were met individually, and 2 were brought together in the same meeting.

Ethical Considerations
The Centre Hospitalier Universitaire Sainte-Justine Ethics Review Board approved this study (CER-2022-4083), and all participants signed an informed consent form before participating in the study. Consent was obtained in person, either on the first contact or the day of the interview, after receiving a positive response to the mail invitation. All original consent forms were archived at the Sainte-Justine Research Center.

Participants’ personal information (eg, name and email) was saved separately from the study data in a password-protected Excel (Microsoft Corp) file. Personal information was linked to study data using a code for each participant. The data will be kept in a secure directory in the hospital server for 7 years, after which it will be destroyed.

No personal information was used during interviews. Only the participant codes were mentioned at the beginning of the interviews. The recordings were immediately deposited in the secure directory at the end of each interview. Once listened to and transcribed, this file was saved in another folder in the same secure directory.

A CAD $10 (US $7.5) gift card was offered to participants as a gesture of appreciation for their participation.

Results
This section presents the findings from the data collection and analysis as well as the prototype designed to illustrate the proposed structure for clinical data representation.

Description of the Existing Process
The observation activities allowed us to understand the clinical workflow related to team members’ interactions and how they used the existing clinical systems.

Clinical Workflow
Overview
Figure 1 presents a typical day at the PICU. The day usually begins with a handoff meeting (1) between the last medical team and the team taking over during the day, followed by a bedside visit (2) to discuss and validate the patient’s treatment plan. Subsequently, team members performed clinical interventions (3) related to their specific roles and responsibilities before handing over patient information to the next team.
We took time to observe some clinical activities, such as patient information transfer meetings and morning medical rounds.

**Handoff Meeting**

This meeting brought together pediatric intensivists or patrons, and fellows from 3 specialties: general acute pediatrics, called Pediatrics A; chronic pediatrics, Pediatrics B; and cardiac surgery, Pediatrics C. The goal was to assess the medical conditions and illness evolution of inpatients and new admissions to establish a treatment plan for the next 24 hours. Generally, patients were presented, starting with discharged patients, followed by critical or extremely ill patients, and then stable patients. For each patient, a predefined plan covered the body’s systems, including respiratory, cardiovascular, neurological, gastrointestinal, hematologic, immunologic, renal, and metabolic systems, as well as the infectious process, tegument, and musculoskeletal system. Patients were also assessed psychosocially before the medical team concluded the global assessment by proposing a treatment plan.

**Medical Round**

After the handoff meeting, the team began a collaborative round at the patient’s bedside to discuss the patient’s current condition with the nurse in charge. Parents could participate in discussions to complete the information and ask about their children’s condition. Once the discussion was completed, a patient status summary was presented with a proposed treatment plan, including new laboratory or imaging orders, medication adjustments, outpatient referrals, and other diagnostic or therapeutic interventions as needed. Once the plan was approved, a medical team member recorded the assessment summary by creating a new medical progress note in the patient’s record. This note included important laboratory results, vital signs, ventilation, the patient’s global evolution in the unit, and their evolution within the human body systems. For example, the **neurological level** included sedation and comfort assessment data, whereas the **respiratory level** included ventilatory parameters assessment and likely respiratory distress signs.

**Clinical Activities**

After the medical round, clinicians were responsible for executing the patient treatment plan and completing the associated tasks according to their profile and skills. They frequently referred to patient records to review collected clinical data, including nurses’ observations, prescriptions, laboratory results, and notes provided by external consultants such as medical specialists and health professionals (eg, respiratory therapists, physiotherapists, nutritionists, and social workers). In addition, they could access the laboratory and medical imaging systems to analyze detailed examination results. Clinicians must document all interventions in their clinical notes on the EHR. Clinical notes were entered in free text, which meant that the information structure and volume and the terminologies and expressions used differed among clinicians. **Textbox 1** illustrates the variability in the medical progress notes taken while assessing patients with respiratory problems.
Examples of respiratory assessment in medical progress notes from electronic health records in the pediatric intensive care unit at Sainte-Justine Hospital illustrating the formatting variability among clinicians.

**Note 1**
- #Decadran BID (0.6 mg/kg/day) last dose for the day
- Extubation 28/04 AM
- AA
- Minimal desaturation, spontaneous resolution overnight
- Bilateral GAE, no added noise, eupneic
- Venous gas 7.37/47/25
- Last RPL 28/04 improvement

**Note 2**
- # HFNC 20 LPM FiO2 40%
- Sat 90-92% More obstruction than usual
- RR 25-30 no drawing
- Secretory + physio in progress during passage
- GAE bilaterally
- Noise transmitted bilaterally
- No labs

**Note 3**
- # Ventolin IV 3 mcg/kg/min * 7h45 this morning
- # Solumedrol 1 mg/kg q6h
- # Ketamine infusion 0.5
- BiPAP Ai 5 / Peep 8 / FiO2 21%
- Reduced EA, but improving, absence of wheezing
- Indrawing
- 7.4/34/20.8

**Use of Existing Systems**

While observing the clinical activities in the PICU, we learned about the main working tools in the unit. We mainly targeted the TVL (table de visualisation de lits [beds visualization table]) unit dashboard and EHR.

**TVL Unit Dashboard**

TVL is a digital display tool developed in the PICU to evaluate the unit’s capacity to receive patients and the nurses’ workloads. Besides allowing all professionals and families to easily locate a patient, as it is displayed on a large screen at the unit’s entrance, the TVL allows PICU staff to view the patient distribution, depending on the team in charge (Pediatrics A, B, and C), and identify discharged patients and new admissions [41,42]. The tool is based on an architectural representation of the units (Figure 2). It mostly contains unit management information, including (1) the patient room or bed, (2) bedside nurse allocation, (3) the team in charge, (4) room index, (5) waiting patients, (6) PICU patients summary, and (7) the legend indicating the meanings of icons (eg, room, workload, and equipment indications). The TVL contains limited information about the patient’s condition, such as ventilatory mode and circulatory support equipment, which limits its use in clinical care.
Figure 2. Tableau de visualisation de lits (beds visualization table; TVL) unit dashboard displayed at the pediatric intensive care unit (PICU) entry (names are hidden), which presents (1) patient room and information, (2) bedside nurse allocation, (3) the PICU team in charge, (4) room index, (5) waiting patients, (6) patients summary, (7) and the legends.

EHR Tool

Patient records in the PICU were managed using a dedicated critical care system known as IntelliSpace Critical Care and Anesthesia (Philips Healthcare). This system is connected to administrative modules to manage patient admissions, transfers, and discharges. It is also connected to physiological monitors for vital signs, mechanical ventilators for respiratory parameters, intravenous pumps and syringes for drug perfusion and feeding data, the pharmacy for medication prescription management, and laboratory modules for biological examination prescriptions [43]. System interoperability consolidates all clinical data from the connected systems (eg, physiological monitors, intravenous pumps, ventilator, laboratory, and pharmacy systems) into the EHR along with free text clinical notes typed by the clinicians. However, clinicians must search several sections, gather information, and analyze it to assess the patient’s condition and adjust the treatment plan. Therefore, a synthetic representation of patient data is required to guide clinicians, limit cognitive overload, and optimize the time spent collecting information relevant to decision-making.

The EHR is an integral tool and reference for clinicians in the PICU, which is used as a source of clinical data collected continuously from the patient’s environment (eg, bedside monitors and ventilators) and data collected from punctual or recurrent interventions (eg, laboratory examinations). The EHR is also used for data entry purposes to document the patient’s assessment and to add some measured values (eg, Glasgow Coma Scale and Comfort Scale scoring). Although the EHR played an essential role in the clinical workflow, the real challenge remained in the clinician’s ability to trace the required data and process it in due course [44]. Therefore, the development of a visual tool provided a targeted view of the EHR’s content without additional entry tasks for the clinicians.

The first observation phase raised our awareness of the importance of optimizing data representation to support clinicians in patient care. Considering that the EHR was the main clinical tool used in the PICU daily workflow for physicians and nurses and that it gathered data from different sources, we focused more on the information-seeking process in the EHR among clinicians and the potential use of decision support tools in their practice.

Data Analysis

Interviews with participants provided insights into the information-seeking process through existing systems and allowed discussions about decision support systems in terms of familiarity with and clinicians’ expectations of such systems.

Information-Seeking

Table 1 presents the use patterns of clinical systems among participants. To gather information for decision-making, clinicians browsed through different sections in the EHR.

The frequency becomes high when the nurse is assigned a team leader.

Clinical data from physiological monitors, laboratory systems, and intravenous pumps were categorized by body systems. Data were displayed in a set of detailed tables containing values for each category and the results of nursing observations. Clinicians must navigate all the tables to find relevant information for patient assessment. Data were collected in the same way regardless of the patient’s problem, which made it difficult to analyze and process. Considering a case of brain injury, the clinician examined the clinical indicators, including biological examinations obtained from the laboratory system and physiological parameters collected from connected devices such as ventilators and feeding pumps. These indicators were associated with the patient’s condition by going through data categories (eg, neurological, respiratory, and cardiovascular) and then refined information to obtain a synthesis to support their decision, which took time. The EHR also displayed vital signs trends for a certain period. The vital signs were fed directly from the bedside monitors which were connected to the patient. Notably, some clinicians believed that trends could be improved by facilitating access to the graphs when analyzing patient data and by ensuring that abnormal values were quickly detected.

Regarding prescriptions, a dedicated section allowed the display of detailed drug information, such as doses and administration modalities, and tracked current prescriptions or added new ones. Furthermore, the ongoing perfusion and the drug boluses could be tracked in the EHR. The nurses collected the scores and measurements important for patient assessment and entered them in the EHR (eg, the Comfort-Behavior Scale score for intubated patient assessment and delirium and Richmond Agitation Sedation Scale score for neurological assessment).

Regarding clinical notes, their use varied based on need. Admission notes describing a patient’s illness and past medical history were generally viewed when the patient was newly admitted but continued to be important as a reference point for patient outcomes during their stay. Medical progress notes were completed daily by the medical team in charge. Data were entered in free text to describe the patient’s evolution before concluding with a treatment plan. Information entry was redundant and unstructured, which complicated its processing. To monitor patient progress in these notes, clinicians often relied on the conclusion and might also rely on brief notes to learn about reassessments made during the day. External consultant notes entered by other medical specialists and health professionals were displayed in chronological order, allowing clinicians to track them by date. However, clinicians were not notified when notes were added or modified and could not use filters to facilitate searches. This meant that PICU clinicians must repeatedly check the external consultants’ sections for new updates. In addition, they must scroll through the chronological list and search through involved specialties to locate the required note.

Although the EHR gathered the necessary data for patient care, clinicians commonly used laboratory and imaging systems for a complete examination of the test results.
Regarding the TVL dashboard, clinicians used it mostly when starting their work shift to track patients and verify who was in charge (e.g., medical team and bedside nurse). Some physicians used a printed version to organize their daily schedule by taking notes directly on paper, whereas a nurse would use it, especially when assigned as a team leader, to manage the workload and resource allocation. Most of the information integrated into the TVL was not helpful in the clinical care context because it was dedicated to bed management. However, clinicians used it to help plan medical rounds.

Decision Support: Expectations and Needs

Overview

The interviews conducted enabled us to assess participants’ familiarity with the CDSS and determine their expectations with respect to these systems. In Table 2, which presents the main results, it is notable that most clinicians interviewed (8/11, 73%) reported being unfamiliar with the CDSS. Clinicians’ practice experience had no impact on their level of familiarity with the CDSS. An experienced clinician does not necessarily have specific knowledge about the CDSS or its potential use in clinical practice. Among physician intensivists, those with strong knowledge related it to their involvement in research to develop clinical decision support tools. However, we found that even clinicians with little knowledge about CDSS operations could express their expectations and needs, both for their professional development and for the benefit of their patients. For clinicians, using the CDSS would optimize their cognitive decision-making process, facilitate daily work planning and managing information flow during the busiest periods, improve clinical tools efficiency, and reduce the risk of errors and oversights by providing timely and easy access to relevant data. In addition, the CDSS could promote coaching for medical and nursing interns and support newly hired staff members. Regarding patients, the CDSS helped to improve clinical care by personalizing data processing based on the patient’s physiological and pathological characteristics while adhering to scientific recommendations and clinical practice guidelines.

aPICU: pediatric intensive care unit.
bCDSS: clinical decision support system.

To ensure the efficient and successful implementation of a CDSS in their workflow, clinicians insisted on the usability and simplicity of design features while avoiding irritating factors, such as duplication of existing data entry and disruption with highly intrusive alerts. The CDSS must also fit into the users’ workflow and contribute to decisions guided and supported by clinical judgment. This meant that a clinician might find that the guidance or recommendations generated by the CDSS did not align with their conclusions based on prior knowledge and experience. In this case, if the clinician chooses to ignore the CDSS guidance, they must justify the final decision.

On the basis of the collected data, we identified 5 main themes related to clinical decision support needs (Table 3). Furthermore, we highlighted the main objectives and the means to respond to them.

[^b]Data not available.

**Patient Prioritization**

Clinicians expressed a need to prioritize patients according to the severity of their condition and to quickly detect any changes. A participant mentioned the value of rapid assessment of the patient status as follows:

> ...give me a quick view, actually, of whether a patient is stable vs. not stable, or critical, or an alert for a change in situation.

To help clinicians prioritize patients during handoff meetings or medical rounds, we aimed to optimize patients’ visualization with a user-friendly, interactive, and customizable display while adding stability indexes according to the patients’ conditions.

**Patient Assessment and Problem Tracking**

- **Patient portrait:** Clinicians were looking for a synthetic presentation of patient’s data to optimize clinical assessment, as expressed by 1 participant as follows:

> If we would be able to make a patient Dashboard with a synthetic presentation of the different elements. Passing some of the elements that the electronic record should do to us, but that doesn’t do too much and that considers the temporality, that considers these important clinical elements and that are in real time, or at least close.

- **Problem monitoring:** Clinicians must recognize patient problems to guide and facilitate data analysis and monitor patient outcomes. This was highlighted by a participant as follows:

> ...help me more finely, when I’m on rounds or when I’m assessing a patient, help me in my reasoning or in my diagnosis or in my assessment of the patient. At that time, to have a more accurate view of the patient’s condition, for conditions that are complex.

Participants highlighted the importance of monitoring patients according to their condition and early detection of problems, as follows:

> (...)Depending on the pathology of the patient, it would be nice if it was the thing that detects it on its own, if the patient has respiratory distress.
Our goal was to optimize the evaluation of the patient’s current state through a synthetic presentation by selecting relevant clinical information for the patient’s assessment and improving the patient’s progress monitoring in intensive care. The complete clinical data remained accessible in the EHRs for detailed analysis.

**Clinical Indicators Monitoring and Notification or Alert Optimization**

Although EHRs enable monitoring of clinical indicators across several sections, including medical and nursing progress notes, clinicians believed that notes could be optimized with automatic data extraction and updates. One participant stated as follows:

> Notes are worth what they are worth, there are people who write good notes, there are people who don’t write good notes. I think there’s a lot of copy-paste. So sometimes you go back into the notes and you’re going to see the exact same thing at 5 days online in different sections. It’s the conclusion that changes a little bit.

Alerts were also crucial for early detection of changes in the patient’s disease course. One participant said:

> It helps, the little logos come out quicker. It helps identify what’s more abnormal, more quickly.

The goal was to monitor indicators according to the body system or problems associated with the system, maintaining the same structure used in presenting and assessing patients during clinical activities and within the EHR. Customizing notifications facilitated data processing and intervention planning. This could be achieved by opting for simple color codes, avoiding intrusive alerts, and duplicating information.

**Access to Evidence-Based Recommendations**

Clinicians must incorporate evidence-based recommendations and guidelines into their decision-making processes. Easy and standardized access to scientific databases is essential. One participant explained the need for clinical practice guidance as follows:

> I think we could do better, to see the number of variations for a problem is that there’s not a lot of scientific rigor. Could this compensate for things that are done by repetition, by reflex without foundation, and that it would be more supervised or with a better scientific basis? Probably.

The aim was to optimize access to clinical practice guidelines either by integrating the recommendations directly into data analysis through reminders and suggestions or providing direct access to scientific databases.

**Integration of Decision Support Algorithms**

This involved development work to associate knowledge bases with patient data using inference engines or artificial intelligence algorithms. Prediction of patient condition deterioration, diagnosis support, prescription support, and sedation weaning were among the main expressed needs.

These algorithms aimed to guide clinical decision-making. Their integration could be performed at diagnostic, therapeutic, and preventive levels. This study aimed to provide a structure susceptible to accommodating new algorithms and decision support features. Therefore, according to the first reflections, we intended to associate these algorithms with body systems or the patient’s problems.

**Data Structure**

To structure emerging elements while adapting data representation to the clinical workflow, we opted for a 3-level system structure (Figure 3). These levels mainly reflect the first 3 identified themes, whereas the themes related to clinical practice guidelines (#4) and decision support algorithms (#5) can be attached to different levels, depending on the context of use and the problem being addressed.

**Figure 3.** The resulting structure for data representation in the pediatric intensive care unit (PICU) with 3 levels of abstraction. CDSS: clinical decision support system.
1. **Unit level (patient prioritization):** The first level provided a global view of patients in the PICU, with various display modes allowing efficient management of patient lists and easy identification of those who were unstable and helping to plan bedside activities. Adding stability indices helped to categorize and prioritize patients based on their condition severity.

2. **Patient level (patient assessment):** For each patient, clinicians could access this second level to obtain a quick overview of the patient’s condition and better understand the underlying cause of their instability. The patient’s synthetic presentation allowed clinicians to assess the patient’s status based on current problems and probable complications and to track important events. Eventually, incorporating guidance and evidence-based recommendations would be pertinent at the second and third levels.

3. **System level (indicator monitoring):** The third level was intended to align with the clinical flow by assessing patients according to their body systems (e.g., neurological, respiratory, cardiovascular, renal, gastrointestinal, hematological, immunologic, infectious, and musculoskeletal tissue systems). This allowed monitoring of the degree of alteration of the system based on associated clinical indicators. Moreover, this level aimed to integrate clinical decision support algorithms developed in response to specific problems (e.g., evaluation of head trauma management associated with the neurological system).

**Prototype Design**

**Overview**

Using the defined structure for clinical data representation, we designed interfaces corresponding to the 3 levels of the structure. Subsequently, design meetings allowed us to adapt the design and integrate, early in the process, the necessary adjustments to meet the end users’ needs. This section presents the design and adjustments of the prototype. Each interface included a targeted functionality in response to the objectives of the associated level.

We used a brain injury care scenario to illustrate the functioning model of the preliminary prototype, knowing that a patient with a severe traumatic brain injury requires attentive monitoring that involves clinical data from different devices (e.g., mean arterial pressure, oxygen saturation, temperature, end-tidal carbon dioxide, and brain tissue oxygenation), laboratory results, ongoing sedation, and medication treatment, along with the interpretation of imaging examinations. To assess the patient’s status and, therefore, adjust their care plan, clinicians should be able to categorize the patient according to a severity scale, identify whether there is a risk of deterioration (e.g., ischemia and hyperemia), define optimal mean arterial pressure in the context of brain injury, and quickly recognize abnormal values depending on the patient’s profile. We expected that this would help clinicians to focus on pertinent details and support the prediction of changes in the patient’s condition.

**Unit Level**

The objective of this level was to visualize all inpatients in 2 display modes and introduce the concepts of stability and system alteration.

The list-mode display (Figure 4) allowed clinicians to select patients by service (Pediatric A, B, or C) or to create their personalized list (My Patients) by adding patients under their responsibility. Every patient on the list was identified with a bed number, name, age, weight, length of stay, and diagnosis. It also included scheduled tests or procedures that required off-unit transportation to assist the clinician in scheduling bedside interventions. Stability indices were added to help clinicians prioritize patients and plan their interventions for the day. These indices included a list of altered body systems and the status to categorize patients according to their conditions: critical, watcher, stable, or discharged. We used red alerts to indicate a severe alteration or criticality level and orange alerts to indicate a moderate level.
**Figure 4.** Level 1 interface in the preliminary prototype: patients list. This figure includes lists management (1.1.1), patient identification (1.1.2), and stability indices (1.1.3).

Furthermore, level 1 provided an architectural view of the unit (Figure 5) inspired by the TVL, which was adapted to assist clinicians in planning medical rounds and bedside interventions. Clinicians could customize the display to view their patients or all inpatients.
Figure 5. Level 1 interface in the preliminary prototype: unit architectural view. This figure includes color-coded boxes for patients according to their stability (1.2.1), the team in charge (1.2.2), medical team location (1.2.3).

The stability indicators displayed observed the same color code for the boxes: red for the critically ill and orange for less acuity. This view allowed us to see the list of available caregivers with their contact numbers and the nurses responsible for the patient’s bedside. Notably, geolocation of the team’s location during medical rounds could help plan clinical interventions. For example, a clinician who needed to join the medical round for a specific patient could check this interface to plan his or her next tasks to match the team’s arrival at the patient’s bedside.

To assess a specific patient, clinicians could select the patient from the patient list or switch to the TVL view and access synthetic data presentation at the second level.

Patient Level

Continuous monitoring of inpatient progress was central to clinical activities in the PICU. Therefore, the patient level (Figure 6) was incorporated into the prototype design to facilitate the evaluation of the patient status and progress during their stay in the unit. The second level provided an overview of the patient’s active problems and likely risks based on monitoring relevant indicators.
Clinicians could easily return to their personalized lists and search for patients. Color-coded notifications indicated the number of critical patients (red) and watcher patients (orange). The patient identification zone included demographic data, initial diagnosis, and length of stay in the unit. The same zone displayed vital signs in real values, with possible access to trends observed in the last few hours. The left menu allowed quick navigation between levels 1 and 2 and through the body systems at level 3. This interface provided information about the patient’s primary diagnosis, with the last revision date, and allowed clinicians to access a direct link to the UpToDate (Wolters Kluwer) knowledge base [45], which was widely used for medical decision support. Secondary pathologies and patient history were also listed and allowed sorting by body systems. Furthermore, active problems were displayed and an interpretation of abnormal indicator values were provided, with reminders for target values, to facilitate the recognition of the patient’s problems. Finally, problems under surveillance were shown to guide clinicians in patient care by targeting probable complications. Decision support systems could be incorporated into this level and connected to a patient’s problem. For example, a patient with respiratory failure (a medical problem) could have a CDSS for the early diagnosis of acute respiratory distress syndrome [36] and another for the management of mechanical ventilation if diagnosed with acute respiratory distress syndrome [46]. This level allowed the tracking of significant events, such as procedures performed in the operating room, specific investigations, and consultant visits. When needed, clinicians could search for additional information by directly accessing clinical applications and systems, which could be related to prescription history, treatment plans, or recent imaging or laboratory tests.

Clinicians could visualize clinical indicators on the third level to closely monitor these indicators related to patient problems (refer to system level section).

**System Level**

The third level (Figure 7) was designed to display groups of indicators related to human body systems and to access decision support tools developed for specific problems involving these systems. Our goal was to prioritize indicators to be monitored based on body system alterations while retaining the ability to add indicators from other systems to refine clinical decisions. In Figure 7, we included indicators of the brain injury care scenario and added a visualization tool to assess clinician adherence to the clinical practice guidelines. The development of a visualization tool will be subject to further research.
The personalized patient list could also be accessed at this level. The patient identification zone included demographic data, initial diagnosis, length of stay in the unit, and data related to patient progress in the care trajectory. For a head injury, clinicians could assess the global adherence to clinical practice guidelines and follow, through trends, changes in the patient’s neurological status and Glasgow score. This zone also provided access to the last computerized tomography scan performed. As in the previous level, the navigation menu allowed users to browse between different levels and different systems at the third level. Altered systems were easily identified using simple color-coded signs (e.g., red for highly severe indicators and orange for less severe indicators). The first group contained specific indicators related to the neurological system; this area allowed clinicians to evaluate adherence to guidelines for brain injury indicator monitoring and management. Abnormal values were systematically displayed, with access provided to trends observed in the last few hours. Furthermore, clinicians could view trends in normal indicators or add other neurological indicators not directly related to head injury care. The interface also allowed users to view indicators belonging to other systems but related to the patient’s problem. For example, surveillance of a patient with a head injury is not limited to neurological indicators but covers variable indicators, such as cardiovascular and respiratory indicators. Other groups were included for bedside monitoring. In addition, the interface enabled data display by date or time range to optimize clinical indicator monitoring.

**Discussion**

**Principal Findings**

In this study, we took the first steps to develop a decision support structure that responds to clinician needs in the PICU. We analyzed the existing situation to evaluate current needs, which led us to develop a 3-level data representation structure, with the first level aimed at prioritizing inpatients based on the severity of their conditions, the second level providing an overview of the patient’s condition and evolution, and the third level allowing close monitoring of clinical indicators related to a specific problem or human body system. From this perspective, the third level was intended to support CDSS integration as developed in response to specific care management needs related to the patient’s condition. In subsequent steps, there will be a testing process involving end users to validate the usability and performance of the designed prototype.

---

**Figure 7.** Level 3 interface in the preliminary prototype. The model includes access to personal list (3.1), patient identification and system global indicators (3.2), navigation menu (3.3), system indicators (3.4), problem-related indicators from other systems (3.5), additional indicators (3.6), and indicators evolution (3.7).
Our goal was to create a system based on the proposed representation and eventual CDSS integration. It is important to note that this system is not intended to replace EHRs designed for documenting patient care or any other existing systems. However, its use should help clinicians prioritize their interventions according to patient’s needs, which could be applied to the handoff meetings while discussing inpatient conditions and planning next-shift interventions. Furthermore, the tool could optimize clinicians’ cognitive processes by readily accessing relevant information when needed, such as for patient presentation during medical rounds, for fast checks on patient status and detection of any changes. In addition, the display of the clinical indicators could be personalized to suit the user’s preference and optimize clinical monitoring by allowing an adequate and efficient classification of indicators either by the human body system or by patient problem, which helps to contextualize data evolution.

Limitations

Although the features presented in the Principal Findings Section are generally appreciated by the clinicians, they, nonetheless, remain prudent regarding the following concepts. The first concept is patient criticality assessment, knowing that criticality could be linked to variable factors, such as a combination of a patient physiological profile, care required, and intensity of that care [47], perception related to patient prognosis, illness progression and response to treatment [48], and severity scores used to measure deviations observed in certain groups of physiological variables [49]. The second concept is problem progression, which could be difficult to track because information at the start and end of a problem is not always accurate. Although a change is usually identified by a deviation from normal or expected values, it ultimately depends on the patient’s progress in their care trajectory [50]. The third concept is that some problems affect multiple body systems and certain specific indicators related to such problems [51]. This requires classifying the indicators by problem and defining abnormal variations for each indicator according to the patient’s physiological and pathological profiles. For example, the mean arterial pressure indicator is related to the cardiovascular system, but for a patient with a head injury, this indicator directly affects cerebral perfusion; therefore, its monitoring is also linked to the neurological system. Furthermore, the thresholds for this indicator may vary with the patient’s age and illness history.

Clinical judgment is crucial for patient assessment and decision-making in critical care. This judgment varies among clinicians and relies on each clinician’s ability to synthesize relevant clinical data, which is not easy to model.

Analyses of these factors will eventually help us to optimize our data representation model in terms of the connections between problems and human body systems. In addition, identifying the factors that influence the progression of problems will help in predicting the deterioration of a patient’s condition and preparing an appropriate intervention.

In our study, we initially envisaged a sample of 30 participants (6 physicians, 4 fellows, 3 residents, 2 specialized nurse practitioners, and 15 nurses) to have a better representation of the targeted population. However, the desired sample was not achieved owing to the limited availability of PICU staff and their high workload during the project period, which was during the Covid-19 pandemic. A total of 11 participants could participate in the interviews. Only 5 (45%) physicians participated in the design meetings during the second phase of the project.

Through the design meetings, we could improve the prototype design. However, we were unable to test the final version with the clinicians. Therefore, we intend to conduct usability tests afterward to identify potential issues and ensure that end users are satisfied with the resulting prototype. Future work should also investigate the integration of the prototype into the clinician’s workflow. Although the prototype intended to synthesize relevant clinical data from other sources into a consistent view, it could increase the clinician’s workload by adding another technological tool to consult the patient’s condition. This requires careful consideration of the tools’ interoperability to follow the clinician’s role.

Conclusions

This study provided a clinical data representation structure to support PICU clinicians in their decision-making process and to assist them in optimizing inpatient care management.

An observation of clinical activities and interviews with participants allowed us to identify the current needs for decision support. Through an analysis of collected data, we created a structure with 3 levels of abstraction to facilitate patient prioritization, assessment, and monitoring. A prototype was designed based on the main structure and then presented to the participants to obtain feedback for improvement.

Notably, the functionalities integrated into the prototype mainly met the clinicians’ expectations regarding information relevance and classification. Adjustments were made to the data representation following the design meetings with the participants. However, further tests will be conducted to ensure the tool’s usability.

To enable the deployment of the proposed decision support structure and its integration into the clinical workflow in the PICU, further analysis and development are needed to establish patient stability indices, automate problem recognition, and define the indicators associated with each body system and the respective alteration thresholds.

Acknowledgments

The authors would like to express their gratitude to the Centre Hospitalier Universitaire Sainte-Justine and the Centre Hospitalier Universitaire Sainte-Justine Research Center for their valuable support and to the caregivers for their participation. Furthermore, the authors would like to thank Cecilia Buratti and Nadia Roumeliotis for their assistance.
No generative artificial intelligence tool, including ChatGPT (OpenAI Inc), was used to draft questions for the interview guide or to write the manuscript.

This study was funded by a chair from Sainte-Justine Hospital and the Ministry of Health of Quebec (PJ) and a cochair from Fonds de Recherche du Québec Santé (RN and PJ). PJ earns a salary from Fonds de Recherche du Québec Santé.

Data Availability

Data sharing is not applicable to this study as no data sets were generated or analyzed during this study.

Authors’ Contributions

NY performed the data collection. SL and NY performed the prototype and design validation with participants. PJ, RN, and PDP supervised this project. NY drafted the manuscript. The paper was thoroughly reviewed by all authors, and they approved the final submitted research manuscript. They also assumed complete accountability for their contributions and ensured the academic integrity of their work.

Conflicts of Interest

PJ received salary from the ministry of Health of Quebec, Fonds de recherche en Santé du Québec and Ste-Justine Hospital to conduct the research and to finance the research.

Abstract

Background: Novel internet-based applications and associated technologies have influenced all aspects of society, ranging from commerce and business to entertainment and health care, and education is no exception. In this context, this study was designed to evaluate the impact of a dermatology e-learning program on the academic performance of medical students in dermatology.

Objective: The aim of this study is to develop a dermatology blended-learning course for undergraduate medical students, evaluate the knowledge gained by students exposed to this course, and compare the results to those of traditional teaching methods.

Methods: In this prospective study, we evaluated the performance of fourth-semester medical students at the Federal University of Bahia, Brazil. Students who had been in their second year of the medical course in 2019 were considered the control group, while students in their second year in 2020 were considered the blended or hybrid group. The first group attended traditional classes, using printed material (books and handouts), while the second group used our web-based course and e-book as a supplement in a hybrid web-plus-traditional fashion. Neither participants nor evaluators were blinded. The students in both groups were subjected to the same pre- and postcourse face-to-face, multiple-choice, paper-based evaluations, and we compared their performances. The content of the classes was the same for both groups. All didactic activities were developed by a team of certified dermatologists and professors from the university.

Results: A total of 129 students were selected and divided into 2 groups: the control group (n=57) and the hybrid group (n=72). The precourse tests did not indicate any difference between the control group (mean score 2.74, SD 1.25) and the hybrid group (mean score 3.2, SD 1.22 SD; P >.05). The hybrid group had better final-term grades (mean 8.18, SD 1.26) than the traditional group (mean 7.11, SD 1.04). This difference was statistically significant (P <.05).

Conclusions: This study explores pedagogical possibilities in the field of dermatology teaching for medical school students. The results suggest that the performance of undergraduate students who attended the course with additional e-learning material was superior when compared to the performance of those who participated in the traditional course alone.

Introduction

During medical school, dermatological teaching in various countries, including the United Kingdom, is usually restricted [1,2]. Students are exposed to the topic as part of short-term internships or as an optional discipline [1,2]. In some institutions, dermatology disciplines are not even offered [1,3]. Published surveys in different countries have demonstrated that
the amount of time devoted to dermatology in the medical student curriculum represents only 0.24%-0.3% of the 4 years of study [1]. In the last few years, even after curricular reformulation, the time devoted to teaching dermatology has decreased or remained the same [4-6]. McCleskey et al [4] found that only 10% of medical schools require a clinical dermatology rotation and that 93% of institutions offer dermatology as an elective rotation, usually a 4-week clerkship.

The current available time for dermatology training in medical schools worldwide is insufficient to learn about the various cutaneous diseases that students are likely to encounter in their future medical practice [5,7]. In view of this reality, the use of technologies that are able to optimize learning in dermatology has a great impact.

A meta-analysis evaluating the efficacy of educational interventions that improve diagnostic dermatological skills found that a blended curriculum that integrates multiple modalities of clinical dermatology teaching may be the most effective approach to meeting learning objectives [3]. The results observed by Lujan and DiCarlo [8] showed that first-year medical students learn through a variety of learning styles, with only 36.1% preferring a single way of acquiring new information. In recent years, we have noticed a growing interest among researchers in using new technologies to improve medical education [9-11]. The use of e-textbooks, podcasts, anatomical models, and virtual and interactive 3D computer models has positively impacted the educational experience of medical students [9]. Students exposed to interactive technology tools during their learning period demonstrate significant improvement on their performance tests [11].

Despite existing evidence that web-based teaching tools associated with interconnected content, when carefully selected, can assist the learning process, conventional teaching methods are still mainstream in medical teaching [12-14]. Teaching is mainly conducted in the form of hall lectures and laboratory sessions [1,12]. Despite large investments, there is a lack of sufficient evidence to support the effectiveness of digital interventions in the education of health professionals [15].

This study explores some pedagogical possibilities in the field of dermatology teaching for medical school students. It evaluates the use of web-based tools and an e-book developed specifically for this purpose, explores their impact on medical students’ learning, and compares this form of learning with traditional learning.

**Methods**

**Overview**

In this paper, we analyze the impact of web-based teaching tools on the performance of medical students at the Federal University of Bahia (UFBA), Brazil, and compare the results with those of traditional learning. Hence, we conducted a prospective study including medical students with computer literacy in the fourth semester at UFBA who were studying dermatology between June 2019 and June 2020. All the content was set in and developed in Brazil.

Students who had been in their second year of the medical course in 2019 were considered the control group, while students in their second year in 2020 were considered the blended group. The students were randomly allocated into the control or blended groups, and neither participants nor evaluators were blinded. All didactic activities were developed by a team of certified dermatologists and professors from UFBA.

All students participated in face-to-face activities. The classes included patient care in a general dermatology outpatient clinic. During the care, dermatological physical examination findings were emphasized, and the students were instructed to identify patients’ skin lesions and describe them according to the teaching material provided.

In the control group (traditional learning), after treating patients, students participated in an expository class structured into eight modules: (1) semiology, (2) leprosy, (3) syphilis, (4) atopic dermatitis, (5) skin virosis, (6) pyodermitis, (7) superficial mycosis, and (8) skin cancer. Doubts about the modules were clarified on this occasion.

The hybrid activities were composed of 5 distinct stages. In the first stage, we made a photographic record of patients who had dermatological lesions during a medical consultation held at the dermatology outpatient clinic at UFBA. In the second stage, we wrote a book (Manual of Dermatology [16]) using the cases cataloged in the first stage. During the third stage, we planned and prepared the web-based course according to predetermined modules. For each module, a video lesson was made available, lasting an average of 30 minutes, and the Camtasia (TechSmith) program was used for this activity. The video lessons were formatted and published on the Moodle (Moodle HQ) platform. The fourth stage comprised an e-learning module that included an 8-week course administered simultaneously with face-to-face classes.

The students in both groups were subjected to the same pre- and postcourse face-to-face evaluations, and their performances were compared. A total of 40 multiple-choice questions were written in accordance with the recommendations of the National Council of Medical Examiners to compose the pre- and postcourse exams [17]. To evaluate the validity of the content, 2 independent dermatologists examined all questions. The subject of the tests was chosen in accordance with the British Association of Dermatologists’ Undergraduate Curriculum [18].

Students in the control and hybrid groups received identical evidence-based content, and the courses had the same 8-week duration. The e-learning course was developed using the open-source Moodle learning management system.

Students logged in using individual usernames and passwords. A new text, video, and web-based discussion forum that addressed the same content as the face-to-face classes was available each week in an asynchronous mode. The students received weekly email notifications that a new class was available. In addition to face-to-face communication, students in the hybrid group could receive feedback on the discussion boards or by sending direct messages to the tutor. A 40-question multiple-choice test was given to all students in both groups before and after the courses, with scores ranging from 0 to 10.
In the fifth stage, we analyzed the results using Stata (version 13.1; StataCorp) and Microsoft Excel (version 2007; Microsoft Corporation). Initially, the studied variables were evaluated in a descriptive manner, with the data presented as mean (SD) or median (IQR). The Shapiro-Wilk test was used to test normality. Pre- and postcourse scores obtained for each group were compared (intragroup comparisons). The results obtained in the pre- and postcourse tests were also compared between the control and hybrid groups (intergroup comparisons). According to the normality test, a 2-tailed paired t test, or Wilcoxon signed rank test, was applied for intragroup comparisons and a 2-tailed t test, or Mann-Whitney U test, for intergroup comparisons. The internal consistency of the pre- and postcourse assessments was evaluated using Cronbach α coefficients.

Ethical Considerations

This study was approved by the Ethics Committee of the UFBA (1688.502) and conducted in accordance with the Declaration of Helsinki. Informed consent was obtained from all students. This work was not supported by any funding or external support, and no artificial intelligence resources were used.

Results

A total of 129 students were included in this study. The average age was 23 (SD 1.3) years, and 62 students were male. No significant differences were found between the 2 groups in relation to sex and age. The control group (n=57) used traditional classroom paper-based tool activities, while the hybrid group (n=72) used our e-learning course and e-book made specifically for this course in a hybrid web-plus-traditional fashion. Demographic data per group are presented in Table 1. All participants completed the study. The mean pretest score for the control group was 2.74 (SD 1.25) and for the hybrid group, the mean pretest score was 3.2 (SD 1.22; P>.05). The final posttest mean score was 7.11 (SD 1.04) for the control group and 8.18 (SD 1.26) for the hybrid group. The intragroup comparisons of pre- and postcourse scores obtained for each group were statistically significant (P<.05).

Table 1. Demographic data.

<table>
<thead>
<tr>
<th>Course</th>
<th>Male, n (%)</th>
<th>Female, n (%)</th>
<th>Age (years), mean (SD)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Hybrid group (n=57)</td>
<td>27 (47)</td>
<td>30 (53)</td>

</tr>
<tr>
<td>Control group (n=72)</td>
<td>35 (49)</td>
<td>37 (51)</td>
<td>22 (1.3)</td>
</tr>
</tbody>
</table>

Intergroup comparisons of the pretest scores demonstrated that there was no significant difference between the control and hybrid groups (P>.05), indicating that the baseline knowledge for each group was comparable (Figure 1). The results indicated increased scores in the hybrid group, implying the hybrid delivery method outperformed the traditional approach. A statistically significant difference in the postcourse scores between the 2 groups was achieved.

Discussion

Overview

The results of this study expand earlier findings on how hybrid learning can enhance learning outcomes in medical education. Moreover, this model was found to increase the effectiveness of teaching and learning methods in improving knowledge acquisition, which is consistent with the results of several other studies.

Although dermatology is essentially a visual specialty with great potential to benefit from today’s digital technologies, the conventional way of teaching still prevails [13,19]. At our university, medical education follows a traditional lecture-based curriculum, and this was the first time that digital technology was used. Nearly all aspects of web-based education were new and had to be understood [20]. We know that e-learning offers medical schools powerful and flexible learning resources [21] and presents several advantages, including (1) increased monitoring of student progress in a simpler and more accurate manner [8]; (2) the possibility of watching classes several times at more convenient times and places [8]; and (3) allowance for more than one way of student-teacher communication by means of emails, chats, and online discussion forums [22,23]. This last point is an advantage from the students’ point of view—although it may come at the expense of teachers’ time, as it has the potential to consume more of their time when compared with classroom teaching alone (where teachers are only available during class time or office hours) [13,23]. Web-based teaching also allows medical training to continue even in difficult situations (eg, the COVID-19 pandemic), and the greatest benefit is the flexibility offered by teaching platforms [24].

While e-teaching has real advantages, as discussed above, it also comes with some drawbacks. For example, this method does not support direct contact with the teacher or the patient, which may limit the observation of certain diseases and their diagnosis. Moreover, the method is dependent on the availability of electronic devices with adequate internet access [9] and needs a highly educated, motivated, and expert core team of teachers [18]. Silva et al [13] found the same challenges in web-based courses and described a significant technical difficulty in producing educational material for distance learning. The authors also highlighted great difficulty in facilitating students’ engagement with each other and in assessing the acquisition of practical skills in dermatology.

The provision of high-quality e-learning is highly labor-intensive. Like Fordis et al [25], we realized that the work spent on making web-based activities was more challenging than face-to-face teaching, especially when considering the design, organization, delivery, and engagement of participants in the discussion. A combination of both methods appears to be the best strategy [22,23,26]. In this study, these limitations were circumvented, as face-to-face activities were performed in both groups, and the students were given face-to-face contact time with both the teacher and patients seen at the clinic. Although some individuals report visual discomfort and others prefer reading a print book, both this study and the literature support the use of e-book technology in modern medical curriculum as an adjunct to traditional methods [9].

In this study, the full e-book content was available for download and could be accessed at any time, regardless of internet access. One of the main concerns about the switch to web-based lectures is the possible difficulty of lengthy readings on a screen and students’ ability to focus on reading. There is a great advantage to reading on the screen of an electronic device, as it allows for an increase in the font and size of the image, which facilitates assimilation of the content and helps individuals with reading difficulties [9]. Singer and Alexander’s [27] results indicated a clear preference of their participants for digital texts, as they generally achieved a better understanding when reading digitally [27]. However, the higher degree of satisfaction on the part of the student was not necessarily compatible with the results obtained in subsequent evaluations [24]. The vast majority approved the use of new technologies for dispensing the dermatological subject, and there were no complaints about this approach in this study.

It is currently believed that although reading on a computer screen may be more superficial and occasionally less accurate, it is the quality of the image presented to the reader that is crucial for the best use of the reading book [9]. Although there was a greater gain in knowledge in the group exposed to the distance e-learning associated with our e-book, some considerations must be made regarding the limitations and difficulties found in this study.

First, the evaluation was conducted in just one institution; ideally, more studies in multiple teaching centers with different realities from ours would be necessary for e-learning to consolidate itself as an effective form of education. Second, since the e-book was written especially for medical students, it is possible that its content made knowledge more accessible and didactic to the hybrid group, whereas the traditional group had to use renowned but conventional dermatology books. Third, we must mention the fact that the students in the traditional group spent 1 hour less per week on practical activities, totaling a reduction of 8 hours from their on-site internship due to the period spent in the in-person theoretical classes. Thus, students in the hybrid group received 8 hours more exposure to practical classes since the theoretical classes were attended at home. This difference may have favored the hybrid group in relation to obtaining better grades. In addition to better grades, increasing the time exposed to the discipline is one of the goals we strive to achieve in dermatological education.

The participants in the 2 groups had different admission years and were asked to maintain the contents and evaluations of the class confidential; however, we did not check for contamination between the 2 groups.

The field of education is destined to evolve. The professor is not the ultimate gatekeeper of definite knowledge; they also learn from students and need to incorporate feedback into the curriculum [28]. Despite this, the highest-quality clinical dermatology education will always require guided clinical exposure and feedback [18]. Innovative technologies cannot replace the need for enthusiastic and knowledgeable clinical teachers [1,28].
Conclusion
This study explores pedagogical possibilities in the field of dermatology teaching for medical school students. The results suggest that the performance of undergraduate students who attended the course with additional e-learning material was superior to the performance of those who participated in the traditional course alone.

Data Availability
The data sets generated during and/or analyzed during this study are not publicly available due to privacy or ethical restrictions but are available from the corresponding author on reasonable request.

Authors' Contributions
CSS developed the web-based course, including an e-book and web-based classes; compiled the bibliography; and wrote the manuscript. CV developed the project and reviewed the paper. MBS participated in the creation of the web-based course and performed the statistical analysis of the data. JDF and VRPDAR helped write the book chapters, develop the web-based classes, and review the manuscript.

Conflicts of Interest
None declared.

Abstract

Background: Chronic pain is one of the most common and critical long-term effects of breast cancer. Digital health technologies enhance the management of chronic pain by monitoring physical and psychological health status and supporting pain self-management and patient treatment decisions throughout the clinical pathway.

Objective: This pilot study aims to evaluate patients’ experiences, including usability, with a novel digital integrated health ecosystem for chronic pain named PainRELife. The sample included patients with breast cancer during survivorship. The PainRELife ecosystem comprises a cloud technology platform interconnected with electronic health records and patients’ devices to gather integrated health care data.

Methods: We enrolled 25 patients with breast cancer (mean age 47.12 years) experiencing pain. They were instructed to use the PainRELife mobile app for 3 months consecutively. The Mobile Application Rating Scale (MARS) was used to evaluate usability. Furthermore, pain self-efficacy and participation in treatment decisions were evaluated. The study received ethical approval (R1597/21-IEO 1701) from the Ethical Committee of the European Institute of Oncology.

Results: The MARS subscale scores were medium to high (range: 3.31-4.18), and the total app quality score was 3.90. Patients with breast cancer reported reduced pain intensity at 3 months, from a mean of 5 at T0 to a mean of 3.72 at T2 (P=.04). The total number of times the app was accessed was positively correlated with pain intensity at 3 months (P=.03). The engagement (P=.03),
information ($P=.04$), and subjective quality ($P=.007$) subscales were positively correlated with shared decision-making. Furthermore, participants with a lower pain self-efficacy at T2 (mean 40.83) used the mobile app more than participants with a higher pain self-efficacy (mean 48.46; $P=.057$).

**Conclusions:** The data collected in this study highlight that digital health technologies, when developed using a patient-driven approach, might be valuable tools for increasing participation in clinical care by patients with breast cancer, permitting them to achieve a series of key clinical outcomes and improving quality of life. Digital integrated health ecosystems might be important tools for improving ongoing monitoring of physical status, psychological burden, and socioeconomic issues during the cancer survivorship trajectory.

**Introduction**

In 2040, it is expected there will be approximately 26 million new cancer survivors in the United States, underscoring the growing importance of survivorship [1,2]. Mullan [3] defined survivorship as a process characterized by 3 different stages: acute survival, from diagnosis to active treatments; extended survival, from treatments to active-surveillance; and permanent survival, in which the probability of recurrence is low. As suggested by Mullan’s definition, cancer survivorship is a complex, multistep, dynamic process characterized by evolving needs and challenges. Pain, fatigue, and psychological distress (eg, anxiety, depression, worry, and fear of cancer recurrence) are typical long-term effects that deleteriously affect survivors’ engagement in work, personal, and social activities [4-6]. In particular, one of the most common and critical long-term effects of cancer in survivors is chronic pain. It has been linked with several physical, psychological, and socioeconomic sequelae. A study by Jiang et al [1] stated that, of 4526 cancer survivors, around 34.6% reported chronic pain, and 16.1% conveyed that it limited daily life and work activities. Notwithstanding, chronic pain throughout the survivorship trajectory is undertreated and untreated [5,7,8]. Since chronic pain affects the quality of life (QoL) of patients with breast cancer [9], it is essential to design, test, and implement patient-driven interventions [10] that enable ongoing monitoring of physical and psychological health status, from the “hospital to the patient’s home,” and support pain self-management and patient treatment decisions throughout the entire clinical pathway. This might be particularly important in extended and permanent survivorship, reducing the risk of cancer survivors exiting the care system [5].

A growing body of evidence has shown that using digital health technologies integrated into dynamic ecosystems enhances the management of chronic pain by assessing patients’ physical health and psychological well-being and providing tailored interventions [11]. Digital health technologies aim to integrate various digital tools and technologies, including patient electronic health records, telemedicine, wearables, and mobile apps, into the health care system [12]. Overall, digital health technology encompasses both eHealth, which involves the use of the internet and related technologies to enhance health care systems through information and communication technology [13,14], and mobile health, which focuses on health practices supported by mobile devices [15]. The widespread use of digital health technologies has opened an innovative “window of opportunity” for managing chronic pain in a more personalized, accessible, and patient-centered way [8]. Evidence has highlighted that digital health technologies are valuable solutions for remotely collecting patient health data (eg, using patient-reported measures or wearable devices), improving symptom management, and decreasing patient appointments and hospitalizations [16]. Jongerius et al [17], in a systematic review, highlighted that digital health technologies are used in cancer clinical practice for the following different reasons: to stimulate the adoption of preventive behaviors, to increase early cancer identification, to manage cancer care, and to provide assistance to cancer survivors. Overall, digital health technology supports patients and the health care system to achieve several critical outcomes for better cancer clinical management [17-19]. For example, Zhu et al [19] reported that an app-based program named “Breast Cancer e-Support” was able to decrease symptomatology related to anticancer treatments and therefore improve self-efficacy and QoL... In addition, Maguire et al [20] designed and tested ASyMS (Advanced Symptom Management System) for the management of chemotherapy toxicity; it not only enables the evaluation and monitoring of patient symptomatology related to anticancer treatments but also provides tailored and evidence-based recommendations to manage symptoms [20].

Considering the specific case study of chronic pain in cancer survivorship, digital health technologies enhance access to nonpharmaceutical interventions; address pain-related mobility issues; improve patient networking and connections; foster self-management, self-efficacy, coping, and patient engagement; and facilitate communication among health care professionals of various specialties (eg, physicians, nurses, physiotherapists, psychologists) [18,21,22]. For example, Ranney et al [18] described that 89.5% of patients with chronic pain reported using digital health tools (eg, websites to search for health information, social media, and mobile apps), and such usage is associated with improved chronic pain coping mechanisms.

Different digital health technologies have been designed to manage cancer and pain in the clinical pathway [23]. For example, an educational digital intervention called the “Pain...
Education after Cancer Collaborative” (PECAN project) was developed for survivors of breast cancer; in the intervention, a decision tree system is used to provide tailored educational information to cancer survivors based on their answers to specific queries [24]. In addition, a Mobile Pain Coping Skills Training Protocol has been proposed to support patients’ understanding of the pain experience and strategies to cope with the pain [25]. More generally, Hauser-Ulrich et al [26] recently developed a text-based chatbot named “SELMA” (PainSELFManagement) aimed to booster self-management of chronic pain in different types of diseases, supporting health care professionals in the delivery of evidence-based interventions. Moreover, digital health technologies could encourage patients to be more involved in their treatment decisions, through the implementation of specific decision aids [16,27-29]. Studies have stressed that the implementation of tailored decision aids in mobile apps increases patients’ awareness about treatment preferences (eg, pharmacological vs nonpharmacological treatments), reduces decisional conflict, and enhances adherence to treatments [30-32].

Even with the key role of digital health technologies in the cancer clinical pathway, few studies on digital and integrated health ecosystems are currently available [33]. Consequently, in this pilot study, our primary endpoint was the usability of the novel digital integrated health ecosystem, PainRELife, for managing and monitoring chronic pain in patients with breast cancer throughout the survivorship trajectory. Further, we aimed to evaluate the PainRELife ecosystem’s effectiveness at enhancing pain self-efficacy, improving shared decision-making, and reducing pain perception as secondary endpoints. The PainRELife ecosystem stands out as the first to seamlessly integrate all the essential components required for comprehensive pain management within a single platform. This includes features such as pain monitoring, physical and psychological assessment, e-diaries, exercises, educational resources, and decision aids. Furthermore, it incorporates a dedicated platform for health care providers and a robust big data cloud infrastructure. This holistic integration sets our ecosystem apart in the realm of pain management solutions.

Methods

Study Design and Patient Recruitment

PainRELife Ecosystem

This pilot study is nested in a national project titled “PainRELife, Sustainable and integrated big data ecosystem for continuity of care and decision support for patients with pain” (ID: 1173269). This national project guided the development and testing of an integrated health ecosystem for the management of chronic pain. Specifically, the PainRELife ecosystem consists of a cloud technology platform interconnected with electronic health records, which is named the Nu Platform, connected to the Fast Healthcare Interoperability Resources (FHIR) server for data analysis related to the patient care pathway. Health care providers use the Nu Platform to collect and store patient clinical data, and it enables the ongoing monitoring of patient health status (eg, pain, psychological well-being, and decision preferences about treatments; see Figures 1A and 1B), from diagnosis and active treatments to follow-ups (see Figures 1C and 1D). In addition, a big data infrastructure linked to the FHIR server enables a series of dynamic dashboards aimed at providing a systematic, intuitive outline of patient population features that might be used by researchers, clinicians, and health care stakeholders. The Nu Platform is associated with a mobile app for patients named PainRELife, which collects health care data. This technological solution permits dual communication between patients and health care professionals. Information collected by the mobile app is saved in the Nu Platform and overseen by health care professionals [7].

The PainRELife mobile app enables patient education and the collection of patient-reported outcomes. The mobile app is composed of an “educational section” that includes educational resources to improve learning about chronic pain throughout the cancer pathway (throughout the different phases of survivorship: acute, extended, and permanent; see Figure 2D) [3] and a “pain and psychological well-being assessment section” that contains a set of validated questionnaires (eg, pain intensity and interference, anxiety, and depression; see Figures 2A and 2B). Furthermore, the mobile app includes an e-diary (see Figure 2C) and exercises for pain and emotion-body mapping (see Figures 2E and 2F), enabling a holistic evaluation of psychological well-being and the pain experience. In addition, the mobile app incorporates a decision aid section, which is structured in 2 modules: profiling patients’ preferences and a decision tree (see Figure 2G). These modules are designed to empower patients with breast cancer by increasing their awareness of treatment preferences and facilitating shared decision-making regarding their care. The “profiling patients’ preferences” module aims to assist patients with evaluating and comprehending essential aspects of both pharmacological and nonpharmacological treatments. This includes understanding how interventions and treatments work to reduce pain or aid in recovery, identifying their advantages, and recognizing potential disadvantages. The decision tree module enables patients with breast cancer to tailor their health care preferences using the subjective expected utility approach [7] (see Figure 2G). This empowers patients with breast cancer to actively participate in the decision-making process, aligning their treatment choices with their unique needs and goals.
Figure 1. Health care professional interface on the Nu Platform: (A) home page displaying all available activities for health care professionals, (B) patient questionnaire list providing the measures used to assess psychological and physical status administered via the PainRELife mobile app, (C) patient list providing a directory of all patients registered on the Nu Platform, (D) clinical evaluation page offering access to detailed information on clinical events and therapeutic suggestions.

Figure 2. Patient interface on the PainRELife mobile app: (A) home page showing an overview of the mobile app sections, (B) pain and psychological well-being assessment section displaying the questionnaires that patients are required to complete, (C) patient’s e-diary, (D) educational section showing some of the educational content within the mobile app, (E) and (F) pain and emotion-body mapping exercises, (G) decision aid section showing an example for preferences for pharmacological and nonpharmacological treatments.

Participants
Participants of this pilot usability study included 25 patients with diagnosed breast cancer and pain (mean age 47.12, SD 8.41 years) admitted to the Division of Medical Senology and the Division of Pain Therapy and Palliative Care of the European Institute of Oncology (IEO). Participants were introduced to the mobile app after their clinic visit and instructed to use it for 3 months consecutively. Participants were recruited according to the following established set of inclusion criteria: >18 years
old, affected by breast cancer, has undergone surgical intervention for breast carcinoma, experiencing post-surgical pain (≥3 on a numeric rating scale [NRS]), and in possession of internet access and a personal smartphone. We excluded patients with breast cancer who had a previous or ongoing psychiatric or neurological disorder or other disease requiring active analgesic treatments. The inclusion and exclusion criteria were established considering that chronic pain is a common side effect (related to both the surgery and anticancer treatments) for patients with breast cancer (~60% experience it), and persistent acute pain after surgery is considered a risk factor for developing chronic pain during survivorship [34]. A full and detailed description of the research protocol of this pilot study was published previously [7].

**Instruments**

Patient sociodemographic and medical data were gathered through electronic medical records and a set of ad hoc items during the enrollment consultation. For the perceived pain assessment, the NRS was used to evaluate pain using a numerical range from 0 (no pain) to 10 (severe pain) [35]. Further, a set of validated self-measures was used to evaluate the primary and secondary endpoints. In detail, the Mobile Application Rating Scale (MARS) was used to evaluate the eHealth platform usability. MARS is a self-administered questionnaire with 29 items evaluating the following dimensions: engagement; functionality; aesthetics; quality of the information received; subjective perception of the app quality; expected impact on knowledge, attitudes, and probability to change user behaviors) at 3 months; in addition, the total number of times the PainRELife mobile app was accessed by each participant was determined.

Further, a new variable named total app quality was created using the mean values of the engagement, functionality, aesthetics, and information quality MARS subscales. The final measurement of app quality was the average value of the 4 means [43]. Pearson correlational analysis was performed among all self-reports used (NRS, PSEQ, SDM-Q-9, MARS) and the total number of times the app was accessed during the 3 months of the study. A repeated measures ANOVA was performed to detect variation in pain intensity (NRS) from T0 (baseline) to T2 (3 months). Further, a new dichotomous variable named “frequency of use” was created considering the entire number of times the app was accessed (mean 22.92, SD 15.60; range 2-73) and the lowest number of times the PainRELife mobile app needed to be accessed (21 times) by participants to finalize the study’s tasks. The “frequency of use” variable permitted dividing the participants into groups based on higher and lower frequencies of access. Further, a Student t test was run to evaluate the difference between the “frequency of use” and PSEQ, SDM-Q-9, and MARS scores. Data were analyzed using SPSS version 26.0 (IBM Corp).

**Ethical Considerations**

This study received ethical approval in December 2021 (R1597/21-IEO 1701) from the Ethical Committee of the IEO and respects the Declaration of Helsinki and Good Clinical Practice Guidelines. All participants read and signed the informed consent form, which encompassed a comprehensive and exhaustive explanation of the primary and secondary endpoints, study procedures, and possible risks and benefits. Participants were not compensated and were able to withdraw their participation at any time during the study. Concerning privacy and confidentiality protection, all data collected were deidentified and anonymized, complied with national data protection legislation, and will be stored in the IEO databases for 10 years.

The authors affirm that human research participants provided informed consent for publication of their data.

**Results**

**Participant Characteristics**

The sociodemographic, cancer, and treatment characteristics are listed in Tables 1-3.

Usability

The total MARS score (ranging from 1 to 5) provided overall medium-to-high mean values for each subscale (range 3.31-4.18; see Table 4) and a mean total app quality score of 3.90 (SD 0.506), suggesting generally good usability as evaluated by the participants. This was also confirmed by the total number of times the participants accessed the app during the entire study (mean 22.92, SD 15.60; range 2-73). In particular, 3 of 5 subscales had the highest scores: functionality (mean 4.14, SD 0.630), information (mean 4.18, SD 0.608), and behavioral change (mean 4.05, SD 0.666).

On the functionality subscale, 57% (15/23) of the participants judged that the mobile app is straightforward to use. Moreover, 91% (21/23) of the participants affirmed that the interactions are reliable and intuitive (ease of use: 8/23, 35% agree; 13/23, 57% strongly agree), positively evaluated the design (gestural design: 8/23, 35% agree; 12/23, 52% strongly agree), and evaluated the navigation properties as good (navigation: 12/23, 52% agree; 8/23, 35% strongly agree). However, some slight uncertainties were observed regarding the general performance of the mobile app, specifically moving between pages and sections (performance: 8/23, 35% undecided; see Table 5).

Concerning the distribution of responses in the information subscale, 78% (18/23) of the participants reported that the information in the mobile app is evidence-based (information: 9/23, 39% agree; 9/23, 39% strongly agree), relevant, focused on chronic pain in breast cancer and its management during the disease clinical pathway (quality of information: 9/23, 39% agree; 11/23, 48% strongly agree), and trustworthy (credibility: 22/23, 96% strongly agree). Further, the amount of information (quantity of information: 7/23, 30% agree; 9/23, 39% strongly agree) and how the information is reported using different setups (visual information: 11/23, 48% agree; 9/23, 39% strongly agree) were considered positive by the participants (see Table 6). Finally, most participants stated that the mobile app's goals are achievable (goals: 11/23, 48% agree; 3/23, 13% strongly agree), even if 30% (7/23) reported some concerns.

Last, the distribution of responses in the behavioral change subscale revealed that 83% (19/23) of the participants strongly agreed that the mobile app had improved awareness about the issue of chronic pain in the cancer disease pathway, and 70% (16/23) agreed that the app increased chronic pain–related knowledge. Likewise, 70% (16/23) of the participants reported that the mobile app might support attitudes toward chronic pain (attitudes: 9/23, 39% agree; 7/23, 30% strongly agree; see Table 7).

In addition, most of the participants reported that the mobile app would potentially be helpful to bolster help-seeking behaviors (help seeking: 5/23, 22% agree; 9/23, 39% strongly agree) as well as support an intention to change (intention to change: 5/23, 22% agree; 9/23, 39% strongly agree). Still, 39% (9/23) showed concerns about the capacity to transform intention into a fundamental behavioral change (see Table 7). Overall, participants judged the app to be well-targeted (engagement subscale: mean 3.31, SD 0.617) and the app’s layout to be adequate (aesthetics subscale: mean 3.98, SD 0.849); likewise, the overall subjective quality was adequate (subjective quality subscale: mean 3.50, SD 0.494).
Table 4. Mobile Application Rating Scale (MARS) subscale scores.

a."This app is likely to increase awareness of the importance of addressing chronic pain."
b."This app is likely to increase knowledge/understanding of chronic pain."
c."This app is likely to change attitudes toward improve chronic pain."
d."This app is likely to increase intentions/motivation to address chronic pain."
e."Use of this app is likely to encourage further help-seeking for chronic pain."
f."Use of this app is likely to decrease chronic pain."

Frequency of Use and Pain Self-Efficacy

According to the Student t test, younger participants used the mobile app less (mean 44.15, SD 7.11) than older participants (mean 50.33, SD 8.80; t23=-1.937, P=.03; d=0.77). A difference in pain self-efficacy was observed between participants with higher versus lower frequency use (t23=1.644, P=.057; d=0.65). The latter data indicate that, at T2, participants with a lower pain self-efficacy (mean 40.83, SD 14.58) used the mobile app more than participants with a higher pain self-efficacy (mean 48.46, SD 7.90).

Pain Intensity and Shared Decision-Making

The repeated measures ANOVA revealed that participants reported a reduction in pain intensity from T0 (mean 5, SD 1.68) to T2 (mean 3.72, SD 2.59; F2,48=3.407, P=.04). A positive correlation was found between the total number of times the mobile app was accessed and pain intensity at T2 (r=0.458, P=.03).

No correlations were detected between the MARS subscales and PSEQ or NRS. A negative correlation was observed between the subjective quality subscale and the number of times the mobile app was accessed (r=-0.498, P=.02). Further, the engagement (r=0.445, P=.03), information (r=0.427, P=.04), and subjective quality (r=0.548, P<.007) subscales were positively correlated with shared decision-making.

Discussion

Principal Findings

Considering the primary endpoint of this pilot study, patients with breast cancer provided a generally positive rating for the usability of the PainRELife mobile app. Patients with breast cancer appreciated both the quality and quantity of the health information provided on chronic pain and how chronic pain should be managed during the survivorship trajectory. Specifically, the information in the different sections and modules were perceived as informative and comprehensible (20/23, 87%) and from credible sources of information (18/23, 78%). Most of the patients with breast cancer reported that habitual use of the mobile app helped increase help-seeking behaviors for chronic pain (14/23, 61%), their general attitudes toward chronic pain, and their willingness to identify preeminent strategies for managing chronic pain. These results are particularly noteworthy considering that many studies have suggested that chronic pain syndrome in patients with breast cancer is commonly undiagnosed and not often considered by oncologists [8]. In addition, many cancer patients report poor knowledge about cancer-related chronic pain, available interventions, and possible health system resources [44]. Furthermore, the positive correlation between the total number of times the mobile app was accessed and pain intensity (P=.03) might indicate that patients with breast cancer who had a higher pain level might have utilized the mobile app to find evidence-based information and strategies to self-manage their pain. This possible interpretation might be linked to the difference in pain self-efficacy observed between the participants with higher versus lower frequency mobile app use. Specifically, participants with lower pain self-efficacy used the mobile app more than participants with higher pain self-efficacy. Perhaps the participants with lower pain self-efficacy used the mobile app to find a strategy or way to manage their pain. Self-efficacy has a crucial role for patients with cancer, and studies have reported that it improves psychological well-being, reduces fear of cancer recurrence, enhances self-care, and improves management of symptoms such as pain [45,46]. Vinnikova et al [47] observed that individuals might use mobile apps to learn more about their health problems and monitor their physical and psychological status. Furthermore, considering that self-efficacy is an attribute of cancer pain self-management, the prevalent use of the mobile app by participants with a lower self-efficacy could explain the percentage of participants who reported concerns about intention to change and the capacity to transform intention into a fundamental behavioral change [48].
A second series of results are linked to the secondary endpoints. Participants reported a reduction in pain intensity at 3 months ($P=.04$). We argue that the use of the mobile app might have relieved the pain experience, disease, and treatment-related symptomatology as observed in other previous studies [16,19]. One noteworthy finding is related to the association between specific features of the mobile app, evaluated with the MARS, and shared decision-making. Indeed, participants who provided higher positive evaluations about engagement ($P=.03$), information ($P=.04$), and subjective quality ($P=.007$) also reported higher perceptions of having shared decisions along their care pathway. We argue that patients with breast cancer who feel involved in their treatment decisions are more engaged with the mobile app. For this type of patient, information retrieved in the mobile app might be used to reinforce and reiterate the ability to achieve a shared decision throughout their care pathway.

**Limitations**

Despite the interesting and challenging results, this pilot usability study had some limitations that must be considered. The primary limitation is the relatively small sample size of patients with breast cancer and the decision to use a single group to test usability. This decision might have caused a loss of pertinent information about the patients’ perceptions of the usefulness of this digital health technology. However, our sampling strategy is consistent with the pilot study design and methodological guidelines [49-51]. Related to this point, we must also mention that the statistical significance reported for pain self-efficacy might be considered borderline ($P=.057$). However, the effect size is medium-to-large ($d=0.65$), which supports the statistical difference between the groups. We argue that the $P$ value might be due to the small sample size [52]. We also argue that this could be a significant result that has to be further investigated in successive studies, considering the positive effect of cancer pain self-management on QoL, when compared with pharmacological treatments such as opioid consumption [48].

In addition, the “frequency of use” variable had a moderately high SD (15.60). However, the distribution of the participants between the low frequency (n=13) and high frequency (n=12) groups was homogeneous and balanced. Furthermore, we hypothesized the presence of selection bias resulting from the inclusion criteria, which required participants to have internet access and a personal smartphone. This criterion may have limited the inclusion of certain vulnerable groups among patients with breast cancer, such as older adults or individuals with lower health literacy and socioeconomic challenges who could be at higher risk of undiagnosed chronic pain. Most of our patients with breast cancer also reported medium-to-low pain during the entire study and were in the acute and extended stages of the survivorship trajectory, which might have affected the frequency of mobile app use. Indeed, even if the total number of times the mobile app was accessed was relatively high and satisfactory, in the last month of the study, some participants decreased their total usage; 2 of 25 participants used the mobile app only at enrollment. The last limitation is related to the previous one and concerns the lack of assessment of the timing of mobile app use. Indeed, only the total number of times the mobile app was accessed was collected and evaluated. These limitations have been intensely discussed in the full protocol published elsewhere, and we plan to address them in future studies [7].

**Conclusions**

The data retrieved from this pilot study evaluating patients’ experiences using a novel and integrated health ecosystem for the management of chronic pain for breast cancer survivors are consistent with other studies highlighting that digital health technologies, when developed using a patient-driven approach, might be considered valuable tools for increasing the participation of patients with breast cancer in clinical care. In addition, these tools permit the achievement of critical clinical outcomes and improvement in QoL [4,8,22]. Moreover, health-integrated ecosystems permit secondary key outcomes such as reducing the burden on health care professionals and optimizing health system resources. Finally, we argue that digital integrated health ecosystems might be important devices for improving the ongoing monitoring of physical status, psychological burden, and socioeconomic issues during the cancer survivorship trajectory.

Abstract

Background: Research is needed on how faith and prayer apps fit within the values of racial and ethnic minority (REM) groups, as well as whether such apps are effective in promoting mental health and well-being.

Objective: This study aims to determine the feasibility and preliminary effectiveness of using the mobile app Pray.com on mental health and well-being among REM participants.

Methods: This study was a single-group (N=77), 4-week feasibility trial in REM groups (65/77, 84% Black or African American). Participants were asked to use the Pray.com app at no cost for at least 5 times per week for 5 minutes per day. Participants completed questionnaires at the baseline and postintervention time points. Feasibility questionnaires were only completed at the postintervention time point, including qualitative interviews (n=15). The feasibility questions included acceptability (ie, satisfaction, intent to continue use, perceived appropriateness, and fit within culture), demand (ie, self-reported app use, expressed interest, and perceived demand), and practicality (ie, ease or difficulty of use, ability to use the app, and cost-effectiveness). Frequency and descriptive statistics were used to analyze feasibility outcomes. Changes in dependent variables were analyzed using paired-sample 2-tailed t tests. Partial correlations were conducted to explore the association between app use and outcomes, controlling for baseline scores.

Results: Participants reported (54/72, 75% responded with “very likely” or “likely” to the feasibility questions) that they perceived the Pray.com app as acceptable. These findings were supported by qualitative interviews (n=15). Most participants (62/72, 86%) did not meet the app use prescription but expressed interest in using the app in the future and perceived demand for it in their communities. In addition, participants reported that the app was easy to use and perceived it to be inexpensive (US $7.99). Participants reported improved mental health (ie, stress and depressive and anxiety symptoms) and well-being (ie, satisfaction with life, spiritual well-being, religious commitment, and racial or ethnic identity development) at postintervention despite relatively low average levels and high variability of app use (average total of 45.83, SD 111.90 min over the course of the study). Greater app use was significantly associated with improvements in mental health and spiritual well-being. However, app use and study methodology limitations suggest that the study results may not accurately capture the full impact of Pray.com use.

Conclusions: This is the first study to assess the feasibility of a faith and prayer app for mental health and well-being in a sample of REM individuals. Our findings suggest that the use of a faith and prayer app (ie, Pray.com) could be feasible and significantly
impacting for the improvement of mental health symptoms and well-being in REM individuals and their communities, especially Black and African American individuals with a Christian affiliation. Further research is warranted.

**Introduction**

**Background**

Religious and spiritual identity can extend across and within various cultures, even worldwide, although religious experiences are largely influenced by and intersect with cultural context. Some have conceptualized religion as a form of culture [1], and previous research has examined how religious expressions differ by culture [2]. Religion can serve as a primary social identity [3] that intersects with other salient features of identity, such as one’s racial or ethnic identity [4]. Put simply, one’s religious experience and expression notably intersect with one’s cultural identity and context.

Despite the heterogeneity of religious expressions, researchers have identified certain core dimensions of religion, including cognitive, emotional, behavioral, and social features [5]. A substantial body of research suggests that religion enhances individual well-being [6-16]. However, less is known about the role of culture in the connection between religion and individual health and well-being.

For racial and ethnic minority (REM) populations, the religious or spiritual aspect of one’s identity might be particularly important. For example, Constantine and Sue [17] outlined a theoretical model describing optimal human functioning for people of color in the United States. One of the key premises of their argument was that one’s cultural context affects what is considered optimal human functioning for various groups and it is necessary to consider the impact of cultural values on the well-being of people of color. In their model, cultural values, beliefs, and practices such as collectivism, racial and ethnic pride, spirituality and religion, interconnectedness of mind, body, or spirit, and family and community are viewed as important predictors of optimal human functioning for people of color.

In this study, we focused on religion or spirituality as an important factor contributing to the mental health and well-being of REM groups. Indeed, research has supported the importance of religion in the lives of such groups (eg, African American and Latinx groups), and these individuals tend to engage in religious or spiritual practices at a higher rate than the US population overall [18,19]. For example, studies have found high levels of religious participation in African American individuals (ie, 89% are religious; 78% attend services regularly; and 90% pray, meditate, or use religious materials) [20]. Furthermore, previous research has supported a strong connection between religiousness and well-being in African American individuals [21,22]. For example, in a sample of African American individuals, racial or ethnic identity was positively related to both satisfaction with and meaning in life, and these relationships were partially mediated by religious commitment [23].

Similarly, engaging in religious practices has been linked to increased social support and psychological well-being and decreased perceived stress and physical pain in Latinx populations [24,25]. Furthermore, types of religious coping (eg, positive vs negative) affected symptoms of both depression and obsessive-compulsive disorder [24,26]. As religiosity tends to be more emphasized by Latinx immigrants in comparison with US-born Latinx populations [27-29], some scholars have hypothesized that a decline in religiosity may partially explain the Latino health paradox, in which more recently immigrated Latinx individuals tend to display better health outcomes than more assimilated and US-born Latinx individuals [30,31].

Regarding Asian and Asian American populations, religious identity was positively associated with self-esteem, positive affect, and meaning in life in a sample of Asian American adolescents [32]. In a sample of Chinese American and Korean American older adults, religious support and beliefs were associated with increased life satisfaction and decreased depressive symptoms [33]. In a sample of Korean adult immigrants, religious support was associated with higher well-being in the midst of experiencing financial hardship and difficulties with English [34]. Interviews with Filipino American individuals regarding their faith revealed that their experiences with religion and spirituality had both positive and negative effects on their well-being [35], although recent research has proposed that the negative effects of religion may be explained by scrupulosity in communities in which religious participation plays a large role in culture [26].

This high degree of religious participation by REM individuals is observed not only in the United States but also worldwide. For example, high rates of religious identification are observed in territories with high numbers of REM individuals, such as Latin America or the Caribbean, Middle East or North Africa, and sub-Saharan Africa [36]. Overall, it is clear that, for various REM populations, religious and spiritual identity are important factors that affect one’s quality of life. Thus, it is imperative to identify how religious identity, practices, and engagement empower REMs and assess how current practices can be implemented, changed, or improved to enhance religious and spiritual experiences and increase well-being in these populations.

**Different Pathways to Religious and Spiritual Well-Being**

Technological advances have permitted various ways for individuals to facilitate well-being through engagement in
religious and spiritual practice [37-39]. Although various media have previously encouraged several methods toward transcendent connection, the global health pandemic of 2020 accelerated the development of digital tools that allow individuals to enhance their well-being via religious and spiritual practices [37,38]. Many of these behavior changes have persisted, and individuals are engaging in technologically mediated religious and spiritual practices more regularly.

For example, individuals may interact with religious and spiritual content through mobile apps. One such app is Pray.com, which is an app that allows participants to engage in Christian-based faith and prayer content, such as reading the Bible, listening to sermons, or hearing stories or other creative content to engage with their spiritual faith. This app can be downloaded to any smartphone or internet-enabled (mobile) device, and it includes the opportunity to receive notifications to remain engaged in one’s religious practices. The Pray.com app was chosen for this study because of its popularity and potential reach but was not specifically designed for REM individuals.

Such research on the role of technology in religious and spiritual practices is nascent, and most research has been conducted on the Christian faith as it is a prominent part of public and political life in the United States [40]. Among the largest religious groups in the United States, Black Protestant denominations tend to use technology in their religious practices to a greater degree [41], yet digitally based interventions struggle to be representative of REM groups [42]. Thus, there is a dearth of research including REM diverse samples, and less research has focused on how such apps align with the cultural values of such participants. There is a need for research that explores how such apps fit (or do not fit) with the cultural values of REM participants as well as whether such apps are effective in promoting mental health and well-being. To our knowledge, this is the first study to assess the feasibility and preliminary efficacy of a faith and prayer app for mental health and well-being in REM individuals. Accordingly, the goal of this research was to examine how individuals self-identifying as belonging to REM groups engage with technologically mediated religious and spiritual practices to enhance their mental health and well-being.

Study Overview and Hypothesis

The purpose of this study was to determine the feasibility (ie, acceptability, demand, and practicality) and preliminary effectiveness of using the mobile app Pray.com on mental health (ie, stress and depressive and anxiety symptoms) and well-being (ie, satisfaction with life, spiritual well-being, religious commitment, and racial or ethnic identity development) among REM participants. We predicted that Pray.com would be feasible in REM individuals and be associated with improved mental health and well-being outcomes at 4 weeks.

Methods

Ethical Considerations

This study was approved by the institutional review board of Biola University (F22-013) and registered at ClinicalTrials.gov (NCT05626673). All participants provided electronic consent before taking part.

Study Design or Recruitment

This study was a single-group, 4-week feasibility trial. This method was chosen as this was a preliminary study of the feasibility and effectiveness of the app in a sample of REM individuals. Participants were recruited using convenience sampling through faith-based organizations (eg, churches and religious psychology organizations), personal contacts of the researchers, and social media between January 2023 and April 2023 and were directed to a link to complete the web-based eligibility survey.

Participants and Procedure

Potential participants completed a web-based eligibility questionnaire via Qualtrics (Qualtrics International, Inc). Potential participants were eligible if they (1) self-identified as belonging to an REM group, (2) were aged ≥18 years, (3) owned a smartphone and were willing to download a mobile app, and (4) were willing to engage in Christian-based religious practice on a mobile app. Eligible participants were directed to a web-based informed consent form and informed of the potential risks of taking part in the study. After signing the consent form, participants were asked to complete a series of web-based baseline questionnaires (time 1) related to mental health and well-being. Once the questionnaires were completed, participants were provided with instructions on how to download the Pray.com mobile app.

Intervention

Participants were asked to use the Pray.com app at no cost for at least 5 times per week for 5 minutes per day. The Pray.com app was chosen because of its popularity and potential reach. The app was not specifically designed for REM individuals. This dose was chosen as frequent private prayer has been associated with significant mental health benefits [43], and frequency may be more important than the duration of time spent in prayerlike practices. We chose a brief minimum period to increase adherence and consistency. Participants were contacted at time 2 (approximately 30 days after completing time 1) and invited to complete the web-based questionnaires again as well as a feasibility questionnaire about their experience using the app. After completing the time 2 questionnaires, participants were compensated with a digital gift card, debriefed about the purpose of the study, and invited to contact the researchers if they had any questions about their participation. A subset of participants (n=15) was invited (using random selection) to participate in a qualitative interview with a member of the research team (making this a mixed methods study). These qualitative interviews were conducted on the web via Zoom (Zoom Video Communications) and transcribed (and subsequently coded by the qualitative data analyst). The participants who completed the qualitative interviews were compensated with an additional digital gift card.
Measures

Feasibility (Time 2)

All feasibility measures were assessed at the postintervention time point (4 weeks). We measured feasibility using the guidelines by Bowen et al [44], including acceptability, demand, practicality, and preliminary efficacy (ie, trends in changes in stress, depressive and anxiety symptoms, satisfaction with life, spiritual well-being, religious commitment, and racial or ethnic identity development). Benchmarks for feasibility included (1) acceptability (ie, satisfaction, intent to continue use, perceived appropriateness, and fit within culture; ≥75% of participants reporting satisfaction with the app and that the app was appropriate and fit within their cultural identity or worldview), (2) demand (ie, self-reported app use, expressed interest, and perceived demand; ≥75% of participants adhering to the Pray.com prescription, expressing interest in future use, and perceiving the app as demanded within their community), and (3) practicality (ie, ease or difficulty of use, ability to use the app, and cost-effectiveness; ≥75% of participants reporting ease of use and that they could pay for the app).

The feasibility measures were developed by psychology and behavioral health researchers. Textbox 1 presents a list of the feasibility questions.

A subset of participants (n=15) completed a semistructured qualitative interview that focused on exploring their experiences using the app in a deeper way. The qualitative interview focused on topics similar to those in the feasibility questionnaire (eg, acceptability, demand, and practicality), as well as including an open-ended question asking for general feedback about the app. Textbox 2 presents a list of the interview questions.

Textbox 2. Interview questions.

Acceptability
- Satisfaction
  - What did you like the most about using the Pray.com app?
  - What did you like least about using the Pray.com app?

- Intent to continue use
  - What factors would influence your decision to continue using the Pray.com app in the future?
  - What factors would keep you from using the Pray.com app after the study is over?

- Perceived appropriateness
  - What about the Pray.com app was most relevant to helping you with your mental health?
  - What about the Pray.com app was most relevant to helping your spiritual life?
  - How did Pray.com contribute to how you feel about meditation/mindfulness?

- Fit within culture
  - What aspects of using the Pray.com app were a good fit within your religious beliefs or worldview?
  - What aspects of using the Pray.com app did not seem to fit within your religious beliefs or worldview?
  - What aspects of using the Pray.com app did not seem to fit within your cultural (ie, racial/ethnic) identity or worldview?
  - How well represented was your racial/ethnic group on the Pray.com app?

Demand
- Expressed interest
  - What aspects of the Pray.com app are you most interested in?
  - What aspects of the Pray.com app are you least interested in?

- Perceived demand
  - What could be improved about the Pray.com app to make it a better fit for you?
  - What could be improved about the Pray.com app to make it a better fit for your religious community?

Practicality
- Ease or difficulty of use
  - What aspects of the Pray.com app were difficult to use?
  - What aspects of the Pray.com app were easy to use?

- Ability to use the app
  - What aspects of the Pray.com app did you feel like you had the ability to use?
  - Was there anything about the Pray.com app that you felt like you did not have the ability to use?

- Other
  - Do you have any other feedback about your use of the Pray.com app?

Perceived Stress Scale (Time 1 and 2)
The Perceived Stress Scale-10 (PSS-10) [45] was used to measure participants’ subjective levels of stress. The PSS-10 is a 10-item measure in which participants rate items related to stress (eg, “how often have you been angered because of things that happened that were outside of your control?”) on a scale from 0=never to 4=very often within the previous month. A mean perceived stress score was calculated, with higher scores indicating higher levels of perceived stress. Previous research has demonstrated high reliability and construct validity of the PSS-10 [45,46], including in a sample of REM participants [47].
In this sample, the Cronbach α for the PSS-10 ranged from .81 to .84 across time points.

**Hospital Anxiety and Depression Scale (Time 1 and 2)**
The Hospital Anxiety and Depression Scale (HADS) [48] was used to measure participants’ symptoms of anxiety and depression. The HADS is a 14-item measure in which participants rate 7 items related to anxiety (eg, “I feel tense or ‘wound up.’”) and 7 items related to depression (eg, “I still enjoy the things I used to enjoy”) on a scale from 0 to 3 (end points vary across items). Mean scores for anxiety and depression were calculated, with higher scores indicating more severe symptoms of anxiety and depression. Previous research has demonstrated evidence for the reliability and construct validity of the HADS [49], including cross-culturally [50]. In this study, the Cronbach α for the anxiety and depression subscales of the HADS ranged from .83 to .84 (anxiety) and from .79 to .84 (depression) across time points.

**Spiritual Well-Being Scale (Time 1 and 2)**
Participants’ spiritual well-being was assessed using the Spiritual Well-Being Scale (SWBS) [51,52]. The SWBS comprises 20 items divided into 2 subscales: religious well-being (10 items; eg, “I feel most fulfilled when I’m in close communion with God”) and existential well-being (10 items; eg, “I believe there is some real purpose for my life”). Participants rated each item on a scale from 1=strongly disagree to 6=strongly agree, with higher scores indicating higher levels of spiritual well-being. The SWBS has previously demonstrated high internal consistency and construct validity [51,52], including in samples with African American individuals [53]. In this study, the Cronbach α for the SWBS ranged from .91 to .92 across time points.

**Satisfaction With Life Scale (Time 1 and 2)**
Participants’ life satisfaction was measured using the Satisfaction With Life Scale (SWLS) [54]. Participants rated 5 items related to life satisfaction (eg, “In most ways my life is close to my ideal”) on a scale from 1=strongly disagree to 6=strongly agree, with higher scores suggesting higher life satisfaction. The SWLS has demonstrated high internal consistency and construct validity in previous research across various populations and contexts [54], including diverse populations [55]. In this study, the Cronbach α for the SWLS ranged from .73 to .83 across time points.

**Religious Commitment Inventory–10 (Time 1 and 2)**
Religious commitment was measured using the Religious Commitment Inventory–10 (RCI-10) [56]. Participants rated 10 items assessing religious commitment (eg, “I spend time trying to grow in understanding of my faith”) on a scale from 1=not true at all of me to 5=totally true of me. Scores were measured using the mean of all 10 items, with higher scores suggesting higher levels of religious commitment. The RCI-10 has shown evidence of internal consistency and construct validity [56], including in diverse samples [56,57]. In this study, the Cronbach α for the RCI-10 ranged from .84 to .88 across time points.

**Multigroup Ethnic Identity Measure–Revised (Time 1 and 2)**
Racial or ethnic identity development was measured using the Multigroup Ethnic Identity Measure–Revised (MEIM-R) [58]. Participants rated 6 items assessing racial or ethnic identity development across 2 subscales—commitment (eg, “I have a strong sense of belonging to my own ethnic group”) and exploration (eg, “I have spent time trying to find out more about my ethnic group, such as its history, traditions, and customs”)—on a scale from 1=strongly disagree to 5=strongly agree, with higher scores indicating higher levels of commitment and exploration, respectively. The MEIM-R has demonstrated evidence of internal consistency and construct validity [58]. In this study, the Cronbach α for the MEIM-R ranged from .79 to .84 across time points.

**Statistical Analysis**
The data were analyzed using SPSS (version 28.0; IBM Corp). Frequency and descriptive statistics were used to analyze the feasibility outcomes and demographic characteristics. As not all participants answered every question (ie, it was a free-response survey), the sample sizes differed across analyses. We reported all available completed data. Self-reported use frequency was categorized as ordinal, reflecting the use of the app as (1) less than once per week, (2) up to 2 times per week, (3) 3 to 5 times per week, or (4) ≥5 times per week. All other feasibility questions were categorized as ordinal. Changes in dependent variables between time 1 and time 2 were analyzed using paired-sample 2-tailed t tests. To assess the relationship between objective app use and changes in dependent variables, partial correlations were conducted to explore the association between app use and scores on time 2 variables controlling for scores on time 1 variables. P values of <.05 were considered significant.

With regard to the qualitative data, interview transcripts were imported into NVivo (QSR International) for coding and analysis. Thematic analysis methods were used based on the inductive or deductive approach proposed by Braun and Clarke [59]. In brief, this involved first identifying top-level themes based on the main issues and questions covered in the interviews (feasibility and mental health and well-being outcomes). Within these, emergent themes were identified inductively from the transcripts and labeled appropriately. An iterative process was used in which relevant extracts of interview data were allocated to these, with the coding being continually reviewed and revised until the analyst felt confident that it most accurately reflected the lived experiences of the research participants as reported in their interviews.

**Results**
Of the 77 final participants in our study, 72 (94%) completed time 2 measures. There were no significant differences in our main variables between completers and noncompleters.

**Participants**
We received 707 initial responses to the eligibility survey; however, the vast majority of these were found to be inauthentic responses (eg, bots and duplicate IP addresses). Accordingly,
we checked the data using elimination of duplicate IP addresses
and consistent responses to demographic information. Then,
we installed various data quality checks such as bot detection
and reCAPTCHA (Google) and accuracy on 3 quality-check
questions (eg. “Please select disagree”). This resulted in a final
sample of 77 participants. Table 1 shows the sample
demographic characteristics. Table 2 shows the religious or
spiritual engagement at the beginning of the study.

**Feasibility**

**Acceptability**

All the acceptability benchmarks were met. Most participants (64/72, 89%) reported being very satisfied or satisfied with the app and that they were very likely or likely to continue to use the app in the future (63/72, 88%). No significant differences between men and women were observed regarding app acceptability.

The app was perceived as appropriate. Most participants reported that using the app was very relevant or relevant to improving their mental health (57/72, 79%) and spiritual lives (62/72, 86%). Most participants (60/72, 83%) reported that they strongly agreed or agreed that their racial or ethnic identity was well represented on the app and that the content was a good fit with their racial or ethnic identity (53/72, 74%) and cultural worldview (59/72, 82%). Most participants reported that they strongly agreed or agreed that Pray.com was a good fit with their religious beliefs or worldview (58/72, 81%) and cultural identity or worldview (55/72, 76%). Participants reported that the app was more relevant to improving their spiritual life than their mental health ($P=.01$). There was no significant difference between fit with religious or cultural worldview ($P=.23$). Table 3 shows participant ratings of the acceptability of the app.
Table 3. Participant ratings of the acceptability of the app (N=72).

**Demand**

All demand benchmarks were met except for self-reported use (at least 75% of participants used the app at least 5 times per week for 5 min/d) as this could not be determined from the answer choices selected by the participants. Most participants (58/72, 81%) self-reported that they used the app between 3 and 5 times per week (35/72, 49%) or >5 times per week (23/72, 32%). However, objective use data showed that participants used the app for an average of 45.83 (SD 111.90) minutes and a total of 5.77 (SD 8.19) days throughout the entire study period, suggesting that app use may have been overreported. Regardless of app use, most participants (61/72, 85%) indicated that they were extremely interested or interested in continuing to use the app in the future and that they believed that there would be interest or a great deal of interest in the app in both their religious (59/72, 82%) and cultural communities (56/72, 78%). There was no significant difference between perceived demand in one’s religious community and in one’s cultural community (P=.13). No significant differences were observed between men and women regarding demand for the app. Table 4 shows participant ratings regarding demand for the app.

Not really, n (%) | 2 (3) |

Within participants’ cultural community, mean (SD) | 4.11 (0.82) |

A great deal, n (%) | 26 (36) |
Interested, n (%) | 30 (42) |
Somewhat interested, n (%) | 14 (19) |
Not really, n (%) | 2 (3) |

**Practicality**

Almost all participants (58/72, 81%) reported that it was very easy or easy to use the app and that they were very able or able to use and navigate the app (63/72, 88%). The monthly price of the app was perceived to be very cheap or cheap by most participants (55/72, 76%). Although only half (39/72, 54%) reported that paying the monthly fee of the app would be very cheap or cheap.
easy or easy, most participants (56/72, 78%) reported that they would be very likely or likely to pay the monthly fee. No significant differences were observed between men and women regarding the practicality of the app. Table 5 shows participant ratings regarding the practicality of the app.

**Mental Health and Well-Being Improvement Over Time**

Regarding mental health symptoms, participants reported significant improvement in perceived stress ($P=.004; d=0.35$), depression ($P=.02; d=0.29$), and anxiety ($P=.01; d=0.32$). Effect sizes were in the small to medium range. Regarding well-being, participants reported significant improvement in satisfaction with life ($P<.001; d=0.52$), spiritual well-being ($P<.001; d=0.48$), religious commitment ($P=.02; d=0.28$), and racial or ethnic identity development ($P=.048; d=0.24$). Effect sizes were in the small to medium range. Table 6 shows the $t$ test reporting of improvements.
Mental Health and Well-Being Improvement With Objective App Use

Participants used the app during the study period (approximately 4 weeks) for an average of 45.83 (SD 111.90) minutes and a total of 5.77 (SD 8.19) days. Partial correlations were conducted, controlling for baseline variable scores, between total minutes and total days of app use and outcome variables. When controlling for the outcome variable at baseline, greater app use was associated with decreased stress and depressive and anxiety symptoms and increased spiritual well-being at the postintervention time point (Table 7). These results suggest that greater app use is associated with decreased mental health symptoms and increased spiritual well-being over time.

Table 7. Partial correlations between app use and dependent variables at the postintervention time point (N=77).

Qualitative Analyses

Acceptability

When the interview participants (n=15) were asked what they liked most about the app, the types of responses fell into 2 main categories: general aspects and specific features.

General Aspects of the App

In total, 20% (3/15) of the participants reported that they mostly liked the wide range of topics and content available on the app, whereas 13% (2/15) referred to its relatability. Others (3/15, 20%) mentioned liking the most how convenient the app was to use via their phone, compared with hard-copy methods of accessing spiritual content, and how educational it was for them (2/15, 13%). Other participants mentioned liking the community aspect of the app (1/15, 7%) and the overall look of the app and its interface (1/15, 7%).

Specific Features of the App

A total of 27% (4/15) of the interviewees reported that they most liked the notifications that reminded them to pray regularly, and 13% (2/15) reported that they particularly liked the podcasts: “I’ve been getting addicted to the podcasts very early in the morning.”

In total, 27% (4/15) of the interview participants mentioned that they especially liked the daily scriptures or Bible passages. Other favorite features mentioned by individual participants included the daily motivational messages (1/15, 7%), daily prayer time (1/15, 7%), and streaks (1/15, 7%) enabling them to track their own progress. The participants were also asked which aspects of the app they were most interested in. In descending order of frequency in which they were mentioned, these were reported to be daily prayers (6/15, 40% of the participants), preaching and sermons (5/15, 33%), daily motivations (3/15, 20%), scriptures (3/15, 20%), podcasts (3/15, 20%), books (1/15, 7%), and storylines (1/15, 7%).

What Participants Liked the Least About the App

When asked what they liked the least about the Pray.com app, 60% (9/15) of participants reported that there was nothing they did not like about the app.

Among the 40% (6/15) who did report on features that they disliked or liked less, several of these were related to technical issues encountered when using the app (eg, delays in reminders, delays in content updates, and inability to save activity when exiting).

Individuals also commented on morning prayers being too long (1/6, 17%) and sermons being too short (1/6, 17%) and disliking the 21-Day Prayer Journeys (1/6, 17%). When asked which
aspects of Pray.com they were the least interested in, 40% (6/15) indicated that there were no aspects they were uninterested in. A total of 13% (2/15) said that they were the least interested in certain preachers or those they knew less about, and 7% (1/15) referred to content perceived as irrelevant to them, such as anxiety meditations. In addition, some participants said that they were least interested in movies (2/15, 13%), meditations (1/15, 7%), prayer journals (1/15, 7%), and prayers (1/15, 7%).

**Intent to Continue Use**

We asked the participants what factors would influence their decision to continue using the Pray.com app. In total, 60% (9/15) indicated that they would continue to use it because of the beneficial effect it had had on their spirituality, especially the notifications that reminded them to pray. Others stated that the convenience and ease of use of the Pray.com app were factors that influenced their intention to continue using it (7/15, 47%) and that range, quality of content, or continued access to content (3/15, 20%) would influence their continued use.

**Perceived Appropriateness**

Many participants mentioned that they had experienced positive impacts of the Pray.com app on their mental health. A total of 27% (4/15) reported that these benefits were due to a feeling of greater connectedness, either with God or with others who share their religious beliefs. In total, 20% (3/15) described how they had benefited from the ease of being able to locate mental health content on the app. A total of 20% (3/15) of the participants reported that their levels of stress or depression had decreased since they had started using the app. Some participants cited specific types of content that had helped their mental health: meditations (3/15, 20%), daily podcasts (2/15, 13%), scriptures (1/15, 7%), and songs (1/15, 7%).

The participants were also asked how the app had influenced their feelings about meditation and mindfulness. In response, 40% (6/15) indicated that they had an improved understanding or that using the app had changed their misconceptions about meditation and mindfulness. In total, 27% (4/15) of the participants described how the app had helped them enter a meditative state or how much they had enjoyed the meditations.

**Impacts on Spirituality**

When asked about the impact of the Pray.com app on their spirituality, 33% (5/15) of the participants indicated that it had helped them develop spiritual habits or increase their familiarity with the scriptures. A total of 27% (4/15) of the participants referred to having increased their frequency of praying since they had started using the app. Another 27% (4/15) of the participants explained how the app had given them a more spiritual focus or direction in their lives. In total, 13% (2/15) of the interviewees described ways in which the app had taught them how to pray more effectively. A total of 13% (2/15) highlighted ways in which they had gained new spiritual insights or understanding through using the Pray.com app.

**Fit Within Culture**

When asked whether the Pray.com app was a good fit with their religious beliefs or worldview, 20% (3/15) of the participants commented that all aspects were a good fit. In total, 67% (10/15) of the participants specified ways in which particular content or preachers on the app were a good fit with their religious beliefs or worldview. When asked which aspects were not a good fit with their religious beliefs or worldview, 20% (3/15) cited specific content not relevant to them, such as parenting content, or that they or others in their community might not agree with, such as meditation or options for gift buying on the app.

**Fit Within Cultural and Ethnic Identity**

A total of 60% (9/15) of the interviewees specifically said that the Black community was well represented among the preachers. Although one participant expressed a perception that Black preachers only accounted for approximately 20% of all those on the app, he did not see this as a problem. A further 40% (6/15) of the interviewees similarly commented on how inclusive and nondiscriminatory Pray.com was. One participant mentioned that the app was a good fit with their cultural identity because of the type of language used, which he could relate to and understand.

**Demand**

In total, 80% (12/15) of the interviewees made suggestions for ways of improving the app to make it a better fit for them personally. These fell broadly into the following categories: features, technical improvements, and cost.

**Features**

Interviewees suggested more or different types of notifications, the ability to interact with others on the app (eg, in a forum or groups), or being able to post questions or comments to the preachers.

**Technical Improvements**

A total of 27% (4/15) of the participants said that technical improvements would make the app a better fit for them personally. These generally referred to specific technical problems they had encountered (eg, allowing the app to continue running while using the phone and inability to save content).

**Cost**

In total, 13% (2/15) of the participants suggested improvements related to the cost of subscriptions, including continued free access to the full app, a payment plan to make subscriptions more affordable, and a free trial option.

**Practicality (Ease of Use)**

Interviewees mentioned specific aspects or features of the app that were easy for them to use. A total of 40% (6/15) of the participants stressed that navigating the app was particularly easy for them. Other individuals commented that the podcasts or live prayers (3/15, 20%), meditations (1/15, 7%), website (1/15, 7%), and registration process (1/15, 7%) were easy for them. A small number of participants did describe some difficulties they had encountered when using the app. In total, 13% (2/15) of the participants explained that they had not realized that there was a notification option that they needed to activate. Others mentioned difficulty in locating the streak data (1/15, 7%) and using the display on the side of the podcasts (1/15, 7%).
Discussion

Principal Findings

Overview

The purpose of this study was to determine the feasibility (ie, acceptability, demand, and practicality) and preliminary effectiveness of using the mobile app Pray.com on mental health (ie, stress and depressive and anxiety symptoms) and well-being (ie, satisfaction with life, spiritual well-being, religious commitment, and racial or ethnic identity development) among REM participants. We also explored the associations between objective app use (total minutes and days) and the outcomes measured. In addition, follow-up interviews were conducted to provide further insight into feasibility outcomes. This is one of the first studies to assess the feasibility and preliminary effectiveness of a faith- and prayer-based app in REM individuals for the purpose of improving mental health and well-being.

Overall, participants reported high levels of satisfaction with the app, intent to continue use, appropriateness of the app, and fit within their culture. Interestingly, most participants (62/72, 86%) did not meet the app use prescription provided by the researchers (ie, at least 5 min/d, 5 d/wk) but expressed interest in using the app in the future and perceived demand for it in their communities. In addition, participants reported that the app was easy to use and perceived it to be inexpensive. Only approximately half (39/72, 54%) of the participants reported that paying the monthly fee would be easy for them, but most (56/72, 78%) said that they would be willing to pay. Even though most participants did not use the app as often as prescribed, the results indicated that app use was associated with significant mental health improvements over time. Critically, with regard to preliminary effectiveness, participants reported improved mental health (ie, stress and depressive and anxiety symptoms) and well-being (ie, satisfaction with life, spiritual well-being, religious commitment, and racial or ethnic identity development) over the course of the study despite relatively low average levels and high variability of app use. Greater app use was significantly associated with improvements in mental health and spiritual well-being. These findings suggest that Pray.com is feasible for REM adults. Future research is warranted to determine the efficacy of Pray.com on mental health and well-being outcomes in REM populations using randomized controlled trials.

Feasibility

Using a faith and prayer mobile app for mental health and well-being was found to be feasible in REM individuals, particularly for Black and African American adults (who constituted most of our sample). Most of the participants (64/72, 89%) expressed high satisfaction with the app and that the app was a good fit with their cultural and religious beliefs or worldview. A number of interviewees (6/15, 40%) also indicated that they perceived a fair representation of different cultural backgrounds in the app content. The findings related to cultural fit are promising as, historically, REM groups have not been well represented in apps, especially in apps that claim to have health benefits [60]. Ramos et al [61] have suggested that apps with a focus on improving mental health may have the ability to reduce unmet mental health needs if users believe that the content is appropriate for them and fits within their culture. Others have suggested that apps should be adapted to various cultures for increased benefits [42,62]. However, Black and African American populations are still underrepresented in mobile health research, limiting our ability to inform the development and design of apps for REM groups [63]. Our qualitative findings show that a small subset of participants reported that cultural fit could be increased if content such as parenting was improved or potential culturally controversial content such as meditation or options for gift buying on the app were addressed. This is one of the first studies to explore a faith-based app for mental health and well-being among REM groups. These initially promising findings suggest that more research in this area is warranted.

The findings on feasibility and cultural fit in our study are also exciting in light of the sometimes mixed reception of mindfulness and meditation in certain cultural and religious groups [64,65]. The positive reception and perceived cultural fit of the Pray.com app in a sample of religious REM individuals provides evidence that these apps may be an important avenue to help introduce the benefits of prayer, mindfulness, and meditation in a context that is experienced as a good fit with one’s cultural and religious worldview.

Although most participants (>54/72, 75%) reported high levels of feasibility across the board, one area in which responses were mixed was cost-effectiveness. Namely, although approximately three-quarters (56/72, 78%) of the participants expressed willingness to pay the monthly fee for the app, only approximately half (39/72, 54%) expressed that it would be easy for them to do so. This was supported by the qualitative data, in which some participants suggested improvements related to the cost of subscriptions (eg, a payment plan and free trial option). Individuals considering subscribing to an app for the purpose of improving or maintaining mental health and well-being should weigh the costs and potential benefits of subscribing to the app. Thus, when developing or implementing apps to provide access to faith and prayer content to various cultural groups, it is critical to keep cost-effectiveness and affordability in mind.

Previous research has demonstrated that overall product satisfaction and perceived quality are directly linked to increased purchase intentions, whereas increased product involvement may indirectly increase purchase intentions through overall satisfaction and perceived product quality [66,67]. Although only half of the sample expressed that it would be easy to pay the monthly fee, participants did say that paying the monthly fee was feasible and were interested in continuing use. Hence, despite some perceived expensiveness of the app, participants reported intent to continue use, likely based on high satisfaction with the app and its high relevance to improving mental and spiritual well-being.
Preliminary Effectiveness on Mental Health and Well-Being

Participants reported improved mental health as a result of using the Pray.com app. Specifically, participants reported significant improvements in mental health symptoms, including decreased stress, depression, and anxiety symptoms, over the course of the study. This was confirmed in the qualitative interviews; interviewees noted that their stress and depression levels decreased because of their increased hope and enjoyment of the present moment as encouraged by app content (eg, daily podcasts, scripture, and songs). In addition, the qualitative interviews suggested that it was easy to search for and access religious content related to stress, depression, and anxiety on the app. Prior work has demonstrated that spirituality can help operate as a buffer against stress and adversity [68]. To the degree that increased involvement with spiritual content can facilitate coping and help individuals in periods of stress, future research should explore potential mediators responsible for such benefits (eg, spiritual meaning [68]) and the contextual factors in which such benefits are maximized.

Interestingly, participants reported an initial hesitancy toward meditation, but interviewees reported that engagement with the meditation content on the app helped them enter a meditative state, which reportedly helped them face problems directly and better absorb information. This is an important finding given that some conservative Christians may hold negative views toward meditation because of its relationship with Buddhism [65]. For example, some more theologically conservative religious individuals may mistrust practices founded on traditions outside their own religion or view them as taboo. Accordingly, there might be hesitation to engage with content that does not squarely align with one’s religiously endorsed practices or that may not be prescribed by one’s religious teachings. Future work should explore the boundary conditions of these hesitations and what predicts such attitudes toward these practices.

Furthermore, the sample reported significantly greater well-being over time over the course of the study (ie, spiritual well-being, religious commitment, life satisfaction, and racial or ethnic identity development). Along these lines, interviewees expressed that engagement with the app (eg, podcasts, scripture reading, and meditations) positively affected their faith, spiritual well-being, and daily spiritual practices. Such findings are consistent with those of previous research suggesting that religious and spiritual identity and engagement are positively associated with well-being across REM groups [22,24,32]. Our findings are also consistent with those of other app-based mental health interventions that suggest that apps may serve as a self-management tool or adjunctive treatment [69,70]. However, app-based interventions have typically lacked diversity in their samples, and therefore, considering the preliminary nature of this study, outcome consistency cannot yet be determined [61].

The finding that participants reported higher levels of racial or ethnic identity over the course of the study was interesting and warrants further exploration. Religion and spirituality have been theorized to be important cultural factors in promoting positive psychological well-being in people of color [17]. For example, in a sample of African American individuals, religious commitment was related to higher levels of racial or ethnic identity and satisfaction with life [23]. It may be that the religious content on the app can provide a way to help encourage positive messages about one’s racial or ethnic identity and help people of color cope with and counter negative messages or narratives related to one’s racial/ethnic identity that are experienced in the broader culture (eg, racism and microaggressions). To be sure, future research sampling from a broader range of REM groups is important.

Given that the literature consistently demonstrates a significant association between religion or spirituality and well-being among REM populations, this app may provide a supplemental digital avenue to increase mental and spiritual well-being among REM groups, with the potential for greater improvement with increased use. This is especially important given the historical lack of access to mental health resources among African American and other REM individuals [71]. Future research should use rigorous methodological designs that rely on random assignment to experimental and control conditions, such as randomized clinical trials, to establish the causal effect of using a faith and prayer app for the purpose of improving mental health and well-being in REM groups.

Mental Health and Well-Being Improvement Association With Objective App Use

There was considerable variability in the degree to which participants used the app. Not all participants adhered to the instructions to use the app 5 minutes a day, 5 days per week. Greater objective app use was associated with decreased stress as well as depressive and anxiety symptoms. On average, participants used the app for 45.83 (SD 111.90) minutes and a total of 5.77 (SD 8.19) days throughout the course of the study. This is not consistent with what participants self-reported, and average app use across the study period was not consistent with what we asked participants to do (use the app for 5 min/d, 5 times/wk). Adherence to web-based and digital interventions is typically lower than that to in-person interventions [72], and future research should implement strategies to promote and ensure participation.

Examining well-being outcomes, objective app use was only significantly associated with an increase in spiritual well-being. Interestingly, improvements in satisfaction with life, religious commitment, and racial or ethnic identity development were not associated with app use. Religious commitment was also high in our sample at baseline as 73% (56/77) always identified with a religion and 26% (20/77) reported that they were new identifiers or reidentifiers, and it may take longer than 4 weeks for a religiously committed sample to observe significant changes in religious commitment. Most participants (57/77, 74%) attended in-person services at least once a week, and almost 25% (18/77, 23%) attended at least once or twice a month, whereas 56% (43/77) participated in a religious group at least once a week and 38% (29/77) participated in a religious group once or twice a month. Religious and spiritual practices outside of an app may be one reason why well-being outcomes significantly improved at the postintervention time point but only spiritual well-being was associated with app use. Future
research should consider testing the use of a technology-mediated religious or spiritual practice against samples who attend and do not attend in-person religious services or activities.

In addition, behavior change is complex and may affect individuals in a variety of ways [73]. It is possible that the amount of behavior requested (5 times a week for 4 weeks) was not appropriate for each participant. Although satisfaction with life, religious commitment, and racial or ethnic identity development outcomes were not significantly associated with app use, merely having access to technology-mediated religious or spiritual practices may have contributed to the significant improvements observed. Others have reported that perceived access may be no less valid than actual access and may be a stronger predictor of use than actual access [67,74]. Future research should assess the amount of time spent in digitally mediated religious and spiritual practices that are feasible and elicit changes in well-being outcomes such as satisfaction with life, religious commitment, and racial or ethnic identity development.

Limitations and Future Research
The results of this study should be interpreted within the context of its limitations. First, this was a feasibility study, and we found initial evidence to our survey that the app was perceived as feasible by participants. Although small effect sizes were observed, clinical significance cannot be determined at this time. We encourage future research that uses a more rigorous methodology that relies on longer study periods and random assignment to experimental and control conditions, such as randomized clinical trials. A longer randomized controlled trial would be beneficial for establishing the causal effect of using a faith and prayer app for the purpose of improving mental health and well-being. Randomization and comparison with a control condition will also limit the potential of confounding factors such as possible COVID-19 impact as well as social and economic characteristics. In addition, all outcome measures were self-reported, and the findings should be interpreted based on the potential bias that self-reporting introduces, such as social desirability bias.

Second, a large percentage of participants who initially responded to our survey were determined to be inauthentic responses (eg, bots and duplicate IP addresses). This is a common problem when using the internet and social media to recruit participants. Once we realized the problem, we implemented additional strategies to ensure data quality, such as bot detection and reCAPTCHA and checking responses. Future research should implement these strategies from the beginning of data collection. In addition, it may be helpful to require a face-to-face meeting with potential participants before they enter the study.

Third, our sample predominantly comprised Black or African American individuals who were aged between 26 and 36 years and reported being affiliated with the Christian faith. Our findings may not be generalizable to other REM populations, age groups, or religious or spiritual faiths. For example, religion or spirituality may be experienced differently by older individuals [75], leading to different needs regarding interventions. In addition, as participants self-selected into the study, they may have had expectancy effects regarding the effectiveness of faith-based interventions and may have experienced confirmation bias regarding the effects of using the app. Future work including using purposeful sampling with greater racial or ethnic, denominational, and age range diversity would be desirable to test the generalizability of our findings. In addition, information from these studies could be used to help increase the cultural and religious inclusivity of the app.

Fourth, because of the web-based and autonomous nature of the study, we were not able to control how many minutes and days the participants actually engaged with the app. At the onset of their participation, participants were instructed to “engage in the app at least 5x/week and at least 5 minutes/day.” Although our results suggest that greater app use was associated with improved mental health symptoms and increased spiritual well-being, the study results may not have captured the full impact of app use as accurately as a study design in a more controlled setting would have. Future research should strive to establish causal mechanisms of a faith-based app that may elicit improved outcomes and use engagement strategies to ensure adequate and appropriate app use to better capture the relationship between technology-mediated religious and spiritual practice and mental health symptoms and well-being. Future research should also collect subscription rates after the study to increase the validity of the feasibility findings.

Conclusions
In conclusion, this is the first study to assess the feasibility of a faith and prayer app for mental health (ie, stress, depression, and anxiety) and well-being (ie, religious commitment, spiritual well-being, satisfaction with life, and racial or ethnic identity) in a sample of REM individuals. Our findings suggest that the use of a faith and prayer app (ie, Pray.com) is feasible and may be significantly impactful for the improvement of mental health symptoms and spiritual well-being in REM individuals and their communities, especially Black and African American individuals. Participants also reported some critical feedback about some of the content as well as about the technological interface of the app. These findings should be interpreted based on the preliminary nature of the study and the context of its limitations. This study lays the foundation for future work to be conducted in REM groups to assess the impact of technology-mediated religious or spiritual practice on health and well-being.

Abstract

Background: US schools increasingly implement commercially available technology for social media monitoring (SMM) of students, purportedly to address youth mental health and school safety. However, little is known about how SMM is perceived by stakeholders, including the students who are the focus of these efforts.

Objective: We aimed to assess attitudes toward SMM in schools among 4 stakeholder groups and examine reasons for holding supportive, neutral, or unsupportive views toward the technology. We also sought to explore whether any differences in attitudes were associated with binary sex, race, ethnicity, sexual orientation, or gender identity.

Methods: In October 2019, we conducted a convergent parallel mixed methods web-based survey of young adults (aged 18-22 y; n=206), parents (n=205), teachers (n=77), and school administrators (n=41) via Qualtrics web-based panels. We included Likert-type survey items to assess perceived benefits, risks, and overall support of SMM in schools and test for differences based on stakeholder group or demographic characteristics. We also included open-ended questions, and the responses to these items were analyzed using thematic content analysis of reasons given for holding supportive, neutral, or unsupportive views.

Results: The tests of group differences showed that young adults perceived lower benefit (P<.001) as well as higher risk (P<.001) and expressed lower overall support (P<.001) of the use of SMM in schools than all other stakeholder groups. Individuals identifying as nonheterosexual also perceived lower benefit (P=.002) and higher risk (P=.02) and expressed lower overall support (P=.02) than their heterosexual counterparts; respondents who identified as people of racial and ethnic minorities also perceived higher risk (P=.04) than their White counterparts. Qualitative thematic content analysis revealed greater nuance in concerns about SMM. Specifically, the primary reasons given for not supporting SMM across all stakeholder groups were (1) skepticism about its utility, (2) perceived privacy violations, and (3) fears of inappropriate or discriminatory use of the data. Within the young adult group in particular, concerns were also raised about (4) unintended and adverse consequences, including the erosion of trust between students and school institutions and administrators, and the chronic adverse effects of constant or prolonged surveillance. Thematic analysis also showed that individuals in every stakeholder group who indicated overall support of SMM were likely to cite the potential for enhanced school safety as the reason. Young adults’ overall stances toward SMM were the most polarized, either strongly for or strongly against SMM, and responses from teachers indicated similar polarization but more often favored support of SMM in schools.
Conclusions: This study found differing perspectives among stakeholder groups regarding SMM in schools. More work is needed to assess the ways in which this type of surveillance is being implemented and the range and complexity of possible effects, particularly on students.

**Introduction**

Background

In recent years, the United States has witnessed a troubling increase in both youth suicide [1] and incidents of school gun violence [2]. To address these concerning trends, public K-12 schools have implemented security measures, including the increased use of security cameras in schools as well as lockdown drills and protocols, based on data from the National Center for Education Statistics [1]. In addition, according to a recent survey, nearly 90% of school teachers reported that their school used technology during the 2021-2022 school year to track student activity on school-issued and personal devices, such as by accessing the content of students’ internet searches or remotely viewing students’ computer screens in real time [2].

As part of the increased surveillance of students, a growing number of schools have turned to commercially available social media monitoring (SMM) technology, which some companies claim will prevent harms on school campuses by monitoring students’ activity on the web, including, in some cases, activity that occurs outside of school hours [3-5].

SMM technology works by scanning public content posted by students on social media platforms such as Twitter, Facebook, and Instagram for certain words and phrases that might signal a threat of harm to oneself or others, in most cases without the explicit knowledge of students. The next step in the use of this SMM technology is the flagging of posts containing potentially problematic references to harmful behavior, such as suicide or self-harm, bullying, violence, or hate speech. When such posts are detected, the monitoring software alerts school officials, who can then notify teachers and parents or intervene by taking disciplinary measures or contacting school authorities or law enforcement. There is limited transparency regarding the specific workings of SMM (eg, algorithms, training data, and quality control) and limited evidence of its efficacy; for example, general overflagging of lesbian, gay, bisexual, transgender, queer, and similar minority (LGBTQ+)–related words has been noted across some SMM technologies, which raises issues of negative and disproportionate impact on certain groups of students and discrimination more broadly [3].

It has been difficult to determine exactly how many schools in the United States currently use SMM services. One of the first publicized uses of SMM technology was in September 2013, when the Glendale Unified School District in California hired the firm Geo Listening to monitor the social media content of 13,000 middle and high school students residing in their district [4,5]. Since 2013, the number of schools implementing SMM technologies has grown significantly. According to SmartProcure, a database for government purchase orders, in 2018, SMM services were purchased by schools to directly monitor the social media activity of >3 million students across 63 public school districts in the United States. This represented a 10-fold increase from 2013 when just 6 school districts were found by SmartProcure to have purchased such services [6]. More recently, Social Sentinel, a leading provider of SMM services, has claimed that it serves “thousands of schools in more than 35 states” [7]. The increasing frequency of anecdotal reports of SMM use in the media, usually in response to episodes of gun violence in schools, is consistent with this trend; for example, after the tragic shooting at Robb Elementary School in Uvalde, Texas, in May 2022, The Dallas Morning News reported that Uvalde was among at least 52 school districts in Texas alone that hired the firm Social Sentinel to monitor the social media content of its tens of thousands of students with the purported goal of preventing harm to students [7,8]. This statistic for just 1 SMM company may be a conservative estimate of school-based SMM across the United States.

Contrary to what might be expected, studies of general school surveillance practices suggest associations with decreased student perceptions of safety [9-12]; for instance, 1 study found that the use of security cameras outside of school was associated with higher perceived safety, but the use of cameras inside was associated with lower perceived safety, support, and equity [13]. Another study of American middle and high school students found that visible security measures (cameras, guards, and metal detectors) were associated with higher odds of students’ fear of exposures to violence, bullying and other harms at school [14]. Furthermore, a meta-analysis of qualitative studies found that students thought that the presence of closed-circuit television cameras often resulted in risky behaviors shifting from monitored areas to less-monitored areas (eg, hallways and restrooms) [15]. A 2021 survey conducted by the Center for Democracy and Technology also reported the “chilling” effects of web-based surveillance [16]. Specifically, 6 out of 10 students reported feeling uncomfortable expressing their true thoughts and feelings on the web if they knew they were being monitored. The report argued that chilling effects that curb exploration and self-expression could be especially problematic for minors and might also make students less likely to seek web-based resources for mental health, to their detriment [16].

Youth and minoritized communities are also likely to disproportionately experience unintended adverse effects of surveillance; for instance, the Center for Democracy and Technology report also speculated that web-based monitoring might pose a risk that LGBTQ+ students may be outed as a result of surveillance [16]. In addition, some minoritized youth
have more fraught relationships with institutions such as law enforcement or disciplinary frameworks; for example, students of color are known to face higher rates and severity of punishment than their White peers, and thus, if surveillance leads to punishment, the effects of surveillance are more likely to fall on them. In fact, there is anecdotal evidence that school-based SMM has led to false positives [17], particularly with students of color. In addition, SMM algorithms may not accurately process content written in nonstandard English or languages other than English, and therefore SMM can disproportionately single out and label as dangerous students who are more likely to use nonstandard English or slang [6].

Objectives

Although schools are increasingly deploying SMM technology, there has been no systematic assessment of how it is perceived by school stakeholders or how it might affect the students whom it purportedly aims to help. To address this gap, we conducted an exploratory survey assessing attitudes toward SMM in schools among 4 key stakeholder groups: school administrators, teachers, parents, and young adults. This survey included both closed-ended quantitative and open-ended qualitative questions to assess stakeholders’ attitudes. As a secondary aim, we also sought to statistically test for any differences in attitudes as a function of stakeholders’ self-reported gender, race, ethnicity, and sexual orientation.

Methods

Ethical Considerations

This study was reviewed and approved by the University of California, San Diego Office of Institutional Review Board Administration (191060) and received a waiver of signed consent. Each participant provided informed consent via radio button selection at the bottom of the web-based landing page that included written information about the study. Survey participants were compensated by Qualtrics.

Recruitment

From October 7 to 15, 2019, we conducted an 8-minute web-based survey of young adults and parents via Qualtrics web-based consumer panels, as well as of teachers and administrators via Qualtrics web-based business-to-business panels. Participants on these panels are recruited from various sources, including website recruitment, member referrals, targeted email lists, gaming sites, customer loyalty web portals, permission-based networks, and social media. Qualtrics validates consumer panel members’ names, addresses, and dates of birth via third-party measures, and panel members are subject to additional quality control measures such as LinkedIn matching, telephone calls to the participant’s place of business, and other third-party verification methods (provided by companies such as TrueSample, RelevantID, and Verity). Although we originally desired to have an equal representation of teachers and administrators, this was not feasible owing to cost for the recruitment service. We also oversampled parents and young adults with the reasoning that, to date, these groups have been largely absent from dialogue and decision-making pertaining to SMM.

Eligibility and Screening

Young adults were eligible if they were aged between 18 and 22 years and either a high school graduate or current high school student. Parents were eligible if they had children aged between 14 and 22 years. Teachers and administrators were eligible if they were employed in the education industry and were middle or high school teachers or administrators. For teachers and administrators, Qualtrics used a combination of the profiled information they had on file to target these professionals and screening questions at the beginning of the survey to confirm information for the specific survey respondents who qualified for the survey.

Survey Design

The survey measure included (1) screening questions (4-7 items, dependent on skip logic), (2) basic demographic questions (8 items), and (3) questions soliciting views about SMM (9 items) that were modeled after another survey on public views of genome editing [18]. In the last category (Multimedia Appendix 1), there were 7 items that were measured on a 7-point Likert-type scale ranging from 1=strongly disagree to 7=strongly agree: 3 items asked about the perceived efficacy of SMM for addressing school-related violence, bullying, and mental health issues (ie, potential benefits of SMM); 3 items asked about the level of concern for SMM as it relates to privacy, data misuse, and discrimination (ie, potential risks of SMM); and 1 item asked about the overall level of support of the use of SMM in schools. There were also 2 open-ended questions: “Please describe how you feel about middle schools and high schools monitoring students’ social media activity.” “Is there anything else you would like to share about this issue?” This combination of closed- and open-ended questions reflects our use of a convergent parallel mixed methods design in which the quantitative and qualitative data collection occurred concurrently.

Data Collection

We defined sample size quotas for the survey that aimed to collect responses from 200 young adults, 200 parents, 60 teachers, and 40 administrators. Qualtrics distributed the survey via a dashboard service whereby the survey would appear on a panel member’s dashboard if their profile indicated that they potentially met the inclusion criteria. We estimate that the survey was made available to between 14,400 to 16,000 individuals via this method, and 1600 individuals clicked a link to view the study information and consent page for the study. Of these 1600 individuals, 690 (43.13%) provided consent to participate in the study. Study data were collected and managed using the Qualtrics web-based survey platform. A soft launch to pilot-test the survey and check for any administration problems collected 30 responses that were used to establish quality benchmarks. Once data collection closed, responses were reviewed for completeness and quality in 2 phases. First, Qualtrics research panel staff filtered out all respondents who did not complete the survey or who completed the survey in less than half the median response time. Second, study team members filtered out any respondents who left gibberish in response to the open-ended questions.
Data Analysis

Overview

We generated descriptive statistics to summarize and compare the sociodemographic characteristics of study participants. Quantitative data analyses were conducted using SPSS software (version 28.0; IBM Corp), and significance was set at \( P < .05 \) for all analyses. To enhance interpretability, an SMM benefits score was created by summing responses on the first 3 survey items pertaining to potential benefits from SMM (ie, to help address mental health, bullying, and threats of harm or violence; range: 3–21, with higher scores suggesting greater perceived benefits). Across this set of survey items, the Cronbach \( \alpha \) value was .853, indicating high internal consistency. An SMM risks score was created by summing responses on the next 3 survey items pertaining to the potential risks of SMM (ie, it potentially violates privacy, leads to abuse or misuse of information, and leads to potential discrimination; range: 3–21, with higher scores suggesting greater perceived risks), and the Cronbach \( \alpha \) value was .828. The final quantitative survey item assessed overall support of SMM in schools.

Quantitative Analyses

We used 1-way analysis of covariance and Bonferroni-adjusted post hoc pairwise comparisons to test for statistically significant differences among the 4 stakeholder groups on (1) SMM benefits, (2) SMM risks, and (3) overall support, controlling for sex (female vs male), race and ethnicity (non-Hispanic White vs all other groups), and sexual orientation (heterosexual vs all other groups). Partial eta–squared (\( \eta^2_p \)) was used as a measure of effect size, and the values of 0.01, 0.06, and 0.14 represent small, medium, and large effects, respectively [19]. To examine our second question regarding differences in the perceptions of SMM as a function of demographic characteristics, a series of independent samples 2-tailed \( t \) tests were conducted on the full sample to compare SMM benefits, SMM risks, and overall support of SMM by sex (female vs male), race and ethnicity (non-Hispanic White vs all other groups), and sexual orientation (heterosexual vs all other groups).

Qualitative Analyses

In analyzing the 2 open-ended questions, most participants answered such that their response to the second open-ended question was an extension of their answer to the first open-ended question. Thus, we considered responses to both items together and conducted thematic analysis with a contextualist lens [20]. Our inductive approach began by studying the short responses repeatedly to identify commonly discussed content, generating a list of 15 initial codes. A single coder then collated and refined the codes into a list of themes. As a final step, we integrated the data by merging the quantitative results with the qualitative results [21]. Specifically, the qualitative comments were sorted and read to identify similarities and differences within and among stakeholder groups, demographic groups, and levels of overall support of SMM in schools. In this way, we used triangulation to yield a more holistic understanding of the data and draw the conclusions set forth in the results presented.

Results

Sample Characteristics

A total of 690 individuals entered and consented to the survey. Of the 690 responses, 161 (23.3%) were identified as poor-quality completes and were removed from the data set. This yielded a final survey sample of 529 participants, which included young adults (n=206, 38.9%), parents (n=205, 38.8%), teachers (n=77, 14.6%), and school administrators (n=41, 7.8%). Table 1 provides descriptive statistics of the demographics of our sample.

Quantitative Results

Stakeholder Group Comparisons

There were significant differences by stakeholder group in perceived SMM benefits, SMM risks, and overall support of SMM after controlling for sex, race, ethnicity, and sexual orientation. Table 2 provides the results of the analysis of covariance analyses, and Figure 1 shows the proportions within each group who were supportive, neutral, or unsupportive of SMM. Follow-up pairwise comparisons (data not shown) found that young adults were significantly different from all other groups and by comparison perceived lower benefit, higher risk, and less overall support of use of SMM in schools than parents, teachers, and administrators.

Figure 1. Overall opinion about the use of social media monitoring in schools by stakeholder group. Using data from question 7 of the survey, we collapsed all the agree categories (strongly agree, agree, and somewhat agree) into supportive and all the disagree categories (strongly disagree, disagree, and somewhat disagree) into not supportive; neutral refers to responses of neither agree nor disagree.

Demographic Group Comparisons

There were also significant differences by sexual orientation, race, and ethnicity. Specifically, nonheterosexual individuals perceived significantly lower benefit, higher risk, and less overall support of the use of SMM than their heterosexual counterparts. In addition, individuals identifying as people of racial and ethnic minorities perceived significantly lower benefit and higher risk than their non-Hispanic White counterparts. Tables 3, 4, and 5 provide the results of the 2-tailed $t$ tests. There were no significant differences as a function of sex.

Qualitative Results

Overall Stances Toward SMM and Stakeholder Group Differences

Generally, responses from the young adult cohort were the most polarized, with most respondents being either strongly in favor or strongly against the use of SMM in schools. Responses from teachers indicated similar polarization, but they were more commonly in favor of school-based SMM.

Reasons to Support SMM

Across all stakeholder groups, among those who indicated that they supported the use of SMM, the primary reason offered for this support was its potential utility to assist in identifying or preventing violence and bullying. One respondent noted as follows:

Kids are bullied every single day and are taking their lives. They won’t hardly talk to anyone and it mostly happens on Facebook or Instagram and things of that sort. I believe it would be a good idea to slightly monitor social media. [Young adult respondent 3MtgW]

Another respondent stated that SMM might be a valuable service “if watching children’s social post[s] could save a child from bullying, suicide or abuse” (Parent respondent 23gc8). Surveillance, according to respondents, could be a tool in a school or school district’s safety toolbox as “an extra layer of protection to make sure the school is safe” (Teacher respondent YQzyo) and “no different [than] installing metal detectors to screen for weapons” (Administrator respondent 3MGxE).

Justification for respondents’ support ranged from feeling that SMM was “a necessary evil” (Parent respondent 27JO1) to feeling that SMM was “absolutely necessary” (Teacher respondent 3fjYb) and “a good and wise thing to do” (Young adult respondent BKwWJ).

Reasons for Concern About SMM

Overview

Across the stakeholder groups, individuals who were unsupportive of SMM cited similar reasons for their stance. Specifically, our qualitative analysis showed that the primary reasons given for not supporting SMM that were cited across all stakeholder groups were (1) skepticism about its utility, (2) perceived privacy violations, and (3) fears of inappropriate or discriminatory use of the data captured in SMM reports. Importantly, the critics of SMM also felt that SMM in schools could lead to (4) unintended and adverse consequences, such as the erosion of trusted relationships among students, parents, and schools or the chronic adverse effects of constant or prolonged surveillance. We expand on each of these areas in the following subsections, and additional relevant quotes are provided in Textbox 1.
Skepticism About the Utility of SMM

- Administrators: “Sometimes the content posted can also be figurative speech so you can’t really determine if they mean it or not. Example: ‘I’m so going to kill you.’ 99% of the time that term is used jokingly.” (Administrator respondent 6JO0U)
- Teachers: “Well, I’m not sure how it would be done. It’s not easy to monitor...Hiring a social media monitoring staff seems just a bit too far for me. My school uses Twitter and Facebook to interact with students but there are so many app based forums which are far more popular with the youth. As is typical, us adults are ten years behind the kids in terms of tech.” (Teacher respondent 2YJac)
- Parents: “[I] post things on social media that I can understand but it may not exactly tell you who I am as a person. I’m not sure how true to light you can actually see a person as far as social media goes.” (Parent respondent 3Gv1Z)
- Young adults: “[S]tudents would feel very violated and would try not to post revealing content or get around this by making another account with fake information.” (Young adult respondent 2rMEm)

Perceived Privacy Violations

- Administrators: “Invasion of privacy and over reach of responsibility.” (Administrator respondent 2CVC0)
- Teachers: “The harms and benefits of surveillance aren’t mutually exclusive. It’s a question of which are more important. In my opinion privacy and misuse are a bigger concern than mental health and bullying. There are other ways to deal with those problems. On the other hand, there are fewer ways to protect the students privacy and prevent schools from abusing their power. Who is watching the watcher?” (Teacher respondent 25G66)
- Parents: “What happens to the data and how are concerns then addressed! Schools often seem to do a poor job of intervening when kids are being bullied even without access to online social media accounts!” (Parent respondent 2vktc)
- Young adults: “I feel like it can help see bullying in schools and some threats to the school, but it does violate privacy. When a student steps into their freedom are revoked, but once they are out of school they have a right to privacy and monitoring would take away from that right.” (Young adult respondent 22Gqu)

Fears of Inappropriate or Discriminatory Use of Data

- Administrators: “I have concerns that middle and high school staffs are not fully equipped to deal with bullying and school violence. I fear that certain students from certain backgrounds will be discriminated against based on what they write/say on social media platforms.” (Administrator respondent 3241I)
- Teachers: “I am concerned how the information would be used—who would be ‘singled’ out for further actions?” (Teacher respondent 1GPQI)
- Parents: “I’m afraid schools will abuse it and students will get in trouble for every little thing school administration disapproves of.” (Parent respondent 3CUT0)
- Young adults: “I think it’d be a good idea but I also think that a lot of teachers would mistreat some students. I’ve had it happen to me before over something I didn’t even post and I can tell you it made me more depressed than before. The idea is good but you can’t trust teachers to be fair, they are only human and it could really hurt a student’s mental health when the teachers act like children themselves.” (Young adult respondent 2dM7k)

Skepticism About the Utility of SMM

The main question raised by those who did not support the use of SMM in schools was whether any SMM company, presumably operated by adults, could accurately and reliably catch troubling posts. Some felt that once students were aware of the monitoring, they would simply make their posts private, rendering the monitoring efforts ineffective. Stakeholders were also doubtful that teachers and administrators could correctly interpret students’ social media posts, given the loss of context and the challenge of deciphering irony in web-based messages. Finally, stakeholders questioned the overall feasibility of SMM because “adults are ten years behind the kids in terms of tech” (Teacher respondent 2YJac). On this point, another respondent wrote that “the threats are made through apps 9 times out of 10 where the message disappears” (Parent respondent yNHHU), referring to apps that allow users to send text messages that are automatically deleted after a period of time or once read by the recipient.

Perceived Privacy Violations

A major concern expressed by those who were unsupportive of the use of SMM was that monitoring would violate student privacy because “kids have the right to a life outside of school” (Teacher respondent 2fkRi) and such monitoring “removes a space where students can feel totally free to be themselves” (Young adult respondent 1mjXY). Other comments expressing concern ranged from those who simply stated that SMM was an invasion of privacy to those who felt discomfort with schools taking such actions:

[I]It feels a bit weird. Like an over reaching of boundaries. It just feels not right for schools to be monitoring personal social media accounts usually meant for friends or family. [Young adult respondent 3QF2F]

The words “private” or “privacy” were explicitly mentioned in roughly a third of all young adult and administrator comments (72/206, 35.5% and 16/41, 39%, respectively), whereas parents and teachers mentioned these words less often (27/205, 13.2% and 15/77, 19%, respectively).
Fears of Inappropriate or Discriminatory Use of Data
The most frequently cited concern among those who were not supportive of SMM was the potential for SMM reports to be used in discriminatory ways (eg, discriminatory punishment). However, these concerns were raised primarily by young adults and parents, with teachers and administrators citing this concern in only 2 instances. Respondents worried that SMM might “become too far reaching and subjective” (Parent respondent 3iqKX). Young adults, in particular, feared that they would get in trouble for simply “posting what they feel like or how they feel” (Young adult respondent 1dnr8) “because staff at the school may not agree with posts or get offended by them and cause them to feel negatively toward that student and treat them unfairly” (Young adult respondent WjMZk). More broadly, respondents across all stakeholder groups recognized the possibility for SMM to exacerbate unconscious or conscious biases.

Unintended and Adverse Consequences
Finally, respondents wondered how the use of SMM might have some unforeseen and adverse impact:

* It is a slippery slope...It seems like a good idea as far as safety, but I worry about what the information could be used for and if it will cause more trouble than good. [Administrator respondent 2SIJs]*

Young adult stakeholders, in particular, raised specific concerns about the potential for SMM to have the opposite of its intended effect (bold emphasis added by the authors); for instance, a young adult respondent noted the potential psychological and behavioral impact of SMM:

* If I were to be monitored, I would simply not use social media at all. The idea of people overlooking my online presence is anxiety-inducing and should not be allowed. [Young adult respondent 3lXio]*

Similarly, another young adult respondent stated as follows:

* Monitoring students constantly can lead to a sense of paranoia as students are constantly being watched in real life, by their parents, teachers and if monitoring is enabled on social media. [Young adult respondent 1lirF]*

A different young adult respondent brought up the potential chilling effect of SMM on students:

* I feel like schools monitoring students’ social media activity is like being a helicopter parent which isn’t necessarily bad, but it may restrict the student’s freedom knowing they’re always watched, that if they say something someone doesn’t agree with, they may be punished. [Young adult respondent 2uy40]*

Another young adult respondent pointed out the potential strain on students’ relationship with educational institutions:

* That’s a big overstep, also considering developmental psychology of that age group that seems like it would not go over well at all with the students and would brew animosity towards the schools. [Young adult respondent 32JeH]*

All these examples indicate that young adults felt that SMM in schools, contrary to its stated purpose, might increase feelings of anxiety and paranoia, potentially leading to detrimental mental health outcomes and ultimately worsening student relationships with teachers, administrators, and the school system overall.

Discussion
Principal Findings
This study assessed attitudes toward SMM in schools and identified similarities and differences across groups of young adults, parents, teachers, and school administrators, as well as across demographic groups. We found that the young adults we surveyed perceived lower benefit as well as higher risk and expressed lower overall support of the use of SMM in schools than all other stakeholder groups. In addition, individuals identifying as nonheterosexual also perceived lower benefit as well as higher risk and expressed lower overall support than their heterosexual counterparts. Respondents identifying as people of racial and ethnic minorities also perceived higher risk than those identifying as White. Qualitative thematic analysis highlighted the nuances of stakeholder attitudes and found that individuals in every stakeholder group who indicated support of SMM were likely to cite enhanced school safety as the reason. Individuals who were unsupportive cited skepticism about the utility of SMM, perceived privacy violations, and fears of inappropriate or discriminatory use of data. Young adults, in particular, also raised concerns about unintended consequences, including the erosion of trust between students and school institutions and the chronic adverse effects of constant or prolonged surveillance. Taken together, this study provides some of the first empirical documentation of stakeholders’ attitudes toward the use of SMM technologies in schools and is a first step toward generating needed discourse around this emerging technology.

Although we anticipated a priori that young adults would express the most unfavorable views of SMM, the qualitative responses we received indicated that this group thoughtfully considered potential benefits as well as potential drawbacks of SMM in schools. Specifically, young adults across the board, including those who were neutral or generally supportive of SMM, raised concerns about privacy and discrimination. This suggests that even young adults who favor school-based SMM may be concerned about potential harms to students, including that it could lead to negative mental health outcomes, the opposite of its intent. These findings suggest that young people do see problems or concerning trends in their schools and see a need for intervention but are skeptical about whether SMM is an appropriate or effective solution to such problems. The young people in our survey also demonstrated a keen awareness of trends in social media and web-based communication that SMM service providers and clients need to be aware of when using SMM and interpreting social media content.

The diverging viewpoints between young adults and the other stakeholder groups is also an essential finding because students are the primary targets of SMM; yet, they have had very little decision-making power in the implementation of these
surveillance systems. The skepticism among young people toward these technologies further problematizes their general absence from the decision-making process, especially when schools that use SMM services often do so without students’ consent and, in some cases, without their knowledge [22]. Our results highlight how schools that consider or implement SMM should at a minimum engage in dialogue with students and recent graduates and consider how to make surveillance practices and policies more transparent. More research is also needed to better understand young adults’ concerns about currently evolving technologies and surveillance methods to minimize potential harm to students. This is particularly relevant for those who are not yet adults and may have fewer legal protections should school-based actions be taken against them based on social media data received from SMM companies. Similarly, constructing policies and ethical standards for SMM in schools would require bridging any gaps between the perceptions and knowledge of young adults and those of other stakeholder groups, perhaps by developing shared conceptual frameworks.

Expressed skepticism about SMM efficacy is also particularly salient, given that SMM continues to operate as a quickly moving target. The tragic school shooting in Uvalde, Texas, provides an unfortunate example of a case when SMM in schools did not function as claimed. The Dallas Morning News reported that according to records from GovSpend, an organization that tracks state and local government spending, the Uvalde Consolidated Independent School District was among at least 52 Texas school districts that hired Social Sentinel to monitor the social media activity of its tens of thousands of students [7,8]. However, like other SMM service providers, Social Sentinel only monitors public social media activity and, consequently, was unable to detect the shooter’s private communications related to the shooting [23]. The failure of SMM to prevent this tragedy has raised questions about the efficacy of such technologies and whether the potential harms of SMM might outweigh the potential good [24]. Our findings suggest that any cost-benefit analysis of SMM in schools must directly probe perceived costs and benefits from the members of all stakeholder groups and seek to recruit individuals across the spectrum of attitudes because, although there were commonalities in attitudes expressed across participants, the groups did diverge on issues. In particular, discrimination was more important to parents and young adults than to administrators, and the group approximating the population considered vulnerable of school-attending youth—young adults—provided richer descriptions of unintended consequences, of which other stakeholder groups and SMM companies need to be aware. It will also be important to gather insights from the public and individuals situated within the technology industry and predictive sciences who can provide expert opinion on what constitutes efficacy regarding purported SMM benefits.

We found that SMM perceptions also significantly differed by respondent sexual orientation such that nonheterosexual respondents saw fewer benefits (P=.002) and greater risks of SMM (P=.02), leading to less overall support of SMM (P=.02). LGBTQ+ individuals, as a group, have been reported to be frequent social media users [25], more so than heterosexual individuals [26] or the general public [27]. Previous literature has underscored the importance of social media for LGBTQ+ individuals. Specifically, social media is used as a space for identity exploration, social support, making platonic or romantic connections, and finding resources [28,29]. Moreover, social media has been described as a “safe space” [30] for LGBTQ+ youth. Given the levels of anonymity [31] or privacy settings [32] that social media can afford, LGBTQ+ individuals can manage how or whether to disclose their identities as well as express themselves more fully with less fear of stigma or marginalization than with in-person interactions. Through this lens, SMM might continue to disproportionately affect LGBTQ+ individuals and jeopardize the safety and anonymity they feel in using social media. We also found that the perceptions of SMM risks differed by race and ethnicity such that people racial and ethnic minority respondents perceived greater risks. This finding may be explained by the “racial discipline gap” [33] or the disproportionate rate of school disciplinary sanctions against students of color. Given the long history of differential disciplinary treatment (eg, suspensions and expulsions) of students belonging to racial and ethnic minority groups compared with their non-Hispanic White counterparts, respondents may have concerns about the potential inequitable disciplinary actions taken as a result of SMM surveillance.

More broadly, some of these concerns have also been underscored by a recent US Congressional investigation [34] of 4 educational technology companies, which found that their surveillance platforms may be misused for disciplinary purposes, that surveillance often occurs around the clock (with alerts sometimes bypassing school personnel and going straight to law enforcement), and that parents are not adequately informed. This investigation concluded that “these surveillance products may continue to put students’ civil rights, safety, and privacy at risk” [34] and called on “the federal government...to track the potential impacts of student surveillance technology on students in protected classes...and work to ensure that products used by schools maintain student safety and privacy.” Our study seeks to answer this call to action by generating new insights about stakeholder perceptions of SMM. Moreover, although this study takes 1 step in this direction, more discussion among key stakeholder groups is essential to enhancing awareness and understanding of these technologies and their potential consequences. Failure to do so could have significant consequences, including the erosion of trust among stakeholders, such as students, parents, and educational institutions. Youth mental health and school safety are both urgent and increasingly complex societal challenges, and SMM represents an effort to look to science and technology for a solution. However, per the “technologies of humility” espoused by Jasanoff [35], we must reflect carefully on the ethical dimensions of this landscape and seek to understand and alleviate vulnerability to harm and be mindful of the distribution of risks and benefits.

The need for greater discourse in this area has also been amplified by the COVID-19 pandemic because the blurring of educational and digital spaces has led, and likely will continue to lead, to greater adoption of digital monitoring technologies. The expansion of school administrators’ guardianship and jurisdiction over students beyond school grounds and into digital
spaces is likely to continue in this environment, meaning that critical scholarship and further investigation into these technologies are urgently needed. This urgency is further underscored by the lack of tangible and effective solutions to ongoing issues around youth violence, bullying, and suicidality. The immense pressure on schools to address such issues will likely lead to the further adoption of SMM without fully considering the potential consequences and harm that may result from such decisions.

This work has some limitations. First, we designed this as an exploratory survey, and thus the items were not validated for specific populations. Future surveys that use validated measures could more meaningfully probe associations between attitudes toward SMM and the characteristics of students. One future direction could be to use the insights from the qualitative data to inform the creation of more specific survey items assessing the perceived benefits and risks of SMM. Second, our findings reflect a sample of convenience, and future studies should seek to obtain nationally representative samples and samples with higher response rates. Third, although the data collected by our open-ended questions were valuable for our analysis, future studies might use in-depth interviews and focus groups to gain a deeper understanding of stakeholder attitudes and beliefs. Finally, this work did not survey current middle or high school students, which would be a fruitful approach in future work to gain more direct insight into young people’s perspectives and attitudes toward SMM.

Conclusions

The results of this study reveal commonalities as well as divergences across stakeholder groups, both in surveyed attitudes regarding SMM in schools and open-ended responses provided directly by participants. The results also highlight the need for greater inclusion of individuals identifying as members of marginalized groups. Future research could examine what steps can be taken to foster greater inclusion of these groups in dialogue and decisions regarding the use of SMM in schools and investigate the real and potential harms and consequences of the use of SMM technologies for those being surveilled.

Abstract

Background: Majority of individuals, including both younger and older adults, had to adapt to digital means to cope with lockdown measures and pandemic-induced lifestyle changes during the COVID-19 pandemic. While internet accessibility was beneficial during the pandemic, existing literature suggests that excessive use could lead to the rise of problematic internet use in adolescents and younger adults. However, the effects on older adults remain unclear.

Objective: This study aimed to examine differences in internet use during the lockdown phase of the COVID-19 pandemic and explore how age differences in mental health could be explained by time spent on the internet.

Methods: A door-to-door survey of a nationally representative sample of 602 adults in Singapore was carried out using computer-assisted personal interviewing during the early phase of the COVID-19 pandemic (October to November 2020). Participants were categorized into younger (21-59 years old) and older (60 years or above) age groups. We assessed self-reported measures of depression, anxiety, and stress; psychosocial adaptability; ability to perform essential activities; social support; health status; digital media use patterns, and time spent on the internet. Procedures complied with existing safe distancing measures.

Results: Older adults reported being less able to use digital platforms to meet needs and acquire information updates compared with younger adults during the lockdown period of the pandemic. Older adults spent significantly less time on the internet for both work and personal uses per day (mean 146.00 min, SD 9.18 min) compared with younger adults (mean 433.27 min, SD 14.32 min). Significant age differences in depression, anxiety, and stress were found, with younger adults showing poorer mental health. Mediation analysis showed that age differences in depression, anxiety, and stress were partially explained by time spent on the internet. These variables together explained 43%, 40%, and 40% of the variances in depression, anxiety, and stress scores, respectively.

Conclusions: The findings showed that younger adults spent significantly more time on the internet compared with older adults during the lockdown phase of the pandemic. They were also ahead in their ability to use digital resources to meet needs and engage socially compared with older adults. Despite this, the mental health of younger adults was poor, and this was partially accounted for by the amount of time spent on the internet. Since past research suggests that excessive time spent on the internet could lead to disordered use, the benefits brought by digital technologies could have been attenuated during the lockdown phase of the pandemic. Considering this potential negative effect, it is imperative to educate both young and old adults in the appropriate use of information and communication technology.

Introduction

COVID-19 has brought about significant changes to the lives of people, with negative impacts on well-being. During the initial stages of the COVID-19 pandemic, “spatial distancing” was a promoted practice that entailed keeping a safe distance between individuals and reducing the number of close interactions. This put older adults at a disadvantage and may lead to feelings of social isolation and possibly exacerbate health disparity among older adults [15]. While the benefits of ICT during the pandemic seem apparent, this grey digital divide, has been an ongoing global issue during the digital exclusion of older adults, otherwise known as the growing number of older adults have been adopting ICT [11,12]. The use of information and communication technology (ICT) was critical during the COVID-19 crisis. ICT not only allowed for the dissemination of timely COVID-19–related information to the public to act upon, but also made it possible to work and study remotely. Arguably, the psychological impact of isolation was mitigated by ICT as friends and families were kept connected despite the physical restrictions imposed by lockdowns [8]. ICT provided access to various forms of entertainment and even materials guiding physical exercises [9]. Access to entertainment through ICT is important as it can help to alleviate the stress of daily living [8,10]. Although a growing number of older adults have been adopting ICT [11,12], the digital exclusion of older adults, otherwise known as the “grey digital divide,” has been an ongoing global issue during the pandemic [13,14]. Older adults face problems in a variety of basic tasks (eg, booking of tickets, claiming benefits online, and gaining access to health care services through appointments) and face exclusion because they cannot connect with their peers through online platforms owing to limited digital skills [14]. Because of the effects of restrictions in social gatherings and spatial distancing during the pandemic, this grey digital divide puts older adults at a disadvantage and may lead to feelings of social isolation and possibly exacerbate health disparity among older adults [15].

While the benefits of ICT during the pandemic seem apparent, especially if used for the purpose of communication, information, and task performance [7,16], excessive use of ICT can be problematic. For instance, the use of ICT without moderation for online gambling, viewing pornography, playing video games, viewing social media, and shopping may lead to higher risks of disordered use [2,17,18]. Research has shown that the disordered use of the internet, also known as problematic internet use, can cause emotional distress and significantly affect different domains in one’s life, including personal, family, and social relations. It can also lead to adverse effects on work or education and other areas of functioning [2,18]. In the current COVID-19 pandemic, an increase in problematic internet use has been reported and excessive internet use has been suggested as a means to cope with the enforced sedentary norms [19,20] in part due to lockdown measures and possibly pandemic-induced life changes [21,22]. The negative consequences of excessive internet use on mental health have been reported in studies during the current pandemic [23,24]. Research conducted around the same time as the inception of this study has shown that there was an increase in problematic internet use during the COVID-19 pandemic [25-32]. However, other than the studies conducted in Taiwan [28] and Japan [29], most of these studies adopted a convenience sampling approach in data collection, and the inferences made from these studies could be limited owing to the sampling bias and poor generalizability [33] associated with this sampling approach. Moreover, the populations of interest in most of these studies were younger adults and adolescents. A recent review on problematic internet use during the COVID-19 pandemic affirmed our aforementioned observation [34]. The authors of the review called for future studies comparing age influences. Only the study carried out in Japan by Oka et al [29] examined age differences. The study found that internet gaming–related problems in younger adults (<30 years) increased during the pandemic, and the numbers were much higher than those for more mature adults. Properly sampled studies comparing the effects of internet use on well-being between younger and older adults were largely missing during the lockdown period of the pandemic.

In view of the identified gaps, this study aimed to examine (1) differences in internet use between younger and older adults during the lockdown phase of the COVID-19 pandemic, and (2) the influence of internet use on the relationship between age and mental health. Given what we know about the internet use of younger adults during the pandemic, we hypothesized that younger adults would have greater use of the internet as compared with older adults, and such a difference in digital use would affect the relationship between age and mental health. This study was conducted in Singapore, an island country and city-state in maritime Southeast Asia. According to official statistics [35], internet use in Singapore has increased from 58% in 2019 to 81% in 2021 among residents aged 60 years or older. The findings from this study may contribute to our understanding of the role of internet use for mental health issues among older adults in countries with increasing internet adoption rates.

Methods

Study Design, Setting, and Participants
This study employed an observational cross-sectional study design. Residents aged 21 years or above were recruited using stratified random sampling with stratification based on housing type, geographical region, gender, and age group. A door-to-door survey was conducted by experienced interviewers between October 17, 2020, and November 27, 2020, not long after partial lockdown restrictions were gradually lifted [20]. The in-person surveying approach ensured inclusion of study participants who might not have access to the internet to mitigate selection bias. The questionnaire administered by the interviewers was worded in the English language, which is the main language in Singapore. To be included in the study, participants were required to have resided in Singapore during the lockdown phase of the pandemic (known locally as the circuit breaker (CB) period between April 7, 2020, and June 1, 2020), in which spatial distancing measures were imposed (known locally as safe distancing). They were also required to be able to speak English and be aged 21 years or older. Interviewers were trained by a geriatrician to exclude older adults who exhibited possible signs of cognitive impairment (eg, drowsiness, agitation, and incongruent language) during the process of taking informed consent. Additionally, among those aged above 70 years, the Abbreviated Mental Test (AMT) [36] was used to screen for possible signs of dementia and other cognitive impairments, and participants were excluded if they failed 1 of the 3 items in the AMT. Safe distancing rules were adhered to during the data collection period.

Ethical Considerations
Ethics approval was obtained from the National Healthcare Group Domain Specific Review Board (2020/00973), and written informed consent was obtained from all participants. Participants were reimbursed with grocery vouchers worth SGD 10 (USD 7.50) for participation. All data collected were deidentified prior to analysis.

Survey Measures

Digital Platform Use
Digital platform use was a single item measure. Participants responded to the question “What did you use digital media for during the CB [circuit breaker] period?” Participants selected from a list of 7 common uses: (1) food delivery, (2) online banking, (3) grocery shopping, (4) online shopping (excluding groceries), (5) online entertainment, (6) social media, and (7) online telecommunication. Participants could also specify, in free-text format, other uses beyond the 7 listed if required. The option “did not use” was available if participants did not make use of any of the platforms.

Perform Essential Activities
The ability to perform essential activities was measured using a 6-item measure. The individual items have been reported in the Results section given the focus on the activities related to internet use (eg, “I was able to use online services to settle what I needed to do [eg, online banking and filling application forms].” “I was able to use telecommunication platforms for work or education purposes,” and “I was able to use online platforms to obtain my supplies [eg, groceries and buy take outs] whenever there was a need to”). Participants responded on a 5-point Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree). The scale has good internal consistency ($\alpha=.81$).

Use of the Internet Before and After the Pandemic
Use of the internet before and after the pandemic was determined by whether participants reported the use of any of the 9 online services commonly used in the local setting (eg, Redmart, Shopee, Taobao, FairPrice Online, Foodpanda, Grabfood, Cold Storage online, Deliveroo, and Lazada) before as well as after or during the pandemic. Participants could also report any other platforms that they used, which were not listed as options in the survey, in free-text format.

Time Spent on the Internet
Time spent on the internet was measured using the following question that was asked in the context of the pandemic: “On average, how much time do you spend on the internet per day (for both work and personal uses)?” Participants reported the number of hours and minutes.

Mental Health
Mental health status was measured using the shortened version of the Depression, Anxiety, and Stress Scale (DASS-21) [37]. The DASS-21 consists of three 7-item subscales designed to measure levels of depression ($\alpha=.87$), anxiety ($\alpha=.76$), and stress ($\alpha=.87$). A sample item for depression is as follows: “I felt that I had nothing to look forward to.” A sample item for anxiety is as follows: “I felt scared without any good reason.” A sample item for stress is as follows: “I found myself getting agitated.” Items were rated on a 4-point Likert scale ranging from 0 (did not apply to me at all) to 4 (applied to me very much or most of the time). Details of interpreting the scores and the use in this study have been described previously [38].

Psychosocial Adaptability
Psychosocial adaptability was an 8-item composite measure (eg, “I was able to adjust my regular social activities to my satisfaction,” “I was able to adjust the way I interact with those I lived with to my satisfaction,” and “I was able to adjust to how I spend my free time [eg, hobbies and entertainment] to my satisfaction”). Participants responded on a 5-point Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree). The internal consistency of the scale was good ($\alpha=.82$).

Social Support
Social support was measured using the Resilience Scale for Adults subscale [39]. Sample items in this 3-item measure included “I have some close friends/family members who really care about me” and “I always have someone who can help me when needed.” Participants responded on a 5-point Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree). The scale has good internal consistency ($\alpha=.86$).

 JMIR Form Res 2024 | vol. 8 | e46824 | p.713

(page number not for citation purposes)
Health Status

Health status was a single-item measure from the 36-Item Short Form Survey (SF-36) [40]. Participants responded to the question “In general, would you say your health is” using the following options: 1 (poor), 2 (fair), 3 (good), 4 (very good), and 5 (excellent).

Other Measures

Data on the background characteristics of the participants were collected, including (1) age, (2) gender, (3) marital status, (4) nationality, (5) ethnicity, (6) religion, (7) education level, and (8) occupation.

Power Analysis

Based on an a priori power analysis (G*Power 3.1.9.7) using a power of 0.80 and an error probability of 0.05, a sample size of 300 participants was required for each group to detect a between-group difference of a small to moderate effect size.

Results

Participant Characteristics

A total of 602 participants (Table 1) were recruited for the study (mean age 53.30 years, SD 16.26 years). Of these 602 participants, 302 were categorized as younger (21-59 years old; mean age 39.87 years, SD 11.46 years) and the other 300 were categorized as older (60 years or above; mean age 66.82 years, SD 5.84 years). The majority of the younger adults completed tertiary education (213/302, 70.5%) and were employed (234/302, 77.5%), while the majority of the older adults completed secondary education (145/300, 48.3%) and were largely retired (145/300, 48.3%) or were no longer in employment (44/300, 14.7%).

<sup>a</sup>Younger adults refer to participants aged 21-59 years.

<sup>b</sup>Older adults refer to participants aged 60 years or above.

**Internet Use Patterns**

Up to a third of older adults (102/300, 34.0%) in the study sample reported not using digital media to communicate or run errands during the CB measurement period compared with only 2.7% (8/302) of younger adults who did not do so. Among older adults who did not use the internet (102/300, 34.0%), an overwhelming majority did not have tertiary education (94/102, 92.2%). For older adults, the top 3 reasons for using the internet (Table 2) were social media (154/300, 51.3%), telecommunication (120/300, 40.0%), and online banking (111/300, 37.0%), whereas for younger adults, the top reasons...
were social media (253/302, 83.8%), online banking (234/302, 77.5%), food delivery (211/302, 69.9%), and telecommunication (210/302, 69.5%).

\(^b\)Older adults refer to participants aged 60 years or above.

Use of Resources to Meet Needs

Overall, agreement scores on the ability to use digital platforms to meet needs were lower for older adults (mean 3.37, SD 1.14) than for younger adults (mean 4.17, SD 0.78) \((t_{600}=10.04; P<.001; d=0.82)\), and the difference was large in magnitude. The ability to use digital resources for information updates related to the pandemic was lower for older adults (mean 3.28, SD 1.20) than for younger adults (mean 4.22, SD 0.75) \((t_{600}=10.50; P<.001; d=0.86)\), and the difference was large in effect size.

More specifically, for older adults who were able to use the internet (Table 3), the agreement scores in their ability to do so were lower compared with the scores for younger adults in the areas of using telecommunication \((t_{427}=7.55; P<.001; d=0.76)\), obtaining supplies \((t_{477}=8.97; P<.001; d=0.82)\), using online services \((t_{503}=8.17; P<.001; d=0.74)\), and changing appointments \((t_{498}=3.53; P<.001; d=0.31)\). The effect sizes of the differences were large on the whole, except for the last variable.

\(^a\)Younger adults refer to participants aged 21-59 years.

\(^b\)Older adults refer to participants aged 60 years or above.

Use of the Internet Before and After the Pandemic

Among older adults, there were minimal changes in the nonuse of the internet for online shopping for essential items (Table 4) before and during or after the pandemic (186/300, 62.0% and 183/300, 61.0%, respectively). This relationship was similar among younger adults, although a much smaller proportion of younger adults did not use the internet for online shopping for essential items before and during or after the pandemic (45/302, 14.9% and 39/302, 12.9%, respectively).
Time Spent on the Internet

There was a significant negative relationship between time spent on the internet and age \((r=-0.63; \ P<0.001)\), indicating that increasing age is associated with decreasing time spent on the internet. On average, older adults indeed spent significantly less time on the internet for both work and personal uses per day (mean 146.00 min, SD 9.18 min) compared with younger adults (mean 433.27 min, SD 14.32 min) \((t_{500}=16.84; \ P<0.001; \ d=1.38)\).

Age, Time Spent on the Internet, and Distress

Zero-ordered bivariate correlations revealed that there was a negative relationship between age and the well-being indicators of depression scores \((r=-0.36; \ P<0.001)\), anxiety scores \((r=-0.22; \ P<0.001)\), and stress scores \((r=-0.19; \ P<0.001)\).

There was also a significant positive association between time spent on the internet and depression scores \((r=0.31; \ P<0.001)\), anxiety scores \((r=0.23; \ P<0.001)\), and stress scores \((r=0.28; \ P<0.001)\). Time spent on the internet was also positively associated with stress concerns \((r=0.08; \ P=0.04)\).

Use of the Internet and Mental Health

Links between internet use patterns in this sample and mental health were explored. The findings showed that mental health was significantly better among those who did not use the internet for social media compared with those who did (Table 5). The effect sizes of the differences however were small \((d_{\text{depression}}=-0.27; \ d_{\text{anxiety}}=-0.17; \ d_{\text{stress}}=-0.31)\). This was similarly the case among those who did not use the internet for online shopping compared with those who did (Table 6), with the effect sizes being small \((d_{\text{depression}}=-0.44; \ d_{\text{anxiety}}=-0.17; \ d_{\text{stress}}=-0.31)\).

Main Effects of Time Spent on the Internet and Age on Distress

The main effects of time spent on the internet and age on distress were examined using regression modeling. The regression models were statistically significant for depression \((F_{5,501}=39.64; \ P<0.001)\), anxiety \((F_{5,501}=19.84; \ P<0.001)\), and stress \((F_{5,501}=31.40; \ P<0.001)\). The models explained 28\%, 17\%, and 24\% of the variances in depression, anxiety, and stress, respectively (see Table 7 for the adjusted and unadjusted models).

To facilitate comparison of the effect sizes, all variables were standardized. Examining the variables in the models, time spent on the internet and age were significant predictors of depression, anxiety, and stress. This was the case even after controlling for the effects of individual adaptability, social support, and health status. Standardized regression coefficients showed that the

</table>
magnitude of the effect of time spent on the internet was higher than that of age for anxiety ($\beta_{\text{age}}=-0.16; \beta_{\text{time spent on the internet}}=0.18$) and stress ($\beta_{\text{age}}=-0.17; \beta_{\text{time spent on the internet}}=0.21$), but this effect was lower for depression ($\beta_{\text{age}}=-0.24; \beta_{\text{time spent on the internet}}=0.20$). Overall, the findings suggested that distress was associated with decreasing age, and likewise, this was the case for those who spent more time on the internet.

To examine if the effect of age on mental health was influenced by time spent on the internet, mediation analysis was conducted using the approach advocated by Baron and Kenny [41]. The bootstrapping method with 1000 resamples to estimate the 95% CI was additionally conducted to investigate the significance of indirect effects [42]. A significance level of $P<.05$ was used for all analyses.

To facilitate interpretation of the effect sizes, all variables were standardized to reflect the strength of correlations. Results on the partial mediating role of time spent on the internet for the effect of age on mental health are shown in Figure 1.

In all models, mediation analyses showed that there was a significant indirect effect of age on mental health through time spent on the internet. For depression, the indirect effect of time spent on the internet was as follows: $ab=-0.08; z=-2.66; P=0.008$. The mediation effect accounted for 23% of the total effect ($\beta=-0.36$). For anxiety, the indirect effect of time spent on the internet was as follows: $ab=-0.09; z=-2.15; P=0.03$. The mediation effect was moderate and accounted for 39% of the total effect ($\beta=-0.24$). For stress, the indirect effect of time spent on the internet was as follows: $ab=-0.11; z=-3.20; P=0.001$. The mediation effect was moderate and accounted for 42% of the total effect ($\beta=-0.22$). Examining the $r^2$ of the models, all variables together explained 43% of the variance in depression, 40% of the variance in anxiety, and 40% of the variance in stress.

Overall, the effect of age on mental health was partially explained by time spent on the internet. On interpreting the $r^2$ of the models and effect sizes, a conclusion could be drawn that the mediating role of time spent on the internet for the effect of age on mental health was relatively substantial, especially for anxiety and stress. However, as full mediation did not occur, for time spent on the internet, which played a substantial role, the effect through age was not a major causal pathway.

$^a$Adjusted for adaptability, social support, and health status.

Figure 1. Mediation models illustrating the partial mediating role of time spent on the internet for the effect of age on mental health (mental health was indexed by depression, anxiety, and stress individually). All presented effects are standardized. The $a$-path is the direct effect, $b$-path is the direct effect, $c_1$-path is the direct effect, and $c$-path is the total effect.
Discussion

Principal Findings

This study examined the relationship among age, internet use, and mental health during the lockdown phase of the COVID-19 pandemic. Specifically, we compared internet use between younger and older adults and examined the mediating role of internet use in the relationship between age and mental health. In support of our hypothesis, older adults were reported to spend less time on the internet as compared with their younger counterparts. In addition, internet use was found to partially mediate the effects of age on depression, anxiety, and stress.

Given that ICT is ubiquitous in today's world, digital exclusion of older adults is emerging as an imperative concern amid rapidly aging populations. Previous studies have reported poor adoption of ICT among older adults [43-46], but findings specific to older adults during the early phase of the COVID-19 pandemic were sparse. The findings of this study extend this empirical evidence by demonstrating that such an age-related digital divide was pervasive during the COVID-19 pandemic. In support of our hypothesis, internet use among older adults during the lockdown period was found to be less as compared with that among their younger counterparts. Specifically, the use of digital platforms for essential services and entertainment purposes was less prevalent among older adults than among younger adults. While age has been known to be a predictor of internet use [47,48], the large effect size ($d=1.38$) found in this study suggests that the magnitude of such a grey digital divide is substantial and warrants more attention. Given that higher education is also associated with greater internet use [47], our results may be confounded by lower education levels among older adults in the study sample. Such a difference may also be plausibly attributed to the negative relationship between age and technology acceptance [49] or fear of stereotype threats regarding technology use in older adults [50].

Imposed spatial distancing measures during the COVID-19 pandemic have proliferated the adoption of technology to help individuals meet essential needs and stay connected with one another. This has been claimed to amplify the digital divide between younger and older adults [15,51,52]. Indeed, our findings showed that older adults not only used less internet than their younger peers, but also reported to be less able to use online services to run essential activities during the lockdown phase of the pandemic. This suggests that older adults were less capable of adapting to digital means to meet their basic needs. Our findings corroborate the results of another study reporting that the inability of older adults to use digital devices limited their access to transportation, medical care, and food supplies during the pandemic [52]. Consequently, this has raised concerns that the negative impacts of the pandemic on mental health may be disproportionate in certain groups, such as older adults, who may risk being excluded from the society due to such a digital divide [53].

While lockdown measures were well intended to mitigate infections during the COVID-19 pandemic, they had detrimental effects on the psychological well-being of individuals [5]. The results of this study suggest that both age and internet use are significant predictors of mental health, and importantly, such associations persisted even after accounting for adaptability, social support, and health status. As purported by the socioemotional selectivity theory [54], we found that older age was associated with better mental health. Specifically, we previously reported that older adults had lower depression, anxiety, and stress levels as compared with younger adults [38]. Our results are consistent with those of other studies that reported better mental health in older adults during the pandemic as compared with younger adults [54-57]. In contrast, higher internet use during the lockdown period was found to be associated with poorer mental health. While digital technologies certainly could aid individuals in the continuation of their work and daily essential activities during the lockdown, they could also be used in a disordered manner [17,18]. Our results suggest that it could be the case of the latter since mental distress has been observed to be higher in those with higher internet use (ie, spent more time on the internet and used more social media and online shopping). Indeed, the risk of problematic internet use was reported to have increased during the pandemic [2].

Many studies conducted during the earlier phase of the COVID-19 pandemic focused on the effects of internet use on younger adults and adolescents who were often conveniently sampled [25,28,30-32]. In this study, a door-to-door survey using a stratified random sampling method ensured that potential sampling bias issues were circumvented. This study ensured that there were adequate responses sampled from participants in the older age group (ie, over 60 years of age) and therefore contributed to the literature by showing the effects of internet use in not only younger adults but also older adults. This study was therefore able to address calls [34] for research comparing the linkages among age, internet use, and mental well-being during the COVID-19 pandemic. Importantly, our statistical modeling suggests that internet use acts as a partial mediator for the effects of age on depression, anxiety, and stress levels. This suggests that the inverse relationship between age and mental distress could be partially explained by the amount of time spent on the internet by younger adults. As mentioned earlier, younger adults were found to spend more time on the internet as compared with older adults. Such increased use may be problematic and consequently have negative effects on mental health. Indeed, problematic internet use during the COVID-19 pandemic has been reported to be associated with poorer mental well-being [58,59]. Studies have reported that pandemic-related stress is associated with tendencies toward problematic digital use [59-61]. Given that younger adults were found to have greater stress concerns during the pandemic [38], it may be the case that younger adults experienced greater stress and thus engaged in greater problematic internet use, which resulted in poorer mental health. More research is recommended to investigate this. Our findings support the recommendations to mitigate the risk of problematic internet use during the pandemic [2].

Despite the negative relationship between internet use and mental health, it is important to note that not all types of digital use had detrimental consequences on mental health, and ICT use for the right purposes could be potentially beneficial. For example, a recent scoping review revealed that internet use for
communication purposes was associated with better mental health for older adults during the COVID-19 pandemic [62]. Indeed, older adults have reported the importance of ICT to help them maintain their social connections during the lockdown period [63-65]. This study showed that social media use was the highest among the various uses of the internet even for older adults, and a future study can consider investigating how older adults use social media and assessing the benefits they derive from it during the pandemic. Given that some older adults may experience loneliness due to lack of physical contact, especially under the exceptional circumstances imposed by the pandemic, the use of ICT can help to allay the negative effects of social isolation. Thus, in view of the large digital divide between younger and older adults found in this study, greater efforts are necessary to close such a divide, including advocating for age-sensitive design of technologies [49,52] and deterring stereotype threats associated with technology use [50]. Considering the potential negative relationship between internet use and mental health, it is also imperative to educate older adults in using ICT appropriately.

Limitations
Notwithstanding the contributions of this study to existing literature, it is important to acknowledge some limitations. First, the study sample consisted of community-dwelling adults, and thus, the findings may not be generalizable to specific subgroup populations who may be more vulnerable. The relationship between age and mental distress observed in this study may differ if other groups of older adults are included, such as those residing in nursing homes or experiencing diminished mental capacity.

Second, the interpretation of this study’s results is limited by its outcome measures. Although this study established the partial mediating role of internet use for the effects of age on depression, anxiety, and stress, the study did not collect measures that would be important indicators of disordered use of the internet in younger adults, including online gambling, viewing pornography, and playing video games. Nonetheless, there is evidence from various studies indicating that increased time spent on the internet during the earlier phase of the COVID-19 pandemic was the main contributory factor for a number of mental health problems, such as depression, anxiety, and stress [66-68]. The findings from this study are therefore aligned with the existing research and add to this field by presenting data from a developed country with high digital adoption rates. However, a future study can consider examining how the pandemic could have possibly exacerbated problematic internet use and whether time spent on the internet is indeed an adequate proxy. The digital divide and its relationship with mental health can be influenced by a myriad of factors going beyond problematic internet use. There is a possibility that increased internet use in younger adults during the lockdown period was attributed to having to work remotely from office, and the distress experienced could therefore be attributed to this new form of work arrangement rather than problematic internet use per se. Given that the study was making reference to the first lockdown period, younger adults may not have adapted to this form of working arrangement despite the known benefits of ICT, including continuation of their work and running of other essential activities.

Finally, all measures of this study were collected from participants’ retrospective recollection of their experiences during the lockdown period. Since time spent on the internet was not based on any objective indicator, we cannot rule out the possibility that this or other attitudinal responses are subject to recall bias.

Conclusion
This study showed that older adults lagged behind younger adults in the use of digital resources during the pandemic, which could have helped them in communication and socialization, and the findings support existing literature on the poor adoption of ICT among older adults. This study further contributes to the literature by showing how through mediation modeling, the negative relationship between increasing age and mental distress appears to be partially explained by the amount of time spent on the internet by younger adults. Without moderate use, the benefits brought by digital technologies could have been attenuated during the lockdown phase of the pandemic. It is imperative to educate both young and old adults in the appropriate use of ICT.

Abstract

Background: One life event that requires extensive resilience and adaptation is parenting. However, resilience and perceived support in child-rearing vary, making the real-world situation unclear, even with postpartum checkups.

Objective: This study aimed to explore the psychosocial status of mothers during the child-rearing period from newborn to toddler, with a classifier based on data on the resilience and adaptation characteristics of mothers with newborns.

Methods: A web-based cross-sectional survey was conducted. Mothers with newborns aged approximately 1 month (newborn cohort) were analyzed to construct an explainable machine learning classifier to stratify parenting-related resilience and adaptation characteristics and identify vulnerable populations. Explainable k-means clustering was used because of its high explanatory power and applicability. The classifier was applied to mothers with infants aged 2 months to 1 year (infant cohort) and mothers with toddlers aged >1 year to 2 years (toddler cohort). Psychosocial status, including depressed mood assessed by the Edinburgh Postnatal Depression Scale (EPDS), bonding assessed by the Postpartum Bonding Questionnaire (PBQ), and sleep quality assessed by the Pittsburgh Sleep Quality Index (PSQI) between the classified groups, was compared.

Results: A total of 1559 participants completed the survey. They were split into 3 cohorts, comprising populations of various characteristics, including parenting difficulties and psychosocial measures. The classifier, which stratified participants into 5
groups, was generated from the self-reported scores of resilience and adaptation in the newborn cohort (n=310). The classifier identified that the group with the greatest difficulties in resilience and adaptation to a child’s temperament and perceived support had higher incidences of problems with depressed mood (relative prevalence [RP] 5.87, 95% CI 2.77-12.45), bonding (RP 5.38, 95% CI 2.53-11.45), and sleep quality (RP 1.70, 95% CI 1.20-2.40) compared to the group with no difficulties in perceived support. In the infant cohort (n=619) and toddler cohort (n=461), the stratified group with the greatest difficulties had higher incidences of problems with depressed mood (RP 9.05, 95% CI 4.36–18.80 and RP 4.63, 95% CI 2.38-9.02, respectively), bonding (RP 1.63, 95% CI 1.29-2.06 and RP 3.19, 95% CI 2.03-5.01, respectively), and sleep quality (RP 8.09, 95% CI 4.62-16.37 and RP 1.72, 95% CI 1.23-2.42, respectively) compared to the group with no difficulties.

**Conclusions:** The classifier, based on a combination of resilience and adaptation to the child’s temperament and perceived support, was able to identify psychosocially vulnerable groups in the newborn cohort, the start-up stage of childcare. Psychosocially vulnerable groups were also identified in qualitatively different infant and toddler cohorts, depending on their classifier. The vulnerable group identified in the infant cohort showed particularly high RP for depressed mood and poor sleep quality.

**Introduction**

One life event that requires extensive resilience and adaptation is parenting. However, parenting difficulties have become highly varied and complex, especially for mothers, who are increasingly expected to balance their family and social roles [1,2]. The dynamics of parenting are further complicated by the rise of working parents, leading to evolving parenting environments and an amplified demand for social support [3]. The challenges of parenting have been compounded by the SARS-CoV-2 pandemic, which brought about blockades, physical distancing, and social isolation, adversely impacting mental health. These challenges are exacerbated by factors such as economic insecurity and the increased burden of childcare and housework [4].

A meta-analysis shows that 19.2% of women experience a major depressive episode during the first 3 months post partum, with most of these episodes occurring after delivery [5]. For this reason, most medical institutions in Japan evaluate the mother’s mental status during the 1-month health examination. Common risk factors of postpartum depression were high life stress, the increased burden of childcare and housework [4], insecurity and the increased burden of childcare and housework [4], and complex, and individual mother’s personalities and cognitive characteristics must be comprehensively considered to support safe child-rearing practices [7,8]. Hence, we developed the Comprehensive Scale for Parenting Resilience and Adaptation (CPRA) to assess parenting difficulties based on environmental factors, maternal personality traits, and a mother’s perception of her child [2]. Thus, the CPRA could be used to evaluate the complexities of parenting difficulties.

Timely access to face-to-face social support has proven to be psychologically and socially challenging for mothers who struggle with parenting [9]. Studies have indicated that prior parenting knowledge and experience lead to resilience, as primiparous women have significantly lower resilience to perinatal depressive mood than multiparous women [10,11]. A web-based platform could be easily accessible for busy and vulnerable mothers. Thus, a web-based assessment and timely intervention could provide parenting resources to such inexperienced mothers. Web-based screening and communication are expected to play a significant role not only for parenting under the “new normal” lifestyle due to the SARS-CoV-2 pandemic but also for parents who do not prefer face-to-face communication.

The Japanese government supports the Society 5.0 project, which aims to integrate cyber and physical spaces (also known as the cyber-physical space) where data science can contribute to task executions and coordination [12]. In this project, we created a web-based screening system linked to an app that calculates gestational age and provides parenting information services. This system enabled researchers to collect data from mothers in various parenting environments across Japan without requiring hospital visits. However, the real-world data obtained by this system were heterogeneous. Machine learning is considered more suitable than model-driven conventional statistical methods for classifying characteristics and developing interventions based on complex data, even with a small sample size [13]. Especially in mental health research, machine learning is used for diagnosis, treatment support, research and development, and clinical work management. The increase in the number of studies suggests that machine learning may be useful for the detection and diagnosis of mental health conditions such as depression, schizophrenia, and Alzheimer disease [14].

A systematic review screened 482 papers and evaluated 11 papers that used machine learning to predict postpartum depression; it found that although a solid conclusion was not achieved since the algorithms and data sets used were heterogeneous, all studies reached an area under the curve greater than 0.7, indicating that predicting postpartum depression by machine learning is feasible [15]. Machine learning methods also allow the use of blood test data from before the onset of perinatal depression to identify high-risk populations who are the most in need of preventive interventions [16].
The disadvantages of machine learning include its complex algorithms and reproducibility. For example, k-means clustering is a machine learning–based algorithm that groups similar data by analyzing its structures and patterns; each data point is assigned to a cluster to minimize variance within the cluster while maximizing it between clusters. However, reproducing these clusters in a different data set can be challenging. Therefore, we used explainable k-means clustering to overcome these limitations [17].

The purpose of this study is to create a vulnerability classifier based on cross-sectional survey data on maternal resilience and adaptation and to examine the identified psychosocially vulnerable groups. This study also attempts to determine the psychosocial status of mothers during other child-rearing periods, by confirming whether the classifier can be applied to infant and toddler populations to identify similarly vulnerable groups.

**Methods**

**Study Design and Setting**

This study included a cross-sectional survey and machine learning stratification. Recruitment, opt-in informed consent, and data collection were conducted through a web application that rewarded participants with the equivalent cost of the internet resources used to complete the survey. We used a Japanese web service company called Milcare to conduct the survey. For those who downloaded Milcare’s app, which is used to record the number of weeks of pregnancy, an advertisement for the survey was shown in the app for the duration of our survey setting. The system was designed to provide survey participants incentives such as gift cards and childcare goods through the app. The app was available to Japanese smartphones and had been downloaded approximately 5000 times at the time of the survey. All data reported by the participants in the web-based survey were included as outcomes. The response period was from January to June 2020. A maternal personality traits classifier was created from the newborn cohort using explainable k-means clustering. The classifier was then applied to the infant cohort and the toddler cohort, and the features of each group were analyzed.

**Participants**

The target population of this study was parenting mothers with newborns to 2-year-old toddlers. The eligibility criteria for the participants were (1) mothers with children aged <2 years; (2) web-based consent to participate in the survey through the Milcare web service; (3) ability to read, write, and understand Japanese while using the internet; and (4) ability to complete a questionnaire using a smartphone. The exclusion criteria were those who (1) completed the survey in less than 8 minutes (the minimum time required to read and answer all questions) and (2) abandoned the survey during the process.

**Ethical Considerations**

Ethical review approval was obtained because this study involves human subjects: Osaka University Hospital Observational Research Ethics Review Committee (19290-2) and Research Ethics Review Committee of RIKEN (2020-23(2)). Data for the study were analyzed anonymously and no individuals were identified. In addition, consent for primary data acquisition and secondary use was obtained.

**Patient and Public Involvement**

Although some of the researchers have parenting experience, neither patients with depressive moods nor the public were involved in the design, planning, conduct, or reporting of this study.

**Assessment**

The mothers’ resilience and adaptation were assessed using the CPRA. The CPRA consisted of 5 domains (child’s temperament and health, environmental resources, perceived support, mother’s cognitive and behavioral characteristics, and psychological adaptation to parenting) and 21 subscales (Table 1). Responses were collected on a 5-point Likert scale with higher scores indicating increased parenting difficulty [8].

Depressive mood was assessed using the Edinburgh Postnatal Depression Scale (EPDS). In Japan, an EPDS score of 9 or above is used as the cutoff for clinical screening, which has a sensitivity of 75% to 82% and a specificity of 93% to 95% for high-risk depression [18-20]. Therefore, we defined an EPDS score of 9 or above to indicate depressive mood in this study. The Sense of Coherence (SOC) scale was used to assess how one understands, manages, and feels emotional meaning when experiencing stress [21]. The Postpartum Bonding Questionnaire (PBQ) was used to assess mother-infant bonding, with a high score (≥13) indicating impaired bonding [22]. The Pittsburgh Sleep Quality Index (PSQI) was used to assess sleep quality, where a high score (≥5.5) indicates poor sleep quality [23,24].

Explainable Clustering With Decision Tree

To classify the characteristics of resilience and adaptation difficulties, a clustering algorithm, explainable k-means clustering, was used. Explainable k-means clustering is an unsupervised clustering algorithm, characterized by its use of decision trees with minimum leaf size for data set partitioning. These trees are meticulously designed to contain a constrained number of nodes and leaves, adhering to the principle of parsimony. Specifically, the number of leaves is deliberately set to correspond with the desired number of clusters (k) in the k-means algorithm. This strategic design enhances both the interpretability and comprehensibility of the clustering process. Consequently, this framework facilitates the application of classifiers to external populations, provided that these populations are quantified on analogous scales. Such an approach underscores the algorithm’s use in ensuring coherent and interpretable clustering outcomes, which are pivotal for the analysis of heterogeneous data sets [17]. For estimating the number of groups, gap statistics analysis was conducted using the CPRA data set from the newborn cohort. Gap statistics analysis compares the change in cluster dispersion with that expected under an acceptable, reference null distribution using the output of any clustering algorithm [25]. Using these results, participants in the newborn cohort were stratified into groups using an unsupervised explainable k-means algorithm with a decision tree, depending on the 5 CPRA domains. Last, the clustering-based anomaly detection algorithm, the so-called decision tree, was applied to the infant cohort and the toddler cohort.

Comparison of Mothers’ States in the Identified Groups

We described the characteristics of the CPRA domain scores and the psychological assessment scores (EPDS, PBQ, and PSQI) for each group. The stratification of groups in each cohort was plotted and the mean score of the 21 CPRA subscales for each of the 5 stratified groups was calculated and plotted as a radar chart.

Statistical Analysis

We analyzed the characteristics of the stratified groups in each cohort, using the group with no difficulties as a reference. The prevalence of depressive moods (EPDS score ≥ 9), bonding problems (PBQ score ≥ 13), and sleep problems (PSQI score ≥ 5.5) was used for logistic regression analysis with relative prevalence (RP), 95% CI, and P value. The distributions of the CPRA and psychosocial scores of the stratified groups in the cohorts were compared using the Kruskal-Wallis test. The results of the Kolmogorov-Smirnov test showed deviations from the normal distribution for many variables, and the Levene test may have violated the assumption of equal variability in the EPDS and PBQ (Multimedia Appendix 1). Therefore, the Kruskal-Wallis test was performed as a multiple-group comparison.

All data from participants who completed the survey within the specified time frame were included in the analysis. Participants’ characteristics were expressed using descriptive statistics, and P < .05 was considered statistically significant.

All statistical analyses were performed using R (version 3.6.2; R Foundation for Statistical Computing). We used the ExKMC package to produce explainable k-means clustering and the ggstatsplot and ggplot packages for data visualization, all of
which are available on GitHub (GitHub Inc) [17,26]. The ExKMC package automatically produces the shallowest tree depth.

**Results**

**Participant Characteristics**

From the web-based recruitment, 1559 participants completed the web survey. Data from those who took at least the minimum required time to read and answer the questions were analyzed. The participants were divided into the newborn cohort (n=310; mean age 31, SD 4.60 years), infant cohort (n=619; mean age 31.5, SD 4.15 years), and toddler cohort (n=461; mean age 32.1, SD 4.16 years). The newborn cohort was analyzed to generate a classifier, and the classifier was applied to the infant cohort and toddler cohort (Figure 1). The CPRA domain scores and the psychosocial assessments (EPDS, PBQ, and PSQI) in each cohort are represented in Table 2.

Overall, parenting difficulties as assessed by the CPRA tended to be more severe during the newborn period, which is up to 1 month post partum (Table 2). Statistically significant differences were observed in the environmental and psychological domains of the CPRA, as well as for the EPDS, PBQ, and PSQI (all \(P<.001\)).

Explainable Clustering

Using gap analysis to decide the optimal number of the clustering revealed that 5 groups were suitable for k-means clustering (grouping) of the participants based on the similarities in CPRA scores. Using the explainable k-means method, the participants in the newborn cohort were stratified into 5 groups based on multivariate factors, and a decision tree explaining how to stratify these groups was generated using 2 evaluation axes: perceived support–related and child’s temperament–related difficulties (Figure 2). Using the classifier as a decision tree algorithm, 5 groups were stratified in each of the 3 cohorts. According to the classifier rules, Group 0 represented those with no perceived support–related difficulties, Group 1 represented those with moderate perceived support–related difficulties (Support+), Group 2 represented those with moderate perceived support–related difficulties and child’s temperament–related difficulties (Support+Child+), Group 3 represented those with severe perceived support–related and child’s temperament–related difficulties (Support++Child++), and Group 4 represented those with severe perceived support–related and child’s temperament–related difficulties (Support++Child+++; Figure 2). A split of similar proportions was achieved, with the maximum difference of 5% occurring in Group 4. To illustrate the distribution of the stratified groups in each cohort, we focused on the child and support scores, which were used as features for classifier generation; plotted them on the vertical and horizontal axes, respectively; and colored each group to visualize them (Figure 3). The CPRA scores for each cohort were concentrated at 2-3 points, but the distribution of outliers was different for each cohort (Figure 3). The 21 subscales of the CPRA for each stratified group in each cohort were plotted in a radar chart (Figure 4).

Figure 4. Comprehensive Scale for Parenting Resilience and Adaptation scores for 21 factors in the groups. C: child’s temperament; S: perceived support.

Regression Analysis and Characteristics of the Detected Groups

Psychosocial conditions in each cohort were plotted as density plots for the EPDS, PBQ, SOC, and PQSI scores, colored according to the stratified groups (Figure 5). In the newborn cohort (n=310), Group 4 (Support++Child++) was the group with the greatest difficulties, having higher incidences of problems with depressed mood (RP 5.87, 95% CI 2.77-12.45), bonding (RP 5.38, 95% CI 2.53-11.45), and sleep quality (RP 1.70, 95% CI 1.20-2.40) compared to the group with no difficulties in perceived support (Group 1; Table 3). In the infant cohort (n=619), the stratified group with the greatest difficulties had higher incidences of problems compared to the group with no difficulties, with depressed mood (RP 9.05, 95% CI 4.36-18.80) and sleep quality (RP 8.69, 95% CI 4.62-16.37) having a greater RP than the newborn cohort, but a smaller RP for bonding (RP 1.63, 95% CI 1.29-2.06; Table 3). In the toddler cohort (n=461), the stratified group with the greatest difficulties had higher incidences of problems with depressed mood (RP 4.63, 95% CI 2.38-9.02), bonding (RP 3.19, 95% CI 2.03-5.01), and sleep quality (RP 1.72, 95% CI 1.23-2.42) compared to the group with no difficulties.

Figure 5. Mothers’ condition in the stratified groups. Postnatal depressive mood was assessed using the EPDS, postpartum bonding was assessed using the PBQ, sense of coherence was assessed using the SOC, and sleep quality was assessed using the PSQI. 1N: newborn cohort; 2I: infant cohort; 3T toddler cohort; C: child’s temperament; EPDS: Edinburgh Postnatal Depression Scale; PBQ: Postpartum Bonding Questionnaire; PSQI: Pittsburgh Sleep Quality Index; S: perceived support; SOC: Sense of Coherence.

### Discussion

#### Principal Findings

The classifier based on the resilience and adaptation assessment (CPRA) stratified the mothers in the newborn cohort, the start-up stage of childcare, into 5 groups and identified vulnerable psychosocial groups. The score of resilience to the child’s temperament and perceived support was selected as an important feature for building an explainable classifier, instead of environmental resources, the mother’s cognitive-behavioral characteristics, and psychological adaptation to parenting. Depending on the decision tree–based explainable classifier, psychosocially vulnerable groups were also identified in the qualitatively different infant and toddler cohorts. The identified group with high sensitivity to the temperament of their children and difficulty in perceiving support showed high RP for depressed mood and poor sleep quality, especially in the infant.
cohort. This group was particularly vulnerable to severe psychosocial problems in the infant cohort.

Limitations
The study data were collected using a web-based self-reported survey to acquire large-scale nationwide data. Therefore, the degree of objectivity, the participants’ backgrounds, and family characteristics (i.e., the partner’s housework load and the child’s developmental disabilities) were not guaranteed. The possibility that false responses were treated as true values cannot be excluded. Nevertheless, a web-based survey method with limited psychological barriers was chosen because it increased the ease of participation, so that even mothers who are too busy to make time for a formal interview or have difficulties with interpersonal conversations could be represented. This study saw a greater prevalence of perinatal depressive mood (EPDS>9; 480/1390, 34.5%) than that reported by a previous face-to-face Japanese study (15,506/108,431, 14.3%). This disparity may be due to the anonymity of the survey environment, which allowed mothers to share grievances beyond supporting the image of a good, tolerant mother. We are conducting a face-to-face observational study and analyzing the target population gap caused by the data collection environment, as the question of whether web-based or in-person data accurately reflect the true state of a participant must be considered in the context of increasing web-based communication to minimize error.

The lack of background information also limits the analysis of individual factors in this study. Environmental variables could have a significant impact on the mother’s family environment, but the CPRA could not assess “home-town delivery,” a common practice in Japan where mothers return to their parent’s homes before and after childbirth. Future research using the CPRA with more detailed data on individual characteristics, such as the home environment or family structure, will be needed. In addition, those who had difficulty perceiving support and were sensitive to their child’s temperament are particularly prone to serious psychosocial problems in the infant cohort, but it is difficult to determine whether this is a bias in the cross-sectional survey population or whether those with resilience difficulties are more specific to the infant period. Therefore, we are conducting a longitudinal survey with the environmental information to examine the effects of the environmental setting or the time period.

The accuracy of the clustering algorithm will be limited because of the nature of this algorithm, with a trade-off between explainability and accuracy [17]. In addition, no general method of predetermining k is established [27]. Although the EPDS, PBQ, SOC, and PSQI scores were significantly different across the 5 groups, especially the groups with no versus greatest difficulties in resilience and adaptation, we believe that further investigation is needed to use the partition score as a clear cut-off point for detecting persons with psychosocial disabilities.

Comparison With Prior Work
Previous studies have reported that personality traits can influence perinatal depressive mood. For example, a study involving 15,012 mothers, including 13.1% with depressive moods (an EPDS score≥9 in 1 month was defined as “postpartum depressive symptoms” in that study), indicated that increased neuroticism and reduced extraversion were associated with postpartum depressive symptoms [28]. Regarding interventions for perceived support or parenting resources, a review showed that online peer support groups offered informational and emotional support and positively impacted maternal mental health [27]. A path analysis of web-based survey data collected from Japanese parents of children aged 3-5 years revealed that childcare support had no direct positive effect on children’s social development; however, the benefits of childcare support were mediated by its impact on parents’ psychological state and parenting style, which improved child social development [29]. This indicates that supporting mothers, according to their adaptive tendencies, may positively affect their children’s development. A study of 398 Australian women from the prenatal period to 1 year post partum suggested that the dual intervention of social support and the recognition of prenatal depressive symptoms is a promising strategy to prevent persistent depressive symptoms [30]. This is because digital technology supports the core values associated with psychosocial intervention and fulfills the “ancillary values” that constrain how coproduction operates [31]. To assess the effects of such web-based psychosocial intervention for mothers, we are conducting a randomized controlled trial of a web-based screening and feedback program using the same assessment instruments.

Our study was conducted before and after April 2020, and although the pandemic may have had an impact, we did not detect any significant differences when comparing the different survey periods (Multimedia Appendix 2). This may be because the study was completed in June 2020; however, the data set collected from 5 countries during the COVID-19 pandemic from July to December 2020 also showed that the symptoms of maternal depression and anxiety can be predicted using machine learning algorithms and that efficient tools can be used to predict maternal depression and anxiety [32].

Conclusions
The classifier, generated from the data from the most stressful and confusing period (newborn cohort) using an unsupervised clustering algorithm with enhanced explanatory and applicability, could be adapted to another parenting cohort (infant and toddler cohort), and psychosocially vulnerable groups were detected. Mothers with high sensitivity to the temperament of their children and difficulties in perceiving support would be prone to depressed mood and poor sleep quality, especially in the infant cohort. To overcome the study’s limitations, further research in other study designs is needed. Considering the additional research, the classifier will help support child-rearing in the Society 5.0 era according to the resilience and adaptation characteristics of individual mothers and is likely to contribute to the implementation of web-based child-rearing support.
Acknowledgments

This work was supported by MEXT “Innovation Platform for Society 5.0” Program grant (JPMXP0518071489). TI received grants from the Japan Society for the Promotion of Science KAKENHI grants (JP20K21837 and JP21K02356). Abstract

Background: Tumor immunotherapy is an innovative treatment today, but there are limited data on the quality of immunotherapy information on social networks. Dissemination of misinformation through the internet is a major social issue.

Objective: Our objective was to characterize the quality of information and presence of misinformation about tumor immunotherapy on internet-based videos commonly used by the Chinese population.

Methods: Using the keyword “tumor immunotherapy” in Chinese, we searched TikTok, Tencent, iQIYI, and BiliBili on March 5, 2022. We reviewed the 118 screened videos using the Patient Education Materials Assessment Tool—a validated instrument to collect consumer health information. DISCERN quality criteria and the JAMA (Journal of the American Medical Association) Benchmark Criteria were used for assessing the quality and reliability of the health information. The videos’ content was also evaluated.

Results: The 118 videos about tumor immunotherapy were mostly uploaded by channels dedicated to lectures, health-related animations, and interviews; their median length was 5 minutes, and 79% of them were published in and after 2018. The median understandability and actionability of the videos were 71% and 71%, respectively. However, the quality of information was moderate to poor on the validated DISCERN and JAMA assessments. Only 12 videos contained misinformation (score of >1 out of 5). Videos with a doctor (lectures and interviews) not only were significantly less likely to contain misinformation but also had better quality and a greater forwarding number. Moreover, the results showed that more than half of the videos contain little or no content on the risk factors and management of tumor immunotherapy. Overall, over half of the videos had some or more information on the definition, symptoms, evaluation, and outcomes of tumor immunotherapy.

Conclusions: Although the quality of immunotherapy information on internet-based videos commonly used by Chinese people is moderate, these videos have less misinformation and better content. Caution must be exercised when using these videos as a source of tumor immunotherapy–related information.

immunotherapy; internet videos; quality; misinformation; health informatics; Chinese

Introduction

Background

Tumor immunotherapy is an innovative treatment today. After the implementation of China's new medical insurance rates in 2022, the monthly treatment cost of immunotherapy has entered the “thousand era,” which greatly improves the accessibility of drugs. However, tumor immunotherapy has obvious uncertainty and complexity [1]. Accurate transmission of immunotherapy information to the population is important to the survival and quality of life of patients with cancer [2]. The study found that
patients were open to video education and found it helpful and worth watching [3].

The world’s population is increasingly referring to health-related internet-based information as it represents an easily accessible educational tool [4,5]. The Chinese population, overseas Chinese individuals, and people who master Chinese worldwide prefer web-based video applets or websites, such as videos on TikTok, Tencent, iQIYI, or BiliBili [6]. These sites, similar to YouTube, are popular for their rich content, convenient log-in methods, quick sharing, and 24-hour multiplatform seamless application experiences. Recently, the originality, interactivity, and sociable nature of TikTok and BiliBili have provided the younger generation a better user experience and sense of engagement while seeking health information [7]. The penetration and usage of TikTok and BiliBili are also on the rise among some older age groups [8]. However, the medical content available on the internet is controversial and has not been properly examined. Di Bello et al [9] reported that YouTube videos have contributed to the spread of misinformation by underestimating the role of information on immunotherapy for urological tumors in a multimodality approach and missing the findings of published clinical trials. Not only were audiences not availing of accurate therapy, but also they were opting for therapies that may be harmful, which could lead to other complications [10,11].

Objectives
This study aims to report an evaluation of the quality, reliability, and content of videos related to tumor immunotherapy on the internet among the Chinese population. Our findings could serve as a guide for health care providers and awareness campaigns.

Methods

Ethical Considerations
Ethics approval was not required as this descriptive study was conducted by examining publicly accessible videos on the internet. Also, no human participants or animals were included in this study. The study data are anonymous.

Search Strategy and Data Collection
Using the keyword “肿瘤免疫治疗” (“tumor immunotherapy” in Chinese), we searched TikTok, Tencent, iQIYI, and BiliBili on March 5, 2022, which yielded 1820, 395, 400, and 1000 results for each search, respectively. The videos were sorted in accordance with the video’s default “the most viewed” sorting parameter, and the first 50 videos per website were evaluated.

Inclusion and Exclusion Criteria
A total of 200 videos were considered from all the searches. Duplicate videos, paid videos, and videos not related to tumor immunotherapy were excluded. After the screening, we obtained 118 videos for further data extraction and analysis (Figure 1).

Figure 1. Search strategy and video screening procedure.

Variables Extracted
Basic information obtained included the URL, video duration, likes, forwarding number, subscription, comments, and upload date. Profiles of the uploaders were recorded and classified under 5 categories: lectures, interviews, health-related animations, academic institutions or universities, and news agencies. The extracted data were recorded in Excel (Microsoft Corp).

Scoring System
The videos were evaluated independently by 2 authors (CN and Y-BF). The raters were blinded to each other’s ratings (they could not consult each other). We reviewed the screened 118 of 3615 videos on TikTok, Tencent, iQIYI, and BiliBili on “tumor immunotherapy,” using the Patient Education Materials Assessment Tool (PEMAT)—a validated instrument for obtaining consumer health information (Multimedia Appendix 1) [12]. Moreover, we adopted 6 questions from Goobie et al [13] to evaluate the videos’ content. These 6 questions ask to what degree a video addresses the definition of a disease, its signs and symptoms, risk factors, evaluation, management, and outcomes. Each aspect was scored on a 3-item scale: 0=not addressed, 1=partially addressed, and 2=sufficiently addressed.

The DISCERN quality criteria [14] and the JAMA (Journal of the American Medical Association) Benchmark Criteria [15] were used for assessing the quality and reliability of the health information. The modified version of the original DISCERN questionnaire was used to assess the reliability and quality of the health information. It consists of five questions, each with a “yes/no” answer (yes=1 point; no=0 points; maximum score=5): (1) Is the video clear and complete? (2) Are reliable sources of information used? (3) Is the information presented balanced and unbiased? (4) Are additional sources of information listed for reference? (5) Are uncertain areas mentioned? The JAMA assessment is used to evaluate web-based videos and resources on the basis of 4 criteria: authorship, attribution, disclosure, and currency (1 point each).

- Authorship (1 point): the video should include authors, contributors, and contact information.
• Attribution (1 point): the references and sources should be listed properly.
• Disclosure (1 point): conflicts of interest, financing, sponsorship, advertising, support, and video ownership should be disclosed.
• Currency (1 point): the dates on which the videos were published and updated should be indicated.

After the scores are calculated, a score of 4 indicates that the source is of high quality.

We assessed the presence of misinformation using an analogous 5-point Likert scale [16,17]. Videos were independently coded by 2 authors with random coding checks to verify intercoder reliability. Each video was rated separately, and its mean score was calculated.

**Statistical Analysis**

The mean, median, IQR, and SD were used as descriptive statistics for continuous variables. To identify differences among the variables extracted, the Mann-Whitney U test was performed. The intraclass correlation coefficient was determined to ensure interrater reliability. A P value of less than .05 was considered significant. Statistical analysis was performed by using the GraphPad Prism 8 (GraphPad Software, Inc).

**Results**

The 118 videos about tumor immunotherapy mostly uploaded by channels dedicated to lectures, health-related animations, and interviews (Table 1; median length 5 minutes; 93, 79% uploaded in and after 2018). The median forwarding number and number of likes was 12 and 15, respectively. However, the median understandability and actionability of the videos were 71% and 71%, respectively. Overall, the quality of information was moderate to poor in 54% of videos (overall DISCERN scores of 1-3 out of 5) and 64% of videos (overall JAMA scores of 1-2 out of 4).

Only 12 videos contained misinformation (score >1 out of 5). Videos with a doctor (published by channels dedicated to lectures and interviews) not only were significantly less likely to contain misinformation but also had better quality and a greater forwarding number. Videos on Tencent and BiliBili had lesser misinformation than TikTok and iQIYI. Regarding DISCERN criteria and JAMA Benchmark Criteria, the quality of information on TikTok and iQIYI was higher than that on BiliBili and Tencent.

Moreover, our results show that more than half of the videos contain little or no content on the risk factors and management of tumor immunotherapy. Overall, over half of the videos had some or more information on the definition, symptoms, evaluation, and outcomes of tumor immunotherapy (Table 2).

The overall scores for all internet videos are presented in **Figure 2**.

**Figure 2.** Completeness of content in internet-based videos.

### Discussion

We screened 118 videos on “tumor immunotherapy” from TikTok, Tencent, iQIYI, and BiliBili commonly used by the Chinese population. Chinese websites or applets uploaded videos related to tumor immunotherapy for the first time in 2011, and the number of videos has significantly increased since 2018. The median duration of the videos was 5 minutes, which is acceptable to the public.

Numerous studies have evaluated videos on YouTube only and not on other networks [<sup>18-20</sup>]. Our study evaluated information about tumor immunotherapy on the most popular Chinese
websites or applets, using validated instruments to evaluate the quality of information. Videos on BiliBili and TikTok had a significantly greater forwarding number and likes than those on iQIYI and Tencent; a possible reason is that there is no advertisement played before videos on BiliBili and TikTok.

Health care providers should recommend trustworthy sources of information to patients and should actively participate in social media for dissemination of evidence-based medicine. There is a great need for accurate tumor immunotherapy–related content that is also understandable and actionable. Suggestions for content creators include discussing both the benefits and risks of management alternatives, refraining from the use of medical terminology, and presenting the viewer with clear action items. Meanwhile, patients should be wary of internet-based videos. Misinformation, albeit well-intentioned, may be disseminated when a poorly informed patient advises others. Patients should talk to their physicians not only about immunotherapy but also their need for more information.

In conclusion, although the quality of tumor immunotherapy–related information on internet-based videos commonly used by Chinese people is moderate, it has less misinformation and better content. Caution must be exercised when using these videos as a source of tumor immunotherapy–related information.

Abstract

Background: Routine cognitive screening is essential in the early detection of dementia, but time constraints in primary care settings often limit clinicians’ ability to conduct screenings. MyCog Mobile is a newly developed cognitive screening system that patients can self-administer on their smartphones before a primary care visit, which can help save clinics’ time, encourage broader screening practices, and increase early detection of cognitive decline.

Objective: The goal of this pilot study was to examine the feasibility, acceptability, and initial psychometric properties of MyCog Mobile. Research questions included (1) Can older adults complete MyCog Mobile remotely without staff support? (2) Are the internal consistency and test-retest reliability of the measures acceptable? and (3) How do participants rate the user experience of MyCog Mobile?

Methods: A sample of adults aged 65 years and older (N=51) self-administered the MyCog Mobile measures remotely on their smartphones twice within a 2- to 3-week interval. The pilot version of MyCog Mobile includes 4 activities: MyFaces measures facial memory, MySorting measures executive functioning, MySequences measures working memory, and MyPictures measures episodic memory. After their first administration, participants also completed a modified version of the Simplified System Usability Scale (S-SUS) and 2 custom survey items.

Results: All participants in the sample passed the practice items and completed each measure. Findings indicate that the Mobile Toolbox assessments measure the constructs well (internal consistency 0.73 to 0.91) and are stable over an approximately 2-week delay (test-retest reliability 0.61 to 0.71). Participants’ rating of the user experience (mean S-SUS score 73.17, SD 19.27) indicated that older adults found the usability of MyCog Mobile to be above average. On free-response feedback items, most participants provided positive feedback or no feedback at all, but some indicated a need for clarity in certain task instructions, concerns about participants’ abilities, desire to be able to contact a support person or use in-app technical support, and desire for additional practice items.

Conclusions: Pilot evidence suggests that the MyCog Mobile cognitive screener can be reliably self-administered by older adults on their smartphones. Participants in our study generally provided positive feedback about the MyCog Mobile experience and rated the usability of the app highly. Based on participant feedback, we will conduct further usability research to improve support functionality, optimize task instructions and practice opportunities, and ensure that patients feel comfortable using MyCog.
Mobile. The next steps include a clinical validation study that compares MyCog Mobile to gold-standard assessments and tests the sensitivity and specificity of the measures for identifying dementia.

Introduction

Primary care visits provide an important opportunity to detect pathological cognitive decline in the early stages [1,2], yet less than half of all cases are detected in primary care [3]. Medicare covers cognitive screening as part of the Annual Wellness Visit for adults aged 65 years or older, however, primary care clinics face several barriers to conducting regular cognitive screenings with their patients, including constraints on time and clinic staff [4]. Completing a screening remotely before a primary care visit offers several benefits to both patients and clinicians [5]. Patients can complete the screening at their leisure in the privacy of their own homes, and providers can review the results before a visit. Critically, a complete screener before a visit benefits all stakeholders (eg, clinicians, patients, and support staff) by saving time to address other important issues in person [6].

Mobile apps offer an ideal mechanism for many older adults to complete at-home cognitive screeners. More than 60% of older adults in the United States own a smartphone [7], and over 30% regularly use mobile health apps [8]. Moreover, low-income and minority groups are more likely to access their personal health information on smartphones compared to other electronic devices [9]. A small body of emerging research supports the feasibility of self-administered cognitive screeners on personal smartphones in research contexts [10-12]. The cognitive assessments in these studies vary in administration frequency, length, and structure but tend to find high levels of adherence (70% or higher), receive positive feedback in exit surveys, and show convergent validity with established cognitive screening measures [11,13,14]. However, no screeners to date have been validated for clinical use before a primary care visit [15]. Further research is needed to determine if older adults will be able to access the app and complete cognitive screeners independently, if the data collected from these screeners are reliable, and how older adults will perceive the app from a usability and acceptability perspective.

To encourage broader cognitive screening practices within primary care, the National Institute on Aging funded MyCog Mobile (1R01AG074245-01), a cognitive screening app that participants can self-administer remotely on personal smartphones and sends results directly to their primary care provider’s electronic health record. MyCog Mobile is the smartphone-based counterpart to MyCog, a tablet-based app that was developed for in-person self-administration in clinical settings [16]. MyCog Mobile uses 2 measures from MyCog adapted for remote assessment on a smartphone: Picture Sequence Memory (called MyPictures in the mobile app), which measures episodic memory, and Dimensional Change Card Sorting (called MySorting in the mobile app), which measures executive functioning. When combined with self-report, these 2 measures have demonstrated good sensitivity and specificity to detect cognitive impairment [16]. To expand the breadth of cognitive domains assessed, the pilot version of MyCog Mobile also includes 2 additional measures that are not in the original MyCog tablet app: a measure of working memory (MySequences) and a measure of memory for faces (MyFaces). We modeled each of the MyCog Mobile measures on existing mobile measures in the Mobile Toolbox [17], a comprehensive research platform and assessment library that allows for remote cognitive measurement on a personal smartphone (see Measures section).

MyCog Mobile is unique for 2 important reasons. First, it is a clinical screener meant to be used to help primary care providers make appropriate referrals and care recommendations, as opposed to a pure research measure such as the Mobile Toolbox. Second, MyCog Mobile is intended to be self-administered in a completely unsupervised remote setting, as opposed to the MyCog tablet app which is used in clinics under staff supervision. As such, MyCog Mobile underwent an extensive human-centered design process in which the platform and measures were optimized to be used by older adults in this context [5]. To ensure that the MyCog Mobile measures can be reliably self-administered by older adults in a remote setting, we piloted the screener in a sample of 51 adults aged 65 years or older who completed the measures on their personal iOS (Apple) smartphones. This pilot study will inform a subsequent construct and clinical validations, in which the sensitivity and specificity of the screener will be tested against clinical gold standards in a sample of healthy adults and used to differentiate healthy adults from those with cognitive impairment. Primary research questions for this pilot study include (1) Can older adults complete MyCog Mobile remotely on their smartphones? (2) Are the internal consistency and test-retest reliability of the measures acceptable? and (3) How do participants rate the user experience of MyCog Mobile?

Methods

Ethical Considerations

The research procedures were reviewed and approved by Northwestern University’s institutional review board (STU00214921). All participants provided informed consent and were compensated with a US $50 Visa gift card for their participation in this study. The data presented in this paper are
anonymous and free of identifiers that could be linked to specific participants.

**Sample**

We collaborated with a third-party market research agency to recruit older adults (N=51; Table 1) to take the measures on their smartphones twice, about 2 to 3 weeks apart. The agency contacted potential participants in their large database of thousands of older adults who had previously indicated interest in participation in research studies. Sample recruitment was broadly stratified by age, gender, racial and ethnic identity, and highest level of education. Inclusion criteria included (1) aged 65 years or older; (2) ownership of an iOS smartphone version 14 or higher; (3) being English-speaking; and (4) willing to complete the measures twice within approximately 2 to 3 weeks.

**Procedure**

Participants were asked to download the MyCog Mobile app onto their devices and complete the 4 activities in the battery and answer 2 demographic questions (age and education level). They received an email from this study’s staff with instructions to download the app and information on how to contact staff for support if needed. The app shows 2 brief intro screens (Figure 1) and then the cognitive screening begins with the learning trial of MyFaces. Participants then complete, in order, MySorting, MySequences, 2 demographics questions (age and education level), the recall subtests of MyFaces (see below), and, finally, MyPictures. After finishing their baseline MyCog Mobile assessment, participants completed a usability survey to provide feedback on their experiences. Participants were asked to self-administer MyCog Mobile a second time within 2 to 3 weeks of their baseline administration.
Measures

MyFaces

MyFaces is an associative memory test originally developed by Rentz and colleagues [18] to predict cerebral amyloid beta burden. The MyCog Mobile version of this task was adapted from the Mobile Toolbox Faces and Names test, which was also based on the original test [17]. Participants are first shown 12 pictures of people paired with their names. After an approximately 5- to 10-minute delay, participants’ memories are tested in 3 subtests: the first subtest (recognition) asks the participant to select the person they saw in the learning trial from 3 options. The second subtest (first letter) asks participants to indicate the first letter of the name of the person presented on the screen (Figure 2). The third subtest (name matching) asks participants to select the name of the person presented from among 3 possible response options. A raw accuracy score is given for each of the 3 subtests.

Figure 1. MyCog Mobile introduction screens.
**MySorting**

MySorting is a measure of executive function and cognitive flexibility adapted from the MyCog Dimensional Change Card Sorting [16] and the Mobile Toolbox Shape-Color Sorting test [17]. Respondents are asked to sort images across 2 dimensions—shape and color—as quickly as they can. The relevant dimension for sorting is indicated by a cue word ("shape" or "color") that appears on the screen (Figure 3). Scores are given for accuracy and response speed.

Figure 2. MyFaces first letter subtest example screen (face censored for publication).

Figure 3. MySorting example screen.
**MySequences**

MySequences is a measure of working memory adapted from the Mobile Toolbox sequences test [17]. MySequences requires participants to remember strings of letters and numbers and arrange them in order, with the letters in alphabetical order first and then the numbers in ascending numerical order (Figure 4). Trials begin with strings of 3 alphanumeric characters and increase in length, reaching a maximum difficulty of 10 characters. Scores reflect the number of correct trials.

**Figure 4.** MySequences response entry example screen.

---

**MyPictures**

MyPictures is a measure of episodic memory adapted from the MyCog Picture Sequence Memory [16] and the arranging pictures task in the Mobile Toolbox [17]. A series of images depicting independent, nonsequential activities is presented in a specific order and placed in specific, sequential locations on the screen. Following this presentation, the images are scrambled, and the participant is asked to recall the original position of the images accordingly (Figure 5). There are 2 trials. Scores are given for exact match (the number of pictures in the correct positions) as well as adjacent pairs (the number of correctly ordered pairs of pictures next to each other) on each trial.
Simplified System Usability Scale

The Simplified System Usability Scale (S-SUS) is a modified version of the original System Usability Scale designed for adults aged 65 years and older with or without cognitive impairments [19]. Participants rate their level of agreement with statements about their experience using MyCog Mobile on a 5-point Likert scale. The original System Usability Scale has demonstrated evidence of its internal consistency, sensitivity to change, and concurrent validity with other usability measures.

Custom Usability Items

We also asked participants to respond to 2 additional 5-point Likert-scale items regarding their experience using MyCog Mobile: “the time to complete the MyCog Mobile Cognitive Screening was” (1=shorter than I expected, 3=about as much time as I expected, and 5=longer than I expected); and “how would you rate the experience of completing MyCog Mobile overall?” (1=very bad, 3=neutral, and 5=very good). Participants also provided feedback on the experience in 3 free-response items: (“what would you do if the app wasn’t working or you weren’t sure what to do next?”; “is there anything you would change about using the MyCog Mobile App to improve the experience?”; and “is there anything else you would like us to know about your experience using the MyCog Mobile app?”).

Analysis

All analyses were conducted in R (R Core Team, 2023), and packages and codes are available on the Open Science Framework [20]. With 51 participants, we had 80% power to detect effect sizes of 0.38 or greater, which was adequate to evaluate our primary outcome of reliability metrics. Internal consistency was assessed using various methods that aligned with each task’s paradigm. For MySorting and MySequences, we calculated median Spearman-Brown correlations between bootstrapped random split-half coefficients for the accuracy scores. For MyPictures, we used the Pearson correlation between trial 1 and trial 2 adjacent pairs’ scores to calculate the Spearman-Brown split-half reliability ($2r/(1+r)$). For MyFaces, we used a look-up table to find expected a posteriori scores and SDs based on the sum of the accuracy scores across the 3 subtests [21,22] and then calculated the empirical and mean marginal reliabilities [23]. We considered internal consistency coefficients of 0.70 or greater to be acceptable [24]. We used intraclass correlations (ICC$s$) to evaluate test-retest reliability for each of the measures. ICC$s$ and practice effects are reported for the MySorting total score, MySequences total score, MyPictures sum of adjacent pairs’ scores across trials 1 and 2, and the total score across all 3 subtests for MyFaces. We considered ICC$s$ less than 0.50 to be poor, 0.50 to 0.75 acceptable, 0.75 to 0.90 good, and above 0.90 excellent [25]. Practice effects were evaluated through paired 2-tailed t tests of baseline and retest scores. CIs (95%) that contained 0 were considered to indicate nonsignificant practice effects.

We also conducted exploratory analyses of the relations between test performance, usability, and education, respectively, using Spearman $\rho$ correlations. Spearman $\rho$ correlations were used...

Figure 5. MyPictures practice example screen.
over Pearson $r$ correlations because we were interested in monotonic relationships between variables rather than strictly linear ones. Correlations with age were not conducted due to the restriction of age range by study design. To assess the usability of the screener, we examined the score distributions on the S-SUS and custom Likert-scale items and qualitatively evaluated the results from custom usability survey items. A total score greater than 70 out of 100 possible points is considered above average and an acceptable level of usability [26,27]. Further, 2 authors independently reviewed and coded the free-response items. Codes were then reconciled, grouped, and categorized by representative themes. Although we counted each code’s frequency, the survey free-response items were an informal method of gathering feedback rather than a formal quantitative or qualitative study, and our analysis is exclusively descriptive.

**Usability**

The mean overall usability rating on the S-SUS was acceptable (mean 73.17, SD 19.27). Ratings were not significantly correlated with education or performance on any of the measures. Analysis of the S-SUS items demonstrated Likert scale ratings in generally favorable directions (ie, positively worded items were greater than the neutral rating of 3, and negatively worded items were less than 3; Table 3). On additional custom Likert-scale items, participants indicated the time it took to complete the S-SUS was slightly less than expected on average, and the overall experience was positive.

**Free-Response Feedback**

On the first free-response item, “what would you do if the app wasn’t working, or you weren’t sure what to do next?” participants’ responses indicated several strategies they would use for help (Table 4). Most expected to be able to directly contact someone for support through an email or phone call. Several participants indicated they would use an in-app help resource or search for help resources online. Although most participants indicated they would try to solve the problem, 3 participants stated they would not finish MyCog Mobile if they encountered a difficulty (eg, “[I would] disregard it and continue on as I had before the app”).

On the second free-response item, “is there anything you would change about using the MyCog Mobile App to improve the experience?” most participants did not offer any suggestions or gave positive feedback (Table 4). Several participants suggested the instructions for the cognitive tests needed clarification (eg, “some of the exercises were not well explained or confusing. Particularly the ones where random letters and numbers were given, and they had to be reorganized. Simplifying the instructions would be helpful”). Some participants expressed concerns about their memories in response to this question or commented on the difficulties of the test items (eg, “I just wish I was smarter [and] had a better memory”). Regarding visual accessibility of the app, 2 participants indicated difficulty with the print size, and 1 indicated difficulty with the visual contrast of the tasks. Of note, 1 participant remarked they would prefer to complete MyCog Mobile in the clinic (eg, “while the app itself was easy & straight forward to download and access the survey material, I would most likely defer its home use and prefer an ‘in doctor’s office’ cognitive testing experience”). However, another participant remarked on how easy it would be to complete MyCog Mobile before the appointment (eg, “I really don’t see that anything was difficult. The app would work very well prior to a doctor visit.”). Further, 3 participants offered feedback on the process of participating in this pilot study, which will be considered for future study administration but is not relevant to the MyCog Mobile user experience specifically.

On the final free-response item, “is there anything else you would like us to know about your experience using the MyCog Mobile app?” most participants did not provide any feedback. As with the previous free-response item, several participants expressed concerns about their abilities (eg, “I found it to be quite challenging, especially since my memory isn’t what it once was.”). Some commented the instructions were confusing (eg, “no at 1st it was sort of confusing once I got into it, it was easier”), and 2 wanted more opportunities to practice before starting the live items. (eg, “I would like to see more practice questions to help the user feel more relaxed and confident”). Further, 2 participants wanted more explanation around the purpose of the test (eg, “perhaps a brief description of what the test is designed for, for example: to test mental recall, to test cognitive ability, to test onset of dementia or Alzheimer’s”). Only 1 participant reported difficulties loading the app for this study. Conversely, many participants provided positive feedback (eg, “it was simple and easy to use”).

Discussion

Principal Findings

The findings suggest most healthy older adults can reliably complete the MyCog Mobile screener remotely on their smartphones. The 4 performance measures that comprise the MyCog Mobile screener demonstrated acceptable internal consistency and test-retest reliability. The performance demonstrated positive correlations with education as expected, except for MyPictures, which did not correlate with education. Participants in our sample rated the usability of MyCog Mobile as above average and rated the experience “Good” to “Very Good” overall. They indicated the time to complete MyCog Mobile was about as long as they expected. These results provide evidence of the feasibility and acceptability of remote self-administration of the MyCog Mobile cognitive screener and support its further evaluation in larger clinical samples to understand its diagnostic accuracy and construct validity.

The feedback on free-response items indicated that most participants had a positive user experience and revealed several actionable insights for the next iteration of the MyCog Mobile app. First, participants expect a dedicated support representative to be available if they have difficulty using the app. Clinics that implement MyCog Mobile into their workflows will have to consider how to best respond to the needs of patients. For example, clinics may choose to dedicate resources for support or inform patients that the screener is optional, and they may defer the use of the app until their clinic visit if they encounter problems. Participants also indicated that they expect a help resource within the app. Currently, participants can use the “Pause” icon to stop the activities and review the instructions. However, an additional button labeled “Help” may be easier to navigate for older adults. Participants indicated that they would use several strategies to troubleshoot on their own if they encountered difficulties (eg, restarting the app); however, clinics should expect some participants not to finish MyCog Mobile if problems arise. For these patients, clinics will have to default to their previous screening workflows (eg, using in-person screeners like the MyCog tablet app or a traditional paper-and-pencil screener).

Concerning what could be improved with the app, some participants offered feedback on the instructions for the activities and asked for more opportunities to practice before completing live items. Although this feedback came from a minority of patients (7/51, 14%), we will conduct further cognitive interviewing to ensure instructions are optimized for all users. Currently, participants are only allowed to try practice items again if they respond incorrectly. However, adding the opportunity to try practice items again if the item is correct may be helpful for participants. Further, 2 participants also reported trouble reading the print on a smartphone screen. To address this, we increased the font size of the print to maximize the readability of the text which will be implemented in the subsequent MyCog Mobile validation studies.
Several participants provided feedback that reflected insecurities about their abilities or performance on the test. Some reported that the items were too difficult, however, the item difficulties cannot be changed to preserve the validity of the test. Instead of changing the items, steps could be taken to assure patients that it is normal for the items to be challenging. Based on feedback in a previous study, we designed the introduction screen (Figure 1) to alleviate potential concerns about the purpose of the test. For the next iteration of MyCog Mobile, we will collect participant feedback on how to optimize the introduction screen to make patients feel comfortable and assured when completing the screener at home.

Limitations

The generalizability of our findings is limited by the relative homogeneity of our small sample about racial and ethnic identities. Representation of racial identities other than White was low or nonexistent, and representation of Hispanic or Latino populations was relatively small. Findings will need to be replicated in these populations in future studies to ensure MyCog Mobile has equal validity evidence for these groups. Moreover, due to the constraints of the grant, we developed the first version of MyCog Mobile for iOS devices (iPhones) only. iPhones are among the most expensive smartphones, which may have biased our sample toward higher-income participants (though we did not collect income information). Future work will focus on developing and validating MyCog Mobile for Android.

In this small pilot study, we were not able to conduct qualitative interviews with patients but rather gave them opportunities to provide feedback via free-response survey items. While free-response items can capture a breadth of spontaneous viewpoints, they may not achieve the depth or nuanced understanding of participants’ experiences and perspectives that can be gleaned from qualitative interviews. Consequently, our findings might not encompass the subtleties or the full range of participant experiences with MyCog Mobile.

The recruitment of older adults with cognitive impairments was outside of the scope of our pilot study; however, it is important to note that MyCog Mobile has yet to be researched in these populations. We expect older adults who are currently struggling with cognitive decline will likely have difficulty using MyCog Mobile, and the app may be more appropriate for participants who are cognitively intact or in the early stages of cognitive decline. The forthcoming clinical validation of MyCog Mobile will provide valuable information about the sensitivity and specificity of the measures for detecting cognitive decline. The forthcoming clinical validation of MyCog Mobile will provide valuable information about the sensitivity and specificity of the measures for detecting cognitive decline as well as the feasibility of using the app with cognitively impaired populations.

Further, I potential limitation of the MyCog Mobile app is older adults’ familiarity with mobile health apps in general. Although smartphone ownership is increasingly more common across age groups, some older adults still do not own smartphones or feel confident using them. The participants in our sample rated the user experience highly; however, the acceptability of a remote cognitive screening app is likely to be lower in a general population sample that has not chosen to participate in a highly controlled research study. Based on the results of the clinical validation, we will conduct a field test of MyCog Mobile, in which we will collect feedback on the acceptance of the app in real-world contexts.

Comparisons With Prior Work

Our findings are consistent with the small body of research on the feasibility and acceptability of smartphone apps for cognitive screening but also offer some novel contributions. Several studies have examined repeated cognitive assessments on smartphones in research contexts for older adults, although these have primarily examined adherence [11,13,28]. Further, ecological momentary assessment study found that both cognitively normal and older adults with mild cognitive impairment were able to complete cognitive assessments on their smartphones with an adherence rate of 85% in the context of a research study [29]. We observed a 96% adherence rate in our pilot study (albeit with only 2 administration time points), but it is unclear if patients will respond the same way when MyCog Mobile is used in the context of a real-world primary care visit, even if they are asked to complete the activities once annually.

Research on attitudes toward cognitive screening in primary care suggests that most older adults are open to cognitive screening in primary care if they perceive there is a benefit [30]. In our sample, the average response to “I would use the MyCog Mobile app before an appointment with my doctor” skewed positive, but 10 (20%) out of 51 participants responded with "Disagree" or “Strongly Disagree.” Future iterations of the app will focus on communicating the benefits of cognitive screenings to older adults, especially in the absence of clinical staff to explain the assessments when they are taken at home. Moreover, clinics should expect there to be a portion of patients who do not complete MyCog Mobile before the visit and will need to complete usual-care cognitive screenings in the clinic. MyCog Mobile is not intended to replace all in-person screening practices, but rather supplement such practices. Likewise, MyCog Mobile is not intended to provide a clinical diagnosis, but rather to identify potential cognitive impairment, and lead to appropriate referrals for more comprehensive evaluation. For the portion of patients who are willing and able to complete MyCog Mobile on their smartphones before their appointment, clinics can use in-person time to focus on other important aspects of the visit.

Conclusions

Pilot evidence suggests the MyCog Mobile cognitive screener can be reliably self-administered by older adults on their smartphones. Participants in our study generally provided positive feedback about the MyCog Mobile experience and rated the usability of the app highly. Based on participant feedback, we will conduct further usability research to improve support functionality, optimize task instructions and practice opportunities, and make patients feel comfortable using MyCog Mobile. Additional next steps include a clinical validation study that compares MyCog Mobile to gold-standard assessments and tests the sensitivity and specificity of the measures for identifying cognitive impairment.

Abstract

Background: The automatic generation of radiology reports, which seeks to create a free-text description from a clinical radiograph, is emerging as a pivotal intersection between clinical medicine and artificial intelligence. Leveraging natural language processing technologies can accelerate report creation, enhancing health care quality and standardization. However, most existing studies have not yet fully tapped into the combined potential of advanced language and vision models.

Objective: The purpose of this study was to explore the integration of pretrained vision-language models into radiology report generation. This would enable the vision-language model to automatically convert clinical images into high-quality textual reports.

Methods: In our research, we introduced a radiology report generation model named ClinicalBLIP, building upon the foundational InstructBLIP model and refining it using clinical image-to-text data sets. A multistage fine-tuning approach via low-rank adaptation was proposed to deepen the semantic comprehension of the visual encoder and the large language model for clinical imagery. Furthermore, prior knowledge was integrated through prompt learning to enhance the precision of the reports generated. Experiments were conducted on both the IU X-RAY and MIMIC-CXR data sets, with ClinicalBLIP compared to several leading methods.

Results: Experimental results revealed that ClinicalBLIP obtained superior scores of 0.570/0.365 and 0.534/0.313 on the IU X-RAY/MIMIC-CXR test sets for the Metric for Evaluation of Translation with Explicit Ordering (METEOR) and the Recall-Oriented Understudy for Gisting Evaluation (ROUGE) evaluations, respectively. This performance notably surpasses that of existing state-of-the-art methods. Further evaluations confirmed the effectiveness of the multistage fine-tuning and the integration of prior information, leading to substantial improvements.

Conclusions: The proposed ClinicalBLIP model demonstrated robustness and effectiveness in enhancing clinical radiology report generation, suggesting significant promise for real-world clinical applications.

(Keywords: clinical image; radiology report generation; vision-language model; multistage fine-tuning; prior knowledge)

Introduction

Radiology reports offer essential textual descriptions of radiographs and play a pivotal role in the medical diagnosis and treatment process. Their precise interpretation can directly influence patient outcomes, underscoring the gravity of each assessment. However, even for seasoned radiologists, interpreting these images can be a meticulous task, often taking several minutes per image. In an era where timely medical intervention can be lifesaving, streamlining this process becomes imperative. Recognizing the immense potential to ease the workload of the health care sector and improve patient care, there has been a growing interest in the research for automatic radiology report generation.
As shown in Figure 1, several attempts have been made in the medical field to create medical reports from images. In the early stage, most researchers used traditional deep learning methods, such as convolutional neural networks (CNNs) and recurrent neural networks (RNNs), to produce radiology reports. IU X-RAY proposed by Demner-Fushman et al [1] was a significant step in this direction. In addition, Shin et al [2] innovatively applied a CNN-RNN model for structured report creation. Wang et al [3] used a nonhierarchical CNN-long-short term memory approach, emphasizing both semantic and visual cues. Vinyals et al [4] introduced visual attention mechanisms in the realm of image captioning with CNN-RNN structures. Subsequently, radiology report creation has evolved to adopt transformer-based models [5,6]. The Knowledge-Driven Encode, Retrieve, and Update model is designed to allow the LLM to draw upon its internal knowledge and understanding of medical images and texts to generate better reports. The proposed ClinicalBLIP achieved state-of-the-art performance with layer normalization [19] is proposed to enhance the understanding of clinical images by a general visual encoder. The training target is the text generation loss of the large language model (LLM) without introducing extra clinical knowledge with clinical images to generate better reports. However, it is important to address challenges related to data quality, integration, and rules when using VLMs in clinical settings. Thus, designing an effective fine-tuning method to boost VLM's knowledge and understanding of medical images and texts is a very interesting research direction.

Recently, vision-language models (VLMs) [12-15] have become leading approaches, which use pretrained transformer models to handle both visual and textual data at the same time. These models are very good at understanding and creating content based on images and texts. One key feature is cross-modal learning [16,17], where VLMs learn to match specific image patterns with their related descriptions or findings. This understanding helps in making reports that are more relevant and accurate. VLMs have the potential to greatly improve radiology report generation by increasing accuracy, making processes faster, and ensuring consistency. However, it is important to address challenges related to data quality, integration, and rules when using VLMs in clinical settings. Thus, designing an effective fine-tuning method to boost VLM's knowledge and understanding of medical images and texts is a very interesting research direction.

In this study, we fine-tune a medical VLM named ClinicalBLIP through a multitask fine-tuning strategy for the radiology report generation task. First, a joint optimization method that combines self-attention fine-tuning via low-rank adaptation (LoRA) [18] with layer normalization [19] is proposed to enhance the understanding of clinical images by a general visual encoder. The training target is the text generation loss of the large language model (LLM) without introducing extra clinical image-text pairs for further pretraining. Second, the joint fine-tuning process for both the image-text transformation layer and the multilayer perceptron (MLP) layer of the language model is designed to allow the LLM to draw upon its internal capability to generate the final report. In addition, we further incorporate the prior information to light the specialized clinical knowledge inherent in the LLM. Also, the clinical tag and brief description of the image as a text prompt are fed into the model for training and prediction. Experiments were conducted on the IU X-RAY [1] and MIMIC-CXR [20] data sets. We compared the proposed model with 11 competitor methods and analyzed the performance in several aspects. It is demonstrated that the proposed ClinicalBLIP achieved state-of-the-art performance and can effectively combine the introduced textual prior knowledge with clinical images to generate better reports.

### Methods

#### Data Set

We evaluated our proposed method on the IU X-RAY [1] and MIMIC-CXR [20] data sets. Both data sets have been automatically deidentified.

The IU X-ray data set comprises 7470 images and 3955 reports. The images consist of chest x-rays originating from Indiana University. Each report in the data set primarily encompasses multiple attributes such as comparison, indications, findings, and impressions. Reports with empty findings were excluded, resulting in 3337 remaining reports. Subsequently, we divided the remaining reports into training and testing sets in a 4:1 ratio, yielding 2668 reports for training and 669 reports for testing.

The MIMIC-CXR data set was created by the Massachusetts Institute of Technology. The images are sourced from 65,379 patients who presented to the Beth Israel Deaconess Medical Center Emergency Department between 2011 and 2016. We used 152,173 medical reports for training and 1196 reports for testing. In this data set, each data entry comprises a specific report and 1 to 3 corresponding images.

Figure 1. Example of a radiology report generation task.
Overview of the Proposed Method

Our work aims to transform clinical radiographs, accompanied by additional information, into textual descriptions that convey the same semantic meaning as the images. To achieve this, we introduce the ClinicalBLIP model, as depicted in Figure 2. This model comprises three core modules: (1) a visual encoder for converting clinical images into semantic representations; (2) query transformer (Q-Former), a crucial component for bridging the image-text gap; and (3) a LLM for generating textual reports based on queries learned from Q-Former and textual prompts.

Figure 2. Overview of the proposed ClinicalBLIP model. LLM: large language model; Q-Former: query transformer.

Initially, we briefly introduce the structure and pretraining of the ClinicalBLIP, which draws inspiration from Li et al [21], especially how Q-Former as an intermediate module effectively connects visual and textual data. Subsequently, we delve into the details of how to effectively fine-tune the task of radiology report generation.

Q-Former to Bridge the Modality Gap

Q-Former is designed to link a fixed image encoder with a standard LLM. Notably, it can extract a consistent set of features from the visual encoder, regardless of the input image resolution. As shown in Figure 3, the model is composed of two primary transformer submodules: (1) an image transformer for direct interaction with the visual encoder and (2) a text transformer that serves as both encoder and decoder. The efficacy of the Q-Former is greatly influenced by learnable query embeddings, which facilitate self-attention and cross-attention layer interactions. These embeddings also enable communication with text through similar attention mechanisms. During its 2 pretraining phases, that is, vision-language representation learning and vision-to-language generative learning, Q-Former uses distinct attention masks for specific tasks, controlling the interaction between queries and text.

Figure 3. Model architecture of query transformer (Q-Former).

Vision-Language Representation Learning From Visual Encoder

In the representation learning phase, Q-Former, connected to a frozen visual encoder, undergoes pretraining with image-text pairs. The objective here is to train the model to enable queries to extract visual representations corresponding to the text. Inspired by Li et al [22], 3 pretraining tasks are jointly optimized, using the same input format and model parameters. As illustrated in Figure 3, these tasks include image-text contrastive learning, image-grounded text generation, and image-text matching. Image-text contrastive learning aligns
image and text representations by contrasting the similarity of a positive image-text pair against that of negative pairs. Image-grounded text generation encourages the Q-Former to compel the queries to extract visual features that contain the whole information of the text. Image-text matching seeks to capture fine-grained alignment between image and text representations through a binary classification task. Each task uses a specific attention-masking strategy to control the interaction between queries and text.

**Vision-to-Language Generative Learning From LLM**

During the generative pretraining phase, Q-Former, connected to a frozen LLM, leverages its language generation capabilities. A fully connected layer is used to linearly project the output query embeddings to match the dimension of the LLM’s text embedding. These embeddings then act as visual prompts, guiding the LLM based on the visual representation captured by Q-Former. Since Q-Former has been trained to extract visual representations that are informative for language, it effectively serves as an information filter, providing only the most relevant information to the LLM and excluding unnecessary visual details. This setup reduces the load on the LLM to learn vision-language alignment, mitigating the risk of the catastrophic forgetting problem.

**General Vision-Language Instruction Tuning**

Following the pretraining phases, as in Dai et al. [23], Q-Former undergoes a vision-language instruction tuning process. Here, the LLM integrates visual encodings from Q-Former with additional instruction text tokens. The instruction interacts with the query embeddings through the Q-Former’s self-attention layers. This interaction aids in extracting relevant image features, which are further provided to optimize the LLM for following instructions. Both quantitative and qualitative analyses confirm the effectiveness of the instruction tuning process in achieving vision-language zero-shot generalization.

**Effective Fine-Tuning of Radiology Report Generation**

To enhance the performance of a general visual encoder and an LLM for medical image understanding and report generation, various aspects need careful consideration. As shown in Figure 4, a multistage parameter fine-tuning approach is used to improve model performance, namely visual encoder enhancement and vision-language joint training.

In the first stage, the model’s weights are adjusted to focus more on relevant features within medical images. This refinement aids in understanding critical elements such as lesions, organs, and more. Concurrently, layer normalization is applied to maintain a consistent response across varying image scales and brightness levels. The primary objective here is the generation loss of the LLM, aiming to improve the quality of final reports by enhancing the visual encoder’s ability to use visual information more effectively during report generation, without the need for additional medical text data for further pretraining.

In the second stage, the joint training process encompasses the fusion of visual and textual inputs, and crucially, the incorporation of the attention layer and MLP layer of the LLM. The model simultaneously processes information from the visual encoder and textual sources. The attention layer enables dynamic focus on specific regions of medical images, aligning with features crucial for report generation. Meanwhile, the MLP layer transforms the combined visual-textual data, boosting the model’s ability to generate contextually accurate and coherent medical reports. The whole approach ensures full use of the model’s attention and transformation capabilities, yielding medically precise and linguistically sound reports, thus effectively bridging the gap between visual and textual data.

Moreover, general LLMs often struggle with the absence of specialized medical domain knowledge in the medical report generation task. To mitigate the issue, we incorporate the prior information into the model during the second stage. Specifically, medical tags related to the medical image and a brief image description are embedded as text prompts. In training, these prompts are linked to corresponding medical images, facilitating the model’s comprehension of the image content. This association enables the model to better learn medical
domain-specific terms and concepts. This embedding of text prompts guides the model with domain knowledge, addressing its limitations in the medical field. During prediction, these prompts provide additional contextual information, enabling the model to better comprehend medical images, identify features within them, and express the medical reports in a more professional manner.

In our research, we analyze 2 relevant data sets: IU X-RAY [1] and the MIMIC-CXR [20]. Each of them has unique prior information as input. The IU X-RAY data set enriches the model with essential prior information, including “problem,” “image,” and “indication.” The input template for the IU X-RAY data set is formatted as follows:

“Problems: {problem} \n Image: {image} \n Indication: {indication} \n”,

exemplified by “Problems: normal \n Image: Chest, 2 views, frontal and lateral \n Indication: Pruritic \n”.

In contrast, the MIMIC-CXR data set lacks direct access to similar prior information. To maintain consistency, we use the CheXBERT [24] model to extract medical observations from the reports within the MIMIC-CXR data set. The input template for this data set is formatted as follows:

“Symptoms of existence: {} \n Symptoms of non-existence: {} \n”,

illustrated by “Symptoms of existence: Cardiomegaly, Atelectasis \n Symptoms of non-existence: Edema, Consolidation \n”.

**Experimental Settings**

We adopt the InstructBLIP [23] as the base model, in which contrastive language-image pretraining [13] and Flan-T5-XL [25] are used as visual encoders and LLM structures, respectively. In the training phase, we integrated LoRA [18] into both the visual encoder and the language model. This integration of LoRA was strategically implemented within the query projection and value projection stages during self-attention operations, enhancing the model’s ability to capture and leverage relational information. For the training process, we configured our settings as follows: a batch size of 3 was used, and gradient accumulation was carried out over 4 steps to facilitate stable and efficient training. The initial learning rate for the Q-Former parameters was set to $1 \times 10^{-4}$, while the initial learning rate for the LoRA-related parameters was established at $5 \times 10^{-4}$. To dynamically adapt the learning rate during training, we used a cosine decay learning rate scheduler, optimizing the convergence and fine-tuning process. Furthermore, to enhance the training efficiency and minimize memory consumption, we used float16 precision, a half-precision training technique, which effectively balances training speed and model performance. This comprehensive approach allowed us to train our model effectively, incorporating LoRA’s enhancements for improved performance and robustness. All the experiments are conducted on a graphics processing unit (NVIDIA V100).

To evaluate the performance of the ClinicalBLIP model, we compared our method with the following 11 state-of-the-art methods. R2GEN [9] is a memory-driven radiology report generation model with a relational memory to record the information from the previous generation processes and a layer normalization mechanism to incorporate the memory. CA [26] is a contrastive attention model to capture and depict abnormalities by comparing the input image with known normal images. CMCL [27] is a novel competence-based multimodal curriculum learning framework to alleviate data bias by efficiently using limited medical data for medical report generation. Posterior-and-Prior Knowledge Exploring-and-distilling [28] is an effective approach to exploring and distilling posterior and prior knowledge for radiology report generation. R2GEN enhanced with cross-modal memory networks [29] is a radiology report generation model with cross-modal memory networks in which a memory matrix is used to record the alignment and interaction between images and texts, and another memory is used to perform querying and responding to obtain the shared information across modalities. ALIGNTRANSFORMER [30] is a radiology report generation model to alleviate the data bias problem and model the very long sequence. Knowledge Matters [31] is a novel radiology generation framework assisted by general and specific knowledge. Meshed-Memory Transformer [32] is a simple but effective progressive text generation model to produce the radiology report by incorporating high-level concepts into the generation progress. Reinforcement Learning Over a Cross-Modal Memory (CMM-RL) [33] is an enhanced radiology report generation model with reinforced cross-modal alignment to alleviate the requirement of annotated supervision while facilitating interactions across modalities. Cross-Modal Contrastive Attention (CMCA) [34] is a novel model to capture both visual and semantic information from similar cases. Observation-Guided Radiology Report Generation (ORGAN) [35] is a generation framework that can maintain the clinical consistency between radiographs and generated free-text reports.

We adopted natural language generation metrics to evaluate the methods. Specifically, we selected Bilingual Evaluation Understudy (BLEU) [36], Metric For Evaluation of Translation with Explicit Ordering (METEOR) [37], and Recall-Oriented Understudy for Gisting Evaluation (ROUGE) [38]. BLEU-1, BLEU-2, BLEU-3, BLEU-4, METEOR, and ROUGE-L are reported.

BLEU is primarily used to evaluate the quality of machine-generated translations by comparing them to 1 or more reference translations. It computes a precision-based metric by counting the number of n-grams (contiguous sequences of n items, usually words) in the generated translation that matches any reference translation. In this work, BLEU is used to evaluate the generated text report.

METEOR is based on the harmonic mean of unigram precision and recall, with recall weighted higher than precision. It incorporates features not found in other metrics, such as stemming and synonymy matching, along with standard exact word matching. The metric was designed to address some of the issues found in the more popular BLEU metric and to produce a good correlation with human judgment at the sentence or segment level.
ROUGE compares an automatically produced text against a reference or a set of reference text. It measures the overlap of n-grams and word sequences between the generated text and reference text. ROUGE captures both precision and recall, providing a more balanced evaluation, and can be adapted for different summary lengths.

**Ethical Considerations**

This study complied with all relevant ethical regulations. All the publicly available data sets have been deidentified and anonymized. With institutional review board approval (OHSRP#5357) by the National Institutes of Health Office of Human Research Protection Programs, the IU X-RAY data set was made publicly available by Indiana University, and no informed consent was necessary [1]. The MIMIC-CXR data set was originally approved by the institutional review board of the Beth Israel Deaconess Medical Center and the requirement for individual patient consent was waived [20].

**Results**

**Quantitative Evaluation**

Tables 1 and 2 provide the quantitative results of the IU X-RAY and MIMIC-CXR test sets, respectively. The detailed results show that the ClinicalBLIP model exhibited robust performance when compared with other methods across the IU X-RAY and MIMIC-CXR data sets. For the IU X-RAY data set, as shown in Table 1, although ClinicalBLIP was slightly inferior to the competitor methods on some individual metrics, it significantly surpassed the competitor methods on most metrics. With a BLEU-A score of 0.296, it boasted an improvement of roughly 6.9% over its nearest competitor, CMCA, which had a BLEU-A score of 0.277. This showcases ClinicalBLIP’s enhanced capability in producing reports that are more aligned with the reference. Moreover, when assessing the METEOR metric, which provides insights into the robustness of generation, ClinicalBLIP achieved a score of 0.570. This was approximately 1.7 times higher than CMCA’s 0.209, reflecting ClinicalBLIP’s superior relevance to the generated report. The ROUGE-L metric further solidified this observation; ClinicalBLIP’s score of 0.534 was about 33.8% higher than ORGAN’s score of 0.399, suggesting that ClinicalBLIP consistently maintained a high level of linguistic quality and relevance in its results.

For the MIMIC-CXR data set, as shown in Table 2, there were areas where ClinicalBLIP did not have the highest score, but its comprehensive performance remains commendable. The BLEU-A score for ClinicalBLIP stood at 0.162, which, while marginally behind ORGAN’s score of 0.184, indicates a competitive translation quality. However, ClinicalBLIP made a strong comeback in the METEOR metric, recording a score of 0.365, which is approximately 1.25 times higher than ORGAN’s score of 0.162. This underlines ClinicalBLIP’s proficiency in generating semantically relevant reports. Furthermore, with a ROUGE-L score of 0.313, ClinicalBLIP managed to surpass ORGAN by roughly 6.8%, emphasizing its consistent linguistic excellence.

In summary, while individual metrics might have seen close competition, the overall trend clearly indicates the comprehensive strength of the ClinicalBLIP model. Its consistently high scores across various data sets and metrics demonstrate its versatility and reliability in the realm of clinical report generation.

Ablation Study

We also conducted an ablation study to analyze the impact of fine-tuning on different modules, such as the original InstructBLIP (without any fine-tuning on this task), LLM, visual encoder, and prior information, and show the results in Table 2. Based on the ablation study results presented in Table 3, several observations can be made regarding the performance of different methods on the IU X-RAY data set. The ClinicalBLIP method achieved a BLEU score of 0.296, a METEOR score of 0.570, and a ROUGE-L score of 0.534, indicating its robust performance across the metrics. When the effective tuning was removed, namely InstructBLIP, there was a significant drop in all metrics, especially in the BLEU score, which dropped to a mere 0.011. This highlights the importance of effective tuning for the model’s performance. Similarly, removing prior information also led to a decline in performance, with the METEOR metric showing a noticeable drop, to 0.339. The removal of LLM tuning and visual encoder tuning resulted in reduced scores, but this was not as drastic as in the former cases. The BLEU score dropped to 0.149 and 0.245, respectively, while the METEOR score was 0.458 and 0.513 for the same conditions.

In summary, effective fine-tuning and prior information played a vital role in achieving optimal performance, and LLM tuning and visual encoder tuning were also important components for enhancing the model’s results. All the components together contributed to the best results.

**Discussion**

**Principal Results**

Our proposed model, ClinicalBLIP, achieved the best METEOR and ROUGE-L scores and competitive BLEU scores on the test sets of both IU X-RAY and MIMIC-CXR. The primary outcomes of this study are to (1) propose a multistage fine-tuning strategy that separately enhances the visual encoder and the LLM’s understanding of medical image and text, allowing the LLM to harness the knowledge acquired during the pretraining process and (2) incorporate the medical tags of medical images and brief introductions of these images in the form of prompts into the model’s training and prediction processes, the large model can effectively combine the introduced text-based prior knowledge with medical images to generate a more accurate report. Experimental results demonstrate that ClinicalBLIP has great potential to help medical experts facilitate radiology report generation and improve the efficiency of decision-making for clinical diagnosis and treatment.

**Case Study**

In addition to quantitative evaluations, we conducted an extensive set of qualitative case studies to analyze the generated report. Figure 5 shows 4 cases selected from the generated reports on the MIMIC-CXR test set.

By comparing the prediction and the gold standard, it can be found that case 1 and case 2 are good cases. For case 1, although the prediction and the gold standard are not exactly the same, there are differences in the order of symptom descriptions and word choices; the deep semantic meanings expressed by the two are basically consistent. However, the gold standard provides more details than the prediction, which also explains why the BLEU score is not ideal in certain situations. For case 2, both the prediction and the gold standard reports are closely aligned and convey the same overall findings. The patient’s chest x-ray does not reveal any significant abnormalities. This is a good case as it highlights the consistency and accuracy of radiological interpretation.

Besides the first 2 good cases, there are also areas that need improvement and enhancement. Cases 3 and 4 in Figure 5 show 2 bad cases. For case 3, both the prediction and the gold standard state that the heart is within the normal size, and the lungs appear clear with no signs of pleural effusion or pneumothorax. However, the prediction mentions mild anterior wedging of a midthoracic vertebral body with slight degenerative changes along the midthorax. In contrast, the the gold standard report mentions degenerative changes in the thoracic spine but does not specify the location or type of degeneration. The discrepancies in the description of the bony structures between the prediction and the gold standard report could also be of concern. Different types and locations of degenerative changes can have different clinical implications. For case 4, while the prediction and the gold standard largely align on most observations, there are subtle differences in phrasing. For instance, the prediction mentions the cardiomesediastinal silhouette is normal in size, whereas the the gold standard emphasizes the normal contours of the heart and mediastinum. Such subtle linguistic variations can potentially lead to misunderstandings in diagnosis or interpretation, especially in critical medical decisions. Therefore, even though the general assessments align, precision in wording remains essential.

In summary, it is crucial to ensure that automatic or artificial intelligence–based predictions in radiology are meticulously validated and cross-referenced with expert opinions to ensure patient safety and accurate diagnosis.
Figure 5. Cases generated by ClinicalBLIP on the MIMIC-CXR test set.

Comparison With Prior Work
In the medical or clinical field, there has been a surging interest in developing artificial intelligence applications for image captioning, that is, radiology report generation. Most studies have focused on improving the quality of the generated report by using cross-modal memory to facilitate the generation process [28], reinforcing learning to align the cross-modal information [32], and planning and iterative refinement for long text generation [25]. However, these methods have not explored the capabilities of large VLMs for this task. In this study, we successfully applied large VLMs to the radiology report generation task by designing effective multistage fine-tuning strategies and incorporating prior knowledge mechanisms. We validated our approach on multiple task data sets and achieved state-of-the-art performance.

Limitations and Future Work
Although ClinicalBLIP has made significant strides and shown promising outcomes, there are still some unresolved issues. As mentioned above, ClinicalBLIP has discrepancies in terminological expressions in some cases compared to the gold standard and sometimes lacks or misinterprets comprehensive details in certain descriptions. Therefore, in future work, we will continue to optimize ClinicalBLIP, considering the integration of reasoning techniques like chain of thoughts into the fine-tuning process. This aims to enhance the model’s semantic consistency in professional expressions and provide more detailed descriptions while also verifying the model’s generalization capabilities on more data sets. Moreover, we will seek collaboration from professional practitioners, including both directions for model improvement and methods for model evaluation.

Conclusions
In this study, the ClinicalBLIP model was introduced, leveraging large VLMs for radiology report generation. Tested on the IU X-RAY/MIMIC-CXR data sets, ClinicalBLIP significantly outperformed several competitor methods in METEOR and ROUGE scores, showcasing its potential to enhance automatic report generation in clinical radiology and streamline patient care processes.
Acknowledgments

This work was jointly supported by grants from the Research Project of Shenzhen Institute of Information Technology (grant SZHTZ2022KJ050), and the project was funded by the China Postdoctoral Science Foundation (grant 2023M741843), and the Natural Science Foundation of China (grant 62106115).

Authors’ Contributions

JJ and XC proposed the methods, designed and carried out the experiments, and drafted the manuscript. YH supervised the research and participated in the study design. YP critically revised the manuscript and made substantial contributions to interpreting the results. YX provided guidance and reviewed the manuscript. All authors provided feedback and approved the final version of the manuscript.

Abstract

Background: Overweight and obesity rates among the general population of the Netherlands keep increasing. Combined lifestyle interventions (CLIs) focused on physical activity, nutrition, sleep, and stress management can be effective in reducing weight and improving health behaviors. Currently available CLIs for weight loss (CLI-WLs) in the Netherlands consist of face-to-face and community-based sessions, which face scalability challenges. A digitally enabled CLI-WL with digital and human components may provide a solution for this challenge; however, the feasibility of such an intervention has not yet been assessed in the Netherlands.

Objective: The aim of this study was two-fold: (1) to determine how weight and other secondary cardiometabolic outcomes (lipids and blood pressure) change over time in a Dutch population with overweight or obesity and cardiometabolic risk participating in a pilot digitally enabled CLI-WL and (2) to collect feedback from participants to guide the further development of future iterations of the intervention.

Methods: Participants followed a 16-week digitally enabled lifestyle coaching program rooted in the Fogg Behavior Model, focused on nutrition, physical activity, and other health behaviors, from January 2020 to December 2021. Participants could access the digital app to register and track health behaviors, weight, and anthropometrics data at any time. We retrospectively analyzed changes in weight, blood pressure, and lipids for remeasured users. Surveys and semistructured interviews were conducted to assess critical positive and improvement points reported by participants and health care professionals.

Results: Of the 420 participants evaluated at baseline, 53 participated in the pilot. Of these, 37 (70%) were classified as overweight and 16 (30%) had obesity. Mean weight loss of 4.2% occurred at a median of 10 months postintervention. The subpopulation with obesity (n=16) showed a 5.6% weight loss on average. Total cholesterol decreased by 10.2% and low-density lipoprotein cholesterol decreased by 12.9% on average. Systolic and diastolic blood pressure decreased by 3.5% and 7.5%, respectively. Participants identified the possibility of setting clear action plans to work toward and the multiple weekly touch points with coaches as two of the most positive and distinctive components of the digitally enabled intervention. Surveys and interviews demonstrated that the digital implementation of a CLI-WL is feasible and well-received by both participants and health care professionals.
Conclusions: Albeit preliminary, these findings suggest that a behavioral lifestyle program with a digital component can achieve greater weight loss than reported for currently available offline CLI-WLs. Thus, a digitally enabled CLI-WL is feasible and may be a scalable alternative to offline CLI-WL programs. Evidence from future studies in a Dutch population may help elucidate the mechanisms behind the effectiveness of a digitally enabled CLI-WL.

Introduction

Background
The morbidity and mortality burden associated with obesity, diabetes, and cardiovascular disease (CVD) continues to increase globally [1]. The prevalence of diabetes and CVD has nearly doubled since 1990 to over 536 and 520 million cases worldwide, respectively [1,2]. Obesity, as a major risk factor for CVD and diabetes, is also associated with a decrease in life expectancy between 5 and 20 years, depending on the severity of the condition and comorbid disorders [3]. In addition, overweight-related diseases are expected to give rise to treatment costs equivalent to 8.4% of health spending in Organization for Economic Cooperation and Development countries [4].

A substantial portion of the risk of diabetes, CVD, and obesity is attributable to modifiable lifestyle factors such as an unhealthy diet, lack of physical activity, and smoking, which subsequently lead to metabolic imbalances and overweight or obesity [1-3]. Overweight and obesity are often the direct result of a disturbed energy balance, generated through a combination of the above-mentioned factors as well as excessive dietary energy consumption [5,6]. Despite being common knowledge, the principles of living a healthy lifestyle are insufficiently followed by the general population. Indeed, recent data show that over 50% of the Dutch population do not meet daily activity guidelines and that many elements of an individual’s environment are often obesogenic [7,8]. In addition, other health behavioral aspects such as deficient sleep and poor stress management also increase the risk of developing excess weight [9-11]. It is therefore unsurprising that overweight and obesity rates among the general population of the Netherlands keep increasing: in 2021, almost 50% of Dutch adults were living with overweight and 13% were living with obesity [12].

Therefore, successful approaches to preventing and treating overweight/obesity, CVD, and associated risk factors ought to tackle at least the four essential lifestyle components of nutrition, activity, sleep, and stress management, along with smoking and alcohol consumption when possible [13-15]. Preferably, this is done in a personalized way, since different individuals will be exposed to different triggers and face different challenges that lead to excess weight or failure to lose weight [16,17]. Combined lifestyle interventions (CLIs), especially those targeting weight loss (CLI-WLs), provide a potential solution for people who are overweight or obese to initiate and maintain healthier lifestyle behaviors [18]. Since 2019, some CLI-WL programs have been covered by basic insurance in the Netherlands for individuals meeting prespecified criteria such as obesity in case of a BMI≥30 or overweight and increased risk of comorbidities, including diabetes and CVD [19]. Dutch CLI-WL programs are 2-year programs delivered at varying intensities throughout this period, which consist of guidance mostly on physical activity and nutrition [18]. These programs consist of both individual and group sessions to educate participants, allowing them to share experiences and provide support [18]. The program is typically carried out completely offline by lifestyle coaches, physiotherapists, and dietitians accredited to deliver CLI-WL to patients referred by general practitioners [18]. Internationally, interventions similar to the Dutch CLI-WL have been shown to be effective in terms of weight reduction and health improvements, even when compared with standard care or pharmacological treatment [20]. However, reports on the effectiveness of Dutch CLI-WL programs since their inclusion in the basic insurance package have been inconsistent, with the effects of the interventions either falling short of expectations or not structurally translating to sustained weight loss in the medium to long term [21-23]. Previous studies have shown that the biggest barrier experienced by participants is the challenge of implementing and following lifestyle changes in a sustainable way [23,24].

A growing number of digital programs that can support individuals and providers in addressing health risks and conditions are being developed and made available to the public [25]. These so-called digital therapeutic solutions stem from an emerging field at the cross-section between health care and technology. Similar to pharmaceutical therapies or hardware medical devices, these therapeutics are evidence-based software products for the prevention, management, and treatment of health conditions. Several studies suggest that interventions including digital elements such as remote data monitoring and the possibility to digitally communicate with providers are associated with higher engagement from participants and subsequently with better health outcomes [26,27]. The incorporation of these digital elements—which are considered critical components of successful behavior change programs—can therefore help overcome the cited barriers to engagement in face-to-face programs such as accessibility, transportation, and scheduling [24,25,28]. In fact, digital therapeutic solutions, ranging from digital weight loss programs based on intensive dietary coaching to tracking and gamification apps, have been shown to induce weight loss to varying degrees, surpassing what offline interventions achieve [29,30]. Therefore, deploying a digitally enabled CLI-WL could broaden access to prevention and care, while delivering superior or at least comparable outcomes to those reported for currently available, completely offline CLI-WL programs in the Netherlands.
to the novelty of digitally enabled CLI-WL programs in the Netherlands, there is a research gap that we seek to bridge with this research.

**Objectives**

The objective of this pilot study was to provide a real-world contribution to the discussion surrounding the feasibility of digitally enabled CLI-WL programs in the Netherlands. In this study, we assessed the changes in weight and concomitant cardiometabolic risk factors of a cohort of Dutch adults with overweight or obesity and cardiometabolic risk who participated in the pilot of a digitally enabled CLI-WL. In addition, we also conducted surveys and semistructured interviews to assess the critical positive and improvement points reported by participants and health coaches to further guide the development of future iterations of the intervention.

**Methods**

**Study Sample**

As of December 2021, 420 users were enrolled in the Ancora Health Lifestyle program through employer health programs or as a direct-to-consumer option. A study on a subset of this cohort was published previously in JMIR Cardio [31]. Body weight, blood pressure, and lipids (total and low-density lipoprotein (LDL) cholesterol) were measured at baseline. Participants who were classified as obese (BMI≥30) or overweight (BMI≥25) with one or more cardiometabolic risk factors were asked to participate in a 16-week digitally enabled CLI consisting of digital and human components. The cardiometabolic risk factors considered were a diastolic blood pressure≥80 mmHg or systolic blood pressure≥130 mmHg, dyslipidemia (LDL cholesterol≥3.0 mmol/L, total cholesterol≥5.1 mmol/L, high-density lipoprotein cholesterol<1 mmol/L, or triglycerides≥1.8 mmol/L), or prediabetes (hemoglobin A1c≥5.7% or fasting glucose≥5.6 mmol/L). An overview of the study flow is given in Figure 1.

**Combined Lifestyle Intervention**

After baseline measurements, users were provided access to a web-based digital app where they could register and track health behaviors, weight, and anthropometrics data at any time. This app is a certified Class I medical device that generates evidence-based lifestyle recommendations spanning across nutrition, physical activity, sleep improvement, stress reduction, and tracking behaviors (such as logging weight) that are tailored to the individual’s prevailing risk profile. Other preliminary evidence of the health benefits of lifestyle interventions delivered to a subset of this cohort with the Ancora Health platform for health goals other than weight loss (eg, lipids, blood pressure, and nutrient imbalances) has been published previously [32-34].

The intervention was initiated with a 30-minute intake consultation conducted by video call. The intake consultation provided counseling on health risks, recommendation of targeted lifestyle medicine actions, and a “handshake” to undertake these actions for the following period. During the intervention, coaching was delivered digitally through one-on-one chat-based contact with optional audio/video calls alongside this format. Coaching was delivered by a health care professional with a background in either lifestyle coaching, nutrition, physiotherapy, or psychology, depending on the prevailing behavioral coaching required. This coaching was complemented by weekly progress reports. This approach builds on the Fogg Behavioral Model.
was acceptability and accessibility, two critical process evaluations [36] and the Conceptual Framework for guidelines published by the Medical Research Council for The user research framework reported in this study was based in the interview process than completely unstructured interviews. interviewing, while simultaneously providing greater direction and 6 of the coaches delivering the intervention, either author conducted semistructured interviews with 17 participants After the entire cohort completed their intervention, the first

**Measurements at Intake, During the Program, and After the Program**

Upon enrollment to the program, participants underwent a baseline assessment where a comprehensive lifestyle questionnaire, a blood biochemistry panel, and physical measurements were collected using the InBody model 570 for body composition and the InBody BIOBP750 cuff for blood pressure. After the baseline assessment, users could access the digital web app to register and track their health behaviors and modify weight data at any time during the intervention. At follow-up after the intervention, which participants could voluntarily enroll for, the subset of blood biochemistry parameters found to be abnormal at baseline and the lifestyle questionnaire and physical measurements were reassessed. Weight and other cardiometabolic risk factors were remeasured at the health center for participants who were able to return for a remeasurement. Participants not able to return were asked to self-report their weight after receiving instructions from their lifestyle coaches (namely to measure it in the morning, before eating) (Figure 1). For self-reporting participants, other markers were not remeasured. According to the definition used in the criteria for participation in a CLI-WL in the Netherlands, we classified BMI values between 25 and 30 as “overweight” and values greater than or equal to 30 as “obese.” Changes from baseline in weight, blood pressure, and lipid markers were calculated by subtracting the end values from the first reported values, and the percent change was calculated by dividing the observed change by the baseline value. After the entire cohort completed their intervention, the first author conducted semistructured interviews with 17 participants and 6 of the coaches delivering the intervention, either physically or via audio/video in Dutch or English. Semistructured interviews allow for greater flexibility for both the interviewer and participant than traditional, structured interviewing, while simultaneously providing greater direction in the interview process than completely unstructured interviews. The user research framework reported in this study was based on guidelines published by the Medical Research Council for process evaluations [36] and the Conceptual Framework for Implementation Research [37,38]. The focus of the interviews was acceptability and accessibility, two critical process indicators in the adoption of digital interventions. While there is no consensus definition of acceptability, it can be broadly defined as “people’s affective attitudes toward a new digital health intervention,” “usage intentions or actual usage,” and “satisfaction after having engaged with the intervention” [39]. Since most available acceptability measures in pilot or feasibility studies of digital health interventions lack a theoretically or empirically established cutoff, it has been suggested that 1 to 5 ratings and accompanying free-text responses may provide a sufficiently precise measure of acceptability [40].

The interview guide had questions for the coaches and participants focused on their experience coaching or partaking in the intervention, and on what they thought were the most important positive and improvement points for the quality of the intervention.

**Statistical Analysis**

Descriptive statistics were calculated to characterize the population at baseline in terms of demographics and clinical parameters. Paired remeasurement versus baseline changes in weight, blood pressure, and cholesterol in participants who were remeasured after a median of 10 months were assessed with the Student t test or Wilcoxon signed-rank test depending whether or not the data were normally distributed. All categorical variables are reported as percentages and continuous variables are reported as mean and SD. The \( \chi^2 \) test and analysis of variance were used to evaluate differences in categorical and continuous variables, respectively, at the cohort level. We considered \( P < .05 \) to indicate a statistically significant difference between cohorts and in pre- and postintervention measurements. All data analyses were performed using R software v4.0.3. Themes and coach/participant opinions were registered following an inductive process after the main findings of the interviews conducted by the first author were discussed in a multidisciplinary setting with the coaches, with no preexisting framework or theoretical constructs used to classify data [41,42].

**Ethics Approval**

The study was declared exempt from institutional review board approval through a waiver issued by the Medical Ethical Committee of the University Medical Centre Groningen (waiver number METC#2021/488).

**Results**

**Baseline Characteristics**

Baseline characteristics of the total study sample are shown in Table 1. We found that 208 of the 420 participants (49.5%) were classified as either obese or overweight with one or more cardiometabolic risk factors. Of these, 53 participants enrolled in the pilot study. These individuals were older, had higher lipid levels and blood pressure, as well as higher weight and BMI compared to the rest of the cohort (Table 1).

Baseline Values and Changes in Weight and Cardiometabolic Risk Factors

We analyzed weight data for the entire group of 53 participants in the pilot and for the two subsets of participants with overweight and obesity separately (Table 2). In the entire group, the average weight loss achieved was 3.7 kilograms, which equates to an average of 4.2% body weight loss (<.001). In total, 25 individuals (47%) achieved a reduction of at least 5% body weight. In the 37 participants with overweight, the mean weight loss was 2.9 kilograms (3.5% change). For the 16 participants with obesity, weight loss was higher at –5.4 kilograms and –5.6% body weight with a mean baseline weight of 97.3 kilograms (<.001; Table 2).

We also analyzed the changes in cardiometabolic risk factors in participants whose weight was remeasured on location and had abnormal lipid or blood pressure levels at baseline (Table 3). In these participants, total cholesterol, LDL cholesterol, systolic blood pressure, and diastolic blood pressure significantly decreased. In participants with obesity, changes in total and LDL cholesterol as well as in systolic and diastolic blood pressure were not significant, which was attributed to the very small sample size. In participants with overweight, total cholesterol, LDL cholesterol, and diastolic blood pressure were significantly decreased, whereas there was no significant decrease in systolic blood pressure.

None of the participants who were remeasured on location, based on information provided in the medical and lifestyle questionnaire at baseline and follow-up, had initiated blood pressure– or cholesterol-lowering medication during the lifestyle intervention.

**Quantitative and Qualitative Participant Feedback**

The subjective, qualitative feedback collected through surveys (n=37) and semistructured interviews (n=17) from pilot participants is presented in Textbox 1.

The quantitative results of the participant survey that was filled out at the end of the intervention period are presented in Table 4. The highest scoring items were linked to the feeling of involvement in the program (item 1, score 4.5/5), the interaction with the coaches (item 9, 4.6/5), and the knowledge displayed by the coaches (item 10, 4.4/5). Importantly, participants also overwhelmingly expressed the wish to continue working toward their health goals after the intervention (item 4, 4.7/5). The items that scored the lowest were linked to the need for one-on-one coaching and the importance of coaching in achieving the proposed health goals (items 7 and 8, 3.7/5 and 3.8/5, respectively).

The subjective feedback provided during semistructured interviews by the coaches (N=6) is presented in Textbox 2. In general, interviewees valued several aspects as the most positive and differentiating factors of the digitally enabled CLI-WL. These included the possibility of setting clear action plans (goals) for participants to work toward; the promotion of healthy eating, exercise, and other lifestyle habits as opposed to enforcing strict diets; and the speedy, problem solving–oriented interactions across the multiple weekly touch points. Both improvement points were related to the intervention curriculum, with health care professionals suggesting improvements in the food-tracking capabilities of the app as well as an expansion of the coaching resources.
Textbox 1. Summarized feedback collected from pilot participants through surveys and semistructured interviews regarding the acceptability and accessibility of the program.

Positive points
- Coaches were friendly, engaged, and approachable for guidance
- Proactive check-ins
- Good, personal advice; coaches helped find solutions to overcome barriers
- Program was (positively) challenging
- Effectively motivated for behavioral change
- Provided support in making effective lifestyle changes

Improvement points
- Expand the features in the app (tracking, connectivity, reminders, personalized content)
- More coaching conversations instead of chat messages

a Scoring runs from 1 ("disagree completely") to 5 ("agree completely"), with 3 being "neutral."

Textbox 2. Summary of the feedback regarding subjective intervention parameters “acceptability and accessibility” provided by coaches (N=6).

Positive points
- Possibility to set clear goals for the intervention period based on a holistic assessment of the participant’s health
- Integrative approach that promotes healthy eating and exercise as opposed to strict diets, including specific elements such as strength-training advice, stress management, and good sleep habits
- Multiple touch points weekly between the Health Engagement team to enable rapid problem resolution and positive experience sharing
- Multidisciplinary expertise for knowledge transfer
- Protocolized digital coaching
- One-on-one coaching with real-life examples

Improvement points
- More insight into the participants’ daily lifestyle patterns during the intervention period
- Expand the database of coaching resources (ie, materials coaches have available to support participants)
Discussion

Principal Results

In this study of 53 participants using the pilot version of a digitally enabled CLI-WL, we observed a mean weight loss of 3.7 kilograms (or 4.2% body weight reduction), with weight loss of more than 5 kilograms (or 5.6% body weight reduction) in individuals with obesity compared to baseline values at a median of 10 months after 16 weeks of online coaching. Both total cholesterol as well as LDL cholesterol decreased by over 10%, and systolic and diastolic blood pressure decreased by 5 and 7 mmHg, respectively. Our process evaluation analysis through surveys and interviews showed that digital implementation of a CLI-WL in the Netherlands is feasible and well-received by both participants and coaches.

Comparison With Prior Work

Evidence for the efficacy and safety of digital (or digitally enabled) and blended CLI-WL and the reduction of cardiometabolic and cardiovascular risk has been building up over the last 5 to 10 years [43,44]. As stated previously, some of the world’s most widely adopted commercial digital therapeutic programs for weight loss have reported achieving reductions in weight varying from 2.0% to 6.8% [30,31,45]. In addition, recent reviews showed that primarily mobile digital interventions targeting overweight and obese populations with high cardiovascular risk can be at least as effective as offline programs in terms of meaningful change of lifestyle and weight loss [22]. Several offline CLI-WL programs were shown to be effective to varying degrees in the Netherlands. Across three of the four interventions available in Dutch health care, weight loss achieved at 1 year varied between 2.9 kilograms and 2.2 kilograms [22,23,46]. Only one of these interventions reported follow-up data at 2 years, where participants lost an average of only 1.5 kilograms [47]. Another study reported an average weight loss of 2.5 kilograms at 18 months [23]. While we currently do not have such long-term data, a digitally enabled intervention that was similar to this CLI-WL (with a total duration of 12 months, including a maintenance phase), delivered in a real-world context, achieved long-term weight reductions of 7.2% and 7.6% in participants with overweight and obesity, respectively [48].

While none of the currently available CLI-WLs provided data on improvement in concomitant cardiometabolic risk factors, it is worthwhile to contextualize the changes achieved in blood pressure and lipids in this pilot study. Evidence for beneficial effects of healthful lifestyle modifications on blood pressure is solid, with several studies suggesting that lifestyle adaptation is preferable to pharmacological treatment in early stages of the disease [49]. Keeping in mind the observational nature of the results reported in this study, these do surpass the results of other recently evaluated digital therapeutic tools, which yielded reductions between 2.4 and 4.3 mmHg in mean blood pressure in randomized trials [50,51]. Similarly, the effect of lifestyle programs on cholesterol levels is well-established, with reductions varying from 7% to 9% to 20% for interventions of different intensity and complexity [52]. Interestingly, for web-based interventions, meta-analyses have shown total and LDL cholesterol improvements of approximately 0.15 mmol/L [53]. When compared to the results achieved previously in another cohort of individuals who participated in an Ancora Health digital lifestyle intervention, this group of individuals with overweight and obesity showed higher baseline lipid and blood pressure values and equal or greater reductions after the program [32,33].

In light of this evidence, it is worth discussing potential reasons why this blended CLI-WL achieved better results compared to those of previous studies. In a study evaluating the features of digitally enabled weight management programs, success was linked to the ability to promote behavioral change [54]. This finding is unsurprising, but what is interesting is that the study further broke down this ability to drive behavioral change to 20 features that were essential to the program. This set of features included specific goal-setting for weight, diet, caloric balance, and physical activity, as well as educational focus on various skills such as regulating eating patterns, time management, and nutritional label reading. In addition, this program also included the development of more general skills such as learning to exercise at certain target heart rates, problem solving, stress reduction, and psychological advice on how to cope with negative thinking and social cues [54]. Interestingly, these features include some of the most positive feedback points gathered during our participant survey, such as the appreciation for the stepwise approach to behavioral change in the program, the program content being relevant and engaging, and the digital support provided by the human coaching for overcoming challenges. In the qualitative assessment, participants further mentioned highly valuing the possibility to set clear goals for the intervention and that the coaching included elements that go beyond those of regular weight loss programs, such as advice on strength training, stress management, and sleep habits.

Other studies have focused on the potential advantages of digitally enabled interventions, such as the ability for participants to access educational information more easily and at their own discretion [44,55]. Unlike offline interventions driven primarily by one health care provider with a specific focus, digitally enabled programs can easily provide information covering a range of topics required to lead a balanced lifestyle across all relevant lifestyle domains. This seems to be especially powerful when apps also provide users with tools to help them track changes in weight and BMI. For instance, in-app actions such as self-monitoring of weight and the consistency of such health behavior tracking, as well as app engagement as measured by log-ins, predicted weight loss even in older populations [44,55]. These elements again come back in the qualitative feedback from participants highlighted in Textbox 2, who highly valued the multidisciplinary nature of the content and of the coaching, and suggested that even more attention should be paid to data collected about participants’ daily lifestyle patterns. In another study comparing a mobile app–based weight loss program with a traditional offline weight loss program, success in the weight loss intervention was linked to the digitalization of components common to the traditional program [56], including providing online food diaries rather than paper diaries or when the same curriculum delivered by the dietitian in person was delivered digitally. One such app-based program featured
Future Perspectives for Digital CLIs in The Netherlands

In the face of increasing rates of obesity, CVD, and (pre)diabetes, it is clear that there is a need for CLI-WLs to be deployed at scale in the Netherlands. However, current market penetration of these insurance-reimbursed programs is extremely low [58]. As the pathogenesis of obesity and (pre)diabetes is multifactorial, the etiology and environmental triggers vary among individuals; moreover, socioeconomic circumstances and barriers to lifestyle change also vary at an individual level. Yet, insurance-reimbursed CLI-WL programs currently offered in the Dutch market lack a data-driven approach to translating user profiles to personalized care pathways, with coaches bearing the burden of translating one-size-fits-all guidelines to a user’s context through their consultations. As suggested by the health care professionals interviewed in this study, supporting the delivery of CLI-WL programs with eHealth solutions such as those described in this research could help tailor the intervention to individual characteristics and needs, as well as tackle the practical issues of lack of time and capacity faced by care providers.

In fact, the Dutch National Institute for Public Health and the Environment (Rijksinstituut voor Volksgezondheid en Milieu [RIVM]) defines several important, evidence-based factors for the successful deployment of a (combined) lifestyle intervention program [59]. Interestingly, although these recommendations have been designed for offline programs, some of them are much more easily achievable with digitally enabled interventions. For instance, the RIVM recommends that participants of a CLI-WL who fail to achieve significant weight loss in the first month should receive increased support, since early weight loss is an important predictor of long-term success. Through its digital capabilities, the CLI-WL described herein allows for weekly monitoring of progress and enables coaches to review data and progress remotely. In addition, coaches are also able to contact the participant proactively to understand and address barriers in the absence of progress. Importantly, one full-time coach can effectively coach more than 100 participants across multiple regions while upholding the recommendation of 15 to 20 minutes of coaching time weekly. This allows for greater reach than possible with offline lifestyle interventions, which are often episodic, delivered at low frequency, and limited to participants within close proximity to the health coach. Importantly, a recent Dutch study showed that the Dutch population is generally sufficiently technology-literate, even across socioeconomic strata, and welcoming of digital technologies, which encourages the deployment of these interventions [60]. Lastly, the RIVM underscores the need for participants to develop self-efficacy skills to sustain behavioral change over the long term. This is in line with previous studies demonstrating that interventions applying theoretical frameworks or models for behavioral change—some of which were technology-based—were more effective at increasing adherence to healthy lifestyle habits than standard advice [61,62]. This program represents the first instance in which the FBM was used as part of a CLI-WL. The positive health outcomes and subjective feedback from users and health care professionals suggest that this approach holds promise and ought to be further explored for future iterations.

Strengths and Limitations

This study has several limitations. The first is the observational nature of the study. The second limitation is the small sample size of the remeasured population. Third, participants were not followed up for the duration of a standard CLI-WL (2 years); rather, these preliminary outcomes were reported after a median of 10 months after the 16-week intervention. As such, the results of the 16-week program should be compared with caution to those of other CLI-WLs that maintained participants engaged for the entirety of the 2-year period. Fourth, participants who could not return to the health center for a remeasurement were asked to self-report their weight after 10 months. As for all self-reported outcome measures, and despite careful instructions provided by the coach, measurement errors cannot be excluded. We are currently evaluating several possibilities to overcome this, such as the delivery of a personalized program box with a connected scale and wearable device. Lastly, the goal of CLI-WLs is to provide sustained positive health outcomes after 2 years (which is also the duration of the insured intervention in public health programs). Therefore, our 10-month results show that the weight loss can be sustained for a medium-long period of time, but we do not yet have data of 2-year follow-up for these participants. More research will also be conducted to evaluate the impact of interventional elements on engagement and health outcomes, such as to identify which elements are most effective for a digitally enabled CLI-WL.

Conversely, one strength of the study is that medication information was gathered at baseline and follow-up. This allows us to verify that weight loss and the improvements reported in lipids and blood pressure did not come from cholesterol- or blood pressure–lowering medications. In addition, by gathering detailed feedback from a majority of participants, we were able to identify critical points for improvement, which contributed to the further maturing of the intervention and informed the development of the mobile app designed to support it. Lastly, this is the first study to report on a real-world application of a digitally enabled intervention targeting health behavior change to promote weight loss in a cohort of Dutch adults with overweight and cardiometabolic risk factors.

Conclusions

In conclusion, a digitally enabled CLI showed sustained weight loss in individuals with overweight and obesity at the 10-month follow-up. Albeit preliminary, these findings suggest that a behavioral lifestyle program with a digital component deployed for this intervention can achieve greater weight loss than previously reported for currently available offline CLI-WLs in the Netherlands. Whereas larger-scale observational studies and randomized trials of other digital interventions have been conducted and shown evidence of effectiveness for digitally enabled CLI-WL in other countries, this study is a demonstration that such an approach can also be effective in the Netherlands. This is an important first step, as the feasibility of these
programs remains a hot topic in public health discussions. Based on the qualitative feedback collected from pilot participants and health care professionals, this first version of the program is being further developed and evaluated. Evidence from future studies in a Dutch population may help elucidate the mechanisms behind the effectiveness of a digitally enabled CLI-WL.

Data Availability
The data sets generated during and/or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions
RG had the original ideation of the manuscript, and made significant contributions to data collection and the drafting of the manuscript. JCF was the main contributor to the first draft of the manuscript. PF was the main contributor to the data analysis. SH contributed to ideation and discussion. SK was involved in the original study ideation. SvD contributed to the Methods, Results, and Discussion sections of the manuscript. NC, HvO, and HP contributed to the Introduction and Discussion sections of the manuscript. BHRW contributed to the Methods and Discussion sections of the manuscript. All authors gave input toward and approved the final manuscript.

Conflicts of Interest
RG, JCF, PF, SH, SK, and SvD are employed by Ancora Health BV. Additionally, JCF, PF, RG, SK, SH, and SvD own shares of Ancora Health BV. As the funder, Ancora Health BV provided support in the form of salaries for all employees. The other authors have no conflicts of interest to declare.

Abstract

Background: The numerous mental health awareness campaigns during the COVID-19 pandemic have shifted our understanding and perception of mental health.

Objective: The purpose of this study is to evaluate predictors of mental health literacy (MHL), that is, one’s knowledge and beliefs about mental disorders. We evaluate whether digital health literacy, empathy, and mentalizing contribute to MHL.

Methods: Our sample consisted of 89 health care major students, aged between 17 and 32 years, studying at a university in Lebanon. The Mental Health Literacy Scale for Healthcare Students (MHLS-HS), the eHealth Literacy Questionnaire (eHLQ), the Basic Empathy Scale (BES), and the Reflective Functioning Questionnaire-8 (RFQ-8) were used.

Results: Multiple regression analyses revealed that the Engagement in Own Health subscale of digital health literacy constituted a predictor of MHL. While empathy and mentalizing did not directly predict MHL, they were found to predict components of MHL.

Conclusions: This is the first study to evaluate digital health literacy, empathy, and mentalizing as predictors of MHL in Lebanon, a country where mental health is still considered taboo. Moreover, this pilot study is the first to provide some support for the predictive role of some digital health literacy subscales on MHL in light of the rise of the digital era following the COVID-19 pandemic.

Introduction

Overview

Despite the negative impact of the COVID-19 pandemic on both physical and mental health, the global health crisis has reshaped our perception and understanding of mental health, reducing mental health stigma and normalizing mental health-related discussions [1]. In a way, the COVID-19 era has promoted mental health literacy (MHL), a concept defined as our “knowledge and beliefs about mental disorders that aid their recognition, management, or prevention” [2]. MHL has been found to enhance self-efficacy for help-seeking, diminish stigma surrounding mental disorders, and, most importantly, increase the ability to maintain psychological well-being [3]. Therefore, it could be argued that promoting MHL could play a central role in preventing and treating mental disorders. Most studies evaluating MHL focus on the general public’s understanding of mental health rather than factors that can contribute to MHL.
Addressing this gap, this study aims to explore predictors of MHL in a sample of health care major students. More specifically, we evaluate whether the availability of practical tools such as digital health technologies or psychological characteristics such as empathy or mentalizing can contribute to MHL in health care major students.

The Role of Digital Health in Promoting MHL

In today’s digital age, health care providers have been increasingly making use of technology in their professional practice [4]. The use of digital health has increased at an even higher rate during the COVID-19 pandemic, as it has become a necessity at the individual, institutional, and social levels [5,6]. Beyond being a highly effective solution to working through health problems during the pandemic, digital health—in other words, accessing health-related information on the web—has the potential to shift the health care paradigm from mere treatment to prevention [7,8]. In Lebanon, Tohme et al [9] found that mental health professionals already had experience delivering web-based consultations before the COVID-19 pandemic, and, despite preferring face-to-face sessions, mental health practitioners reported numerous benefits of using digital health tools.

Initially adopted as a short-term solution to overcome obstacles imposed during the COVID-19 pandemic (eg, lockdown), the use of digital technologies for health has enhanced digital health literacy [10], meaning the ability to seek, find, understand, and assess health-related information from electronic sources in order to address and solve a health problem [11]. Digital health literacy allows individuals to communicate health information and make informed decisions that promote well-being. In a systematic review evaluating the association between health literacy, digital health literacy, and physical health outcomes [12], digital health literacy was found to be associated with perceived and reported better communication with health care providers, health-promoting behaviors, and self-management of health needs [13,14]. As for mental health, Lincoln et al [15] found that low health literacy was associated with negative mental health outcomes such as depressive symptoms. Whether these results apply to digital health literacy is still unknown. Research has yet to establish an association between digital health literacy and mental health outcomes, an association that could be mediated by MHL.

As an extension of health literacy, MHL is a relatively new construct, focusing specifically on accessing web-based information about mental health, namely emotional and psychological difficulties [2]. Hence, most studies on digital health literacy focus on its association with physical health outcomes only. To our knowledge, no study has yet evaluated whether this association applies to mental health. It can be argued, however, that digital health literacy can be a crucial component in promoting MHL. Understanding the potential benefits of digital health literacy in promoting MHL would be useful for policymakers, as it would allow them to devise policies and interventions focusing on promoting the use of digital health in the health care sector. This would equip health care providers with the tools needed to work in a digitized health sector [16,17], contributing to MHL in the general public and potentially leading to better psychological outcomes.

Empathy and Mentalizing as Predictors of MHL

Another line of research focused on pinpointing the psychological factors that could predict MHL, such as empathy. Empathy, or putting oneself in others’ shoes, is understood as one’s ability to understand what the other is feeling and to match that emotion [18]. As a concept, empathy entails both cognitive and affective elements that lead to a sense of emotional understanding [19]. The emotional component of empathy relates to one’s emotional response to the other’s experience, while cognitive empathy involves imagining the other person’s mental state, feelings, and perspective. Both components have been shown to generate a more positive attitude toward mental disorders [20] and are important components of MHL [21]. Indeed, evaluating the association between empathy and MHL, Furnham and Sjokvist [22] established a positive correlation between the 2 constructs, showing that individuals who experience empathy are more likely to be knowledgeable about mental disorders, as they tend to be more interested in reading and learning about mental disorders. Mendenhall and Frauenholtz [23] have also shown that having children diagnosed with mood disorders such as bipolar disorder could promote MHL. More recently, Piper et al [24] confirmed this association by showing that in older people, being in close proximity to someone with a mental disorder predicted MHL. These findings show that familiarity with mental disorders and the ability to recognize mental disorder symptoms could be influenced by one’s personal experience with one’s children and loved ones, their curiosity to know more about mental disorders, and possibly other factors, such as being emotionally present for others. It can be argued that, in turn, this familiarity could decrease stigma toward mental disorders and increase the level of knowledge of symptoms and their appropriate treatments. Hence, exposure to mental disorders (eg, knowing someone with a mental disorder) could relate to greater knowledge and appreciation of mental illness [21], hence being significantly correlated to MHL.

Although empathy and mentalizing are similar constructs, mentalizing refers to one’s ability to envision one’s own mental state as well as others’. These include feelings, thoughts, intentions, and beliefs focusing on a more interpersonal level, thinking about how others’ feelings are affecting us, and how, in turn, this can modify our response to them [25]. Mentalizing does not necessarily entail empathy, as research shows that people diagnosed with psychosis are often unable to empathize with others but are capable of mentalizing [26]. Moreover, although empathy contains a cognitive component, cognitive empathy relates to one’s ability to attribute emotions rather than cognitions, such as in the case of mentalizing. Although the 2 constructs are dissociable in nature, both have common underlying features. As such, it could be argued that mentalizing, just like empathy, could also predict MHL. Indeed, the ability to understand others’ minds and mental states can be central to promoting MHL, since understanding others’ mental states could also mean understanding their mental health status and experiences. Given the fact that displaying empathy has been shown to be associated with increased MHL [21] and that
empathy and mentalization are similar constructs in nature, an association between mentalization and MHL has thus been hypothesized. However, this association has yet to be established in the literature.

MHL is a relatively new concept, hence the gap in the literature as to what contributes to its development. Indeed, the few studies evaluating the predictors of MHL have mainly focused on demographic factors such as age, gender, and level of education [23]. For instance, in Lebanon, the only study evaluating predictors of MHL in a sample of university students revealed that education in psychology was a strong predictor of MHL [27]. However, given the importance of digital health literacy in promoting well-being, this pilot study aims to understand whether digital health literacy contributes to MHL in health care major students. Moreover, we aim to explore psychological factors such as empathy and mentalizing as predictors of MHL. Evaluating these predictors in a population of health care major students would help set the stepping stone for future research, aiming to understand whether interventions and trainings are needed to promote the use of digital health in the health care system. Finally, our results could provide initial support in identifying psychological features that promote MHL in order for health care professionals to not only self-cultivate these features but also target these elements when working with patients in order to increase MHL and promote psychological well-being.

**Methods**

**Participants**

In this study, purposive sampling was used, and the study sample consisted of 89 university students. Participants consisted of both undergraduate and graduate health care major students (ie, psychology, premed tracks, nutrition, pharmacy, and medicine), recruited from the Lebanese American University, a private university in Beirut, Lebanon. Students were aged between 17 and 32 (mean 19.64, SD 2.01) years, and most of the sample (66/89, 75%) identified as women. Inclusion criteria included being a Lebanese university student, being aged 18 years or older, and being fluent in English.

**Measures**

In order to evaluate whether digital health literacy, empathy, and mentalizing predicted our outcome variable (ie, MHL), 4 questionnaires were used. Demographic variables that were collected included age, gender, and academic major.

The Mental Health Literacy Scale for Healthcare Students (MHLS-HS) [3] is a self-report questionnaire used to measure MHL in health care major students. Rated on a 5-point Likert scale (1=strongly disagree and 5=strongly agree), the MHLS-HS comprises 26 items and the following 5 subscales: maintenance of positive mental health (10 items), recognition of mental illness (4 items), attitude to mental illness stigma (6 items), help-seeking efficacy (3 items), and help-seeking attitude (3 items). The MHLS-HS is scored by summing the item scores, with higher scores indicating a better MHL. The MHLS-HS has shown good internal consistency, with α values ranging between .70 and .90 across subscales [3].

The eHealth Literacy Questionnaire (eHLQ) [27] is a self-report questionnaire that measures digital health literacy. The 35-item scale is rated on a 4-point Likert scale (1=strongly disagree and 4=strongly agree) and consists of seven subscales measuring the following components of digital health literacy: (1) using technology to process health information, (2) engagement in own health, (3) ability to actively engage with digital services, (4) the ability to feel safe and in control, (5) motivation to engage with digital services, (6) access to digital services that work, and (7) digital services that suit individual needs. Each subscale contains 5 items, except for subscale 6 containing 6 items and subscale 7 containing 4 items. The average score is calculated for each subscale, with higher scores indicating better digital health literacy. The eHLQ has been found to have good psychometric properties with composite reliability above 0.7 for all 7 subscales [27].

The Basic Empathy Scale (BES) [28] is a 20-item self-report scale that is used to measure empathy in its cognitive and affective elements. The first factor relates to cognitive empathy and is comprised of 9 items, while the second factor relates to affective empathy and is comprised of 11 items. Items are rated on a 5-point Likert scale (1=strongly disagree and 5=strongly agree). Scores are calculated by computing the average for each subscale, with higher scores indicating higher self-reported empathy. Overall empathy is calculated by summing the averages of the 2 subscales. The BES has demonstrated good internal consistency, with α=.79 for the cognitive empathy subscale and α=.85 for the affective empathy subscale [28].

The Reflective Functioning Questionnaire-8 (RFQ-8) [29] originally consisted of a 54-item self-report scale measuring mentalizing capacities. It is rated on a 7-point Likert scale (1=strongly disagree and 7=strongly agree) and is comprised of 2 subscales: uncertainty about mental states (RFQu) and certainty about mental states (RFQc). High scores on RFQc and low scores on RFQu reflect genuine mentalizing, while low scores on RFQc reflect hypermentalizing and high scores on RFQu reflect hypomentalizing, both indicating failure to mentalize. The RFQ-54 has demonstrated good internal consistency, with α=.67 for RFQc and α=.63 for RFQu. A shorter version of the RFQ-54, consisting of 8 items, was created by Fonagy et al [29] for research purposes and was used in this study.

**Procedure**

Data collection took place between October 2020 and December 2020, at a time when Lebanon was under lockdown due to the COVID-19 pandemic. Hence, data collection took place on the web, using Google Forms. Participation took between 15 and 20 minutes to complete.

**Data Analysis**

The aim of this exploratory pilot study was to investigate predictors of MHL. For this purpose, we ran a hierarchical multiple regression with MHL as the dependent variable and digital health literacy (eHLQ, Model 1), empathy (eHLQ and BES, Model 2), and mentalizing (eHLQ, BES, and RFQ, Model 3) as the independent variables. SPSS (SPSS Inc) was used for all analyses.
Moreover, since the literature shows that MHL entails recognition of mental illness, leading to lower stigma toward mental health, as well as help-seeking behaviors [2,3], we ran 3 additional hierarchical multiple regressions with the “Recognition of Mental Illness,” “Attitude Toward Mental Illness Stigma,” and “Help-Seeking Attitude” subscales as the dependent variables, and digital health literacy (eHLQ, Model 1), empathy (eHLQ and BES, Model 2), and mentalizing (eHLQ, BES, and RFQ, Model 3) as the independent variables.

Ethical Considerations

This study received ethical approval from the university institutional review board (LAU.SAS.PT5.27/Oct/2020). The survey was circulated on social media, including an information sheet. Participants interested in taking part e-signed the consent form before accessing the questionnaires. All data were anonymous, with no identifiers linking responses to the participant’s identity. Participants were informed that participation is voluntary and that they could drop out at any time. There was no compensation for participation.

Results

The hierarchical regression analysis predicting MHL revealed that in the first model, “Engagement in Own Health” was a significant predictor of MHL, with $F_{7,81}=2.19; P=0.04$ and accounted for 16% of the variation in MHL. Introducing empathy (Model 2) explained an additional 4% of variation, though the model was not statistically significant ($F_{9,79}=1.75; P=0.18$). Finally, introducing mentalizing (Model 3) did not explain any additional variation in the model, $F_{2,77}=0.23; P=0.80$ (Table 1).

The hierarchical regression looking for predictors of the “Recognition of Mental Illness” subscale of MHL revealed that the first model, digital health literacy, was not significant ($F_{7,81}=9.60; P=0.47$). Introducing the 2 empathy subscales explained an additional 8% of variation, and this change in $R^2$ was significant ($F_{2,79}=3.48; P=0.04$), with affective empathy found to be a significant predictor. Adding the 2 mentalizing subscales to the regression model explained an additional 7% of variation, and this change in $R^2$ was significant ($F_{2,77}=3.58; P=0.03$), with affective empathy and RFQc found to be significant predictors. Together, all factors explained 22% of the variation in the “Recognition of Mental Illness” subscale (Table 2).

The hierarchical regression looking for predictors of the “Attitude to Mental Illness Stigma” subscale revealed that the first model, including the digital health literacy subscales, was not significant ($F_{7,81}=1.83; P=0.09$). Introducing the 2 empathy subscales also led to a nonsignificant model (Model 2) with $F_{9,79}=2.09; P=0.05$. When all factors were included (Model 3), they were found to significantly predict 27% of the variation in the “Attitude to Mental Illness Stigma” subscale ($F_{11,77}=2.54; P=0.009$), with the “Being Motivated to Engage with Digital Services” subscale of digital health literacy and RFQu found to be significant predictors (Table 3).

The hierarchical regression looking for predictors of the “Help-Seeking Attitude” subscale of MHL revealed that in the first model, the “Ability to Process Information,” “Engagement in Own Health,” “Feeling Safe and in Control,” and “Being Motivated to Engage with Digital Services” subscales of digital health literacy were significant predictors in the regression model ($F_{7,81}=4.28; P<0.001$) and accounted for 27% of the variation in the model. Introducing the 2 empathy subscales (Model 2) and the 2 mentalizing subscales (Model 3) did not lead to significant changes in $R^2$ with $F_{2,79}=0.1; P=0.89$ and $F_{2,77}=1.12; P=0.31$, respectively (Table 4).

Discussion

With the global health crisis of the COVID-19 pandemic and the numerous lockdowns across the globe, health care providers have recently switched to web-based health care. Moreover, with the increase in mental health awareness campaigns, the COVID-19 era has drastically shifted our perception of mental health, reducing the stigma surrounding mental disorders. In this digital age of mental health awareness, this pilot study aimed to explore predictors of MHL in health care major students, specifically evaluating whether digital health literacy contributes to MHL. Moreover, we explored psychological factors such as empathy and mentalizing in an attempt to pinpoint predictors of MHL.

Our results suggest that “Engagement in Own Health,” a digital health literacy component, is a predictor of overall MHL. This confirms previous findings showing that health engagement improves patient activation, meaning patients’ ability to manage their health [30]. This ability goes hand in hand with MHL, as it entails recognizing, managing, and seeking treatment for mental disorders [2]. Moreover, the “Ability to Process Information,” “Engagement in Own Health,” “Feeling Safe and in Control,” and “Being Motivated to Engage with Digital Services” subscales of digital health literacy were found to predict MHL components. This partially confirms our hypothesis on the role of digital health literacy in promoting MHL, indicating that some constructs of digital health play a vital role in promoting MHL. In that sense, digital health could be hypothesized to play a role in decreasing stigma surrounding mental health.
mental disorders, allowing individuals to become more open to seeking help. This is especially important in a country such as Lebanon, where mental health remains taboo, thus preventing individuals from seeking help in an attempt to avoid criticism [31]. Our results hint at the importance of digital health practices and services in the health care system and call for future research to further explore whether specialized digital health trainings for health care major students as well as the general public could increase MHL. This is of special importance given the cost-effectiveness of digital services, making them more easily implemented, particularly given the current socioeconomic crisis in Lebanon.

While empathy has been shown to contribute to MHL [21,22], our results did not fully support this hypothesis. It is worth noting, however, that both empathy and mentalizing predicted components of MHL, namely “Recognition of Mental Illness” and “Attitude to Mental Illness Stigma.” This partially confirms findings on the role of empathy in promoting MHL [22-24]. Moreover, these findings support our hypothesis on the role of mentalizing in promoting MHL, a relationship that, to our knowledge, was never explored in the literature. Indeed, mentalizing refers to one’s capacity to think in terms of mental states underlying behaviors [25]; it can therefore be argued that this capacity facilitates people’s awareness of difficulties with emotion regulation, thus pinpointing signs of distress or mental health problems. Given that mentalizing was found to play a protective factor against stigma as it promotes thinking about the potential negative effects of being subjected to prejudice and stigma in general [32], and more specifically in relation to mental illness, we argue for the need for further research exploring this correlation in a larger, more representative sample.

While a recent study has evaluated demographic factors as predictors of MHL in Lebanon [33], to our knowledge, this study is the first to evaluate digital health literacy, empathy, and mentalizing as predictors of MHL in Lebanon. It is also globally the first to hint that mentalizing could constitute a predictor of MHL, making mentalizing a new variable of interest. Moreover, it is the first to examine the positive impact of digital health literacy during the COVID-19 pandemic, an era that has considerably shifted health care practices from face-to-face to web-based. However, it is important to interpret the results in light of some limitations. First of all, since data collection took place in the midst of the COVID-19 pandemic, the sample size was small. Indeed, not many students participated in the study, possibly due to a lack of motivation and a multitude of web-based demands. Second, since the survey was disseminated on the web, only students comfortable with technology took part in the study. This may have biased our results, especially since we evaluate digital health literacy as a predictor of MHL. Indeed, Tohme et al [9] have shown that those who are familiar with social media platforms are more likely to seek help on the web through digital health channels. Finally, the MHLS-HS [3] is new, and its psychometric properties are not fully evaluated. For that, the results of this study would need to be replicated on a larger sample after having validated the scale.

In summary, our findings provide initial support for arguing the role of digital health literacy in fostering and promoting MHL. These findings should be replicated using different measures of digital literacy and MHL in a larger, more representative sample. If findings were to be supported, they could impact recommendations at the institutional, social, and personal levels. At the institutional level, it could hint that digital health literacy practices will become part of university curricula. As for the social level, it could give policymakers support to raise awareness about the importance of digital health and to offer digital health trainings to the general population, including people from different backgrounds, age groups, and socioeconomic status. Finally, at the personal level, health care providers could make a case for the use of digital health, such as telepsychotherapy, mobile health, and telehealth. Since this was a pilot study, in order to gain further insight and be able to generalize our results, it is recommended to replicate this study while collecting data from a larger sample, a sample that is not limited to students or people who have access to and are familiar with technology. Finally, given the significant correlations between health literacy and mental health outcomes [15], as well as our results highlighting the predictive role of some digital health literacy subscales on MHL, future research should evaluate whether digital health literacy can contribute to better mental health outcomes, an association that could be mediated by MHL.

Abstract

Background: Current online interventions dedicated to assisting individuals in managing stress and negative emotions often necessitate substantial time commitments. This can be burdensome for users, leading to high dropout rates and reducing the effectiveness of these interventions. This highlights an urgent need for concise digital activities that individuals can swiftly access during instances of negative emotions or stress in their daily lives.

Objective: The primary aim of this study was to investigate the viability of using a brief digital exercise, specifically a reflective questioning activity (RQA), to help people reflect on their thoughts and emotions about a troubling situation. The RQA is designed to be quick, applicable to the general public, and scalable without requiring a significant support structure.

Methods: We conducted 3 simultaneous studies. In the first study, we recruited 48 participants who completed the RQA and provided qualitative feedback on its design through surveys and semistructured interviews. In the second study, which involved 215 participants from Amazon Mechanical Turk, we used a between-participants design to compare the RQA with a single-question activity. Our hypotheses posited that the RQA would yield greater immediate stress relief and higher perceived utility, while not significantly altering the perception of time commitment. To assess these, we measured survey completion times and gathered multiple self-reported scores. In the third study, we assessed the RQA’s real-world impact as a periodic intervention, exploring engagement via platforms such as email and SMS text messaging, complemented by follow-up interviews with participants.

Results: In our first study, participants appreciated the RQA for facilitating structured reflection, enabling expression through writing, and promoting problem-solving. However, some of the participants experienced confusion and frustration, particularly when they were unable to find solutions or alternative perspectives on their thoughts. In the second study, the RQA condition resulted in significantly higher ratings ($P = .003$) for the utility of the activity and a statistically significant decrease ($P < .001$) in perceived stress rating compared with the single-question activity. Although the RQA required significantly more time to be completed ($P < .001$), there was no statistically significant difference in participants’ subjective perceived time commitment ($P = .37$). Deploying the RQA over 2 weeks in the third study identified some potential challenges to consider for such activities, such as the monotony of doing the same activity several times, the limited affordances of mobile phones, and the importance of having the prompts align with the occurrence of new troubling situations.

Conclusions: This paper describes the design and evaluation of a brief online self-reflection activity based on cognitive behavioral therapy principles. Our findings can inform practitioners and researchers in the design and exploration of formats for brief interventions to help people with everyday struggles.

Introduction

Background

Computer-mediated communication (CMC) platforms offer accessible resources to assist people in managing their stress and negative emotions [1,2]. Nevertheless, current online interventions can be time-consuming and inconvenient [3], necessitating users to commit to a series of hour-long sessions to achieve optimal results. Social media groups and SMS text messaging programs also require a substantial time commitment from users to deliver maximum benefit [3,4]. Although research demonstrates that these programs can be as effective as in-person therapy [5,6], the considerable time investment required may lead to high dropout rates. Consequently, the convenience of online resources is paramount in enhancing their efficacy and user engagement [7].

Therefore, we investigate whether it might be possible to construct a brief digital activity (as simple as answering questions in a web form) that people can easily reference or practice when they experience negative thoughts and emotions in their daily lives. Through a simple interface with a series of questions, we explore whether a brief reflective questioning activity (RQA) could prompt people to reflect on a stressful situation. This process of articulating thoughts and emotions has the potential to enhance an individual’s understanding of their personal challenges and foster a sense of self-agency [8,9], eventually strengthening their belief in their own ability to manage stress and negative emotions [10].

Brief activities such as RQAs, which require minimal effort and may provide tangible benefits, can also serve as a stepping stone to more extensive treatments [11,12]. This approach has tremendous potential in terms of convenience as well because such RQAs can be delivered to anyone anytime via email, app, and SMS text message. We posit that activities such as this can be made generalizable enough so that they can be adapted to fit the unique needs and preferences of individuals from diverse backgrounds and situations; for example, an individual experiencing stress at work may use reflective questioning to reflect on their thoughts and emotions related to a difficult conversation with a coworker, and another individual may adapt the same activity to reflect on their feelings after a breakup or a family conflict.

In our work, we draw on insights from clinical psychology and human-computer interaction literature on how to design brief RQAs that are helpful for people to manage psychological well-being and adopt healthy behaviors [13-15]. Murgraff et al [15] demonstrated that a persuasive 2-page pamphlet distributed at the beginning of an 8-week study period and informing female university students about recommended drinking limits could effectively reduce unhealthy drinking behaviors. Carney et al [16] used a similar intervention to support adolescent users of substances and their caregivers. These studies suggest that extensive interventions are not always necessary to foster healthy behavior; providing a brief guideline with crucial information and actionable practices for self-directed application can be beneficial too.

Our work is focused on the goal of promoting self-reflection, a crucial component of cognitive behavioral therapy (CBT) [17] and psychology in general. One can understand self-reflection as a person’s conscious effort to understand and reevaluate their own thoughts regarding any situations, thoughts, or feelings [18,19]. Self-reflection is often the driving force that converts one’s intentions into action [20]. Furthermore, it allows an individual to view situations from a different perspective, enabling them to understand the opinions of others [20,21]. In recent years, researchers have incorporated many reflective activities into mental health and behavior change interventions, particularly through mobile phone apps that show users summaries of their mood or physical activity [22-24].

Other digital tools have attempted to promote self-reflection through conversational agents [25,26]. As evident with the recent emergence of chatbots such as ChatGPT [27,28], conversational agents continue to become more sophisticated in parallel with advances in natural language processing, but they are still limited in their ability to have nuanced and empathetic conversations [27]. Furthermore, the literature suggests that back-and-forth conversations are not always necessary to elicit self-reflection because asking probing questions with the words why or how can be enough to increase one’s own understanding of a problem [29,30].

However, there are several reasons to speculate that brief RQAs may not effectively help individuals manage their stress. First, prompts for self-reflection may not provide people with something concrete or tangible (eg, new information or social validation) and might require repeated exposure to yield benefits that people can see [31,32]. Moreover, it is unclear whether people would see value in answering reflective questions and whether an extended series of questions would add much value. Answering a static set of questions could not only be perceived as a waste of people’s time but also surface more negative emotions without a conversational partner to give input. Furthermore, people might prefer knowing that their thoughts and emotions are being shared with another person rather than relying on themselves to gain benefits.

Drawing upon these potential opportunities and challenges, we set the following guiding principles for our exploration:

- Minimal time commitment: the activity should be simple enough so that people can complete it in 15 minutes—the equivalent of a midday coffee break at work or a fraction of a person’s morning routine.
- Applicability to the general public: the activity should not be targeted toward a particular domain, culture, or population. In other words, the activity should be generalizable to the point where people can adapt it to their own context and situation.
Scalability: the activity should be implemented and deployed in a way that does not need a significant support structure. This means that the activity should not require a live conversational partner or intensive scaffolding (eg, tutorial videos).

To investigate the feasibility, challenges, and opportunities in the design of digital RQAs, we created a design probe that asks people to answer a series of 9 questions to reflect on a troubling situation. The questions in our RQA are intended to help people articulate their thoughts and emotions about the situation using principles from CBT [33]. We leveraged thought records [34] and behavioral chaining analysis [10], which are techniques that encourage people to connect their thoughts, experiences, and emotions to identify triggers that generate negative patterns and come up with alternative ways of thinking.

We provide insights into the design of our RQA and how it was experienced by users, which we hope will inform the design of future interventions with similar goals. We gathered these observations through 3 studies. For our first study, we used a convenience sample of crowdlancers and university students to administer the RQA and obtain qualitative feedback on the design of the activity. In our second study, we investigated whether the perceived benefits of going through an RQA outweighed the additional time commitment required to answer a series of probing questions. In our third and final study, we investigated the potential impact of the RQA when delivered repeatedly over a 2-week period in a real-world context; we also explored the implications of distributing the RQA over email versus SMS text message. The design of our RQA was kept constant across all 3 studies so that we could maintain consistency across evaluations and determine which observations held true across the different scenarios.

We found that the structured analysis supported by our RQA helped people reduce their stress and identify solutions for improvement. Although our RQA consisted of 9 questions, people did not complain about the time commitment required to complete it and generally wrote thoughtful responses to the prompts. However, deploying the RQA over the course of 2 weeks raised some potential challenges, including the monotony of doing the same activity several times, the limited affordances of mobile phones, and the importance of having the prompts align with the occurrence of new troubling situations. These highlight design considerations and opportunities for researchers and practitioners to consider as they develop their own digital RQAs, such as giving users control over the frequency of prompts and automated question personalization.

Main Contribution

In summary, our main contribution is an investigation into whether people see value in a brief digital RQA without a conversational partner for interaction or advice. We deliver this contribution in four parts: (1) the creation of an RQA probe that people can complete on their computer or mobile phone to reflect upon a stressful situation; (2) insights into the value and pitfalls of RQAs gathered via surveys completed by, and interviews with, 42 Amazon Mechanical Turk (AMT) participants and 6 university students; (3) evidence that people see value in an RQA compared with a baseline activity via a comparison study run on AMT with 215 participants; and (4) observations and design considerations from a 2-week deployment of our RQA using different CMC platforms.

Methods

Overview

In this section, we first discuss the design of our RQA and then describe the logistics of the 3 studies we conducted. The studies were conducted simultaneously with the same RQA design to explore different aspects of the intervention. Study 1 involved gathering feedback on the qualities of the RQA from a broad demographic using surveys and semistructured interviews. In study 2, the perceived benefits of the RQA were compared with those of a shorter baseline activity with the goal of determining whether the additional time commitment required to complete the RQA was justified by the benefits of the intervention. Study 3 aimed to explore how people would perceive the RQA during their everyday lives and how best to prompt engagement using email and SMS text messaging.

The Design of Our RQA

Our research team, which consists of graduate students and faculty members with experience in psychology and human-computer interaction, was guided by existing CBT resources to create an RQA that helps people reflect on a troubling situation in their lives. We first reviewed popular CBT apps and websites intended for personally guided use (eg, Youper [35], Depression CBT Self-Help Guide [36], KokoBot [37], and Woebot [38]) to identify the techniques they used to provide benefits to users. In particular, we found that these resources leverage several components of a CBT exercise called a thought record [10]. A thought record is a worksheet with a grid that includes 5 columns: situation, thoughts, emotions, behaviors, and alternative thoughts. The exercise aims to encourage behavioral chaining—a process through which people draw connections between their thoughts and emotions to identify triggers and irrational thoughts—revealing potential opportunities to reframe their way of thinking [10,39].

Researchers have identified several benefits to thought records and behavioral chaining. Thought records can help people recall memories of prior events that were initially assumed to be unimportant [40]. Identifying the full timeline of an event can help people recognize their own faulty behavior patterns, thus preparing them for similar events in the future [41]. Moreover, informal exposure to negative experiences can increase one’s ability to tolerate troubling situations [42] or recover from problematic behaviors (eg, binge drinking and self-harming) [10]. Thought records are typically introduced as CBT homework assignments that patients can complete between visits with a trained professional, providing them with the scaffolding to complete the activity on their own.

Our RQA attempts to distill this exercise into a brief guided activity that can be completed on a person’s computer or mobile phone without the need for external support. After writing a collection of brief questions to encapsulate these concepts, we iteratively added, removed, revised, and reordered the questions until we reached the RQA structure shown in Table 1.
primary design goal was to give people a structured activity they could use independently to organize their thoughts. Inspired by thought records and behavioral chaining, our activity guides users through the following line of thinking: trigger → thought → feeling → behavior [9,10].

We first start by asking the user to think about a stressful situation and write about it in as much detail as they like. Prior work suggests that this sort of open-ended question allows users to open up about their problems and be comfortable with the activity [9]. The next 5 questions (Q2-Q6) become more specific, asking users to identify the most important stressor, the most troubling thoughts and feelings, and the behaviors that come from these thoughts and feelings. The seventh question then asks users to retype the details of the situation in a structured format. Beyond leading people through the process of behavioral chaining, these questions allow users to iterate upon their initial thoughts regarding their stressful situation. The structured format in the seventh question is also designed to help users draw connections between several components of their situation. This leads to the eighth question, which challenges the user’s mental process by asking them whether they believe that the trigger justifies their thoughts. Doing so can help people identify flaws in their logic or possible cognitive distortions [10]. The final question asks the user to explore alternative ways of thinking that would enable them to see the problem from a different perspective and induce a different emotion [43].

We presented our RQA to 4 clinical psychologists with expertise in CBT to validate its construction and help us consider the best ways of evaluating it. The psychologists verified that our RQA is aligned with activities that would be used in psychotherapy, but they also remarked that the questions focused on advanced techniques that were usually introduced only after several sessions of evaluation and psychoeducation. They suspected too that people might find the activity too lengthy or that people might not know how to respond to some of the questions; 1 psychologist even posited that >2 questions might be excessive for an online format without a conversational partner. The study that follows in this paper demonstrates that although these concerns were warranted, participants found value in the additional line of questioning.

Table 1. The questions that compose our reflective question activity. The design of these questions is influenced by thought records and behavioral chaining. Before seeing these questions, participants were provided with the following prompt: “Think of a particular situation where you felt stressed or had a negative emotion, which you can try to reflect on as you go through this activity. It could be a current situation, one in the past, or one you anticipate in the future.”

*aCBT: cognitive behavioral therapy.*
Study 1: User Perspectives After Onetime Use of Our RQA

Overview

Our first study gathered qualitative feedback on the qualities that people saw in the proposed RQA irrespective of other factors (eg, when it was being used and how it compared with other interventions). We used surveys to collect diverse feedback from a broad demographic. Subsequently, we used semistructured interviews to gather deeper insights into some of the salient topics.

Participants

We initially recruited 50 participants from AMT. Participants were required to have a minimum approval rating of 95%. We did not incorporate explicit attention check questions in our surveys but implemented a thorough manual review process to ensure data quality. Two independent members of our research team examined each response, discarding any that were incomplete or contained nonsensical or irrelevant content.

Because of data quality issues, we discarded data from 8 (16%) of the 50 participants, leaving us with a final sample of 42 (84%). This cohort of 42 AMT crowdworkers included 35 (83%) men and 7 (17%) women, with an average age of 34.6 (SD 9.99) years. We identified these participants as M1 to M42, and they were compensated CAD $4 (US $2.97) for their time. We also recruited 6 additional people via email and word of mouth from a university campus community to serve as interview participants. This cohort of 6 people included 1 (17%) man and 5 (83%) women with an average age of 19.7 years. We identified these participants as L1 to L6, and they were compensated CAD $15 (US $11.15) for their time. There were no inclusion criteria because we were interested in observing how our RQA would be perceived by the general population.

Study Procedure

All participants were asked to complete the RQA online on the Qualtrics survey platform (Qualtrics International Inc), with all questions being presented on a single page. The data from this survey were saved and made accessible to the research team. After participants finished the RQA, they were requested to provide feedback on the activity through a separate survey. The questions included, although they participated in semistructured interviews immediately after completing our RQA. The interviews took 45 to 60 minutes and were held either in person or through different videoconferencing platforms.

Data Analysis

The survey responses were analyzed using a thematic analysis approach [44]. After the interviews were transcribed, 2 researchers examined the data together to familiarize themselves with the general sentiments of the participants. The researchers then individually applied the open coding process [45] to a subset of the data to develop their own preliminary codebooks. After sharing their codebooks with one another, the researchers held multiple discussions to consolidate the codes into a shared codebook. Next, they applied this codebook to a different subset of the data and again refined the codebook. Finally, the researchers reached a consensus and applied the final codebook to separate halves of the data.

The interview transcripts were also analyzed using open coding. However, because the interviews aimed to gain deeper insights into what people had to say in the surveys, we used the same codebook generated from the survey responses.

Study 2: Comparing the RQA With a Baseline

Overview

The observed benefits of reflective questioning may be attributed to the act of discussing a troubling situation rather than the structured questions themselves. Furthermore, clinical psychologists raised concerns that asking participants to answer >2 questions may be overwhelming. To investigate these possibilities, we compared the effects of the RQA with those of simply asking participants to discuss their troubling situation without structured questions. In this baseline activity, participants were required to write about a stressful situation in as much detail as possible in response to a single question. If the structured questions in the RQA provided additional benefits over the baseline activity despite the added time commitment, we posited that the RQA would warrant further exploration as a tool for promoting self-reflection.

Participants

For study 2, we again used AMT and adhered to the same participant recruitment and data quality assurance procedures from study 1. We initially recruited 255 participants for this study. Of the 255 participants, after the data screening process, we excluded 40 (15.7%; n=17, 43% from the baseline group and n=23, 58% from the RQA group) owing to issues related to data quality. This led to a final participant count of 215, with 111 (51.6%) individuals randomly assigned to the baseline group and 104 (48.4%) to the RQA group. Our study included participants of different genders, with 61.9% (133/215) identifying as men, 35.8% (77/215) identifying as women, and 2.3% (5/215) preferring not to disclose their gender. The mean age of the participants was 33.8 (SD 9.51) years. As with study 1, all participants were compensated CAD $4 (US $2.97) for their participation, and there were no inclusion criteria.

Study Procedure

The study had a between-participants design in which participants were randomized into 1 of 2 conditions. The first condition, which we consider the RQA condition, entailed participants completing our 9-question RQA. The second condition, which we call the baseline condition, asked participants to reflect on a troubling situation they were experiencing in as much detail as they wished, answering only a single question.

We expected the RQA to take longer to complete than the baseline condition, given that it involved answering more questions. However, we were also interested in participants’ perceptions of the activity’s length and the value they placed
on the additional time spent. By using a between-participants design, the study aimed to assess whether completing the RQA would lead to differences in outcomes compared with the baseline condition.

Data Analysis
We collected data before and after participants completed their respective activities to evaluate the hypotheses outlined in the following subsections.

Hypothesis 1 (Perceived Benefits)
We hypothesized that participants in the RQA condition would experience more instantaneous stress relief from completing the activity than those in the baseline condition.

To evaluate this hypothesis, we asked participants to rate how useful they felt the activity was. We call this measure perceived utility, and it was measured using a 7-point scale (ranging from −3 for strongly disagree to +3 for strongly agree). We also asked participants to rate the degree to which they were feeling troubled about their selected situation before and after the activity. These ratings were provided using an 11-point scale (ranging from −5 to +5) to increase the resolution with which people could express their stress. We call the difference between the ratings before and after the activity the perceived stress change, with positive values indicating a decrease in stress. Both perceived utility and perceived stress change were compared across conditions using independent samples 1-tailed Welch t tests. For each measure, the null hypothesis (H$_0$) was that the mean for the RQA condition would be less than, or equal to, the mean for the baseline condition. By contrast, the alternative hypothesis (H$_a$) that the mean for the RQA condition would be greater than the mean for the baseline condition.

Hypothesis 2 (Elapsed Time)
We hypothesized that participants in the RQA condition would take more time to complete the activity than those in the baseline condition; yet the perceived time commitment would not be significantly different.

To evaluate this hypothesis, we recorded the time it took for participants to complete the activity, the number of words they typed across all questions, and a self-reported rating using a 7-point scale (ranging from −3 to +3) of whether they felt the activity was worth their time. We call these measures completion time, response length, and perceived time commitment, respectively. All 3 measures were compared across conditions using independent samples 1-tailed Welch t tests. For each measure, the null and alternative hypotheses were set in a similar manner as detailed for hypothesis 1.

Study 3: Observing Repeated Engagement With the RQA
In our third and final study, we aimed to assess the effectiveness of the RQA in a real-world setting as a periodic intervention and explore the most effective ways to prompt engagement through low-cost asynchronous CMC platforms such as email and SMS text messaging.

Participants
We recruited 11 participants (n=8, 73% men and n=3, 27% women) with an average age of 20.6 years. Participants were recruited via email invitations and word of mouth from the same university campus community as study 1 without any inclusion criteria. We refer to these participants as D1 to D11. Participants were not compensated for completing our RQA to avoid undue influence on their level of engagement; however, they were compensated CAD $10 (US $7.43) for completing surveys and CAD $15 (US $11.15) for the interviews.

Study Procedure
Participants were recruited to take part in our study for 2 weeks. During the enrollment phase, participants were asked to specify the hours during each day when they would prefer to receive a notification to complete the RQA. They were asked to provide separate preferences for email and SMS text message, and they were allowed to select multiple times during a given day. Participants were then randomized into 1 of 2 groups. One group received emails during the first week and SMS text messages during the second week, whereas the other group experienced the reverse. The notifications prompted participants to complete the RQA and provided them with a link that took them to a web page containing the RQA. We used the same link each time, and participants were aware of this fact.

Participants were prompted to complete the activity once per day for up to 3 days within a given week, similar to what has been done in previous work [46]. Of the 11 participants, 8 (73%) were available for >3 days, and the days on which they received prompts were randomly selected, whereas 3 (27%) were available for <3 days (D2, D8, and D9), and they received a message on every day of their availability.

At the end of the study, participants were asked to complete an exit survey containing questions about their overall experience and their CMC preferences in the context of the RQA. They were then invited to a semistructured interview session to elaborate on their experience. The interviews lasted 15 to 30 minutes, with frequent topics including the barriers people faced while completing the RQA, the applicability of the RQA to their lives, and the trade-offs of being prompted to complete the RQA repeatedly. Of the 11 participants, 7 (64%) took part in the interviews. The interviews were conducted over the Zoom teleconferencing platform (Zoom Video Communications, Inc).

Data Analysis
We recorded a variety of data to assess how people engaged with our RQA. We measured how often participants responded to our prompts without a limit on how long they took to respond. In other words, if a participant received a prompt in the morning but waited until the next day to complete our RQA, we still counted this as a response. We calculated the response rate in this way because it is well documented that people respond to emails and SMS text messages at their convenience rather than at the moment of reception [47]. As in study 2, we asked participants to rate their stress using an 11-point scale before and after the activity, and we report the change in this rating. We also report the time it took for participants to complete the RQA and the word count of their responses as proxies for...
engagement. We analyzed the interview responses using the same procedure that was applied to study 1; however, we did so with a new blank codebook.

**Ethical Considerations**

We recognize that conducting research on mental health can raise several ethical issues; for example, our particular set of questions can induce stress or symptoms of depression and anxiety, particularly when participants are asked to recall a troubling situation. To mitigate these negative outcomes, we clearly explained the potential risks in the consent materials and reminded participants that the RQA was part of a research study. We also provided survey participants with the contact information of several mental health helplines. The interviewers were trained to clearly explain the goal of the project and maintain an appropriate level of empathy and support. Interviewers were also trained to run the Columbia-Suicide Severity Rating Scale protocol [48] if interviewees showed any indication of self-harm or suicidal ideation. Furthermore, interviewees had the option to skip any question they did not want to answer or to leave the interview session at any point. All our research activities were approved by the University of Toronto Research Ethics Board (36582).

**Results**

**Study 1: User Perspectives After Onetime Use of Our RQA**

During our first study, we elicited 4 major themes related to the benefits and pitfalls of our RQA for first-time users. We provide evidence for each theme in the following subsections.

**Appreciation for Structured Reflection**

Participants were appreciative of the fact that our RQA helped them break down the components of their stressful situation. By deconstructing the situation, participants felt that they were able to become more aware of the causes of their negative emotions, putting their thoughts “in the right order” (L2). Some of the participants also noted that the activity helped them recognize faulty thought patterns:

> The activity helped me pinpoint my maladaptive coping strategy...[it] led me to think more with my brain and less with my immediate emotional reaction. [M17]

**Venting Negative Thoughts Through Writing**

Participants enjoyed expressing their thoughts and feelings through writing because it allowed them to “get out all thoughts and feelings and take that weight off of my shoulders” (L5). Moreover, some of the participants appreciated seeing their thoughts typed out in front of them, commenting that the act of writing helped solidify previously nebulous or disjointed thoughts; for example, L4 thought that the RQA forced them to dissect their feelings that would have otherwise been unorganized.

M11 suggested that writing about their thoughts allowed them to examine their situation “from an outside perspective,” almost as if they were analyzing someone else’s situation instead of their own. This affordance made it easier for them to ignore personal tendencies and instead think more objectively about their thought process.

**Helping Identify Solutions**

Participants also stated that the activity prompted them to adopt a problem-solving approach to improve their situation. They could better identify the root cause of their stress because they were prompted to describe their troubling situation in a structured order, which made it easier for them to find a solution to their problem. As the final question of our RQA prompted users to consider alternative ways of thinking, participants such as L3 felt empowered because they were often able to emerge from the activity with at least 1 prototype solution.

**Incidental Negative Side Effects**

Our RQA did not unilaterally help people become less worried about their troubling situation. L5 noted that as they were considering an alternative line of thinking, they found it confusing to keep track of both their original thought process and the reframed one. L6 felt that this confusion led directly to frustration, whereas others were frustrated because they could not identify a solution by the end of the activity:

> The questions just made me think about how much pain I was in and really didn’t offer any solution whatsoever to the stress. [M19]

Some of the participants also felt at a loss when asked to think of alternative perspectives on their thoughts.

**Study 2: Comparing the RQA With a Baseline**

**Overview**

Of the 215 participants, 111 (51.6%) were randomly assigned to the baseline condition and 104 (48.4%) to the RQA condition. The summary statistics for the measures that were collected during study 2 are shown in Table 2.
Table 2. Summary measures and statistics from study 2. Statistical significance between measures in the reflective questioning activity (RQA) and baseline conditions is indicated in the first column according to independent samples 1-tailed Welch t tests. Means are given with the SE within each condition. For each measure, we set our hypotheses as follows: the null hypothesis (H0) was that the mean for the RQA condition would be less than, or equal to, the mean for the baseline condition; by contrast, the alternative hypothesis (Ha) was that the mean for the RQA condition would be greater than the mean for the baseline condition.

**Hypothesis 1 (Perceived Benefits)**

Participants in the RQA condition saw significantly more utility in completing the activity than those in the baseline condition (t\[213\]=2.82; P=.003; Cohen d=0.38). The average rating for our RQA was 1.2 (SE 0.2), whereas the average rating for the baseline activity was 0.5 (SE 0.2). Although both these averages were near the neutral score of 0, there were many more positive ratings for our RQA. Of the 215 participants who used our RQA, n (79%) gave a nonneutral positive score, whereas only n (57%) did the same for the single-question activity. Participants also reported a statistically significant change in stress rating in the RQA condition compared with the baseline condition (t\[213\]=4.46; P<.001; Cohen d=0.61). Whereas people who used our RQA experienced a mean decrease of 0.7 (SE 0.2) point in their perceived stress rating, people who used the single-question activity actually experienced a mean increase of 0.4 point. A paired 1-tailed t test analyzing scores before and after engaging with the RQA condition indicated a statistically significant decrease in stress scores post-RQA, relative to their levels before starting it (t\[103\]=3.59; P<.001; Cohen d=0.36).

These results suggest that the additional questions from our RQA may not only help in potentially mitigating stress but also possibly counteract an initial increase in stress from revisiting the troubling situation.

**Hypothesis 2 (Elapsed Time)**

Participants in the RQA condition took 8.9 (SE 0.8) minutes on average to complete the activity, whereas those in the baseline condition took only 1.6 (SE 0.3) minutes on average; the difference between the 2 conditions according to this measure was statistically significant (t\[213\]=9.09; P<.001; Cohen d=1.27). We also found that participants wrote significantly longer responses while going through our RQA. Participants in the RQA condition wrote 87 (SE 11.6) words on average, whereas those in the baseline condition wrote 29 (SE 5.5) words on average; this difference was also statistically significant (t\[213\]=4.52; P<.001; Cohen d=0.63). Although the RQA required significantly more effort, there was no statistically significant difference in people’s subjective perceived time commitment (t\[213\]=0.33; P=.37; Cohen d=0.05). We conclude from these results that people found value in the additional time they spent completing the series of questions.

**Study 3: Observing Repeated Engagement With Our RQA**

**Overview**

Figure 1 illustrates participants’ response rate to our RQA sent via email and SMS text message over the course of the study period. The figure not only shows the aggregated data across all interactions with our RQA but also splits the results according to the CMC platform through which the prompts were sent. We do not rely on quantitative data to claim that one way of delivering an RQA is better than the other; instead, we look into qualitative data to understand the role that technology plays in supporting long-term engagement with RQA.
Figure 1. Participants’ response rate to our reflective questioning activity over the study period. The sample size for each data point is also shown below the respective trial number.

Overall Engagement

We observed moderate engagement throughout the 2-week period of our study. We sent participants 54 prompts via email (n=27, 50%) and SMS text message (n=27, 50%), and participants completed the RQA in 27 (50%) of these cases. On 3 (11%) of these 27 occasions, participants completed the RQA twice in response to the same prompt; therefore, our RQA was actually completed 30 times during the study.

On average, people spent 18.5 (SE 1.2) minutes, wrote a total of 212 (SE 24.2) words, and experienced a stress level reduction of 1.2 (SE 0.3) points after completing the RQA.

Participants were much more engaged with our RQAs in this study compared with the AMT crowdworkers in study 2 (ie, they spent more time and typed longer responses), even as they completed it multiple times. One explanation for this discrepancy could be the amount of time participants were willing to commit to the study. Participants in study 2 likely completed our RQA in the midst of other crowdsourcing tasks or during their busy workdays. By contrast, participants from study 3 were able to pick a suitable time at their convenience, which in turn gave room for a longer time investment. A participant validated this hypothesis from their experiences:

Although I initially said that I would be available in the morning, I found the best time to do it in the time between 9 and 11 PM. I used to see the emails and text messages shortly after they came, but I used to only do them at my convenient times in the night. [D3]

Our quantitative and qualitative data show that people could spend as little or as much time as they wanted with the activity without the need for significant scaffolding. In the interviews, participants expressed similar opinions about the benefits of our RQA as they did in our previous studies. Most notably, participants saw benefits to having a structured way of organizing thoughts because it helped them identify triggers and devise an alternate way of thinking.

Repeated Engagement With the RQA

A major goal of this study was to observe how participants engaged with the RQA over time. Unsurprisingly, we observed that the response rate decreased over time. Figure 1 shows that the response rate was 64% (7/11) when participants received their first prompt and then 55% (6/11) for the second prompt. By the time they had seen 6 prompts, the response rate went all the way down to 38% (3/8). When we asked participants to explain this trend during our interviews, the main complaint was that doing the same activity in such a short interval was boring and tedious. D3 mentioned that the length of the activity was acceptable for a onetime event, but when they had to do the activity thrice in the same week, it “came across as a chore.” Another participant expressed similar sentiments:

When it started coming every other day, I felt like I had to do a school homework. So I felt a little bit of pressure to do the activity. [D10]

Participants expressed that they would have preferred to have larger intervals (eg, once a week) between the times they were requested to go through the RQA. This was not only because of the monotony of the task but also because participants struggled to think of new troubling situations to reflect upon:

By the time I got the last prompt, I could not find a stressful situation in my life. Maybe the frequency should vary depending on the amount of stress a person is going through. [D6]

Participants acknowledged that regularly prompting them to do our activity had value. A few of them noted that they would have forgotten to revisit the RQA had they not been given periodic reminders. D1 also believed that they “got more
comfortable with the activity [over time] and started setting aside a time to do the activity.”

Repeated engagement with our RQA also helped people form habits that yielded benefits outside of the activity itself; for example, D10 informed us that they did the activity multiple times in their mind either to think about how their previous responses could be improved or how they could apply these questions in a new situation. D4 found that doing the activity multiple times was a good mental exercise to prepare themselves for less stressful situations that they may encounter during the day.

**CMC Platforms**

Another goal of this study was to gain insights into the role of technology in deploying RQAs. Figure 1 shows that there was a noticeable difference between the response rates for email versus SMS text message. Even in our exit survey, 8 (73%) of the 11 participants said that they would prefer email over SMS text message for doing this activity, whereas the rest of the participants (3/11, 27%) had no preference. One of the main reasons for the preference was the affordances of desktop and laptop computers when it came to completing the RQA. Most notably, participants commented on how computers are better suited for reading and writing longer passages of text:

> Typing is very difficult in mobile phones. The screen size is small and editing stuff is a nightmare. On the other hand, if you want to write a long answer, you would probably do that on the computer because the process is just much easier. [D1]

Participants also felt that doing the RQA on a computer minimizes the chance for distractions; for example, D7 commented that sitting in front of their computer gave them the “right mindset to do the activity.” With a computer, they felt that they had control over their workspace because they could easily close other tabs and applications. By contrast, when they tried to do the activity on their mobile phone, there were cases when a call or a push notification disrupted their train of thought.

Although email was generally preferred for completing the RQA, many people agreed that mobile phones are a great mechanism for sending notifications and reminders. Some of the participants (eg, D4 and D6) expressed the concern that people may not check their emails as frequently as they check SMS text messages:

> Most of the time, I have my phone in my hand, whereas I check my emails at most once or twice a day. So if you need me to do something immediately, you would probably need me to reach via text messages. I can respond to an email even 2 days later. [D4]

Participants also informed us of instances when they switched between the 2 CMC platforms. When D6 was prompted to do the RQA over SMS text message, they sent the link to themselves over social media and then accessed it on their desktop computer to complete the RQA. Some of the participants posited that the 2 CMC platforms could be integrated into the same system:

> What you can do is you can ask me to answer the questions in the text message, but at the same time you will also send me an email that has the links to the actual page. [D6]

Alternatively, others suggested that the RQA could be advertised over social media platforms such as Facebook or Instagram because people normally access their accounts across multiple devices. In doing so, people could have the option to choose whichever platform they see fit.

**Discussion**

**Principal Findings**

In this work, we aimed to understand the benefits of a brief digital intervention that people could complete on their mobile phone or computer to lessen their concerns about a troubling situation. Our second study showed that doing the RQA could be more effective in reducing instantaneous stress compared with simply reflecting on a troubling situation without structured questions, whereas our first and third studies elicited qualitative findings that we hope will inform the design of future interventions in this space. Most notably, we found that participants appreciated the RQA for its ability to help them undergo a structured analysis of their troubling situation, identify solutions to improve their situation, and vent their negative feelings. Although participants felt that the series of questions was worth the additional time commitment, we also saw some obstacles toward long-term engagement with the RQA: the monotony of doing the same activity several times, the limited affordances of mobile phones, and the importance of having the prompts align with the occurrence of new troubling situations.

Our findings indicate that people from the general population saw value in engaging with a simple lightweight reflection activity without an active conversational partner. Although there has been significant research effort toward making mental health platforms more sophisticated and humanlike [37,49], our work shows that simpler interfaces can also yield benefits. Across all our studies, participants expressed that the structured nature of the RQA played a pivotal role in making them more aware of their troubling emotions. By deconstructing past events, participants were able to view their feelings in an organized manner and from a third-person perspective, enabling them to reevaluate whether their feelings were justified. The writing activity acted as a medium through which they could externalize repressed emotions, a helpful practice that has been noted by past psychology research [50]. People often falsely assume that their problems are a reflection of their own identity or their relationship with others. Failing to separate problems from persons can cause people to identify themselves as different from what society considers normal, eventually leading them to fixate on their negative traits [51]. Our RQA provided people with the opportunity to explore the relationship between their problem and their own self but from a different perspective.

The RQA also offered a general structure that people could adapt to their own life situations. We saw that a few of the participants applied the same line of questioning outside of the activity itself, hinting at longer-lasting benefits. We foresee that
RQAs could serve as a gateway for people struggling with stress and depression to engage with more complex activities and therapeutic tools. Validating this potential would require a longer study, but our research already demonstrates the hurdles that RQA interventions must overcome to support long-term engagement.

**Improving the Design of RQAs**

The success of the RQA in our work does not mean that future RQAs could not be even better. Although we observed an average decrease in participants’ stress levels after completing the RQA, some of the participants from study 1 remarked that the activity left them confused and without a concrete solution. We hypothesize that such concerns could be remedied by providing users with sample responses to each question as a source of inspiration. These examples could be curated by researchers, or they could be collected from previous users who voluntarily contributed their responses to a database [52]. Topic modeling could be used to tag the examples with keywords related to their subject matter, and an information retrieval system could rank the relevance of these examples [53]. Collaborative filtering could even be used to gradually collect ratings for each example and then tailor examples to individuals’ preferences [54].

Another way that RQAs could be made better is by personalizing the questions. The activity could ask users to rate the perceived benefit of each question, or we could use the average response length as a proxy for estimating the utility of each question. Using this information, we could extend or emphasize questions that individuals find most beneficial. We could also use this information to remove questions that induce stress. However, thought records and behavioral chaining are intentionally designed processes with many critical steps; therefore, removing questions may detract from the activity’s benefits.

Our 9-question RQA took inspiration from CBT principles, but future work could investigate RQA designs based on other psychological principles; for example, encouraging expressions of gratitude or social connections with others can play a key role in stress and depression management [55,56], and RQAs built around these practices can similarly help people manage their well-being. Future work could also explore different activity structures. Many of the participants (8/11, 73%) in study 3 complained about the inconvenience of typing on their smartphones; therefore, an alternative activity could ask people to record and listen to their own voices for reflection. Another activity could encourage peer support by starting conversations among online peers. Finally, researchers could create brief activities centered around other psychological frameworks beyond CBT, with past examples being centered around mindfulness [57], motivational interviews [58], and acceptance and commitment therapy [59].

**Considerations for Long-Term Engagement**

Our 2-week deployment in study 3 enabled us to gain insights into how people would engage with RQAs over a period of time. Although participants were pleased with the fact that they could specify their hours of availability, receiving prompts for the RQA 3 times within the same week was overwhelming for most of them (3/8, 38%). The biggest criticism was that people received multiple prompts without experiencing a new troubling event; therefore, they either had to go through our RQA while analyzing the same event as before or recalling a troubling event from the distant past. Ideally, the frequency of prompts would adapt dynamically according to a person’s needs. A participant suggested that users should have control over how often they receive reminders to complete our RQA, explaining that individuals who experience more stress than others might benefit more from doing these activities in short intervals. Going a step further, future work could integrate physical activity trackers, smartphone sensors, and Internet of Things devices to automatically detect periods of heightened stress [60,61], turning our RQA into a just-in-time adaptive intervention.

Another issue with completing our RQA too often was that answering the same set of questions became boring and tedious; yet, adjusting the prompt frequency alone may not be enough to resolve these concerns. One way to add variety would be to mix an RQA with other microinterventions, as was done by Paredes et al [13] in their PopTherapy work. Brief interventions such as our RQA could also serve as a gateway to more time-consuming exercises or professional therapy. By giving people a preview of the potential improvement in the mood that they can receive from articulating their thoughts and emotions, habits can be formed, and users may become more motivated to build on this momentum [62].

**Limitations**

Rather than developing a mental health intervention for people experiencing clinical depression or other psychological disorders, our intention was to design our RQA for as broad a population as possible. It would be imperative for researchers to conduct further studies specifically with individuals with mental health disorders to understand the benefits and potential risks of digitally delivered RQAs. We suspect that self-reflection could not only serve as a convenient mechanism for people to practice what they learn in psychotherapy but also perpetuate negative thought patterns. We also recognize that our participant cohorts—AMT crowdworkers and university students—do not represent all aspects of the general public. Most of our qualitative findings were not tied to participants’ specific contexts, and we did not find any obvious evidence of substantial differences among the cohorts. Nevertheless, future work could deploy RQAs to more diverse populations.

**Conclusions**

In this work, we used CBT principles to design a brief RQA that helps people articulate, reflect on, and change their thoughts and emotions about a troubling situation. The 3 studies we presented in our paper provide evidence that people are willing to engage with, and find value in, brief self-reflection activities delivered through CMC platforms, even without scaffolding such as training or real-time feedback. We found that providing people with a brief online activity not only helped them reduce their perceived stress levels related to a self-selected situation but also helped them challenge their potentially negative thought patterns and identify alternative ways of thinking. We also found that people were willing to use the RQA more than once, although future work is needed to strike a balance between
utility and monotony. We hope that our work inspires other researchers to explore new formats for brief interventions that help people with their everyday struggles.

Acknowledgments
The authors extend their gratitude to Dr Norman Farb (University of Toronto) for his valuable input. This work was supported by grants from the Office of Naval Research (N00014-18-1-2755 and N00014-21-1-2576), the Natural Sciences and Engineering Research Council of Canada (RGPIN-2019-06968), and the National Science Foundation (2209819), as well as a gift from the Microsoft AI for Accessibility program. ¹Wellinks (Convexity Scientific, Inc), New Haven, CT, United States
²COPD Foundation, Miami, FL, United States

Abstract

Background: Wellinks is a remote disease management solution that provides novel chronic obstructive pulmonary disease (COPD) care delivery.

Objective: This study evaluated the satisfaction, engagement, and clinical outcomes of Wellinks participants. This study also investigated the cadence of health coaching for patients with COPD.

Methods: A 24-week interventional study was conducted by Wellinks and the COPD Foundation in 2022. Adults with COPD were recruited by the COPD Foundation in the United States and determined to be eligible if they had phone and internet access, owned a smartphone, and were not currently participating in pulmonary rehabilitation. All study participants provided written informed consent. The Wellinks solution included remote health coaching, pulmonary rehabilitation, and group education; participants were provided the Wellinks app and smart spirometry and pulse oximetry devices. Participants were offered 6 coaching sessions in the first 12 weeks. For the second 12-week period, participants either reduced frequency or discontinued coaching; all other components of the Wellinks solution remained unchanged. The COPD Self-Efficacy Scale, Modified Medical Research Council dyspnea scale, pulmonary function, pulse oximetry, and patient-reported healthcare resource utilization were the clinical outcome measures. Nonclinical outcomes included engagement and satisfaction with Wellinks and net promoter score.

Results: In total, 141 adults consented and completed Wellinks onboarding; 84.4% (n=119) of whom remained engaged throughout the 24-week study. Participants had a mean age of 70 (SD 7.8; range 48-88) years, and 55.7% (n=78) were female. Most participants (n=119, 84.4%) completed all 6 coaching sessions during the first 12-week period. Compliance with spirometer and pulse oximeter use was 82.3% and 89.4%, respectively, at week 1 but waned over the study period to 8.5% and 9.2%, respectively, at the end of the study. Participants indicated a high degree of satisfaction with Wellinks, with 95.5% (n=85) and 91% (n=81) of participants indicating that they agreed or strongly agreed that the educational content and health coaching, respectively, were valuable. At the end of the study, the net promoter score was +64 and +55 in the coaching continuation and discontinuation arms, respectively. A significant improvement from baseline to end of the study was observed in the COPD Self-Efficacy Scale total score (P<.001) and domain scores (P<.001 for each domain). In total, 35.1% (n=27) of participants improved by at least 1 category of change on the 5-point Modified Medical Research Council dyspnea scale from baseline to week 24.

Conclusions: This study confirmed the feasibility of using a remote model of care delivery to support people living with COPD. The insights gained in this study have allowed for further refinement and personalization of the Wellinks care model. Findings related to the combined use of technology and personal care delivery should be considered by others developing remote disease management tools.
Introduction

Chronic medical conditions are highly prevalent among US adults and require long-term management strategies that invoke the need for participatory medicine. Strategies and services that support patient self-management are capable of reducing the impact of chronic disease on the individual and on the health care system [1]. Self-management strategies should optimize and preserve health, reduce symptoms and the impact of disease on daily life, improve quality of life, and build patient and provider relationships [1].

Chronic disease management programs have evolved over time to deliver remote health care and are generally inclusive of both technological (eg, wearables and mobile apps) and personal components, such as coaching or counseling [2]. While society is immersed in the Internet of Things, remote health care delivery needs to be more than biometric monitoring alone and to be effectively integrated with the delivery of care [3]. Although available devices can track mobility, heart rate, oxygen levels, blood pressure, cardiac activity, and body temperature and detect posture and falls (and more), the use of the data is limited if it is not integrated, shared, and applied to the delivery of care. Peyroteo et al [3] cite more than 100,000 apps that have been created to use data from various biometric sensors but also note the lack of integration with care systems as a key limitation to maximizing health outcomes.

Chronic obstructive pulmonary disease (COPD) is a chronic medical condition of the lungs affecting more than 16 million adults in the United States [4]. It is among the top causes of disability worldwide and is projected to become the leading cause of death by disease by 2030 [5]. Annual US health care expenditures on COPD exceed US $49 billion, with employer, federal, and state spending on health care services reaching unsustainable levels [6]. Costs aside, the toll on those struggling with respiratory diseases has been widely reported to lead to the significant presence of comorbidities such as cardiac diseases, diabetes, hypertension, osteoporosis, and mental health disorders [7].

Wellinks goes beyond remote patient monitoring. Wellinks is a COPD disease management solution that pairs technology with personalized health coaching and respiratory therapy services to offer a novel approach to COPD remote disease management. Wellinks is a care partner delivering remotely accessible pulmonary rehabilitation, clinical coaching, a mobile app, and connected devices for home monitoring of pulmonary function.

In a previously published 8-week pilot study of Wellinks, it was demonstrated that patients with COPD with an average age of 79.6 years were able to successfully use the devices provided (ie, Flyp nebulizer [Convexity Scientific, Inc], Smart One spirometer [Medical International Research], and NoninConnect smart pulse oximeter 3230 [Nonin Medical, Inc]) as well as enter data into the Wellinks mobile app [8]. Study participants reported the app to be valuable (13/16, 81%) and easy to use (15/16, 94%). This feasibility study provided preliminary evidence for the willingness and capability of this patient population to successfully use the digital tools provided by Wellinks [8].

Since the original pilot study, the Wellinks solution has expanded to include respiratory therapy and health coaching services, in addition to some modifications of the technological components described earlier. With such iteration, not only was it important to replicate the previously reported feasibility results but also to explore clinical outcome measures and refine the duration and frequency of health coaching. Described herein is the ASPIRE study conducted in partnership with the COPD Foundation that was designed to explore clinical and nonclinical outcomes associated with the use of the updated Wellinks solution inclusive of both personal (health coaching and respiratory therapy) and technological components. The objectives of this study were to determine to what degree study participants would engage with the various components of the Wellinks solution over time and whether any clinical outcomes could be identified to correlate with engagement. This study also sought to collect qualitative feedback on the components of the Wellinks solution and observe any impact of decreased frequency of engagement with the Wellinks team, in service of refining the care delivery model offered by Wellinks.

Methods

Study Design

This 24-week, prospective, interventional research study of the Wellinks COPD solution including the use of Bluetooth-connected devices, patient mobile app, COPD-related education, and health coaching services was conducted from December 2021 through September 2022. This study was designed to gather data on the quality of life and clinical impact of the use of the Wellinks COPD solution, in addition to collecting feedback from patients and investigators to inform further optimization of this intervention. The study was posted to ClinicalTrials.gov (NCT05259280).

Ethical Considerations

The conduct and performance of this study were in accordance with applicable sponsor and investigator responsibilities as described in Title 21 Code of Federal Regulations 812 and other Good Clinical Practice guidance. Institutional review board (IRB) or ethics committee oversight was required as human participants or data from humans were used. IRB approval of
the study protocol and study-related materials was obtained from Western IRB prior to beginning any study-related procedures (IRB protocol 20141136).

**Recruitment**

Eligible participants were recruited through the COPD Foundation Patient-Powered Research Network, COPD360Social, and various newsletters. Eligible patients were invited to participate in the study. Participants were required to provide informed consent before study-specific procedures could proceed. Eligible study participants included adults (≥18 years of age) with a diagnosis of COPD. Participants had to have access to a home telephone (landline or mobile) and the internet and must have had a smartphone (ie, iPhone 6S or later model, running iOS 14.0 or later model, and Android 6 or later model). Individuals must have been proficient in the English language, living or staying in the United States throughout the study duration, willing and able to comply with study requirements, and able to provide written informed consent. Exclusion criteria included current participation in other interventional clinical trials and current participation in a pulmonary rehabilitation program.

**Intervention**

The Wellinks COPD solution combined personal and technological elements to remotely support enrolled participants living with COPD. The personal elements of the program included one-on-one access to health and wellness coaches or nurse practitioners trained in health coaching methodologies. Health coaches provided support to participants via phone, video, and text interactions throughout the study period. The role of the coach was to support the participant by providing disease-state and treatment-related education, establishing and supporting the attainment of individual health goals, and encouraging adherence to treatment and attendance at clinic visits. Remote pulmonary rehabilitation programs were provided by the health coach, personalized for each participant, and included individual home-based exercise guides or videos and group educational sessions led by Wellinks respiratory therapists that were held remotely.

The technological elements of the program included a mobile app and Bluetooth-enabled medical devices. The Wellinks mobile app downloaded to an iOS (iPhone) or Android device allowed participants to connect with their coach; track goals, medications, and symptoms; and review data from the connected devices provided. The Smart One personal spirometer was used by participants at home to collect peak expiratory flow (PEF) and forced expiratory volume in 1 second (FEV₁). The NoninConnect 3230 pulse oximeter was used at home to measure blood oxygenation (saturation of peripheral oxygen [SpO₂]) and pulse rate. Data from both devices were transmitted via Bluetooth to the participant’s smartphone. Technical support was available to all study participants throughout the duration of the study to answer questions about the technological components or to troubleshoot any issues.

**Study Procedures**

All baseline assessments were collected via a survey of all consenting participants followed by an onboarding call between a Wellinks coach and the participant to ensure the technical set-up of the app and devices and introduce the coaching process. Participants were instructed to use the connected devices (pulse oximeter and spirometer) at least once a week throughout the duration of the study, use the app to track symptoms and medications, and monitor their own spirometry and pulse oximetry data throughout the study. The frequency of use of each component of Wellinks was recommended to each participant, but in order to best emulate real-world use, the health coaches encouraged but did not mandate the use of all available components.

Participants were sequentially assigned at the time of enrollment in an alternating fashion to arm 1 or arm 2 by the Wellinks head health coach. Participants were not informed of this assignment until the completion of the first 12-week period. In the first 12-week study period, health coaching was offered to all participants in the form of one-on-one 30-minute remote sessions scheduled every other week for a total of 6 sessions over the 12-week period. In addition, participants were instructed to individually perform the remote pulmonary rehabilitation program as directed by their health coach, and they were invited to attend group educational sessions held weekly throughout the study period. In the second 12-week study period, all components of the program remained the same except for the level of personal contact with health coaches. Participants assigned to arm 1 continued with a lower level of engagement with their coach in the form of SMS text messaging or up to 3 brief check-in meetings (15-minute sessions) for an additional 12 weeks. Participants who were assigned to arm 2 discontinued access to the Wellinks health coaches for the second 12 weeks of the study.

**Outcomes**

The nonclinical objectives of this study were to describe the experience of patients using the Wellinks solution through the assessment of patient engagement as well as by patient-reported satisfaction. Outcome measures included compliance with protocol-recommended device use, compliance with attendance at scheduled coaching sessions, ratings of the degree to which participants valued individual components of the Wellinks COPD solution, and net promoter score (NPS; ie, “How likely is it that you would recommend Wellinks to a friend or colleague?” 0=not at all likely to 10=extremely likely).

Spirometer and pulse oximeter data could be synced with the Wellinks app; as such, the use of data from the app provided the necessary data to determine whether participants used these at-home devices. However, the spirometer results could only be viewed by the participants via the app, while the pulse oximeter could be viewed independently of the app. Therefore, the compliance with the pulse oximeter uniquely may be underestimated.

The clinical objectives of this study were to determine whether the use of the Wellinks COPD solution could improve the quality of life for patients with COPD, reduce healthcare resource utilization (HRU) over time, and improve pulmonary function as measured by connected devices. Quality of life was indirectly ascertained by the interpretation of results from the COPD Self-Efficacy Scale (CSES) and Modified Medical
Research Council (mMRC) dyspnea scale, based on known correlations reported in the published literature [9]. Pulmonary function was measured using at-home devices to collect FEV$_1$, PEF, and SpO$_2$. Patient-reported HRU was collected via survey.

The CSES is used to assess the confidence of a patient related to their ability to avoid breathing difficulty based on responses to 34 questions within 5 domains; each question is scored from 1 (not at all confident) to 5 (very confident) [10]. A higher score thus reflects a greater degree of confidence on the part of the respondent. Total scores can range from 34 to 170. The CSES is divided into 5 domains: negative affect, intense emotional arousal, physical exertion, weather or environmental factors, and behavioral risk factors [10].

The mMRC dyspnea scale provides an assessment of a patient’s shortness of breath and its impact on daily activities. At onboarding, data from the mMRC dyspnea scale were combined with patient-reported exercise habits to individualize the remote pulmonary rehabilitation program to be suitable to each study participant’s level of functioning. Participants were assigned to 1 of 6 different exercise programs based on mMRC score (low=0, 1, or 2 or high=3 or 4) and self-reported level of exercise (low, medium, or high) at baseline. mMRC was also assessed at week 12 and week 24 to explore changes over time.

Pulmonary function was measured as a change from baseline to week 12 and week 24 in FEV$_1$, PEF, and SpO$_2$ based on patient use of the Bluetooth-connected spirometer and pulse oximeter provided. When used and connected, these data were captured in the Wellinks app. At the start of the study, participants were asked to use the pulse oximeter and spirometer at least weekly throughout the duration of the study.

Patient-reported HRU was collected through a web-based survey and relied upon individual recall. HRU is a reflection of the patient’s desire or need to seek care and is a measure that can be used to inform the economic impact of an intervention. At baseline, participants were asked to report certain HRU (ie, COPD-related physician visits, emergency department visits, and hospital admissions) in the 3-month and 1-year periods prior to enrollment. Participants were asked the same HRU questions at week 12 and week 24 of the study, each with a 3-month recall period. Outcome measures were assessed at baseline, week 12, and week 24 of the study. Any adverse events or serious adverse events were collected via spontaneous reporting from the study participants.

Statistical Analyses

The planned sample size for this study (n=150) was based on the expected feasibility for recruitment. No formal statistical power calculations were performed to size this study.

Study data were summarized for arm 1, arm 2, and full study cohort. Unless otherwise specified, data were summarized as number and percentage for categorical variables and as mean and SD for continuous variables. All statistical analyses were exploratory in nature. P values for statistical tests are 2-sided tests and not adjusted for multiplicity. Analyses of change from baseline values at week 12 and week 24 were performed for each arm and the full study cohort using 2-tailed t tests. Least squares (LS) mean and LS mean change from baseline at each time point with corresponding SEs for change and P values were produced.

For mMRC, a responder was defined as a participant with an improvement from baseline of 1 category or more. For example, a participant who changes from “3: I have to stop for breath after walking for ~100 yards” at baseline to a postbaseline value of “2: I walk slower than others of my age because I am out of breath, or I have to stop often to catch my breath’” would be classified as a responder at that time point. Participants who either remain in the same category or worsen were classified as nonresponders.

Results

Demographics and Baseline Characteristics

A total of 153 individuals were consented in this study, of whom 141 were fully enrolled (ie, consented and completed onboarding of devices and app). Disposition of participants in the study is described in Figure 1.

The demographics of the study population are presented in Table 1. Study participants had a mean age of 70 (SD 7.8; range 48-88) years, 78% (n=110) were 65 years of age or older, and 55.3% (n=78) were female. The population was 90.8% (n=128) White and 97.9% (n=138) non-Hispanic or Latino. There were no statistically significant differences between the 2 treatment arms for any of the demographic variables.

In the study population, 83.7% (n=118) of participants were former smokers (with 77.1% [n=91] of these having quit more than 5 years ago), and 9.2% (n=13) were current smokers with a mean use of 12 (SD 6.1) cigarettes per day at the time of the study.

It was self-reported that 82.3% (n=116) of the population was under the care of a pulmonologist for their COPD, and 39.7% (n=56) reported a primary care physician participating in the management of their COPD alone or together with the pulmonologist. A majority (74.5%, n=105) of participants had been living with COPD for at least 5 years at the time they were enrolled in this study. The severity of disease was self-reported to be moderate (51.1%, n=72) or severe (39.7%, n=56), and 58.2% (n=82) lacked an exercise plan at the study start. Some degree of home oxygen use was reported by 61% (n=86) of study participants (45.4% [n=64] daily use and 15.6% [n=22] as-needed use).

More than half of the study population self-reported emphysema (71.6%, n=101) or bronchitis (53.9%, n=76). High blood pressure (56.7%, n=80) and anxiety (46.1%, n=65) were among the most common nonrespiratory medical conditions reported by the study population.
Study flow diagram. Flow of participants through the study protocol is described as inclusive of the number of individuals consented to participate (N=153) and enrolled (n=141), followed by completion of certain milestones throughout the 24-week study period. Reasons for withdrawals from the study are reported.

Table 1. Summary of participant demographics. Descriptive information about the study cohort at baseline is presented for the combined cohort and for individuals assigned to arm 1 and arm 2 separately.

Nonclinical Outcomes

**Engagement Metrics**

In total, 84.4% (n=119) of all participants completed all 6 coaching sessions in the first 12-week period of the study. Among participants assigned to arm 1 (continued coaching), attendance diminished session-to-session in the second 12-week period of the study, with only 52.1% (n=38) of those assigned to arm 1 completing the third (final) 15-minute coaching session in the second study period.
Participants were advised to use the Bluetooth-connected spirometer and pulse oximeter at least weekly throughout the 24-week duration of the study. Spirometer compliance peaked at the start of the study with 82.3% (n=116) of participants compliant during week 1, but compliance decreased to a smaller proportion of participants at week 12 (n=59, 41.8%) and week 24 (n=12, 8.5%). Similarly, pulse oximeter compliance also peaked at week 1 with 89.4% (n=126) of participants using the pulse oximeter as recommended, and this rate of compliance decreased to 42.6% (n=60) and 9.2% (n=13) at week 12 and week 24, respectively. Compliance with the spirometer or the pulse oximeter use did not differ by treatment arm. For the entire study period, 21.3% (n=30) and 22.6% (n=32) of participants were compliant with spirometer and pulse oximeter use, respectively, for more than 75% of the study period (18 or more of 24 weeks), while 30.5% (n=43) and 29.1% (n=41) were compliant with spirometer and pulse oximeter use, respectively, for 25% or less of the study period (6 or less weeks).

Similar rates of compliance were observed with the use of the Wellinks app; compliance with mobile app use peaked at the start of the study with 94.3% (n=133) compliance in week 1, which declined to 50.4% (n=71) and 22.7% (n=32) at week 12 and week 24, respectively. For the entire study period, 23.4% (n=33) were compliant with app usage for 25% or less of the study period, and 28.4% (n=40) of participants were compliant with app usage for 75% or more of the study period.

One-quarter of study participants attended multiple educational webinar group sessions (3 or more sessions attended). One-half of study participants did not attend any of the educational webinar group sessions.

The web-based week 12 survey was sent electronically to participants after completion of coaching session 6 and was returned by 78.7% (n=111) of participants. The web-based week 24 survey was sent electronically to participants after 24 weeks had elapsed since the start of the study; 73.9% (n=54) of participants in arm 1 and 51.5% (n=35) of participants in arm 2 completed the week 24 survey. The differences in survey completion rates between the 2 treatment arms may be attributable to the difference in level of engagement with Wellinks; specifically, it is possible that arm 2 participants who had less engagement with the Wellinks team between week 12 and week 24 had less interest or motivation in returning the survey.

### Satisfaction Metrics

Participants were asked via survey at week 12 and week 24 to indicate their level of agreement with various statements aimed to understand whether they valued individual components of the Wellinks solution. Options included strongly agree, agree, neither agree nor disagree, disagree, and strongly disagree. Table 2 presents the proportion of participants who indicated they strongly agreed or agreed with each statement at the end of the study (week 24). Data are shown for the combined cohort not separated by treatment arm due to similar findings across the arms. Only 1 statement appeared to reflect a difference by treatment arm at the end of the study: 92.6% (n=50) of respondents in arm 1 and 68.6% (n=24) of respondents in arm 2 strongly agreed or agreed that “using the Wellinks solution has helped me to learn more about my COPD.” This difference may reflect the higher engagement with health coaches in arm 1 throughout the second half of the study period. There was a low level of disagreement with any of these statements indicating that most study participants find value in the components of the Wellinks solution and the entirety of the offering, regardless of group assignment.

Notes:
- aSurvey responses are from 89 participants who completed these questions in the end-of-study survey at week 24 (n=54 from arm 1 and n=35 from arm 2). The proportion of participants who selected that they “agreed” or “strongly agreed” with each statement is shown. Statements are listed in rank order from the statement with the highest degree of agreement to the lowest.
- bCOPD: chronic obstructive pulmonary disease.
**Net Promoter Score**
Participants were asked after week 12 and week 24 whether they would recommend Wellinks to friends, family members, or associates who also live with COPD to determine the NPS. Overall, the week 12 NPS was +57, and the week 24 NPS was +60. NPS differed by assigned treatment arm; NPS for arm 1 and arm 2 was +64 and +55, respectively, at week 24.

**Clinical Outcomes**

**COPD Self-Efficacy Scale**
CSES scores were collected at baseline, week 12, and week 24 through a web-based survey. At baseline, the mean total score was 103.9 (SD 28.71), with the lowest domain scores on average observed for physical exertion and weather or environmental factors.

The CSES total score significantly improved from baseline to the end of the first 12-week study period during which all participants received the same level of coaching (LS mean change from baseline 11.1, SE 3.10; \( P < .001; n=96 \)). These improvements were sustained across the entire study cohort at week 24 (LS mean change from baseline 23.6, SE 4.81; \( P < .001; n=77 \)).

After week 12, participants were split by assignment to arm 1 or arm 2. Significant improvements in total CSES score from week 12 to week 24 were also observed in arm 1 (LS mean change 8.6, SE 4.04; \( P = .04; n=38 \)) and arm 2 (LS mean change 10.6, SE 4.33; \( P = .02; n=34 \)). In total, 5 participants did not complete CSES at week 12 but did complete the CSES at week 24.

Scores in all domains were significantly improved from baseline to end of the study in both arms (\( P < .001 \) for all domain comparisons except arm 2 for negative affect \( P = .006 \) and intense emotional arousal \( P = .002 \)). The minimally clinically important difference for CSES has not been found in the literature. The greatest differences were observed in the physical exertion and behavioral risk factors domain as shown in Table 3.

\(^a\)COPD: chronic obstructive pulmonary disease.

\(^b\)Domain scores have a scale of 1-5, calculated as the mean rating of each domain question.

\(^c\)LS: least squares.

**mMRC Dyspnea Scale**

The baseline mMRC scores reflect variability in the study population regarding dyspnea. mMRC scores range from 0 (“I get out of breath only when I engage in strenuous exercise”) to 4 (“I am often too out of breath to leave the house, or I get out of breath even when dressing”). The population mean score was 2.0 (SD 1.26) at baseline. The distribution of baseline scores and the mMRC response rates at week 12 and week 24 can be observed in Table 4. In total, 31.6% (n=30) of participants improved by at least 1 category on mMRC from baseline to week 12, and 35.1% (n=27) improved from baseline to week 24. No differences between treatment arms were observed from week 12 to week 24 (\( P = .77 \), chi-square test).
Table 4. mMRC responder analysis. Baseline mMRC scores are shown for the study population (n=141).

\(^a\)mMRC: Modified Medical Research Council.

\(^b\)Week 12 responder status is reported for 95 participants for whom mMRC data were available at baseline and week 12.

\(^c\)Participants were indicated to have “improved” if their score decreased by one or more points from baseline.

\(^d\)Participants were indicated to have “worsened” if their score increased by one or more points from baseline.

\(^e\)Week 24 responder status is reported for 77 participants for whom mMRC data were available at baseline and week 24.

Pulmonary Function and Pulse Oximetry

Interpretation of the FEV\(_1\), PEF, and SpO\(_2\) data collected in this study was limited by the small sample size and the declining use of the connected devices throughout the study period. Use of the pulse oximeter waned over the study period: 126 (89.4%) were compliant with pulse oximeter use in study week 1, which fell to 60 (42.6%) in study week 12, and further to 13 (9.2%) in study week 24. Use of the spirometer also waned over the study period: 116 (82.3%) were compliant with spirometer use in study week 1, which fell to 59 (41.8%) at study week 12, and further to 12 (8.5%) at study week 24. Based on the limited data set, these data cannot be reliably analyzed to make any conclusions about changes in pulmonary function or pulse oximetry throughout the study.

Patient-Reported HRU

Interpretation of the patient-reported HRU data is limited by the infrequency of events reported. In total, 90% (n=127) and 93.6% (n=132) of study participants reported no COPD-related emergency room visits or hospitalizations, respectively, in the 3 months prior to baseline. Similarly, 89.6% (n=95) and 93.4% (n=99) of study participants reported no COPD-related emergency room visits or hospitalizations, respectively, during the study period. As expected, physician visits were more common than emergency room visits or hospitalizations. However, at all time points, participants most commonly reported none or only 1 COPD-related physician visit for the prior 3-month period. The event rate for physician visits is thus also inadequate for detection of any impact of Wellinks; furthermore, there is inadequate data to analyze any effect by treatment group.

Safety

No adverse events were reported by the participants during the study period.

Discussion

Principal Results

Since the Wellinks clinical model has evolved over time to include the availability of respiratory therapy and health coaching services, questions emerged as to whether the target population—people living with COPD—would engage as they had done in a previously reported pilot study of a more basic program offering [8] and whether data may be collected to better optimize the frequency and duration of the personal health coaching component. Thus, the purpose of this 2-arm study design was to collect clinical and nonclinical data to optimize the appropriate duration and frequency of health coaching with Wellinks.

Study participants displayed a high degree of engagement with the health coaching component of Wellinks. By contrast, the study population had substantial attrition in the use of the mobile app and connected devices throughout the entire study duration despite rating all of them as highly valuable.

Importantly, this study provided evidence for the first time of the clinical value of patient participation in Wellinks. Significant improvements in COPD self-efficacy and breathlessness...
(mMRC) were observed for study participants regardless of assignment to arm 1 or arm 2. The improvement in the CSES observed after engaging in the Wellinks program may reflect the increased belief among study participants in their own ability to do certain activities, despite any potential perceived limitations due to their COPD diagnosis. Improved confidence in physical activities would be predicted to perpetuate a greater level of physical activity, and associated health outcome improvements may result.

Approximately one-third of participants demonstrated an improvement in breathlessness over the course of the study; improvements in shortness of breath as measured by mMRC are also reflected in the improvements in CSES, wherein the greatest degree of improvement was observed in the physical exertion domain. Although this study design does not allow for clear causal relationships to be determined, one hypothesis is that the remote pulmonary rehabilitation and education provided by the Wellinks health coaches may have improved breathlessness, which then also resulted in greater confidence (self-efficacy) on the physical exertion domain of the CSES [9]. Taken together, we can infer that the use of Wellinks improved self-efficacy and breathlessness, which may predict an improvement in the quality of life for these patients.

One difference between the treatment arms was observed in the NPS values. It is hypothesized that the higher NPS value observed for arm 1 compared to arm 2 may be attributable to the higher degree of interaction between health coaches and the study participants assigned to that arm. It has been frequently reported that digital interventions have the greatest value when combined with personal coaching or counseling [2,11,12], and this greater value may be reflected in the NPS.

Limitations

The key limitation of this study is missing data for certain outcomes of interest, such as pulmonary function and HRU. Pulmonary function was assessed by way of home use of a Bluetooth-connected spirometer and pulse oximeter. Interpretation of these results is significantly limited by the lack of consistent use of these devices throughout the study period. Very low compliance with the study-directed use of once per week for each device resulted in a very small sample size, from which clear conclusions cannot be drawn. Although data interpretation is thus limited, this design was intentional to best reflect the real-world use of Wellinks; specifically, health coaches did not mandate the use of the devices but did remind participants to use them as appropriate.

Low long-term compliance with the connected devices is not an entirely surprising finding. It has been previously reported that remote monitoring alone with various biometric devices is subject to failure if it is not effectively integrated into the existing health care delivery model [3]. These results suggest that more needs to be done within the Wellinks clinical model to integrate the device data with the remote pulmonary rehabilitation and health coaching components of the program. It would be important to better understand whether the limited use of the devices was due to technical challenges, due to a lack of perceived value, or some other reason. If participants do not recognize the value of the data collected by these devices, it is possible that more can be done to educate patients about the information, provide context for interpreting the results that are recorded, and integrate health care providers into the process. Furthermore, the Wellinks model includes various components that allow for flexibility to meet patient needs; therefore, compliance with certain components may be expected to vary from individual to individual, in part as a reflection of different needs and preferences of each participating person.

HRU was assessed in this study based on participant self-report using a 3-month look-back period. The main limitations to interpreting these data are the low frequency of events reported and the recall bias that can result from this approach. Future studies of Wellinks will rely on verifiable information from electronic medical records or claims databases to inquire about HRU. Missing data were also the result of failure of some participants to complete all surveys per the study protocol. Notably, based on a meta-analysis of 1071 web-based surveys, completion rates average 44% [13], making this survey response rate better than average, although still an important limitation.

Additionally, the enrolled population may reflect a highly motivated subset of people living with COPD, given their existing engagement with the COPD Foundation prior to the study start; those who were recruited from the COPD Foundation Patient-Powered Research Network, by definition, have self-selected to contribute to research activities, which reflects a high degree of motivation. The same attributes may not be present in the general COPD population. Furthermore, the demographics of this study cohort may not fully reflect the demographics of the COPD population in the community. There was slightly more representation of females compared to males, which is consistent with observed trends of increased prevalence of COPD among women, while a decrease in prevalence has been observed in males over recent decades [14]. However, race and ethnicity are known to impact COPD risk but yet are not well represented in this study cohort [15].

Comparison With Prior Work

It has been recognized in prior research that engagement with technology among older adults is dependent upon personal support from professionals or peers [16]. The high receptivity of this study population to personal health coaching sessions as compared to the low receptivity to the use of connected devices may also reflect this need for personal connection and support. In designing digital solutions for this population, it will be important to consider the value of the personal connection between the individual and their coach as a means to achieving greater adoption of associated technologies, such as the app and connected devices included in this study.

There are limitations to comparing the previously published pilot study of Wellinks to the study reported here; the populations differ in important ways (ie, in the pilot study, participants were recruited from a single provider’s practice, whereas in the ASPIRE study reported here, participants were recruited nonpersonally through the COPD Foundation), and the intervention differs as well (eg, the pilot study included most of the same technological components but lacked the health coaching component included here).

 JMIR Form Res 2024 | vol. 8 | e47555 | p.818
 (page number not for citation purposes)
Conclusions
This study demonstrates the interest and satisfaction of an ambulatory COPD population with the additional support and services provided by Wellinks. Health coaching appeared to be the most valuable component of Wellinks in this study. Signals of clinical outcome improvements in this study are encouraging and would best be further explored in larger cohorts to assess meaningful impact on a population level in terms of clinical improvement and impact on HRU.

Strategies and services to improve chronic disease self-management, such as with what Wellinks offers to patients with COPD, have been shown to reduce the burden of chronic diseases on individuals and the health care system at large. The data reported here are valuable not only to further optimize Wellinks but also to inform novel program design by others.

Future Directions
Future studies will explore the ability of newer and modified versions of Wellinks to reduce hospital readmissions following an acute exacerbation as well as to explore the integration of Wellinks into a large accountable care organization. There remains a significant opportunity to bring remote disease management tools to people living with COPD, and these studies will further build the evidence base and support the long-term scalability of the program.

Acknowledgments
This study was sponsored and funded by Wellinks (Convexity Scientific, Inc) of New Haven, Connecticut, and was executed in partnership with the COPD Foundation. The authors wish to acknowledge and sincerely express gratitude to the people living with COPD who have participated in this study. Without the willingness of research participants, it would not be possible to validate and iterate on the tools and services designed to meet their needs.

Data Availability
The data sets generated during this study are available from the corresponding author on reasonable request.

Conflicts of Interest
KAP receives consulting compensation from Wellinks. NL is an independent contractor for the COPD Foundation and a former employee of GSK plc. CRR is a consultant to and shareholder of Wellinks. RJC, NH, PD, and AS are employees of Wellinks.

Abstract

Background: User engagement is crucial for digital therapeutics (DTx) effectiveness; due to variations in the conceptualization of engagement and intervention design, assessment and retention of engagement remain challenging.

Objective: We investigated the influence of the perceived acceptability of experimental intervention components and satisfaction with core intervention components in DTx on user engagement, while also identifying potential barriers and facilitators to user engagement.

Methods: We conducted a mixed methods study with a 2 × 2 factorial design, involving 12 outpatients with atopic dermatitis. Participants were randomized into 4 experimental groups based on push notification (“basic” or “advanced”) and human coach (“on” or “off”) experimental intervention components. All participants engaged in self-monitoring and learning courses as core intervention components within an app-based intervention over 8 weeks. Data were collected through in-app behavioral data, physician- and self-reported questionnaires, and semistructured interviews assessed at baseline, 4 weeks, and 8 weeks. Descriptive statistics and thematic analysis were used to evaluate user engagement, perceived acceptability of experimental intervention components (ie, push notification and human coach), satisfaction with core intervention components (ie, self-monitoring and learning courses), and intervention effectiveness through clinical outcomes.

Results: The primary outcome indicated that group 4, provided with “advanced-level push notifications” and a “human coach,” showed higher completion rates for self-monitoring forms and learning courses compared to the predetermined threshold of clinical significance. Qualitative data analysis revealed three key themes: (1) perceived acceptability of the experimental intervention...
components, (2) satisfaction with the core intervention components, and (3) suggestions for improvement in the overall intervention program. Regarding clinical outcomes, the Perceived Stress Scale and Dermatology Life Quality Index scores presented the highest improvement in group 4.

Conclusions: These findings will help refine the intervention and inform the design of a subsequent randomized trial to test its effectiveness. Furthermore, this design may serve as a model for broadly examining and optimizing overall engagement in DTx and for future investigation into the complex relationship between engagement and clinical outcomes.

**Introduction**

**Digital Therapeutics in General**

With the rapid advancement of digital technology, digital therapeutics (DTxs) have emerged as a promising approach to either enhance the value of conventional health care delivery systems or have the potential to substantially substitute the existing system [1]. DTx refers to “an evidence-based intervention that is driven by high-quality software programs to prevent, manage, or treat a disease or disorder” [2]. Using technology and data analytics, DTx holds numerous benefits in health care: (1) it can encompass a wide range of physical and mental health conditions (mostly chronic) like diabetes, oncology treatment management, insomnia, attention-deficit/hyperactivity disorder (ADHD), and substance use disorder [3]; (2) it can provide personalized care with data-driven treatment options [4]; and (3) it can reduce health care costs [5]. Given these significant potential benefits, it is crucial to understand how the efficacy of DTx in therapy can be improved. To achieve such improvement, diverse and comprehensive research regarding the DTx development process should be conducted to successfully implement and optimize these promising interventions.

**User Engagement Issues in DTx**

It is widely acknowledged that user engagement is important for improving the effectiveness of DTx [6]. Engagement in DTx can be defined as “the extent (eg, amount, frequency, duration, and depth) of use and subjective experience characterized by attention, interest, and affect” [7,8]. Although user engagement significantly impacts the effectiveness of DTx, assessing and retaining it is challenging. The possible reasons for this may include (1) a lack of shared awareness regarding the useful perception of engagement, (2) engagement in DTx is not a stationary but a dynamic process, and (3) it is a multifaceted construct, capturing the user’s behavior, cognitive, and emotional states. Several systematic reviews have investigated DTx intervention components (eg, self-monitoring, reminders, and rewards) that are linked with higher engagement [9,10]. However, the findings of these studies do not provide conclusive evidence about the intervention components that help patients become more engaged with the DTx. This occurs due to substantial variation in the definition of engagement and intervention design in DTx. Thus, an in-depth analysis of the intervention components and a concrete definition of user engagement should be established, particularly during the design phase of DTx.

**Methods for Evaluating Intervention Components in Digital Intervention**

For systematically evaluating how intervention design influences user engagement, the optimization methods from the multiphase optimization strategy (MOST) can be used with a couple of representative intervention components from a wide range of possible options. MOST allows for efficient testing through a randomized experiment, including a factorial experiment, which allows for the simultaneous examination of different intervention design factors [11]. Many recent studies, however, used only traditional randomized controlled trials (RCTs) as the primary study design to test the efficacy of the intervention as a package [12-15] and to examine the relationships between engagement level and clinical outcomes through post hoc analysis [6,16,17]. Using only RCTs as an evaluation design may pose some challenges to the effective evaluation of DTx, as they are considered complex, context-dependent, and individually tailored interventions that purport to maximize its effectiveness [18,19]. Thus, additional evaluation methods for DTx, such as adaptive study designs (eg, sequential multiple assignment randomized trial and factorial trial from MOST), must be considered to provide robust evidence during its design and development phases.

**Aims of This Study**

Here, we aimed to examine the impact of the perceived acceptability of the experimental intervention components (ie, push notification and human coach) and satisfaction with the core intervention components (ie, self-monitoring and learning courses) in DTx on user engagement (Figure 1). We used “Atomind,” a DTx for patients with atopic dermatitis (AD), developed for clinical trial purposes, with a primary focus on optimization as a refinement process before validating its effectiveness through larger RCTs. This was a proof-of-concept study with an experimental 2 × 2 factorial design, using both quantitative (eg, in-app behavioral data) and qualitative (eg, semistructured interviews) assessment methods. We hypothesized that those who received the advanced level of each experimental intervention component would pass the threshold of clinical significance of user engagement metrics in DTx. Moreover, the qualitative analysis of satisfaction with the core intervention component would identify the potential barriers and facilitators to user engagement. This study could...
also inform how to optimize and evaluate other DTx in this field.

**Figure 1.** Overview of the impact of intervention designs on user engagement in “Atomind”.

**Methods**

**Study Design**

This full factorial experiment had 2 experimental intervention components (Figure 2), each of which was implemented at 2 different levels: push notification (“basic” or “advanced”) and human coach (“on” or “off”). Participants were randomly allocated to 1 of the 4 experimental groups in the $2 \times 2$ factorial design. All participants engaged in self-monitoring and learning courses as core intervention components during the 8-week intervention period. We applied a mixed methods approach by collecting quantitative (eg, surveys) and qualitative (eg, semistructured interviews) data to examine the perceived acceptability of experimental intervention components, satisfaction with the core intervention components, and suggestions for improvement in the overall intervention program. We conducted the interviews after 8 weeks of treatment.

**Figure 2.** A $2 \times 2$ factorial design exploring the perceived acceptability of experimental intervention components in this digital therapeutics (DTx) study, featuring different combinations of basic- versus advanced-level push notification and “on” versus “off” human coach.
Experimental Intervention Components

Push Notification
Participants randomized to “basic-level push notification” received basic push notifications that encouraged users to log in and complete tasks at time points chosen by users. Participants randomized to “advanced-level push notification” received not only basic push notifications but also additional push notifications when they did not complete in-app self-monitoring forms, weekly classes, or missions after receiving the basic push notifications. Additional push notifications contained emotionally supportive phrases (eg, “It’s a bit annoying, right? But don’t forget that sustained use of the app can help reduce your symptoms.” And, “Malang is waiting for <username>! Haven’t you finished the class yet? Don’t give up and let’s start!”). Push notifications are classified into 4 different categories: self-monitoring, learning course, mission, and personalized feedback report. An overview of the 2 groups’ push notifications is presented in Multimedia Appendix 1.

Human Coach
Participants with this experimental intervention component turned “on” received tailored guidance and assistance from a human coach. The coach sent weekly motivational messages to maintain participants’ engagement through a different digital application called KakaoTalk, which is the most popular instant messaging app in South Korea, with 94% of the entire Korean population as users. The coach spent a total of 6 hours a week—2 hours a day over 3 days—to manage the participants. The coach kept the participants motivated, held them responsible, provided feedback, and monitored their progress to keep them on track. Participants could address difficulties or questions they encountered with the app through 2-way communication. Besides the app’s information, participants could also ask questions about skin health and mental well-being and receive answers from the coach. Conversely, participants with this experimental intervention component turned “off,” received nothing, and conducted self-care.

Participants
All participants were outpatients who met the eligibility criteria, including individuals who (1) were aged 19 years or older and had mild to severe AD, (2) were able to understand verbal and written Korean, and (3) had their own smartphone. Participants who met the eligible criteria were assigned randomly to 4 experimental groups in a 1:1:1:1 ratio using program IDs generated within the Atomind app.

Intervention
Atomind is an app-based intervention program that helps individuals manage skin conditions and AD symptoms. It was developed by Huray Inc, South Korea (Multimedia Appendix 2). The app’s content is based on cognitive behavioral therapy (CBT) and a mindfulness approach to support healthy behavioral habits and regulate negative emotions. The app prompts users to complete in-app self-monitoring forms on a daily, weekly, and monthly basis, focusing on motivation, skin condition, behavioral change, and mental health. Weekly videos demonstrate educational information that can help relieve AD symptoms and CBT strategies for regulating negative thoughts and emotions. After watching the video, users were asked to demonstrate their understanding by passing a postquiz. The overall topic of the weekly video is listed in Multimedia Appendix 3. Moreover, missions are provided to help users apply their newly acquired skills in real life. Users can access personalized graphic feedback based on their self-monitoring.

Outcomes
Outcome measures were collected by using (1) in-app behavioral data, (2) physician- or self-reported questionnaires, and (3) semistructured interviews. At baseline, participants were asked to complete a demographic questionnaire pertaining to their age, gender, educational level, and health-related measures (medical and family health history, health literacy, etc).

The primary outcome was the user engagement of the intervention, measured by in-app behavioral data on core intervention components, including percentages of self-monitoring forms and learning courses completed. We collected qualitative data on the perceived acceptability of experimental intervention components (ie, push notification and human coach), satisfaction with the core intervention components (ie, self-monitoring and learning courses), and suggestions on any improvement for the overall intervention program through semistructured interviews. The interviews were conducted over the telephone by 2 research team members after 8 weeks of intervention. A semistructured interview guide (Multimedia Appendix 4) was used to guide the interviews, lasting 15-20 minutes for each.

Furthermore, other clinical outcome measures were assessed at baseline, 4 weeks, and 8 weeks of intervention. Designated dermatologists assessed the severity of AD using the eczema area and severity index (EASI), including the severity of 4 signs (erythema, edema or papulation, excoriuation, and lichenification; range 0-72) [20]. Atopic eczema severity reported by patients was measured with the patient-oriented eczema measure (POEM; range 0-28), a 7-item questionnaire for monitoring the care of patients with atopic eczema [21]. Insomnia severity was measured with the insomnia severity index (ISI; range 0-28), a 7-item questionnaire assessing perceived insomnia severity using a Likert-type scale [22]. Perceived stress level was measured with the perceived stress scale (PSS; range 0-40), a 10-item questionnaire assessing psychological stress [23]. Quality of life was measured by the dermatology life quality index (DLQI; range 0-30), a 10-item questionnaire assessing how much the patients’ skin problems have affected their lives over the past week [24], and fear of negative evaluation was measured using the brief fear of negative evaluation (BFNE; range 12-60) scale, which is a 12-item questionnaire assessing the degree of anxiety about perceived negative evaluation [25]. The assessment methods and assessment period for each measurement are shown in Multimedia Appendix 5.

Statistical Analysis
Descriptive statistics were used to analyze quantitative data, including in-app behavioral data and clinical outcomes. We initially recruited and enrolled 12 participants, with 3 individuals for each group; however, of the initial 12 individuals, 3 participants (1 in group 2, 1 in group 3, and 1 in group 4) were...
excluded from the analysis due to medication changes during the intervention period.

We set the threshold of clinical significance (TCS) for user engagement, considering the period of each assessment. Previous research with larger sample sizes has shown that individuals with high efficacy typically maintain an engagement rate between 50% and 80% [26,27]. However, given the smaller sample size in this proof-of-concept study, a more stringent approach has been applied in setting the TCS for user engagement. For self-monitoring, the TCS is determined if the average completion rate of self-monitoring forms is ≥90%. For learning courses, the TCS is set if the average completion rate of learning courses is ≥80% throughout the intervention period.

The perceived acceptability of each experimental intervention component and the satisfaction of each core intervention component were also examined by semistructured interviews. Qualitative data were analyzed using thematic analysis. The verbatim transcriptions of the interviews were used to extract the responses, which were categorized into items focusing on the perceived acceptability of the experimental intervention components, satisfaction of the core intervention components, and suggestions on any improvement for the overall intervention program.

To measure the interventions’ effectiveness, we assessed the changes in the average of clinical outcomes (eg, EASI, POEM, ISI, PSS, DLQI, and BFNE) before and after the intervention in the 4 groups and the 2 different levels of each experimental intervention component.

Ethical Considerations
All study activities were conducted in adherence to ethical standards and received approval from the institutional review boards of the organizing sites, including Severance Hospital (4-2022-0922), Wonju Severance Christian Hospital (CR322035), and Bundang Cha Hospital (CHAMC 2022-05-005-001). The trial was registered on the Clinical Research Information Service (KCT0007675). Participants provided voluntary, written, and informed consent after a thorough explanation of the clinical trial. Privacy measures included data anonymization and secure storage. Participants received US $80 in compensation for their contribution, a detail communicated during the informed consent process.

Results
Sample Characteristics
A total of 12 adults (mean age 31.1 years; range 20-43 years) were recruited between August and November 2022 (Figure 3). Of the 12 participants, 2 (17%) had mild AD, 7 (58%) had moderate AD, and 3 (25%) had severe AD. More details regarding the sample characteristics are presented in Table 1.

Figure 3. Trial profile. AD: atopic dermatitis.

Primary Outcome

Regarding the user engagement rates among different groups (Figures 4A and 4B), groups 2 (90.9%), 3 (95.5%), and 4 (97%) showed higher completion rates for self-monitoring compared to the predetermined TCS (90%). Additionally, groups 2 (83.3%) and 4 (91.7%) had higher completion rates for learning courses than the TCS (80%). These results indicate that group 4, provided with advanced-level push notifications and a human coach, had the highest user engagement during the intervention.
As shown in Figures 4C and 4D, “advanced-level push notification” (93.9%) and “human coach on” (96.2%) were the experimental intervention components that exceeded the predetermined TCS for self-monitoring (90%). The experimental intervention components that exceeded the TCS for learning courses (80%) were also “advanced-level push notification” (87.5%) and “human coach on” (85.4%). Overall, “advanced-level push notification” and “human coach on” demonstrated the highest user engagement among the experimental intervention components.

**Secondary Outcome**

Qualitative data were organized into three key themes: (1) perceived acceptability of the experimental intervention components, (2) satisfaction of the core intervention components, and (3) suggestions for improvement in the overall intervention program. Table 2 presents all themes and subthemes with corresponding quotes.
Table 2. Key themes, subthemes, and quotes from semistructured interviews.

</tr>
<tr>
<td><strong>Push notification component</strong></td>
<td></td>
</tr>
<tr>
<td><strong>Technical aspect</strong></td>
<td></td>
</tr>
<tr>
<td>Basic push notification</td>
<td>• It would be better if we could choose the time to receive notifications, and it would be better if we could receive the notification functioned similarly to a wake-up alarm that rings again if not checked...</td>
</tr>
<tr>
<td>Advanced push notification</td>
<td>• I lead a busy life, so receiving notifications was helpful. In fact, I think it was better for me to receive notifications frequently.</td>
</tr>
<tr>
<td><strong>Content aspect</strong></td>
<td></td>
</tr>
<tr>
<td>Basic push notification</td>
<td>• The (content) of the notifications was all good.</td>
</tr>
<tr>
<td></td>
<td>• It would be nice to have additional features like setting reminders for taking medication. Or maybe some information on whether I've applied moisturizer or taken my medicine today. Something like that would be useful.</td>
</tr>
<tr>
<td>Advanced push notification</td>
<td>• The notification content was good enough as it was, with just simple and neat notifications.</td>
</tr>
<tr>
<td><strong>Human coach component</strong></td>
<td></td>
</tr>
<tr>
<td><strong>Technical aspect</strong></td>
<td></td>
</tr>
<tr>
<td>Human coach off</td>
<td>• It would be better if there was a feature that allowed patients to send messages to report any technical errors or issues...It might be better to communicate using this feature.</td>
</tr>
<tr>
<td>Human coach on</td>
<td>• I wish there was a channel where atopic patients could communicate with each other.</td>
</tr>
<tr>
<td><strong>Content aspect</strong></td>
<td></td>
</tr>
<tr>
<td>Human coach off</td>
<td>• It would be great if we could receive feedback for emergency situations.</td>
</tr>
<tr>
<td>Human coach on</td>
<td>• For example, it would be more effective to ask direct questions like 'have you reduced your medication dosage?' rather than asking about difficulties or inconveniences...</td>
</tr>
<tr>
<td><strong>Key theme 2: satisfaction with the core intervention components</strong></td>
<td></td>
</tr>
<tr>
<td><strong>Self-monitoring</strong></td>
<td></td>
</tr>
<tr>
<td>Building health habits</td>
<td>• I used to forget to take my medicine, but ever since I started using the app to check it, I've been taking it every morning and before bed, and I've been doing it consistently.</td>
</tr>
<tr>
<td></td>
<td>• I've established a routine of recording it separately from the app.</td>
</tr>
<tr>
<td></td>
<td>• By recording the questionnaire every day, I can now monitor the daily improvement or worsening of my condition, which was the best part of the app.</td>
</tr>
<tr>
<td><strong>Learning course</strong></td>
<td></td>
</tr>
<tr>
<td>Acquiring reliable information</td>
<td>• It was great to learn about the parts that I used to miss with reliable information.</td>
</tr>
<tr>
<td><strong>Key theme 3: suggestions for improvement on the overall intervention program</strong></td>
<td></td>
</tr>
<tr>
<td>Diversity of daily self-monitoring form questions</td>
<td>• I wish, that depending on the symptoms, different questions would be asked to determine whether the symptoms improved or worsened from the previous day.</td>
</tr>
<tr>
<td>Burdensomeness of self-monitoring feature</td>
<td>• Taking pictures of my body to check the skin lesion was burdensome. The questionnaire was too lengthy.</td>
</tr>
<tr>
<td>Not tailored contents</td>
<td>• There was information that would have been useful, if symptoms hadn't been so severe. It would be better to recommend it to patients with mild symptoms.</td>
</tr>
<tr>
<td></td>
<td>• The quiz following the video was so simple that I didn't even need to watch it and could simply answer the questions correctly. This is why I stopped watching the weekly videos.</td>
</tr>
<tr>
<td>Motivating factors</td>
<td>• It would be great to include elements that can boost motivation, such as fun factors or any benefits.</td>
</tr>
<tr>
<td>Technical issues</td>
<td>• There were times when I couldn't continue with the survey for a few days because some questionnaire items wouldn't move forward at all. So, it would be great if those issues could be improved.</td>
</tr>
</tbody>
</table>
**Key Theme 1: Perceived Acceptability of the Experimental Intervention Components**

Perceived acceptability was measured using the components’ technical and content aspects. Regarding the technical aspect of the push notification component, 60% (3/5) participants receiving “basic-level push notifications” responded that they would like the push notification frequency to increase. Moreover, 20% (1/5) responded that it would be better to select the time and frequency of the push notifications and be reminded if they did not complete the task. And 50% (2/4) receiving “advanced-level push notifications” were overall satisfied with the current push notification frequency. Regarding the content aspect of this component, both groups responded that they were satisfied with the provided notification contents. However, 20% (1/5) of participants in the group receiving “basic-level push notifications” suggested that it would be helpful to receive a push notification reminding them to take medication or apply some moisturizer.

Regarding the technical aspect of the human coach component, 40% (2/5) participants assigned to the “human coach off” component requested a 1:1 communication channel within the app, as they could not receive assistance from a human coach. A total of 75% (3/4) of participants assigned to the “human coach on” component preferred to have an in-app communication channel rather than using a different instant messaging app (ie, KakaoTalk) for communication with a human coach. And 25% (1/4) of participants also suggested integrating a community feature for patients to communicate with each other. Regarding the content aspect of the human coach component, 20% (1/5) of participants assigned to the “human coach off” suggested adding a telehealth feature for emergencies. And, 25% (1/4) participants assigned to the “human coach on” preferred the coach asking specific questions related to symptom management, such as “Have you taken your medicine today?” or “Have you visited the hospital?” rather than the questions relevant to the app use, like “Is there anything difficult or uncomfortable while using the app?”

**Key Theme 2: Satisfaction With the Core Intervention Components**

Satisfaction was measured for each core intervention component, self-monitoring, and learning courses. Regarding the self-monitoring component, 78% (7/9) of participants reported that self-monitoring helped build health habits, including better medication adherence, reduced scratching behavior, and consistent use of moisturizers. Moreover, they could easily track their symptoms through weekly reports, which helped them monitor their symptoms over time. Regarding the learning course component, 56% (5/9) of participants indicated that they acquired reliable information through weekly videos.

**Key Theme 3: Suggestions for Improvement on Overall Intervention Program**

Suggestions for improvement in the overall intervention program were divided into 5 subthemes. First of all, 33% (3/9) of participants recommended diversifying the questions of the daily self-monitoring form, as they found them to be repetitive and lacking in variation. Second, 22% (2/9) of participants found the self-monitoring burdensome as they had to upload lesion pictures daily. Third, 44% (4/9) of participants felt the learning course was not sufficiently tailored to their needs. They found the video content insufficiently helpful for patients with severe disease; the postquiz questions were unchallenging; and the video was too long. Fourth, 11% (1/9) of participants suggested adding motivating factors to the intervention program to make them more engaged with the app. Lastly, technical issues within the app were mentioned. A total of 33% (3/9) of participants recommended improving its performance, such as fixing bugs in the self-monitoring feature, reducing duplicate push notifications, and improving video sound quality.

**Clinical Outcomes**

Descriptive statistics, for example, mean (SD), were used to analyze clinical outcomes by group and experimental intervention component. The ISI score showed the greatest improvement in group 2 (mean change –4.50, SD 6.36). The EASI, POEM, and BFNE scores showed the highest improvement in group 3 (mean change –10.20, SD 9.90, mean change –3.00 score, SD 15.56, and mean change –4.50, SD 6.36, respectively). The PSS and DLQI scores presented the greatest improvement in group 4 (mean change –3.50, SD 3.54, and mean change –6.00, SD 11.32, respectively).

Regarding the push notification component, the ISI, PSS, DLQI, and BFNE scores showed the highest improvement in the “advanced-level push notification” component (mean change –0.25, SD 6.34, mean change –1.75, SD 2.99, mean change –4.75, SD 8.06, and mean change –3.00, SD 3.46, respectively). Regarding the human coach component, the EASI, POEM, PSS, and BFNE scores presented the highest improvement in the “human coach on” component (mean change –6.73, SD 7.41, mean change –1.50, SD 11.73, mean change –3.00, SD 2.94, and mean change –4.25, SD 3.69, respectively). More detailed results can be found in Figure 5.
Discussion

Principal Findings

Our primary objective was to investigate how the perceived acceptability of experimental intervention components and satisfaction with core intervention components affect user engagement in DTx. We examined in-app behavioral data on core intervention components (ie, percentages of self-monitoring forms and learning courses completed) as a user engagement metric. As hypothesized, the TCS of user engagement was achieved in group 4, where all 2 experimental factors were advanced simultaneously. Furthermore, clinical outcomes related to the mental health of patients with AD improved in group 4. This study identified potential barriers and facilitators of user engagement through semistructured interviews on the patients’ satisfaction with core intervention components. Overall, our analysis of Atomind data suggests that incorporating advanced-level push notifications with a human coach, tailoring contents with various self-monitoring tools, and implementing some motivational factors (eg, rewards) may improve user engagement.

Comparison With Previous Work

To the best of our knowledge, this is the first study to examine the impact of different levels of push notification, human coach,
and satisfaction with core intervention components on user engagement in DTx using mixed methods. Although there is a proliferation of clinical research on user engagement with mobile health apps, the majority only conducted traditional RCTs [28-39] or optimization trials with a single type of assessment method [40-44]. The findings from these earlier studies with traditional RCTs only explained how the intervention as a package affected user engagement; they could not identify the specific intervention elements that impacted it [29]. Additionally, only assessing quantitative data from optimization trials (e.g., factorial experiments) limits the understanding of barriers and facilitators affecting user engagement [45,46]. In contrast, this study clearly showed that advanced-level push notifications and communication with a human coach are the main factors enhancing user engagement. Furthermore, our qualitative analysis showed that advanced-level push notifications were sufficient in frequency to serve as a reminder in busy daily lives, and their content was concise enough to be acceptable. Although communication with a human coach improved user engagement, our qualitative findings suggest that the human coach platform should have been implemented in the internal system of the Atomind app with more diverse questions and detailed responses. Using a mixed methods approach to assess various factors contributing to user engagement in Atomind enabled us to gain insights into the “what, how, and why” of this phenomenon, which is critical to figuring out what steps must be taken to improve an intervention.

Establishing a TCS for user engagement has been applied, as this study is a proof-of-concept study with a small sample size. This approach allows for resource-efficient research with clear go-or-no-go decision-making, lowering the risk of confirmatory bias [19]. Concerning TCS determination, each previous study had its own logic established and multiple metrics to account for user engagement [33,47]. This is because user engagement is a multifaceted concept with no universal consensus on how to perceive it [6,7,34]. Among the various metrics of user engagement from previous research, the completion of specific activities or modules of the intervention was the most commonly used metric for user engagement [29-34,36,39,43,48]. Similarly, we measured user engagement in the app by assessing the completion rate of the core intervention components. In this study, self-monitoring is for daily activity, while learning courses are for weekly activity. Thus, we set up different levels of TCS for each activity to assess user engagement; the completion rate was 90% for self-monitoring forms and 80% for learning courses.

Regarding the clinical outcomes from this study, people who received the advanced level of experimental intervention components saw improvement in the majority of psychological symptoms (e.g., stress, quality of life, and fear of negative evaluation), which was more than the physical symptoms related to AD. These findings correspond with previous research that suggests digital interventions should focus mainly on improving mental health conditions to support better physical health conditions [49,50]. This trend is caused by several inherent factors of mental health interventions, including the stigma associated with mental problems and diagnosis-specific barriers to accessing mental health services [51]. Likewise, Atomind is a digital intervention for patients with AD that encourages healthy behaviors and mental health conditions for effective symptom management. Thus, improving psychological measures by engaging with Atomind indicates that it achieved the intended proximal outcome.

Limitations and Future Directions
First, the statistical power of this study is insufficient to determine significant effects before and after the intervention. However, setting reasonable TCS for quantitative data and collecting qualitative data will support our findings on DTx optimization for use in well-powered RCTs. Second, the Atomind app is only available for use on the Android operating system. To overcome this limitation, we provided Android smartphones during the intervention period to those (n=5) who had other operating systems on their smartphones. Despite this effort, the user experience with Atomind, which is closely related to user engagement, may be affected. Lastly, technical issues with the app occurred frequently during the intervention period, which may affect user engagement. As Atomind was in the development phase, these problems could have taken place; however, its technical system should be improved in a later version and used for future clinical research.

Conclusions
This proof-of-concept, mixed methods study with an experimental 2 × 2 factorial design demonstrates the impact that perceived acceptability of experimental intervention components and satisfaction with core intervention components in DTx have on user engagement. The findings will be used to refine the intervention and inform the design of the next RCT to test its effectiveness. Furthermore, this research design may serve as a model for how to examine and optimize overall engagement in DTx in broad terms; it will help future research investigate the complex relationship between engagement and clinical outcomes.

Acknowledgments
This research was supported by the Seoul R&BD Program (grant BT210048; project name: Development and Demonstration of a Digital Therapeutics Platform Service for Atopic Dermatitis Treatment) through the Seoul Business Agency, funded by the Seoul Metropolitan Government.
Data Availability
The data sets generated and/or analyzed during this study are not publicly available due to the need to maintain privacy and confidentiality, but are available from the corresponding author on reasonable request. Requests for access to specific data points or additional information will be considered on a case-by-case basis.

Authors' Contributions
MK and JS conceptualized and developed the study’s design. MK provided the intellectual framework for this research. EHC, JUS, and TGK were in charge of the recruitment and data collection of participants. JO and BS served as human coaches, providing guidance and assistance to the participants. HL and JYS conducted interviews and handled the analysis of qualitative data. HL and MK contributed significantly to the data analysis and interpretation. HL and MK wrote the manuscript and edited its contents. MK and JS conducted a thorough review of the manuscript. All authors approved the final version of the manuscript for submission.

Abstract

Background: Privacy in our digital world is a very complicated topic, especially when meeting cloud computing technological achievements with its multidimensional context. Here, privacy is an extended concept that is sometimes referred to as legal, philosophical, or even technical. Consequently, there is a need to harmonize it with other aspects in health care in order to provide a new ecosystem. This new ecosystem can lead to a paradigm shift involving the reconstruction and redesign of some of the most important and essential requirements like privacy concepts, legal issues, and security services. Cloud computing in the health domain has markedly contributed to other technologies, such as mobile health, health Internet of Things, and wireless body area networks, with their increasing numbers of embedded applications. Other dependent applications, which are usually used in health businesses like social networks, or some newly introduced applications have issues regarding privacy transparency boundaries and privacy-preserving principles, which have made policy making difficult in the field.

Objective: One way to overcome this challenge is to develop a taxonomy to identify all relevant factors. A taxonomy serves to bring conceptual clarity to the set of alternatives in in-person health care delivery. This study aimed to construct a comprehensive taxonomy for privacy in the health cloud, which also provides a prospective landscape for privacy in related technologies.

Methods: A search was performed for relevant published English papers in databases, including Web of Science, IEEE Digital Library, Google Scholar, Scopus, and PubMed. A total of 2042 papers were related to the health cloud privacy concept according to predefined keywords and search strings. Taxonomy designing was performed using the deductive methodology.

Results: This taxonomy has 3 layers. The first layer has 4 main dimensions, including cloud, data, device, and legal. The second layer has 15 components, and the final layer has related subcategories (n=57). This taxonomy covers some related concepts, such as privacy, security, confidentiality, and legal issues, which are categorized here and defined by their expansion and distinctive boundaries. The main merits of this taxonomy are its ability to clarify privacy terms for different scenarios and signalize the privacy multidisciplinary objectification in eHealth.

Conclusions: This taxonomy can cover health industry requirements with its specifications like health data and scenarios, which are considered as the most complicated among businesses and industries. Therefore, the use of this taxonomy could be generalized and customized to other domains and businesses that have less complications. Moreover, this taxonomy has different stockholders, including people, organizations, and systems. If the antecedent effort in the taxonomy is proven, subject matter experts could enhance the extent of privacy in the health cloud by verifying, evaluating, and revising this taxonomy.

KEYWORDS
taxonomy; privacy; security; legal; cloud computing
Introduction

Background

Cloud computing is among the hottest core technical topics in the digital world. It has broad-ranging effects across IT, business, software engineering, and data storage. One of the main effects is an increase in capability. According to the National Institute of Standards and Technology (NIST) definition, “cloud computing is a model for enabling convenient, resource pooling, ubiquitous, on-demand access which can be easily delivered with different types of service provider interactions” [1,2]. Cloud technology can meet the requirements of the health care industry. It has some benefits like helping health organizations to reduce their costs by replacing and migrating all IT infrastructure, platforms, and software to the cloud, and providing integrated services across multiple organizations with delivery of better access to IT knowledge, resources, and services in a more technical and economical way.

The cloud in the health care context can increase medical record accessibility and make medical history available for individuals. Moreover, it can enhance cooperation among various stakeholders in the health industry through the integration of electronic medical information from dispersed locations and can reduce medical error complications to achieve patients’ lifesaving goals [3-9]. A health record includes a chronological account of an individual’s tests and treatments, and is a critical part of any health care lawsuit about health care procedures [10-14]. These documents can play an important role in guarding individuals based on medical ethics concerns, patients’ rights, and the bill of rights in each country [15-18]. Therefore, acceptance of any kind of computing technology with the combination of medical informatic applications can change the boundaries of health care organizations [1].

Despite all these benefits, the sharing and storing of sensitive electronic health data and personal health information through the cloud raise various privacy and security concerns [2,3]. An important concern is the probable release of health information to third parties who are not authorized to access the information. The distributed architecture of the cloud causes many difficulties like service accessibility, data reliability, data management, scalability, interoperability, privacy, security, data ownership, regulation and standards, organizational change, business process reengineering, etc [3-8].

The tradeoffs between the pros and cons of this technology depend on the approaches that governments introduce to address the privacy, security, and legal challenges in such a complicated domain like health care.

The challenges are magnified several times when there are no definite implications for some essential and technical concepts. For example, privacy in the digital world is a term with different meanings, which can clearly include a wide range of concepts and can completely differ from its traditional comprehension [3]. Moreover, some interpreters have explained this word as “vague and evanescent” [4]. Therefore, a lack of transparency in the privacy concept has made policy making difficult [19-21].

In these occasions, judges and legislators cannot obviously speak about privacy harms, especially at intersections with other fields like free speech, effective consumer transactions, and security, which are quite controversial. It is completely understandable that privacy and the related implications are complex and multidimensional, and are thus considered legal, philosophical, or even technical.

Furthermore, the involute definitions of privacy and cloud technological risks have stopped governments from adopting cloud technology in the health industry, and if cloud technologies are introduced in the health industry, issues like security, privacy, and legal obstacles play preventive roles. In other words, using cloud capabilities in the health industry without proper setups can lead to disastrous outcomes, such as blackmail and threats. As the relationship between the growth of eHealth and privacy value is quite obvious, it is necessary to create a balance between the pros and cons of these technologies in this new era. Health care stakeholders in different countries have taken many efforts to identify political and legal challenges in this domain and have developed appropriate supplements and technological infrastructure for the health cloud [22-24]. Moreover, the obstacles have led them to revise and redesign required concepts to make them compatible for the new paradigm [13,14,16,17].

A review of previous taxonomies appears necessary to obtain a better overall view. The most popular and famous taxonomies in this domain were analyzed by their features and attributes. The goals, use, and dimensions of each taxonomy in the privacy era are presented in Table 1.

Almost all reports in Table 1 declared that privacy is a multilateral concept that needs analysis from different sides. In addition, the reports indicated that the data value has grown incredibly, which could be the most valuable asset for organizations and individuals, but privacy-preserving concerns were illustrated as nonignorable challenges. Some reports only dealt with security services and presented those as privacy matters, while others only paid attention to legal issues or data features. Obviously, most of them were not specifically designed based on cloud technology features or health care scenarios.

This institute organized a technical committee to improve the level of privacy and security for European organizations and citizens in Europe and across the world by standard development. In general, ETSI provided an overview of the global cyber security ecosystem.

This independent organization covered working groups or committees on information processing. Among the committees, one of its technical committees has worked on security and privacy protection in information processing systems. The product of this committee provided the most extensive collection of concepts and topics. However, generally, this report could not be considered as a taxonomy.

This methodology has developed a catalog to support information security and the development of cybersecurity evaluation in organizations.

The main goal of this taxonomy was aligning cybersecurity terminologies, definitions, and domains to facilitate EU cybersecurity competency categorization. It included 3 completely intertwined dimensions to provide evidence-based scientific support to the European policy-making process.

This study has several implications. It redefines privacy with concept about privacy.

Despite all previous studies, it appears that more efforts are needed to redefine the privacy concept in the health domain, especially in the cloud context. The nomenclature and classification confusion in privacy terminology prevent businesses from finding a comprehensive solution for the domain requirements [22-24]. It is worthwhile to note that taxonomy use is an effective approach. Regarding the research question, our attempts focus on reaching a comprehensive concept about privacy.

The main challenges are related to what we already know and what we need to know. Therefore, a clear and precise taxonomy would be helpful to identify the specifications of privacy in a dynamic environment and would help in conducting future research projects for evaluating its impacts. A taxonomy was developed in this study, and the study contributions are presented below.

This taxonomy clarifies the privacy concept in eHealth, which is a multidisciplinary context, and tries to eliminate the ambiguity of this subject in cloud environments with regard to the different requirements in health care scenarios and situations.

The proposed taxonomy provides a true and complete perspective regarding the intervention, management, and handling of other variables, as well as the itemization of the expected outcomes and the determination of how best to assess them, thus clarifying the units of analysis in health cloud privacy research.

The findings of this study regarding the privacy taxonomy led to the distinction and clarification of the overlapping and vague structure of related concepts, and privacy was defined by identifying the discrete sets of variables representing specific privacy configurations and definitive boundaries for “security,” “privacy,” and “legal” terms, which are crucial for future research, policy making, and the actual management of privacy. This capability of the taxonomy was considered as the main outcome or contribution of this study, and it conceptually provides quite clear boundaries of these terms in the digital health world.

The proposed taxonomy has 3 layers, of which the first layer has 4 main dimensions, including cloud, data, device, and

Problem Statement

Despite all previous studies, it appears that more efforts are needed to redefine the privacy concept in the health domain, especially in the cloud context. The nomenclature and classification confusion in privacy terminology prevent businesses from finding a comprehensive solution for the domain requirements [22-24]. It is worthwhile to note that taxonomy use is an effective approach. Regarding the research question, our attempts focus on reaching a comprehensive concept about privacy.

The main challenges are related to what we already know and what we need to know. Therefore, a clear and precise taxonomy would be helpful to identify the specifications of privacy in a dynamic environment and would help in conducting future research projects for evaluating its impacts. A taxonomy was developed in this study, and the study contributions are presented below.

**Study Contributions and Objectives**

This study has several implications. It redefines privacy with regard to the health cloud and focuses on identifying the main approaches to deal with the contributed factors and dimensions that rely on taxonomy designing.
legal, and the second layer has 15 components, with each of them having subcomponents (n=57). This taxonomy has some advantages like presenting the hierarchical root of concepts and the inherited features of taxonomies. The specific implementation was performed by selecting published English papers related to the concept of health cloud privacy from several databases and relying on predefined keywords and search strings, followed by a classification design through a qualitative content analysis approach.

Hence, this taxonomy could cover health industry requirements with its specifications like health data and scenarios, which are considered to be the most complicated among businesses and industries. Therefore, this taxonomy could be generalized to other domains and businesses with less complications.

Previous taxonomies in the privacy domain have also been covered in this article, and the designing steps of the new taxonomy are presented in the Methods section.

Methods

Methodology Analysis

One of the main concerns in various disciplines is how to group disciplines based on taxonomies. Such a classification has given taxonomies a pivotal role for researchers and practitioners in investigations and businesses as it has enabled them to comprehend and analyze complex domains [42,43].

Covering both descriptive knowledge and prescriptive knowledge, design science also consists of taxonomies as a type of conceptual knowledge in its epistemology. The research goal at the conceptual level is essentialist; concepts and conceptual frameworks at this level aim at identifying essences in the research territory and their relationships [44].

The term taxonomy is different from other similar words. Compared with classification, in some literature, it refers to groupings that are derived based on empirical studies with involvement of cluster analysis and statistical techniques. This definition is also referred to as numerical taxonomy [45].

Taxonomy is also considered as a classification scheme [46], and it is possible to use the terms of classification scheme, taxonomy, and typology as substitutes of each other. A previous report mentioned 3 approach categories for taxonomy: inductive, deductive, and intuitive [43].

With respect to the inductive approach, empirical cases are taken into account. In the following step, they are analyzed so as to realize dimensions and characteristics in the taxonomy. In this type of analysis, a variety of statistical techniques, such as cluster analysis, or other less rigorous techniques are employed [47].

In the deductive approach, the taxonomy involves theory or conceptualization rather than empirical cases. The method uses a logical process that results from a sound conceptual or theoretical foundation in order to clarify dimensions and characteristics in the taxonomy. It is considered to be similar to the cladistics approach in biology [47]. The method may involve an analysis of empirical cases so that even modification of the taxonomy can be performed.

The intuitive approach is considered in the case of necessity. The objects are categorized based on what a researcher comprehends. In this approach, the taxonomy is offered on the basis of the perceptions of a researcher. This technique is not explicitly used [47].

Our proposed privacy taxonomy is derived by the deductive approach. Thematic analysis, which is often called qualitative content analysis, is considered as the methodology for the implementation of the deductive approach and as one of the most favorable methodologies in taxonomy creation [19]. Content analysis, as a research method, is a systematic and objective means of describing and quantifying phenomena. It is also known as a method for analyzing documents. This research method is used for making replicable and valid inferences from the data to their context, with the purpose of providing knowledge, new insights, a representation of facts, and a practical guide to action. In most cases, those concepts or categories are applied to construct models, conceptual systems, conceptual maps, or categories [20].

This type of taxonomy development needs a complete literature review like a systematic or structured review because a systematic review relies on the following: definite time, definite inclusion criteria, definite information sources, and structured study selection according to predefined PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. This method has been described in the Taxonomy Development Characteristics subsection.

Ethics Approval

This study did not include human participants or animals, and thus, ethics approval was not required.

Eligibility Criteria

Published English papers (inclusion criterion 1) related to privacy aspects in the health cloud (inclusion criterion 2) were used to create a privacy taxonomy for the health cloud.

Information Sources

Designated databases, including Web of Science, IEEE Digital Library, Scopus, Google Scholar, and PubMed, were searched from April to June 2020 to identify relevant articles.

Study Selection

Study selection involved the following 5 different phases:

1. Health and computer science databases were chosen to cover all related publications. This step was applied to papers after 2010.
2. “Health cloud,” “privacy,” “medical ethics,” “data management,” “compliance management,” and “medical devices” were the keywords considered with divergent MeSH (Medical Subject Headings) terms.
3. Different search strategies on keywords were adopted for each electronic database to obtain more relevant papers.
4. The identified papers were screened based on the eligibility criteria using their titles, abstracts, and keywords.
5. Papers not eliminated in the previous phase were read completely.

**Taxonomy Development Characteristics**

The new taxonomy was developed on the basis of the deductive approach in 6 phases. The initial phase involved reading data intensively and assessing the papers. The second phase involved configuring the main dimensions to align with the research goals. This phase analyzed the results through Excel files. The third phase included data coding in main classes where the results were categorized. In the fourth phase, the main classes were structured and then arranged into components and subcomponents in an inductive manner, and subcomponents were designated to components. In the fifth phase, the results were categorically analyzed and then presented. The final phase involved reporting and documentation.

A total of 2042 papers were identified, of which 585 were discarded because of repetition in different databases (first layer of filtering according to inclusion criterion 1). The remaining 1457 papers were analyzed on the basis of their titles, abstracts, and keywords. Ultimately, the outcome was divided into 3 categories (second layer of filtering according to inclusion criterion 2).

In the second layer of filtering, initially, 150 papers were chosen according to the privacy, security, and legal domains in the health cloud, which were related to the first category of this work (Figure 1). By reading the full texts in this category, it can be judged that different headlines like compliance management, data management, data governance, information security services, medical ethics, patients’ rights, privacy issues, and technology considerations play important roles in privacy management discipline and influence privacy preservation in the health cloud environment. The identified domains provided a new map and road for the construction of the taxonomy of privacy. These domains led to the identification of probable dimensions, components, and subcategories in related contexts.

Subsequently, with the above-mentioned domains and according to the second layer of filtering (inclusion criterion 2), the rest of this work was conducted, which helped to group the 1307 remaining papers. The full texts of the papers were analyzed according to their details. The findings of the analysis phases showed that many related factors can influence privacy-preserving topics in the health cloud. Consequently, the identified factors were coded and grouped into direct and indirect groups for taxonomy creation, and they formed the second and third categories of the PRISMA guidelines. These factors influence privacy preservation in the health cloud. The findings of study selection are shown in a PRISMA flow diagram (Figure 1).

In this study, according to a previous report [43], attempts were made to cover all qualitative attributes, such as conciseness, robustness, comprehensiveness, extendibility, and explanatory ability. The aim was to develop a taxonomy based on a set of dimensions, with each including characteristics describing the objects comprehensively in a specific domain of interest.

**Table 2** presents the 6 phases involving the formation and adoption of our taxonomy. The subsequent sections present a detailed introduction with respect to each dimension’s components and subcomponents. The privacy taxonomy can be provided in several different approaches, and hierarchical taxonomy is the most notable method.

---

**Figure 1.** PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram. IC: inclusion criterion.
According to the proposed taxonomy, each circle has its subdomains. In the Discussion section, each dimension’s components and subcomponents are introduced in detail.

### Results

After analyzing the identified papers and considering taxonomy development, with respect to studies related to the first category of the method in the digital world, it was found that only documented rules and regulations did not comply with the privacy, security, and legal requirements in the health cloud. To be more precise, compliance alone cannot consider and resolve all the privacy, security, and legal requirements in such a dynamic environment like the cloud, and as mentioned before, some other headings like compliance management, data management, data governance, information security services, medical ethics, patients’ rights, privacy issues, and technology considerations play important roles. To cover all these domains and overcome previous deficiencies, a taxonomy of privacy, security, and legal issues in the health cloud was designed.

As illustrated in Figure 2, this taxonomy has 3 layers. Different features in this context were initially grouped into 4 dimensions, namely the cloud specification, legal aspect, data specification, and device specification in the context of privacy. This classification provided the first or most comprehensive level of generality in the taxonomy of privacy. Other factor identification was related to the next level of taxonomy, and the second and third levels of taxonomy creation and identification led to the introduction of direct and indirect factors for privacy preservation. Then, the basic building blocks or dimensions, components, and subcategories were realized with a qualitative content analysis. The second layer identified 15 components, with each of them having subcomponents (n=57). This well-organized taxonomy has some advantages like presenting the hierarchical root of concepts and the inherited features of taxonomies.

The findings of this paper helped to process and define privacy by identifying a composite set of variables that represent to the extent possible the true nature of interventions and by incorporating the major dimensions of privacy and their constituent parts. Moreover, the findings led to the creation of a new conceptual diagram, which has been presented in Figure 3. The main outcomes or results of this taxonomy appear in this figure, which provides a definite boundary for each of the ambiguous terms like privacy, legal, and security. This figure displays conceptual coverage and overlapping boundaries of these terms in the digital health world, which are crucial for future research, policy making, and the actual management of privacy.

According to the proposed taxonomy, each circle has its subdomains. In the Discussion section, each dimension’s components and subcomponents are introduced in detail.

Discussion

Principal Findings

The details of each dimension’s components and subcomponents (Figure 2) are provided. The main characteristics included in the taxonomy are described and discussed to answer the research question, and an attempt was made to focus on reaching a comprehensive concept regarding privacy.

The question is as follows: Which dimensions and factors affect privacy taxonomy and should be considered in current health cloud projects or systems for privacy preservation?

As mentioned in the Results section, to provide a clear and precise taxonomy according to the method steps, selected papers were studied and analyzed deeply, which led to 4 new dimensions, namely cloud, legal, data, and device. All these dimensions were related to privacy specifications.

In the below sections, each dimension of the proposed taxonomy, and its components and subcomponents are described extensively to provide better understanding for audiences.

Implications

**Dimension 1: Cloud**

The first dimension of this taxonomy is the cloud, which incorporates all aspects of cloud computing technology. It is an evolving paradigm that is useful in the health care context and has an indirect impact on privacy. The cloud dimension has 3 main characteristics, each of which has its specialty: architecture, deployment, and communication. According to the NIST definition, the cloud can be defined based on its characteristics as follows: an architecture or service model, which is defined based on its limited taxonomy, and it can also be defined based on its deployment model with service delivery or business operation, which can affect its features [48]. It is worthwhile to mention that each state of these components will

![Image of proposed taxonomy of privacy in the health cloud]

[Figure 2. Proposed taxonomy of privacy in the health cloud. IaaS: infrastructure as a service; ICAM: identity credential access management; PaaS: platform as a service; PDA: personal digital assistant; SaaS: software as a service.]

[Figure 3. Definitive boundaries between “security,” “legal,” and “privacy” in digital health.]
affect the privacy of information in the cloud, which cannot be ignored.

Furthermore, several methods of communication can be defined between the cloud providers and the cloud customers in the cloud. Each of them contains characteristics having an indirect effect on privacy. These aspects are grouped into 3 parts in Figure 4, with each containing subcomponents.

**Figure 4.** Components of the cloud dimension. IaaS: infrastructure as a service; PaaS: platform as a service; SaaS: software as a service.

**Architecture or Service Model**
There are several service models defined for the cloud, and their subcomponents constitute the first component of the cloud dimension [48-51].

Software as a service (SaaS) enables the client to receive services from applications where providers use cloud services to provide the services. It is important to note that the client cannot manage and control the cloud infrastructure, including networks, servers, operating systems, and storage, or even individual application capabilities.

Platform as a service (PaaS) enables the client to provide services on the cloud through consumer-created or acquired applications created using some programming languages, libraries, services, and tools in the cloud. The difference is that the client no longer manages and controls the cloud infrastructure, including networks, servers, operating systems, and storage, or even individual application capabilities. Hence, the client only controls the executed application and the configuration settings for the application-hosting environment.

Infrastructure as a service (IaaS) enables the client to provide processing, storage, network, and other fundamental computing resources, where the client can deploy and run arbitrary software including operating systems and applications. The client does not manage or control the underlying cloud infrastructure and has control over operating systems, storage, and deployed applications and possibly limited control of select networking components.

**Deployment Model**
The second subcategory of this component is the cloud deployment model [48,49].

Private cloud is used by a single organization that has different consumers and stakeholders. This infrastructure may be administered or handled by that organization, a third party, or their combination and may exist on or off the premises.

Community cloud is used by a specific community of consumers from organizations with shared concerns. This infrastructure may be administered or handled by one or more organizations in the community, a third party, or their combination and may exist on or off the premises.

Public cloud is provided for open use by the general public. This infrastructure may be administered or handled by a business, academic, or government organization or their combination. It exists on the premises of the cloud provider.

Hybrid cloud is composed of two or more distinct cloud infrastructure (private, community, or public), which remain unique entities. They are bound together by standardized or proprietary technology that enables data and application portability.
Communication

Regarding eHealth, providing health care services depends on several communication technologies. This is because each choice contains its characteristics, for which providing security requirements is very important. This section can be divided into the 3 subcategories of synchronicity, network design, and connectivity in terms of its details [22].

Synchronicity is employed to coordinate scheduling and technology. Depending on the schedule, telemedicine services can be provided in 2 modes. The first mode is “real-time,” and it refers to a situation in which the people involved in the care and the care providers are related at the same time with each other but in different location situations. The second mode is “store and forward,” and it refers to a donating situation in which the people involved in the care and the care providers are not connected at the same time. Both modes include different technological infrastructure, including video conferencing, telemetry, and remote sensing, as well as other modes of interactive health communication.

Network design/configuration contains the 3 modes of virtual private networks, open internet, and social networks, and in all of these, the information is posted and then shared. To effectively protect the confidentiality of the information of these states, different security settings are required.

Connectivity may be divided into wired and wireless, with different levels of bandwidth and the attendant speed and resolution or quality of service.

Dimension 2: Legal

According to the assessed studies, the second dimension of this taxonomy is the legal dimension, which can independently provide a framework of legal issues raised in the health cloud. The identified elements of the legal framework have a direct impact on information privacy, which include the 5 main scopes of compliance, data protection, identity credential access management (ICAM), ownership, and quality of service [3]. It should be mentioned that these scopes have a series of subcategories that have been explained in the below text. According to the research findings, privacy and legal issues are completely related and intertwined issues in terms of eHealth. The legal framework scopes are considered as the main components of this dimension (Figure 5).

![Figure 5. Components of the legal dimension. ICAM: identity credential access management.](https://formative.jmir.org/2024/1/e38372/figure5.png)

Compliance

The scope of compliance contains the 3 subscopes of standard, law/act/regulation, and policy/guideline [3].

Standard is a document confirmed through consensus by a recognized body that is provided for repeated and common use, and involves rules, guidelines, or characteristics for products or related processes and production methods in which compliance is not mandatory.

Legislation is comparable with statutory law. Legislation restricts the legal requirements as well as the cost or punishment for breaking the law. Most regulations are issued by governments [52].

Policy or guideline is a formal, brief, high-level report or proposal that indicates an organization’s principles, goals, objectives, and acceptable procedures for a topic [3]. Guideline is related to general instructions in order to achieve policy principles. It provides a framework to implement the required procedures.

Data Protection

The second scope of this dimension encompasses the details of data protection to provide the technical mechanisms of the requirements introduced in the first scope. Data protection is distributed into the 3 main classes of technical, administrative, and physical issues according to the NIST, Health Insurance
Portability and Accountability Act (HIPAA), and Certified Information Systems Security Professional (CISSP) [53].

Technical aims to define supply-related techniques, such as confidentiality, integrity, and nonrepudiation of cloud-based patient data. **Confidentiality** is the guaranteeing process that makes data property or information available or accessible only for authorized people or processes [54]. **Integrity** is the property to ensure the prevention of data or information tampering in an unauthorized manner. **Nonrepudiation** involves service guarantees to make an action taken undeniable.

Administrative involves security infrastructure with a management and development approach, and the implementation and support of systems are discussed [38].

Physical measures policies and procedures to protect the electronic information systems of an entity and the related buildings and equipment from natural and environmental hazards as well as unauthorized intrusion [53].

**Identity Credential Access Management**

The third scope of the second dimension includes data access management, which is a key factor in patients’ rights and medical ethics. Some pertinent fields like identification and authentication, authorization and access control, auditing and monitoring, and user training issues are also placed in this scope. This is a process in which a unique identity is defined for the person or system [53]. It is known as the first step in the access control process, such that it controls any activity based on the identity or entity of the user.

The process of identification and authentication identifies and authenticates the user, which is possible based on the elements and private data created by the user [53].

Authorization is the process of defining the resources and the level of access for the user [53].

System monitoring or auditing is the last loop of this cycle that plays an important role in recording the log of all the activities, events, and performances of the users who have access. Moreover, it is considered a security check [55], which is very important to identify problems and violations with accounts, access, information disclosure, and system operation.

**Data Ownership**

The fourth scope of this dimension is related to data ownership, which is responsible for concepts such as information ownership and responsibility. Information control not only speaks about the creation, modification, and other convolutional procedures of data, but also deals with the rights of individuals to grant or revoke their access to others [12].

The ownership of data in the cloud may rely on the nature of the stored data [12]. Data owners must be able to assess, control, and restrict their data during storage, use, and disclosure [56,57]. Nevertheless, the existing shortcomings in the implementation of these statements in the cloud are considered as some of the essential problems for implementing the cloud in the health sector [57]. This scope encompasses some subsopes like data location issues, third party issues, and patient consent.

Data location involves the storage of data. One of the points in the cloud is that data storage can be carried out in any places, even unknown ones.

Patient consent is derived from the ethical and basic principles of human and citizenship rights in terms of the patient’s discretion [58,59]. In this regard, the patient has the freedom to decide whether the tests and surgeries on the organs can be performed before any action [59-61].

Third party is considered as a cloud provider that does not have any role in the patient’s treatment process as a beneficiary. Nevertheless, it has access to all patient information that can cause several legal dilemmas.

**Quality of Service**

In the fifth scope of this dimension, some issues, such as contract, service availability, and interoperability, are stated, and this has been referred to as quality of service (QoS). It defines guaranteed levels of performance, availability, reliability, interoperability, throughput, performance, response time, etc, all of which are regarded as major factors influencing the quality of service in cloud computing [62].

Contract issues involve a service level agreement (SLA). This is a mutual agreement between cloud service providers (CSPs) and end users. Quality of service management systems monitor resources, storage, networks, virtual machines, service migration, and fault tolerance [63-65].

Availability involves principles ensuring that authorized users at a proper time have access to the data [53].

Interoperability involves the ability of the system to render services using multiple service providers while preserving the integrity of the data. This feature can be used for all kinds of clouds so that if migration to a different system is required, it can be seamlessly carried out [63,64].

**Figure 6** illustrates the coverage of information security services by legal dimension elements in privacy taxonomy. It is impossible to preserve privacy without considering information security services in dynamic environments, such as the cloud, as these services can ensure benefits in terms of outsourcing the health records [3].
Dimension 3: Data

Data structures are critical in various cloud environments, such as data storage features, data processing methods, and data preserving solutions, designed for this dynamic ecosystem. The third major dimension of our proposed privacy taxonomy is related to data characteristics, which have been divided into the 5 subcategories of data type, data life cycle, data usability, data sensitivity, and data acquisition methods. Figure 7 depicts the structure of the data dimension, although the components of this dimension have an indirect effect on privacy.

Data Type

Any data related to health conditions, reproductive outcomes, causes of death, and quality of life are health data [66]. It is worthwhile to mention that health data can measure several criteria, such as clinical, environmental, and socioeconomic factors, both at the individual and population levels, including information about a person’s behavior related to his or her wellness. The accumulation of collected and utilized health data occurs when interacting with health care organizations. The collected data typically contain the received service types, the
results of those services, and the clinical outputs or information included in those services.

Health data can be classified into 2 structured or unstructured types. The structured type is a standard that can be simply exchanged between health information systems [66]. For example, a patient’s name, date of birth, or blood test result can be recorded in a structured data format. However, unstructured health data are not standard, unlike the structured type. Emails, audio recordings, or physician notes about a patient are examples of unstructured health data.

Advances in the digital world have improved the collection and use of health data and the databases in the health care industry, which have certain complexities. Overall, in terms of health and care, the data can be classified based on the data type as follows [21]: alphabetical data/textual data/narrative data, numerical data/measurements/coded data, signal data, images/graphic data/pictures, voice, and videos/film.

Data Life Cycle

The second scope of the third dimension in the designed privacy taxonomy is data life cycle, which contains 7 phases [67], each including its requirements for privacy. This cycle encompasses the following phases: data generation, data transmission, data storage, data access, data reuse, data archiving, and data disposal. Data life cycle is comparable with the cloud requirements [68-70].

Data generation involves CSPs receiving requests from their users to generate the related data so that they can assign their access control policies.

Data transmission involves CSPs generating a secure transmission channel to verify user data reliability. Besides, they use encryption methods and the digital certificate mechanism between servers.

Data storage involves the role of CSPs to ensure the conformity of the data in the right place according to the agreements and rules.

Data access involves the CSPs ensuring the validity of users’ identity to protect them from spoofing and verifying the proper execution of the data access policy.

Data reuse can lead to leakage of sensitive or personal data, which is a reason for not providing services in the cloud. In the big data era, data sharing has made this phase quite primitive.

Data archiving involves 3 main operations, including band encryption, long-range storage, and data retrieval.

Data disposal is mainly aimed at placing the data completely and effectively in the cloud and removing unnecessary parts.

Medical Data Usability

Medical data have very diverse functions, including personal interests, public health, medical research, and development [21]. The use of the data in applications is categorized into 2 modes of primary and secondary. Primary is a state where the collected medical data are employed to provide medical care. Secondary is a state where the collected medical data are employed for purposes except care.

Here, it is worth noting that digitization and updating based on medical information technology have increased the use of medical data at both primary and secondary levels [21,71]. The data in the patient’s medical file appear in 1 of the following 3 formats based on their origin and applications: demographic data (identification data/date of birth, admission, discharge, biometric identifiers, phone number, and health record number); clinical data (clinical results/images/summaries, medical data, case management, public health data, performance data, and referral management); and administrative data (insurance documents/financial information and nonclinical data focused on record keeping surrounding a service, such as hospital discharge information; it can be part of an electronic health record as well; claims data, which include information regarding insurance claims).

Data Sensitivity

One of the important points in privacy preservation is the grading of data regarding their degree of importance. It is performed according to data sensitivity to classify the data based on their sensitivity and the extent of their impact on the patient and the health organization. Accordingly, these importance-based data cannot be disclosed, changed, or destroyed without permission. Classification of the database helps to specify the level of security required by the data. The data are categorized based on their importance level as presented below [72].

Restricted sensitivity of data involves a situation where the data have high sensitivity (restricted sensitivity), and unauthorized access and disclosure of the data may result in significant risks, leading to severe or disastrous adverse effects on the operations and assets of an organization or individual, particularly a patient or health care institution. This level of sensitivity needs the highest level of security controls that must be applied to restricted data.

High sensitivity of data involves a situation where the data have high sensitivity, and unauthorized access and disclosure of the data may alter or destroy the data, leading to serious adverse effects on the operations and assets of an organization or individual, particularly a patient or health care provider. This level of sensitivity needs a reasonable level of security controls that should be applied to private data.

Moderate sensitivity of data involves a situation where the data have moderate sensitivity, such that unauthorized access and disclosure, alteration, or destruction of the data would result in moderate risks for the operations and assets of an organization or individual, especially a patient or health care institution.

Low sensitivity of data involves a situation where the data have less sensitivity, and unauthorized access and disclosure, including alteration or destruction of the data, would lead to a limited risk to the operations and assets of an organization or individual, especially a patient or health care institution, or there will not be any risks.

Data Acquisition Methods

When emerging health services arise from the context of modern technologies, such as the cloud, mobiles, wireless multimedia sensor networks (WMSNs), and Internet of Things (IoT), some
new scenarios are raised for health care services. These scenarios consist of patient care in hospitals, patient care at home, and self-care scenarios, with each representing a special type. Hence, the protection of data privacy in each scenario requires its characteristics. The important point in terms of privacy preservation in any of these scenarios is to know how to collect the data. Overall, there are 2 collection methods in all these scenarios [21].

In the manual method, data are described subjectively or objectively by the patient and then inferred by health care providers. Then, these data are entered into health information systems manually through personal portals. In the device base method, several medical devices (either wired or wireless) collect data. Subsequently, the collected data are sent to applications for processing to be used by health care providers. Evidently, different types of devices will be fully described in the next section since they play substantial roles in ensuring privacy.

**Dimension 4: Device**

The last dimension identified for the taxonomy of privacy is concerned with devices and their features because, with the advancement of technology, data collection is practically entrusted to devices. Thus, ensuring data privacy is the most important concern of stakeholders in terms of diversity of use.

A medical device is an outfit used to evaluate or diagnose a medical condition [61], for example, electrocardiography machines, ultrasound machines, x-ray machines, different sensors, wireless sensors, and mobile health apps that run on smartphones. Ensuring data privacy on these devices has been an issue in many studies, which makes it challenging in terms of the cloud. As a result, regarding privacy in the cloud, it is essential to consider the features of medical devices. Certainly, the elements defined in this section will have an indirect impact on information privacy in the health cloud. As shown in Figure 8, the device dimension is divided into 2 subcategories: device types and application types.

![Figure 8. Components of the device dimension. PDA: personal digital assistant.](https://formative.jmir.org/2024/1/e38372)

**Device Types**

WMSNs involve wireless sensors, which are some of the most common devices in the medical world. It is considered as the smallest network and has unique features such as large-scale implementation, portability, and reliability [73]. It should be mentioned that the sensor network encompasses a set of independent nodes with low cost, energy, and memory, and limited computing power [73]. The health care industry has experienced a dramatic transformation with the use of WMSNs [74]. The main aim of WMSNs is to collect and transfer environmental data to central databases or remote locations. IoT is another popular tool in recent years [65,75], which has created a new technological paradigm in the health care industry. In eHealth, IoT has provided the possibility of interaction and communication between “things” via the internet. In future health care circumstances, IoT will connect subjects and health care professionals seamlessly [76,77].
These technologies can be used for eHealth applications, such as computer-assisted rehabilitation, early detection of medical issues, and emergency notifications. However, there is an issue because several factors limit the use of these technologies. The most important factor is legal issues related to the privacy and security of the data transmitted [78-81].

Smartphones have become an integral part of life. Thus, they can act as a gateway between the wireless body area network (WBAN) and IoT [82-84]. Essentially, the smartphone’s sensor data or high-resolution camera images are sampled, processed into medical information, and displayed [84]. Using smartphones for medical purposes can be very useful because millions of people have their own smartphones today and can access medical applications designed for health care [61].

Tablets/personal digital assistants have the same applications as smartphones, acting as a gateway to collect medical data beyond providing accessibility to reference textbooks [85].

Personal computers play a pivotal role in information management. Computers potentially alter the traditional approach that physicians use to communicate with patients [86] and have an essential role in information management. In other words, they can change the traditional ways of providing health services to patients and replace them with novel innovative methods [86].

All of the above-mentioned tools with increasing use in medicine must comply with certain features to ensure the privacy of data since ignoring these features can cause some irreparable damage.

**Application Types**

Care processes across virtually all basic medical specialties and subspecializations associated with disease entities, sites of care, and treatment modalities are included. The vast array of these applications and the complexity of the medical practice and medical specialization are listed separately [22]. The second device subcategory is related to application types.

Basic specialties include content areas around specific diseases, including diabetes, stroke, and posttraumatic stress disorder, and such applications have been developed. Moreover, programs may differ by the site of care, including the intensive care unit, outpatient psychiatry unit, emergency department, and home. Some programs were organized around specific treatment modalities such as rehabilitation and pharmacy. Over 40,000 health applications have been used on smartphones [61]. The World Health Organization has classified mobile health applications as follows [70]: toll-free emergency, health call centers, public health emergencies, mobile telemedicine, information initiatives, appointment reminders, community mobilization, treatment compliance, patient records, surveillance, health surveys, patient monitoring, decision support systems, and awareness raising [20]. Depending on the site of care, these applications have several privacy requirements that must be identified and met. In other words, the privacy of a user’s data in the devices depends on the security of the designed computer programs.

**Comparisons to Existing Literature**

From these dimensions, it is understandable that the legal dimension and its subcomponents have direct influence on privacy and other dimensions like data, device, and cloud along with their subcomponents, as well as an impact on privacy preservation concerns in the cloud environment.

In contrast with other taxonomies, this taxonomy sides with health data specification and cloud considerations, which appear critical. Therefore, this article first tries to adopt the privacy taxonomy in the cloud context, especially in the health cloud, and the remainder is dedicated to redefining privacy terms with new details.

The health care domain has the most complicated scenarios and most varied data among businesses. Thus, when a taxonomy fits with its requirements, the taxonomy might be appropriate for other domains, businesses, and scenarios that are complex. In fact, the user of the model should exercise judgment as to the appropriate level of detail necessary to test the target hypothesis.

**Usability and Experimental Use of This Taxonomy**

This well-organized taxonomy has some advantages like presenting the hierarchical root of concepts and inherited features of taxonomies. It provides a heuristic representation of hierarchies with 4 dimensions of privacy and the branches of each dimension. This model allows for more specification of independent variables in model development and with regard to research objectives. Experimental use of this taxonomy depends on the following stages: scenario clarification stage, device and system specification stage, data specification stage, and privacy mapping stage.

In the first stage, the specification of cloud-based scenarios should be clarified. For example, which service model and cloud deployment have been chosen for health care delivery and which communication method has been chosen to connect the stakeholders individually or with each other (synchronized or unsynchronized; wired or wireless).

In the second stage, the use of medical devices and application types for data collection should be prominent and transparent to users because each device has its specific privacy requirements.

In the third stage, data specifications collected in each scenario should be explicited because the veracity in data specifications can lead to variations in privacy strategies. For instance, in one scenario, electrocardiography data detected by the WMSN and transferred via a designated mobile health app to the cloud for storage, processing, and use will have special privacy requirements. In another self-care scenario, subjective data that are just entered through a cloud-based personalized portal need a different set of privacy requirements.

In the fourth stage, to ensure privacy preservation in all means, the identified features in other stages should match with legal components from the proposed taxonomy. For example, proper corresponding security services like authentication, authorization, auditing, confidentiality methods, integrity, and nonrepudiation methods should be chosen for each type of health
care scenario in the digital world. Through these approaches, stakeholders can trust eHealth.

This taxonomy generally has 2 layers of stakeholders (people and organizations, and applications and systems).

The first layer involves people and organizations, including patients; health cloud and general cloud providers; health care providers (eg, physicians and nurses); health care organizations (eg, hospitals, laboratories, drug stores, and physicians’ offices); cloud app developers and vendors; health domain stakeholders (eg, insurance companies and financial organizations); researchers and practitioners working in areas like health, cloud, data management, security, and privacy; medical ethics authorities; organizations planning to design and deploy cloud services and migrate to cloud platforms and services; governments and legislation bodies; and national or international standardization bodies. These groups, according to the scenario clarification stage, device and system specification stage, and data specification stage, map their privacy preferences with respect to the proposed privacy taxonomy.

The second layer involves applications and systems that are affected by this taxonomy, including patient assessment systems; teledmedicine systems; medical imaging systems; public health systems; hospital information systems; clinical information systems; health data secondary use systems; teleconsultation systems; self-care systems; and medical device and wireless system producers (WMSN, IoT, etc). These systems by their provisions can meet privacy requirements according to the proposed privacy taxonomy.

Considering the above-mentioned stakeholders, among the main approaches to deal with privacy challenges, identifying the contributing factors and dimensions can be helpful to manage this domain.

Limitations of the Study and Future Work

This study has some limitations. The interchangeable use of some related terms like “security,” “privacy,” and “legal” made the close assessment of articles difficult, and it was challenging to obtain findings from related comprehensive articles with regard to health industry scenarios.

An attempt was made to include English papers; therefore, the results must be considered within the scope of the English literature and studies in a specific interval. Any papers published before or after the search interval were not included; however, there is always the possibility of missing some relevant information or bias.

Future studies can be conducted to identify or propose definite standards and requirements for privacy preservation in each subcategory of known dimensions. It is hoped that the proposed taxonomy will not only clarify nomenclature proliferation in privacy for the health cloud or eHealth, but also provide a useful guide for research and policy making.

This taxonomy is not a finished product and needs more attention with regard to development and improvement. The process has been initiated with the hope that others in the field will be interested in it and complement the privacy taxonomy in the health cloud. Furthermore, this taxonomy can be considered as the subject matter for experts in various domains of privacy for assessment, testing, revision, and verification.

Conclusion

This research was conducted to identify the factors affecting privacy in the health cloud and classify them to provide a unique and comprehensive taxonomy through the investigation of related papers. It redefines the health cloud privacy term by using a deductive approach.

The proposed taxonomy tries to provide the true and full perspectives of the intervention, management, and handling of other variables, as well as itemize the expected outcomes and determine how best to assess them, thus clarifying the units of analysis in health cloud privacy research.

The subscribed elements have been classified into the 4 main dimensions of cloud, legal, data, and device. Moreover, since taxonomy designing is an iterative process, 15 components and 57 elements were added to these 4 main dimensions in 3 layers. Among all these elements, those classified in the legal dimension had a direct impact on data privacy in the cloud. However, other elements will have an indirect impact on ensuring data privacy in the cloud.

In the second step, this taxonomy tried to clarify the privacy concept in eHealth, which is a multidisciplinary context, and tried to remove the ambiguities between existing definitions in the field of security and define a clear boundary for the words. This led to the distinction and clarification of the overlapping and vague structure of related concepts, and privacy was defined by identifying the discrete sets of variables representing specific privacy configurations and definitive boundaries for “security,” “privacy,” and “legal” terms, which are crucial for future research, policy making, and the actual management of privacy. Therefore, users can have a more accurate definition of the concepts in this field in the future.

This taxonomy is designed to satisfy the needs of emerging technologies, such as mobile health, health IoT, telemedicine, etc, which use cloud devices in their infrastructure. Moreover, it can be considered as supplementary classification and a reference for current privacy, security, or technological taxonomies.

Hence, this taxonomy can cover health industry requirements with its specifications like health data and scenarios, which are considered as the most complicated among businesses and industries. Therefore, the use of this taxonomy could be generalized and customized to other domains and businesses that have less complications.

This paper has also reviewed the most popular previous taxonomies in the privacy domain.
Acknowledgments

I thank the Health Information Department of Allied Medical Sciences for providing very close support, and useful feedback and advice.

Abstract

Background: MTV Shuga is an edutainment campaign designed to equip young people with knowledge, motivation, and informed choices to protect themselves from HIV infection. From 2019 to 2020, a total of 10 episodes of a new dramatic series, MTV Shuga “Down South 2” (DS2), were broadcast via television and the internet, alongside complementary media activities.

Objective: This study aims to investigate whether the intensity of DS2 exposure was linked with positive HIV prevention outcomes in a setting with high HIV prevalence and relatively low levels of HIV testing.

Methods: We analyzed data from a web-based survey of participants aged 15 to 24 years in South Africa in 2020. The survey was promoted via social media platforms of schools, universities, and communities in Eastern Cape, South Africa. The primary exposure of interest was the intensity of exposure to DS2, measured by the number of episodes of DS2 watched on the television or the internet or listened to on the radio (out of 10 episodes). Individuals who had not watched or listened to any DS2 episode were classified according to other MTV Shuga content that they had accessed. We estimated associations between the intensity of DS2 exposure and HIV-related outcomes, including knowledge of HIV status, awareness of HIV self-testing (HIVST) and pre-exposure prophylaxis (PrEP), uptake of HIVST, and demand for HIVST and PrEP, adjusting for potential confounders using multivariable logistic regression.

Results: Among the 3431 survey participants, 827 (24.1%) were exposed to DS2. Specifically, 18.1% (622/3431) watched or listened to only 1 DS2 episode, and 2.4% (82/3431), 1.7% (58/3431), and 1.8% (62/3431) watched or listened to 2 to 4, 5 to 7, and 8 to 10 DS2 episodes, respectively. Increasing the exposure to DS2 was associated with improvements in most outcomes. Exposure to multiple episodes (eg, 2-4, 5-7, and 8-10) was associated with successively higher odds of knowing one’s HIV status, awareness of PrEP and HIVST, and uptake of HIVST compared with no MTV Shuga exposure, albeit with statistical uncertainty around some estimates. The interest in using HIVST or PrEP was high overall (>80%), with no measurable differences by DS2 intensity.

Conclusions: We found evidence consistent with a dose-response relationship between MTV Shuga DS2 exposure and outcomes, including knowledge of HIV status, awareness and uptake of HIVST, and awareness of PrEP among young people in Eastern Cape. This indicates that greater engagement with a youth-focused edutainment campaign can improve HIV testing and prevention options in a setting and population with high need. However, only a few participants accessed multiple DS2 episodes despite its availability on multiple media platforms. We conclude that there is potential to benefit more young people by increasing access to and interest in the show.

(JMIR Form Res 2024;8:e44111) doi:10.2196/44111
Introduction

Background

Over the course of the HIV/AIDS epidemic, edutainment and mass media campaigns have played an important role in health promotion, with some successfully raising awareness of HIV transmission, prevention, and treatment as well as contributing to increases in condom use [1-10]. To reach their target audiences, campaigns have used different modes of delivery such as print (eg, comic books), audio (eg, radio), video campaigns (eg, television), celebrity influencers, the use of peers or community workers, or a combination of different strategies [1,10]. As technology and the internet have become more accessible, edutainment campaigns have expanded to incorporate digital solutions, such as social media, mobile phone apps, websites, and on-demand streaming channels, to achieve broader reach [3,11].

Progress in reducing new HIV infections has been reported in many countries [12]. However, gaps within the HIV prevention cascade persist among young people [13,14], a key target population for HIV prevention in many African countries. In South Africa, for instance, the analysis of survey data indicates that knowledge of HIV status among individuals aged 15 to 24 years has steadily increased from 19% in 2005 to 59% in 2017, but this proportion is still low compared with older age groups [15]. HIV testing is a crucial step in HIV prevention and treatment programming [12]. As a complement to provider- or client-initiated HIV testing and counseling, HIV self-testing (HIVST) can help reduce the testing gap among younger individuals who may prefer convenience and privacy and who may forego or be unable to access health care facilities [12,16]. In addition, awareness and uptake of pre-exposure prophylaxis (PrEP), which is now recommended as part of combination prevention for individuals at increased risk of HIV acquisition, remains low among young people [17]. As new HIV prevention options become available, edutainment campaigns can be adopted to enhance awareness through messaging that resonates with young people. This can, in turn, create demand for, facilitate uptake, and support the effective use of such options among young people.

Evidence of the impacts of edutainment campaigns that rely on dramatized series among young people has grown in recent years but remains limited [1,6,8,9]. MTV Shuga is an edutainment campaign designed to equip young people with knowledge and motivation to protect themselves from HIV infection while navigating healthy relationships. Shuga uses compelling characters and storylines to disseminate messages on HIV prevention through a series of parallel but interlinked storylines, which are offered over multiple episodes and media channels. From 2019 to 2020, a new series of MTV Shuga called Down South 2 (DS2), comprising 10 episodes, was produced in South Africa. DS2 episodes were broadcast via television and the internet alongside complementary media and offline activities, which included a documentary, peer-led discussions, DS2 graphic novels, and community-based viewing events [6,18]. The producers of DS2 conducted formative research through focus group discussions with young people to develop and validate the content, storylines, character development, and scripts, as they did for all previous MTV Shuga series [6,19,20]. Briefly, DS2 storylines largely revolve around characters who have recently left high school and are navigating life and the challenges that many young people face, including financial hardship, family conflict, and sexual relationships. Detailed descriptions of example storylines for DS2 have been documented previously [19]. In a recent evaluation of the DS2 series among young people aged 15 to 24 years in South Africa, we found that young people who engaged with the DS2 campaign (any component) were more likely to know their HIV status, use HIVST, and be aware of PrEP compared with those who did not engage with DS2 [6]. However, this analysis did not explore the intensity of DS2 exposure and whether greater exposure is linked with greater impacts.

In the absence of randomization, exploring whether the impact of an intervention differs across different intensities of exposure can support the plausibility of a causal association between the intervention and the outcomes [21,22]. Although little information exists regarding associations between the amount of exposure to edutainment campaigns and HIV-related outcomes among young people [1,8], published evidence from mass media campaigns in general populations suggests that high exposure intensity is associated with better health outcomes. In an evaluation of a weekly television soap opera on HIV/AIDS in Côte d’Ivoire by Shapiro et al [23], women who had watched ≥10 episodes (out of 20) were more likely to use condoms compared with nonviewers, whereas no effect was seen among women who watched <10 episodes. The authors concluded that repeated exposure to relevant content through continuous engagement partly contributed to the observed effects [23]. In an evaluation of an intervention to address domestic violence in South Africa (Soul City campaign, “SC4”), participants in rural residences with high exposure to SC4 television media (accessed ≥9 out of 13 episodes) were more likely to “do something to stop domestic violence” compared with those with no or low (<5 episodes) exposure, with little effect seen among those with moderate exposure (5-8 episodes) [24].

Objectives

In this study, we investigated whether the intensity of DS2 exposure was linked with differential impacts on HIV prevention outcomes. Understanding and documenting such effects can offer insights to implementers and program designers on ways to maximize engagement and benefits for adolescents and young adults.

Methods

Study Setting, Sample, and Data Collection

The analysis for this paper was based on quantitative data from a mixed methods evaluation study conducted in 2020. This
study aimed to evaluate the impacts of engagement with DS2 on HIV-related outcomes among young people in Eastern Cape, South Africa. The quantitative component used a self-administered web-based survey hosted on a website free of internet data charge for users and captured sociodemographic characteristics; exposure to MTV Shuga content (e.g., how young people engage with DS2 and how many episodes they watched or listened to); and outcomes including knowledge of HIV status, awareness and uptake of HIVST, and awareness of PrEP. The survey was promoted via social media platforms; through targeted advertisements; and via social media accounts of schools, universities, and communities in the Eastern Cape. To avoid the risk of SARS-CoV-2 transmission, all study activities were conducted remotely. Additional details of the mixed methods evaluation are documented elsewhere [6].

Measures

Exposure Variables

In this study, the primary exposure of interest was the intensity of exposure to DS2 dramatic series, measured by the number of episodes of DS2 watched on television or the internet or listened to on the radio (out of 10 episodes). Some individuals had not watched or listened to any DS2 episodes but accessed other formats of Shuga, including Down South 1 (DS1, the first series of Down South), which preceded DS2. Rather than grouping these individuals with those not exposed to any Shuga content, we classified them based on the specific MTV Shuga content they had accessed. These additional categories captured exposure to other MTV Shuga content, for which the intensity could not be inferred. On the basis of this definition, seven exposure categories are analyzed in this paper: (1) no exposure to MTV Shuga content, (2) exposure to any MTV Shuga format other than the DS2 dramatic series, (3) exposure to DS1 series, (4) exposure to only 1 DS2 episode, (5) exposure to 2 to 4 DS2 episodes, (6) exposure to 5 to 7 DS2 episodes, and (7) exposure to 8 to 10 DS2 episodes.

To understand with whom young people watched or listened to DS2 and whether this influenced the intensity of DS2 exposure and the impacts of exposure, we generated a secondary exposure variable with four categories as follows: watched or listened to DS2 (1) alone, (2) with peers only (e.g., friends or partners), (3) with parents (e.g., mother, father, grandparents and siblings or peers), and (4) with siblings (e.g., siblings only or siblings and peers).

Outcome Variables

Outcomes included knowledge of HIV status, awareness and willingness to use HIVST and PrEP, and the uptake of HIVST. Furthermore, we analyzed 3 sexual behavior outcomes (ever had sex, had sex in the past 12 months, and condom use during last sex with current or last partner [in the past 12 months]). The definition of each of the outcomes is summarized in Multimedia Appendix 1. All measures were self-reported.

Analysis

We summarized the frequencies and proportions of respondents reporting each of the above-mentioned outcome measures based on the intensity of DS2 exposure. We estimated the associations between the intensity of DS2 exposure and each outcome using multivariable logistic regression models, adjusting for potential confounding variables. To limit the number of confounding variables adjusted for in the regression models, the selection of covariates in this study was informed by an earlier analysis that assessed the effects of binary exposure to DS2 (yes or no) on the abovementioned outcomes [6]. The initial set of confounding variables was identified using a directed acyclic graph to represent the hypothesized causal relationship between exposure to DS2, study outcomes, and other sociodemographic characteristics [6]. Only variables associated with each outcome at $P \leq 0.10$ in the previous analysis were included in this analysis. From these regression models, we present the unadjusted and fully adjusted odds ratios (aORs) with their respective 95% CIs. To assess evidence of a dose-response relationship between DS2 intensity and the odds of each outcome, we compared 2 multivariable models: in the main model, the intensity of DS2 exposure was included as a categorical variable (model 1), whereas the other model assumed a linear relationship (model 0). The results from model 0 indicated whether the data were consistent with a linear trend, whereas a likelihood ratio test comparing model 0 with model 1 provided additional information regarding whether the relationship was more complex than linear [25]. All multivariable logistic regression models were restricted to individuals with nonmissing responses for each outcome. This decision was informed by the earlier analysis, which showed similar findings between complete case analysis and imputation methods [6]. In a secondary analysis, we assessed (1) whether the distribution of intensity of DS2 exposure varied by who young people watched or listened to DS2 with using $\chi^2$ tests and (2) whether these variations had differential effects on outcomes of interest following the regression approach described previously. This secondary analysis was conducted only among individuals who said they had watched or listened to DS2.

Ethical Considerations

Ethics approvals were obtained from the Biomedical Research Ethics Committee at the University of KwaZulu-Natal (Ref: BREC/00000477/2019), the London School of Hygiene and Tropical Medicine (Ref: 17996), and the World Health Organization (Ref: ERC.0003283). All participants aged ≥18 years provided web-based consent, and participants aged <18 years provided their informed assent, with their parents or guardians providing informed consent [6]. To ensure participants’ confidentiality, we did not collect any identifying information other than mobile phone numbers for those who completed the survey to facilitate transfer of mobile data credit of ZAR50 (approximately US$5). We de-identified the data prior to conducting the analysis.

Results

Characteristics of the Study Sample

A total of 4145 records from the web-based survey were created by the users. In total, 82.8% (3431/4145) of the records were taken forward for analysis after removing records without full consent (407/4145, 9.8%) or sex information (144/4145, 3.5%) and likely duplicates (163/4145, 3.9%). We identified potential
duplicates using a combination of date of birth and mobile phone numbers. Respondents were predominantly female (2020/3431, 58.9%), aged 20 to 24 years (2352/3431, 68.6% vs 1079/3431, 31.5% aged 15 to 19 years), enrolled in education (2857/3431, 83.3%), and resided in urban settings (2923/3431, 85.2%; Table 1). Household ownership of media assets was high, with proportions ranging from 56.8% (1949/3431) for computers or other digital devices to 82.5% (2832/3431) for televisions. Most respondents had their own smartphones (2922/3431, 85.2%), and 50.8% (1744/3431) had their own computer. Digital media engagement was high in the study population: 86.1% (2953/3431) reported using the internet and social media platforms at least once a week, and 74.1% (2542/3431) and 62.4% (2141/3431) watched television or listened to the radio at least weekly, respectively. A detailed summary of the study population has been described elsewhere [6].

**Data:**
- Table 1 presents sociodemographic characteristics of survey participants, including age, sex, schooling, employment, language spoken at home, province, residence, food insecurity, and relationship status.

**Notes:**
- Table entries include counts and percentages for different exposure categories.
- Some categories show higher numbers due to varying sample sizes.
- The data reflects a comprehensive overview of participant characteristics.
Intensity of Exposure to MTV Shuga DS2

The components and proportions comprising each exposure category are summarized in Table 2. Of 3431 respondents, 1487 (43.3%) had been exposed to some form of MTV Shuga content. This comprised 9.9% (n=338) of the respondents exposed to MTV Shuga formats other than the DS2 dramatic series, 9.4% (n=322) of the respondents exposed to DS1 but not DS2, and 18.1% (n=622) of the respondents exposed to 1 DS2 episode. The proportion of respondents exposed to multiple DS2 episodes was low at approximately 2% within each category of 2 to 4 episodes (84/3431, 2.4%), 5 to 7 episodes (59/3431, 1.7%), or 8 to 10 episodes (62/3431, 1.8%). Repeated exposure to DS2 episodes was mainly through television or the internet (Table 2).
Table 2. Components used to define exposure categories and proportions of young people accessing each component (N=3431).

\textsuperscript{b}DS: Down South series.

\textsuperscript{c}DS2: Down South 2.

\textsuperscript{d}DS1: Down South 1.

\textsuperscript{e}Participants exposed to DS1 may have been exposed to other MTV Shuga formats (but not DS2).

\textsuperscript{f}Participants exposed to DS2 may also have been exposed to DS1 or other MTV Shuga formats.
Participants were classified as having watched 1 episode of DS2. hTVET: technical and vocational education and training.

Of the 238 participants who had watched DS2 on television, MTV Shuga website, or YouTube, 162 (68.1%) had started watching DS2 the year before our evaluation. The intensity of exposure to DS2 was similar across most categories of participant characteristics, although there were some relatively small differences of approximately 5% to 8% in absolute terms for schooling or employment status, sexual history, and food insecurity; 9.7% (129/1330) of those who had ever had sex accessed ≥2 DS2 episodes compared with 3.2% (41/1291) of those who had never had sex, the corresponding proportions were 11.9% (26/218) among those who reported experiencing food insecurity often versus 6.2% (70/1139) among those who experienced moderate food insecurity, and approximately 9.5% (69/726) among those in school or university versus 2% (19/967) among those in technical and vocational education and training institutions (Table 1).

Regression Results for DS2 Intensity

The proportion of respondents who knew their HIV status, were aware of PrEP and HIVST, and had used HIVST (ever and in the past year) increased with increasing DS2 exposure intensity. There was evidence of a nonlinear association between the intensity of DS2 exposure and knowledge of HIV status (nonlinear \(P = .06\)), awareness of PrEP \((P < .001)\), and awareness of HIVST \((P = .003)\). For uptake of HIVST and willingness to use HIVST or PrEP, the data were consistent with a linear trend \((P = .38\) for lifetime use of HIVST; \(P = .33\) for use of HIVST in the past 12 months; \(P = .36\) for willingness to test self with HIVST kit; \(P = .76\) for willingness to give kit to partner; and \(P = .46\) for willingness to take PrEP every day). The proportion of respondents reporting each of these outcomes was always the lowest among those not exposed to any MTV Shuga content (Multimedia Appendix 2).

Knowledge of HIV status was 28.1% (431/1535) among those not exposed to any MTV Shuga content and highest among those who had watched or listened to 8 to 10 DS2 episodes (45/53, 84.9%; Multimedia Appendix 2). In the adjusted analysis, increasing DS2 exposure was associated with increasing knowledge of HIV status. Compared with individuals not exposed to any MTV Shuga content, the aORs for those who had watched or listened to 1 DS2 episode, 2 to 4 DS2 episodes, 5 to 7 DS2 episodes, and 8 to 10 DS2 episodes were 2.65 (95% CI 2.01-3.49), 3.92 (95% CI 2.05-7.48), 3.82 (95% CI 1.84-7.91), and 5.72 (95% CI 2.46-13.32), respectively (Figure 1; Multimedia Appendix 2).

Figure 1. Forest plots summarizing the associations between different MTV Shuga Down South 2 (DS2) exposure intensities and HIV testing and pre-exposure prophylaxis (PrEP) outcomes. HIVST: HIV self-testing.
Similarly, increasing DS2 exposure was associated with increased awareness of PrEP in the adjusted analysis: for example, 47.2% (215/456) of those who had watched or listened to only 1 DS2 episode versus 17.1% (251/1469) of those not exposed to any MTV Shuga content (aOR 2.38, 95% CI 1.83-3.09) and 76% (38/50) of those who had watched or listened to 8 to 10 episodes versus 17.1% (251/1469) of those who were not exposed to any MTV Shuga content (aOR 2.38, 95% CI 1.83-3.09; Figure 1; Multimedia Appendix 2). Exposure to DS2 was not associated with willingness to take PrEP (which was high overall at 1851/2284, 81%; Figure 1; Multimedia Appendix 2).

Regarding lifetime awareness of HIVST (ever heard of HIVST), proportions ranged from 18.8% (284/1509) among those who were not exposed to any MTV Shuga content to 56.4% (270/479) among those who had watched or listened to only 1 DS2 episode and to 75% (39/52) among those who had watched or listened to 8 to 10 episodes. In the adjusted analysis, those exposed to 2 to 4, 5 to 7, or 8 to 10 episodes of DS2 had >5 times higher odds of being aware of HIVST compared with those not exposed to any MTV Shuga content (Figure 1; Multimedia Appendix 2). Lifetime use of HIVST was 26.4% (125/474) among those who had watched or listened to only 1 DS2 episode versus 7.8% (115/1483) among those not exposed to any MTV Shuga content (aOR 2.49, 95% CI 1.83-3.38), 32.8% (21/64) among those who had watched or listened to 2 to 4 DS2 episodes (aOR 3.93, 95% CI 2.16-7.15), 35.2% (19/54) among those who had watched or listened to 5 to 7 episodes (aOR 4.74, 95% CI 2.50-9.02), and 40% (21/53) among those who watched or listened to 8 to 10 episodes (aOR 4.57, 95% CI 2.46-8.50).

Likewise, in the adjusted analysis, watching or listening to an increasing number of DS2 episodes was associated with increased odds of using HIVST in the past year (Figure 1; Multimedia Appendix 2). Among those who had never used an HIVST before, interest in using HIVST on oneself or interest in giving an HIVST kit to a partner was high overall (83% for both), with no differences in the number of DS2 episodes accessed (Figure 1; Multimedia Appendix 2).

Compared with respondents who were not exposed to any MTV Shuga content, DS2 audiences who had watched or listened to multiple episodes of DS2 were more likely to ever have sex in their lifetime and had sex in the past 12 months (Figure 2; Multimedia Appendix 3). Among those who reported having sex within the past 12 months, there was no evidence of a departure from a linear trend between DS2 exposure intensity and condom use (P=.23; Figure 2; Multimedia Appendix 3). There was evidence of a nonlinear association between DS2 exposure intensity and sexual history (ever or in the past 12 months; nonlinear P<.001).

**Figure 2.** Forest plots summarizing the associations between different MTV Shuga Down South 2 (DS2) exposure intensities and sexual behavior outcomes.
Effects of Other MTV Shuga Content or Formats

Regarding knowledge of HIV status, awareness of PrEP and HIVST, and lifetime uptake of HIVST, there was evidence that exposure to other forms of MTV Shuga content (other than the DS2 dramatic series) was beneficial, compared with no exposure to MTV Shuga content. For instance, knowledge of HIV status was 74.4% (215/289; aOR 2.52, 95% CI 1.78-3.56) among those who had watched DS1 and 63% (182/289; aOR 1.84, 95% CI 1.33-2.54) among those who had accessed other MTV formats compared with 28.1% (431/1535) among those with no exposure to MTV Shuga content (Figure 1; Multimedia Appendix 2). Furthermore, those exposed to these other forms of MTV Shuga content were more likely to have had sex (ever or within the past 12 months) compared with those with no MTV Shuga exposure (Figure 2; Multimedia Appendix 3).

How Young People Watched or Listened to DS2

Among those who had been exposed to at least 1 DS2 episode and provided information on how they accessed the series, 50.6% (119/235) had watched or listened to DS2 with someone, 33.6% (79/235) accessed alone, and 15.7% (37/235) reported a combination of the 2 (Table 3). Among those who had watched or listened to DS2 with someone, 45.5% (71/156) did so with peers only, 25% (39/156) with parents, and 29.5% (46/156) with siblings. The findings were similar by age group (P=.45; Table 3). The intensity of DS2 exposure did not differ significantly by how young people accessed DS2 (P=.46), although higher proportions of repeat viewers watched or listened to DS2 with a parent than those who watched or listened to 1 DS2 episode. For example, 19.3% (16/83) of the participants who accessed 2 to 4 DS2 episodes did so with a parent compared with 2.9% (1/35) among those who accessed 1 DS2 episode (Figure 3). We were unable to establish whether our outcomes of interest differed by the intensity of DS2 exposure, given how young people accessed DS2, because of insufficient data to conduct the regression analyses.

<sup>a</sup>Among those who had watched or listened to at least 1 Down South 2 episode and provided information on how they accessed the episodes.
Figure 3. Intensity of Down South 2 (DS2) exposure by how young people watched or listened to DS2 episodes.

Discussion

Key Findings

This study aimed to understand whether the intensity of exposure to the MTV Shuga DS2 series had differential impacts on the outcomes of interest. We found evidence that the levels of knowledge of HIV status, awareness of PrEP, and use of HIVST (ever or in the past year) increased with increased exposure to DS2, consistent with a dose-response effect. We found no evidence of an effect of DS2 exposure intensity on the interest in using HIVST or PrEP (a proxy for demand), which was already high in the study population. In our study sample, repeated exposure to DS2 episodes was mainly through television or the internet.

Regarding how young people access DS2, findings indicate a mix of preferences, with the majority watching or listening to DS2 alone or with peers (eg, friends or partners) and less so with siblings and parents. Although there was little influence of these preferences on the intensity of DS2 exposure, we found higher proportions of repeat viewers watched or listened to DS2 with a parent, compared with those who accessed only 1 episode. This suggests that accessing DS2 with parents may have helped some young people to watch more episodes. However, it is worth noting that some of our study participants avoided watching with parents because they feared that it would be awkward or that the parents would judge or lecture them on sex and relationship matters, as documented in our related qualitative research [19]. Others may have preferred watching or listening to DS2 alone for privacy reasons, as documented in another study [11]. These findings point toward the need to ensure privacy and nonjudgmental spaces in the delivery of campaigns targeted to young populations. Our related qualitative research showed that watching or listening to DS2 spurred interpersonal conversations and discussions with peers and sometimes with parents, as reported elsewhere [3,19]. Discussions where peers engaged in debates about DS2 characters and storylines led to shared learning and support systems where people felt safe to discuss sexual health topics and disclose personal information [19]. This could deepen the influence of the show for the viewer (beyond just watching), for example, through greater internalization, and future research could consider these events as mediators along a pathway between exposure (eg, to MTV Shuga content) and HIV and health outcomes.

The observed dose-response effects on knowledge of HIV status, awareness of PrEP, and use of HIVST (ever or in the past year) might reflect that more exposure facilitates increased levels of narrative engagement and, in turn, helps the viewers or listeners to retain a greater amount of relevant content compared with someone with little or no exposure. This might particularly be true when the audience is interested in finding out what eventually happens to the characters, often facilitated by the immersive nature of the DS2 series. As documented in our qualitative research, the emotional and dramatic storylines kept participants engaged as they wanted to know what would happen next [19]. In addition, the re-emphasis of content across multiple storylines allows participants to access content that they may have missed previously. Previous research has documented that participants in dramatized series tend to actively reflect on the plotlines and often compare the characters’ ways of confronting dilemmas across storylines, which presents a learning opportunity for the audience [3,5]. In a cluster randomized trial of MTV Shuga in Nigeria, the effects of MTV Shuga were stronger for viewers who were more immersed or highly identified with the characters while watching the show [9]. Although we did not measure identification with characters in this analysis, we drew on other evidence from the larger mixed methods study, which indicates that young people found the show relatable. In a miniseries called MTV Shuga: Alone Together (which aimed to disseminate timely and accurate information on COVID-19), developed in the same manner as
DS2, ≥90% of young people (in the same study sample as this paper) who had watched the miniseries indicated that they found it entertaining, informative, memorable, and realistic (I Birdthistle, PhD, unpublished data, February 2021). One of the key findings from the nested qualitative study conducted as part of our research to understand why young people engaged with DS2 was that young people found the show relatable as the storylines reflected real-life issues that they or people they knew experienced [19]. Younger participants appreciated how the show embraced the uncertainty that often surrounds such decision-making (as opposed to simplistic or moralistic messaging). In addition, some viewers reported being introduced to HIVST and PrEP for the first time through the show, and less experienced viewers felt more prepared for future sexual relationships and decision-making based on the scenarios explored in DS2 [19]. The high identification with the DS2 characters and storylines likely enhanced the effect of watching DS2. The larger effects among those who watched or listened to multiple DS2 episodes suggest the potential benefits of viewing dramas as a whole rather than as a series of parallel storylines, as documented elsewhere [5]. However, it is worth noting that a viewer or listener may miss relevant content completely when scenes are relatively few and short [6]. Although there is uncertainty around our effect estimates, given the low proportion of participants who accessed multiple episodes of DS2, there remains a clear overall pattern for these outcomes (except those on demand) that more DS2 exposure is better.

We did not find evidence of a dose-response relationship between DS2 exposure intensity and demand outcomes (ie, interest in using HIVST and PrEP), which were already high in the study population. Similarly, higher DS2 exposure intensity did not result in greater condom use. Although DS2 influenced awareness and motivation to use HIV prevention products and services, including HIV testing and PrEP, the actual provision of these products was not part of the DS2 campaign [6]. Qualitative research findings indicate that many participants were unsure of the availability of these services and products in their own setting, which could partly explain the limited effect on demand for these products [6]. This finding highlights the crucial role that actual provision and access to these HIV prevention tools play in influencing behavior, in addition to awareness and motivation to use these methods [26]. It is possible that our analysis is underpowered to detect smaller differences when assessing the dose-response effect for demand measures, given the high absolute proportions of these outcomes in our study sample and the fact that very few study participants accessed multiple DS2 episodes. MTV Shuga audiences who had watched or listened to multiple episodes were more likely to have had sex in their lifetime or in the past 12 months compared with those who had never engaged with the campaign, suggesting that DS2 may be reaching those most in need of HIV prevention methods. In addition, given the social desirability associated with reporting of sexual behaviors, it is possible that those who watched MTV Shuga episodes felt less judged or stigmatized and so were more likely to be open about sexual history.

Only 6% (205/3431) of the study respondents had accessed ≥2 DS2 episodes despite their availability on multiple media platforms (eg, YouTube [Google LLC], South African Broadcasting Corporation, local radio stations, and MTV Shuga website) and our sample’s high engagement with media (3101/3431, 90.4% watching television, listening to the radio, or watching YouTube at least once a week). The low repeated exposure in our study is consistent with results from an evaluation of MTV Shuga DS1 in KwaZulu-Natal, where only 8% of 1853 adolescent girls and young women aged 13 to 23 years had watched ≥1 episode (out of 24 episodes) [27]. In an evaluation of a 24-episode drama series on sexual and reproductive health among Latinx adolescents and young women in the United States in which participants were randomized to either a control group or 1 of the 4 experimental arms (based on different storytelling formats), only 6% of those assigned to experimental arms went on to watch the full episodes after exposure to different formats [3]. These estimates are much lower than those from multimedia studies targeting general populations, where exposure to multiple episodes (≥5) is as high as 30% [4,23]. The low exposure to multiple episodes in our study may reflect various issues inherent in engaging a relatively young population (aged <25 years). First, young viewers or listeners often have no control over when episodes are aired on television or radio channels and given that they might actively avoid watching or listening to MTV Shuga episodes with parents or older siblings for reasons summarized previously, this can limit their ability to access complete or multiple episodes. Limited affordability and availability of the internet and data plans may prohibit access to content offered via streaming platforms such as YouTube or the MTV Shuga website [28]. Even with extensive efforts to create relatable storylines, we acknowledge that it can be challenging to capture the wide range of complexities in the lives of adolescents and young adults in 1 show, and there may be a proportion of participants who are not interested in the show entirely. In addition, it is possible that some young people may have decided to stop watching or listening after 1 episode because they did not find the episode interesting enough. Future research can aim to understand the complete range of reasons for “disengagement” in different contexts and age groups.

Given our study findings that more DS2 exposure is better for many of the outcomes and the fact that a high proportion of our study sample engaged with “offline” DS2 content, it might be worth finding ways to facilitate and increase offline viewing of DS2 episodes. In particular, peer education and school education programs are good complementary options because they (1) do not require constant internet connectivity (which may prohibit access via YouTube or MTV Shuga website) and (2) can create a safe space for young people (who prefer to watch alone or with peers) to watch without having to worry about the reactions and judgment of older adults. In addition, short clips or extensions can be used to deliver and highlight critical components (eg, HIV testing and PrEP) so that people do not miss them. These could be offered through social media platforms, which are popular among young people. We note here that the specific combinations of activities that program designers and implementers use will depend on the scope and
goals of the campaign. For instance, if promoting high intensity of exposure (ie, access to multiple episodes) is the goal, then complementary activities may need to incorporate and deliver full episodes rather than sharing shorter formats (eg, on social media), with the latter more suited for raising awareness and enhancing interest in general. Many web-based platforms also allow viewers to download episodes and watch or listen later, and sensitizing young people about this option can potentially facilitate more access. The recent inclusion of MTV Shuga on Netflix is likely to widen its reach, although it may reach those who are already connected and able to pay for the service. Furthermore, for some young people, getting their parents interested in watching Shuga might improve their exposure intensity. As we learn from the COVID-19 pandemic, public health players need to be innovative and adaptive, and using a combination of strategies to reach the target populations is worthwhile [29].

Strengths and Limitations

One of the study limitations is that we relied on self-reported measures that are subject to recall bias. Some of the behavioral questions (eg, on sexual history) may also be subject to social desirability bias. To ensure participants’ confidentiality and to help minimize social desirability bias, we did not collect any identifying information (although mobile phone numbers for those who completed the survey were obtained to facilitate the transfer of mobile data credit). Furthermore, the survey was self-administered, and we anticipated that participants would complete the interviews in private, which could increase the accuracy of the self-reported information. Regarding recall bias, we feel that most of our behavioral outcome measures are related to events that people are likely to remember (eg, testing for HIV in the last year and taking PrEP). Many of our questions included options such as “don’t know” and “prefer not to answer” to accommodate participants who may not have an opinion regarding the question at hand. Approximately 6 (68%) out of 10 participants had started watching DS2 the year before we conducted our evaluation, and this may have influenced their ability to accurately recall the exact number of DS2 episodes accessed. Participants who were exposed to DS2 but did not know how many episodes they had watched or listened to were assumed to have been exposed to only 1 DS2 episode. Furthermore, we did not collect information on how frequently offline components such as graphic novels were accessed, and thus, individuals exposed to DS2 content not offered through radio, television, or the internet were also assumed to have been exposed to only 1 DS2 episode. We may have misclassified these individuals if they had indeed been exposed to multiple episodes. Although we adjusted for various potential confounders in all our analyses, we cannot rule out residual confounding and other possible explanations for the observed associations. Moreover, it is possible that those with a higher awareness of HIV in general might be more likely interested in accessing DS2, resulting in reverse causality. The strengths of the study include the assessment of multiple outcomes, the rich data on exposure to multiple MTV Shuga content, and information on how young people accessed DS2. Among those not exposed to DS2, we were able to capture exposure to other MTV Shuga content. Although this resulted in “nonnatural” categories of DS2 exposure intensity, it allowed us to identify whether individuals exposed to other MTV Shuga content had better outcomes than those not exposed to any MTV Shuga content at all.

Conclusions

Several studies have examined the effects of edutainment campaigns on sexual and HIV-related health outcomes among young people; however, few have examined the intensity of exposure and whether increased engagement resulted in greater benefits. In this study, we found that increasing DS2 exposure was associated with increasing knowledge of HIV status, awareness of PrEP, and use of HIVST. This is consistent with a dose-response effect and supports the plausibility of a causal association between DS2 and HIV prevention outcomes among young audiences. Overall, relatively few participants viewed multiple episodes of DS2, and supporting young people to view or listen to more episodes of the DS2 campaign can yield benefits for more young people. If promoting high intensity of DS2 exposure (ie, access to multiple episodes) is the goal for a given campaign, incorporating complementary activities that support the delivery of full episodes rather than sharing shorter formats may be useful. A more complete and immersive experience can be offered through better and more equal digital access and through school programs and peer education programs, taking into account young people’s preferences when designing and delivering these campaigns.

Acknowledgments

The authors would like to thank all the young people who contributed their time to this study during the COVID-19 restrictions in 2020. The authors are grateful to Antonio Duran-Aparicio for the support in making this project possible. The authors acknowledge the dedication of MTV Shuga peer educators and coordinators (Yvonne Diogo and Lesedi Thwala) in South Africa; the resilience of the team at Epicentre Health Research; and the commitment of the MTV Staying Alive Foundation, especially Georgia Arnold and Sara Piot.

Abstract

Background: The use of digital technologies for health care has been the focus of social studies, which have concentrated on the digital divide between individuals who use technology and those who do not—with the latter often being considered as individuals with shortcomings. In Denmark, 91% of the population have computers and 97 out of 100 families have internet access, indicating that lack of access to technology is not the primary reason for nonuse. Although previous studies have primarily focused on participants’ perspectives of using internet-based treatment for alcohol use disorder (AUD), no study has investigated individuals’ reasons to prefer face-to-face treatment over blended face-to-face and internet-based cognitive behavioral therapy (bCBT) for AUD among treatment-seeking populations.

Objective: The aim of this qualitative study was to investigate the nonuse of bCBT among patients with AUD. Specifically, this study aims to explore patients’ reasons for choosing not to receive treatment via this format.

Methods: This study was conducted among Danish patients with AUD who were enrolled in the study “Blending internet treatment into conventional face-to-face treatment for alcohol use disorder (Blend-A)” but had not used bCBT. The participant group consisted of 11 patients with AUD: 3 women and 8 men. The age range of the participants was 29-78 years (mean 59 years). Individual semistructured interviews were conducted using cell phones to gather participants’ reasons for not choosing bCBT. The interviews were recorded, transcribed, and analyzed using thematic analysis. Five authors performed the analysis in 3 steps: (1) two authors read the transcripts and coded themes from their immediate impression of the material, (2) one author provided feedback, which was used to group overlapping themes together or create new themes that better reflected the content, and (3) the remaining two authors provided feedback on the analysis to improve its structure, readability, and relevance to the research aim.

Results: We found that the participants had various reasons for choosing face-to-face treatment over bCBT; these reasons were more related to personal matters and lesser to digital health literacy. We identified 4 themes related to personal matters for choosing face-to-face treatment over bCBT: (1) patients’ need for attending sessions in person, (2) preference for verbal communication, (3) desire for immediate feedback, and (4) feeling more empowered and motivated with face-to-face sessions.

Conclusions: This study provides valuable insight into participants’ perspectives on blended therapy for AUD and highlights the importance of considering personal factors when designing digital health interventions. Our study indicates that most of the...
participants choose not to use bCBT for AUD because they perceive such treatment formats as impersonal. Instead, they prefer direct communication with the therapist, including the ability to express and comprehend facial expressions and body language.

**Introduction**

**Background**

Social studies of the use of digital technologies for health care have focused on the digital divide—the division between individuals using technology and those who do not—the latter viewed as merely individuals with deficits [1,2]. These deficits may cover a range of difficulties and barriers, which can occur when engaging with technology [3]. In general, social groups with higher education and higher income seem to have more knowledge, motivation, and competency in initiating steps toward a healthy lifestyle [4], in addition to having fewer barriers toward digital solutions [5]. For example, Heponiemi et al [6] described how individuals who do not use computers have lesser education, higher unemployment, lower income, and poorer health, and found a risk of digital exclusion among those who have lower socioeconomic status, poorer health, or are more socially isolated. Nonetheless, in Denmark in 2020, 97 of 100 families had internet access, 96% had a mobile phone, and 91% had a computer [7], which indicates that people in Denmark are regular users of digital technologies. Therefore, it may be anticipated that digital treatment interventions targeting individuals with alcohol use disorder (AUD), like guided internet-based cognitive behavioral therapy (iCBT), may be an appreciated intervention among the Danish population, although there may be barriers toward seeking treatments for AUD in general and specifically toward digital solutions.

A review [8] has shown the general barriers toward seeking traditional AUD treatments. For example, Wallhed Finn et al [9] conducted a study among nontreatment seekers with alcohol dependence on their perceptions of alcohol consumption, dependence, and barriers toward seeking face-to-face (FtF) treatment for AUD. They found participants to be generally negative toward FtF treatment, for example, due to stigma and shame. For this group of nontreatment seekers, an internet-based intervention like iCBT can be perceived as a potential first step toward entering treatment—both to assess one’s alcohol use and to receive guidance for suitable treatment.

Barriers toward engaging in iCBT for AUD have not been investigated much. In a study on attrition during a web-based treatment for problem drinkers, Postel et al [10] found the second most common reason for noncompletion of an internet-based intervention to be dissatisfaction with the intervention itself, for example, that it was too time consuming or demanding and did not meet personal needs. In another study of user experiences of internet-based treatment for problematic alcohol use, Ekström and Johansson [11] identified the following barriers toward engaging in internet-based AUD treatment: lack of recognition in the content of the intervention, too much text and repetition, too little (meaningful) support or feedback, lack of contact with a therapist, and lack of guidance.

Combining iCBT with FtF CBT is referred to as blended CBT (bCBT). bCBT for AUD may propose a treatment solution that combines a high level of discretion and flexibility in addition to being guided and person-centered [12]. It might, so to speak, offer the best from both the aforementioned treatment modes. Participants in that study [12] were offered bCBT, but they opted out of using bCBT as they preferred solely FtF CBT. We found this intriguing and important since we anticipated that bCBT, in particular, would be perceived as an attractive offer due to the high familiarity of the Danish population with digital technology. Thus, in this study, we wished to explore participants’ reasons for deciding against and opting out of using bCBT. To our knowledge, no study has previously investigated patients’ reasons to prefer FtF over bCBT or iCBT for AUD among treatment-seeking populations.

**Aim**

In this study, we sought to understand individuals’ perceptions of bCBT and iCBT for AUD when they are introduced to this type of treatment format by the therapists. In particular, we aimed to explore participants’ reasons for choosing a treatment strategy that solely consists of FtF treatment and not digital solutions, when offered the possibility of a flexible combination of FtF and iCBT.

**Methods**

**Settings**

This study is a substudy under the study “Blending internet treatment into conventional face-to-face treatment for AUD (Blend-A)” [12]. At the beginning of the overall study, 18 Danish municipal treatment institutions participated, but only 14 clinics remained throughout the whole study period. The clinics are quite similar in structure and treatment content offers. In Denmark, the municipalities offer AUD treatment free of charge to the individual patient. The treatment is based on treatment manuals stemming from evidence-based treatment methods such as CBT and motivational interviewing (MI) [13]. A typical treatment course entails acute treatment for withdrawal symptoms, followed by a series of either individual or group-based sessions. The duration of the treatment courses depends on the patients’ needs.

A treatment layout for AUD that consists of a combination of FtF treatment and internet-based modules, which was developed in The Netherlands [14], was translated and adjusted to fit Danish language and culture [15]. During the Blend-A study,
all participants entered AUD treatment in the participating clinics were offered to receive all or part of their treatment course in Blend-A. Blend-A is operated as bCBT, where patients can use iCBT on a web-based platform, hosted by the Dutch company Minddistrict, in combination with attending FtF CBT sessions at the clinic. The degree of blending is agreed upon among specific clinics, therapists, and patients. One example is that, when blending, the patient would attend FtF CBT every sixth instead of fourth week. The platform entails 21 sessions with written material, visual resources, and assignments following CBT and MI. The therapist can offer a short paragraph of written feedback on some of the solved assignments for further elaboration during the FtF CBT. The format is flexible and the patients can access the web-based platform when it suits them. The platform can be accessed anonymously, if needed. The patient can go back and look at the earlier solved assignments, if needed. The implementation of the study commenced in June 2020 and ran until ultimo December 2022.

**Participant Recruitment**

Participants in this study were recruited among the participants in the Blend-A study who did not engage in bCBT. In total, 1033 participants were enrolled in the Blend-A study; of these, 606 (58.6%) did not register for an iCBT profile on the web-based platform, and thus, did not make use of the CBT offer. All Blend-A participants filled out a baseline survey and were invited to fill out a 6-month follow-up survey, no matter to which degree they had made use of bCBT for AUD, if at all. The 6-month follow-up survey was collected electronically or on the telephone by researchers, not knowing until the last questionnaire, whether the Blend-A participants had actually used bCBT for AUD. A random sample of 60 participants participating in the Blend-A study without bCBT were telephoned by author SB and invited to participate in telephone-based individual interviews for this study about their reasons for not wanting to use bCBT for AUD. Some did not answer the telephone, some did not feel that they could contribute as they could not remember having been offered bCBT, and some did not wish to participate and gave no reason for this. Twelve participants agreed to participate and scheduled an appointment for an interview; in 1 case, however, we failed to reach the participant.

**Data Collection**

Data were collected using semistructured individual interviews with an interview guide, available in Multimedia Appendix 1. The interview guide was not pilot tested, and no repeat interviews were performed. The questions were inspired by relevant subjects found in the literature, asking about the participants’ background, experiences with using digital technology in their everyday lives, and their reasons for not choosing the offered bCBT for AUD. Furthermore, the questions were open-ended, leaving room for pursuing any given direction set by the participant. The interviews were conducted by a psychology student intern, Jakob Godsk Nielsen, and the first author KT. Neither were involved in the clinical treatment in this study. No relationship between the interviewer and interviewee was established prior to study commencement. The interviewees had no prior knowledge about the researchers, and no characteristics about the interviewees were reported to the interviewees other than that the interviewers were researchers. The interviews were conducted over telephone, lasted between 30 minutes and 45 minutes, and were audiotaped and transcribed in NVivo (QSR International) in full length by authors SB and CD. The transcribed interviews were not returned to the interviewees for commenting and corrections, and no field notes were made during the interviews. We used COREQ (Consolidated Criteria for Reporting Qualitative Studies) [16] as a checklist for reporting on the interviews. Data were anonymized and securely stored.

**Data Analysis**

The transcribed interviews were analyzed in the qualitative software support system NVivo by using thematic analysis [17]. First, all transcripts were read to obtain an overall immediate impression of the material. Along reading, the material was coded by themes that came to the mind of the authors (KT and RC, both female postdocs, who holds MA degrees in anthropology and philosophy, PhD degrees within health sciences, and approximately 10 years of experience within the field). Second, another author (ASN) commented on the transcripts with the coded themes. Based on these comments, the authors (KT and RC) recoded the material with focus on overlapping themes grouped together or recoded with new themes that more accurately specified the content. Lastly, the 2 remaining authors (RB and MPF) gave their feedback on the themes, structure, and readability of the analysis, leading to the final themes as expressed by the participants who had chosen not to use bCBT. The participants did not provide feedback on the findings. The collected themes are further described in the forthcoming results section.

**Ethics Approval**

This study was conducted according to the current ethical standards. The protocol for the Blend-A study was approved by the scientific research ethics committee of the Region of Southern Denmark (project identification S-20190166G). The Danish Data Protection Agency gave the permission to collect and store data (record 20/12692). After receiving both oral and written information about the study, the participants signed a consent form. Further, participants were informed about their rights to withdraw their consent at any time, without any consequences on their treatment course.

**Results**

**Participant Sample Description**

Ultimately, 11 participants participated in this nonuse study. The baseline characteristics of the participants are shown in Table 1. The participant group consisted of 3 women and 8 men, with a mean age of 59 (SD 16) years. The youngest participant was 29 years, and the oldest participant was 78 years. Five of the participants were married or in a relationship, 5 were single, and 1 was widowed. The participants were all educated—either within craftsmanship or had a short, intermediate, or long higher education. Five were currently employed, 3 were unemployed, and 3 had retired. They all described having an everyday schedule, wherein they got up and went about their daily activities. Five had an education—either within education or had a short, intermediate, or long higher education. Five were currently employed, 3 were unemployed, and 3 had retired. They all described having an everyday schedule, wherein they got up and went about their daily activities. Five had an education—either within education or had a short, intermediate, or long higher education. Five were currently employed, 3 were unemployed, and 3 had retired. Five had an education—either within education or had a short, intermediate, or long higher education. Five were currently employed, 3 were unemployed, and 3 had retired.
activities. Besides, 2 of them had additional mental illness, and 4 had somatic illness. The participants had used alcohol problematically for 3-30 years (mean 11 years). Their reasons for seeking treatment were to find someone to talk to and to receive help, support, and advice. They expressed that they needed tools to reduce their alcohol use. During the interviews, the participants self-assessed themselves to be super users of technology (n=2), intermediate users (n=7), and having limited digital competencies (n=2). Compared to the profile of 44,516 patients, who had a total of 88,057 treatment courses in Danish alcohol treatment institutions between 2006 and 2014 [18], our study sample was somewhat older.

Table 1. Baseline characteristics of our study participants compared to those of patients seeking treatment in Danish alcohol treatment institutions in 2006-2014.

<sup>c</sup>N/A: not applicable.

Description of Themes

Two participants considered themselves to be technology super users, 7 felt that they were intermediate users, and 2 felt that they were inadequate digital users. The 2 latter participants felt that they had insufficient digital competencies for receiving treatment via the internet, as they did not understand it and felt unacquainted and terrible at it. One participant elaborated as follows:

...I am really bad at internet and all such technical stuff. I am also old. I did not grow up with it. But during that time where I had to be able to use it at work, I learned the basics to manage. Besides that, I have never done more about it. And when I stopped working, I also got rid of the internet. I simply don’t use it. [Participant ID 1002]

It was unclear if the participant was reluctant about bCBT because of insufficient digital competencies or if the participant merely did not find technology use engrossing. The participant did not believe that he or she had the digital competencies to make use of bCBT, even though the participant had been a former internet user and had used technologies at work. However, in general, neither this nor the other participants reported feeling insecure or unsafe about using the internet as such. Nine out of 11 participants who chose to receive FtF CBT instead of bCBT for AUD explained that their choice had rather to do with them feeling a need for attending the sessions in person. This need consisted of multiple facets. The participants seemingly felt being exposed by having to enter a treatment center, thereby accepting that someone might recognize them. They described that when having reached this far in surrendering to the fact that they had an alcohol problem, they could not risk that treatment could fail. The participants had a wish to gain as much as possible from the treatment course, considering FtF CBT to be the safe route to success. The participants considered that when feelings were involved, there was a risk that they would become emotionally upset during the process. When being upset, they anticipated that there might be a difference between being at the computer alone and being in a room with a person who might tell if you were, for example, anxious. One participant described how being in a vulnerable position demands a level of maintenance, which may succeed through verbal communication upheld by the therapist, as this could offer dialogue, nuance, and reflection, asking more deeply into and seeing behind difficult issues. The participants seemed to link physical appearance with the ability to move the therapy forward. Some of the participants explained that videoconferencing and telephone calls would also be okay.
if it was a synchronous conversation but not as a substitute for physical attendance during treatment.

Accordingly, an often mentioned factor that influenced the participants’ choice was that they considered internet-based treatment to be impersonal and that they preferred to be physically present in the same room as the therapist. The perceived benefit of FiF CBT was, according to the participants, the possibility of instantaneous communication. The participants believed being physically near to the therapist would enable a more trustful relationship, as described below:

...here people in question need help, and they need a pat on the back when things go well and help when things go bad. I do not think you can do that over mail (… with an email, you just become a number in a line, instead of a person who needs a shoulder to cry on and an ear that minds to listen…..) When the matter is alcohol, then I do not think it is something that can take place over an email. Because then I think that I would feel pissed on. [Participant ID 957]

The above quote shows how participants perceive internet-delivered therapy to be impersonal—a concept often used in digital technologies although not specified. The quote above shows that what constitutes not perceiving the FiF treatment as impersonal is the ability to feel the presence of the therapist and having the feeling of being understood and respected—something that the participant considered was difficult to be accomplished over an email from the therapist. A participant considered that to receive an email, even if it is a part of the internet-delivered treatment program, was equal to being as a number in a line.

Another factor that had an impact on the participants preferring attending sessions in person was the ability to see the therapists’ body language and look at them into their eyes during the sessions. This ability led the participants to believe that they could better comprehend the therapists and their responses. Being able to have questions elaborated on and clarified immediately was of importance to 5 of the participants. One example concerned personally sensitive subjects, where the participants found it easier to receive a response if they articulated the matters in a conversation compared to an email exchange, wherein the therapist might not have the time to answer right away. The participants’ wish was to have such issues settled instantly. One participant elaborated on the importance of receiving a quick clarification on outstanding matters:

...If I am in front of the therapist I am talking to, I would be able to get a response right here and right now. Then I can park it and it does not have to live inside my body anymore. Then it is out of the body. Away, fine, it is gone, finished (…) then I can move on. Then it doesn’t live inside my brain, fill up space, or spend resources anymore. [Participant ID 1091]

The immediate feedback was of importance to the participants in situations where they felt alone and in doubt about how to understand a question. The physical presence of the therapist enabled them to receive a quick clarification and thus be able to move on. The verbal communication made sense to the participants as they felt safer and assessed it to be more giving. They felt that they could gain more from verbal communication because they could tell, explain, and inform, which enabled them to instantly see reactions or signals from the therapist, which they needed to act on, or give the therapist the possibility to ask questions allowing the participant to elaborate. It was their experience that a message is better understood when you look into each other’s eyes while communicating, as it is easier to reflect on what has been said and let it sink in before one answers and then give a more precise answer based on the discussions and the reflections based on the discussion. Below, is the transcript of one participant as a voice for all:

...It is because there is some communication that you cannot always see, and something happens when you talk to people that does not happen when you write. What happens is that you reflect differently when you have a conversation and a dialogue. It is also easy to write that “all is well.” In a person, you can see if it is and maybe say “well, are you sure about that?” (Laughs). [Participant ID 1128]

Another advantage of FiF mentioned by the participants was that sitting in front of the therapist made them feel more obliged to adhere to the treatment or more compliant in relation to not drinking. The participants expressed how they felt dutiful and believed that if they had agreed upon attending an FiF CBT session, they would not cancel it. They imagined that it would be easier to cancel an internet-based session, thereby giving them an opportunity to choose the easy way out.

The participants also believed that it was beneficial that FiF therapy enabled synchronous sessions with the therapist, while on the web-based platform, the correspondence is asynchronous and the participants can use it when they want, which they believed to be risky for them and thereby the treatment. Sessions held in person make it more difficult to cheat the therapist with regard to drinking compared to web-based sessions, where they considered that it would be easier to continue their drinking. One participant unfolded this drawback as follows:

...When you make an agreement, I think it is nice that you can look each other into the eyes. Especially when it is about alcohol, then I cannot just say “I promise.” There is just something about the human contact. [Participant ID 957]

In other words, the participant considered that the commitment is stronger if expressed FiF to the therapist compared to in writing during a web-based session. Thus, choosing solely FiF CBT rather than also making use of internet-based solutions meant deciding on taking responsibility for and committing strongly to their own treatment. Finally, the participants reported that FiF CBT sessions enable them to concentrate on their situation and focus on the treatment—a dimension that is perceived as necessary to maintain the consistency in their rehabilitation. Thus, we suggest that participants gauge their need for treatment and choose the treatment that best suits them and would be beneficial for them. Participants in this study are aware that they will not continue their treatment if it fails in their life and find that FiF CBT is a better option than just “keeping up appearances” through internet-delivered therapies.
Discussion

This study aims to investigate the perceptions that are prevalent among participants who decide to opt out of the possibility of using bCBT for AUD and instead continue with FtF CBT without merging it with internet-based modules. We found that the participants had various reasons for preferring FtF CBT over bCBT, and these reasons were mainly related to personal choices.

Participants’ Assumed Need for Attending Sessions In Person

Being physically in front of the therapist was considered to strengthen a more personal connection between the participant and the therapist and thus the central reason for preferring a synchronous FtF verbal dialogue. Participants considered that FtF allows for all aspects of communication with the therapist to come into play, including nonverbal communication, eye contact, and body language. In a systematic review on women’s expectations and experiences regarding eHealth treatment, Verhoeks et al [19] found 3 studies that showed women’s negative expectations with regard to receiving eHealth treatment. Those studies showed that the eHealth treatment was perceived as rather impersonal treatment and that the participants valued immediate and empathic responses in their dialogues with the therapist and stressed the importance of nonverbal communication through eye contact and bodily expressions. In the study by Verhoeks et al [19], the women expressed an intuitive preference for FtF CBT. They feared that the absence of personal contact would make their treatment course more impersonal and impact negatively on their alignment with the therapist, their motivation, and consequently on their treatment outcome.

In this study, we found that the participants had similar feelings as they took their rehabilitation process seriously. They chose the treatment form that they believed they could gain the most from—to them, it was FtF CBT. In general, we found that participants choose FtF CBT rather than bCBT because they had been in a vulnerable position in their rehabilitation process. In particular, it was of importance to them to have a sense of privacy and having a person in front of them when the subject is a personal and vulnerable matter. Since some of the participants had recently stopped drinking, they felt vulnerable in the situation because they realized how alcohol had got hold of them and now were dependent on a therapist’s assistance and guidance to help reduce their alcohol use.

Participants Preferring Verbal Communication

In particular, the participants in our study considered verbal communication to be better than digital written communication to express dialogue, nuances, and reflections and to allow clinicians to ask deeper questions and grasp difficult issues. Further, the participants considered that they would gain more from verbal communication than from digital communication, as they assumed that it enabled clinicians to immediately react to participant’s signals and ask questions about their understanding of the said. The review of Verhoeks et al [19] also reported difficulties in explaining complex situations and feelings in written text compared to communicating through verbal FtF sessions. In their study [19], participants commented that they were afraid that the therapist would misunderstand their issues given in writing. In this study, the participants stressed the importance of a conversation, in which they would be able to ask questions and discuss problems with the therapist because they needed a more in-depth dialogue about their problems. These findings are corroborated by Runz-Jørgensen et al [20]. In their study, the participants perceived web-based treatment as undesirable because the therapist would just be waiting for the next person in line and they felt neglected. It should, however, be noted that not all participants agreed with the above interpretation. Other studies report that participants have used text-based interventions for AUD and have found them to be a positive experience in their treatment course [21,22].

The Meaning of Receiving Immediate Feedback on Outstanding Matters

We found that the participants emphasized a need for immediate feedback from their therapist on outstanding matters—a need that they felt that asynchronous digital communication could not fulfill. In situations where they felt alone and in doubt about how to understand a question, it was of importance for them to receive instant elaboration on the matter. Here, the physical presence of the therapist enabled them to receive a quick clarification and thus be able to move on in their rehabilitation. This finding is congruent with findings from the review by Verhoeks et al [19], where the women wished to be able to ask questions and receive feedback from their therapist during their treatment course. The women stressed the importance of physical presence as they otherwise doubted the quality of the feedback. In continuation of this, participants in the study by Runz-Jørgensen et al [20] had a wish for even longer FtF consultations with the therapist as they felt that there was not enough time to ask questions or address concerns that were of importance to them.

It can be hypothesized that integrating videoconference-based conversations with therapists in digital treatment solutions for AUD might acknowledge and apprehend participants’ preferences in terms of being able to communicate at a distance without the loss of sensorial stimulation. Further research is thus needed in order to secure that digital solutions become attractive and preferred by participants. We anticipate that our findings may be used for developing information material addressed to therapists regarding participants’ concerns toward bCBT for the therapist to accommodate the potential participant barriers beforehand. Moreover, our findings may be used to inform participants prior to treatment about their possibilities of combining treatment forms in accordance with their specific needs at specific times.

Strengths and Limitations

This study has limitations. The relatively small sample size (N=11) may be a limitation in this study. However, in an experiment with data saturation and variability, Guest et al [23] found the first 6 interviews to be crucial for the emerging of meta themes. Based on this finding, they recommended a minimum of 6 interviews for developing meaningful themes.
during an inductive analysis. Further, Crouch and McKenzie [24] found that a small number of participants is usable for facilitating the interviewer-interviewee alliance, thereby increasing the validity of semistructured interviews. This study is strengthened by the use of independent parallel coding and code check, which increase internal validity and reliability [25] and thus enhance the credibility of the analysis [26,27]. However, it may be a limitation that we have not used stakeholder check [27]. We saw that, compared to the profiles of the patients in Danish alcohol treatment institutions, our participant population was older. This difference in sample population characteristics may have had an influence on our study results. The relatively higher mean age in our sample may have had an impact, as participants may have less experience with and thereby less interest in using digital interventions [28]. It is also a possibility that the subjects covered in the interview guide and the way of asking by the interviewers may have affected the answers given by the interviewees, but it does not change the fact that they initially did not make use of the bCBT offer.

Conclusion
We found multiple reasons for participants choosing FtF CBT over bCBT. Participants expressed a preference for FtF, in particular, due to positive expectations in the various dimensions of FtF, which they felt were important. The participants were worried that they would not feel as motivated, empowered, and obliged to complete treatment if it partly consisted of iCBT, as they would if it purely consisted of FtF sessions with a therapist.

Acknowledgments
This study was financially supported by TrygFonden (grant 127727). The authors thank the patients and staff at the municipal alcohol use disorder treatment institutions participating in the "Blending internet treatment into conventional face-to-face treatment for alcohol use disorder (Blend-A)" study. The authors also thank all the colleagues working with Blend-A at the Center for Digital Psychiatry and the Research Unit for Clinical Alcohol Research, especially Ramlo Abdulkadir Mohamed and Jeppe Tryggedsson for retrieving data and Jakob Godsk Nielsen for conducting interviews.

Data Availability
The data sets on which this study is based will be made available by the authors on request.

Abstract

Background: The most common age-related musculoskeletal disorder is sarcopenia. Sarcopenia is the progressive and generalized loss of muscle mass, strength, and function. The causes of sarcopenia can include insufficient nutritional status, which may be due to protein-energy malnutrition, anorexia, limited food access and eating ability, or malabsorption. In the United States, 15.51% of older adults have been diagnosed with sarcopenia. Culinary medicine (CM) is a novel evidence-based medical field that combines the science of medicine with food and cooking to prevent and treat potential chronic diseases. CM helps individuals learn and practice culinary skills while tasting new recipes. Therefore, this program could successfully reduce barriers to protein intake, enabling older adults to enhance their diet and muscle quality.

Objective: This study aimed to examine how a web-based CM intervention, emphasizing convenient ways to increase lean red meat intake, could improve protein intake with the promotion of physical activity to see how this intervention could affect older adults’ muscle strength and mass.

Methods: A 16-week, single-center, parallel-group, randomized controlled trial was conducted to compare a web-based CM intervention group (CMG) with a control group (CG) while monitoring each group’s muscle strength, muscle mass, and physical activity for muscle quality. The CMG received weekly web-based cooking demonstrations and biweekly nutrition education videos about enhancing protein intake, whereas the CG just received the recipe handout. Anthropometrics, muscle mass, muscle strength, dietary habits, physical activity, and cooking effectiveness were established at baseline and measured after the intervention. The final number of participants for the data analysis was 24 in the CMG and 23 in the CG.

Results: No between-group difference in muscle mass ($P=0.88$) and strength (dominant $P=0.92$ and nondominant $P=0.72$) change from the prestudy visit was detected. No statistically significant difference in protein intake was seen between the groups ($P=0.50$). A nonsignificant time-by-intervention interaction was observed for daily protein intake ($P=0.08$). However, a statistically significant time effect was observed ($P≤0.001$). Post hoc testing showed that daily protein intake was significantly higher at weeks 1 to 16 versus week 0 ($P<0.05$). At week 16, the intake was 16.9 (95% CI 5.77-27.97) g higher than that at the prestudy visit.

Conclusions: This study did not affect protein intake and muscle quality. Insufficient consistent protein intake, low physical activity, intervention adherence, and questionnaire accuracy could explain the results. These studies could include an interdisciplinary staff, different recruitment strategies, and different muscle mass measurements. Future research is needed to determine if this intervention is sustainable in the long term and should incorporate a follow-up to determine program efficacy on several long-term behavioral and health outcomes, including if the participants can sustain their heightened protein intake and how their cooking skills have changed.

Introduction

The guidance of the National Institute on Aging classifies older adults as those aged 65 years and older [1]. As adults age, several age-related diseases can occur, the most common being cardiovascular disease, cancer, Alzheimer disease, Parkinson disease, osteoporosis, and sarcopenia [2]. A Global Burden of Disease study in 2017 [3] revealed that 31.4% of all diseases were age related. These age-related diseases, combined with the body and life changes that occur with aging, could contribute to compromised nutritional status. These body and life changes can be physiological, psychosocial, and economic [4]. All these factors play a significant role in nutrition and food choices, which are barriers to appetite and diet quality. Therefore, current research strategies aim to acquire healthy aging and prevent age-related diseases.

Aging can lead to age-related musculoskeletal disorders [5] caused by an imbalance between muscle protein’s anabolic and catabolic pathways, leading to overall skeletal muscle mass (SMM) loss [6]. The most common age-related musculoskeletal disorder is sarcopenia. Sarcopenia is the progressive and generalized loss of muscle mass, strength, and function [2,7,8]. Muscles affected include skeletal [9], smooth [10], and cardiac [11]. Consequently, sarcopenia increases fall and fracture risk [12], impairs daily living activities performance [13], increases cognitive impairment [14], decreases the quality of life [15], and leads to death [16].

In research, the general sarcopenia prevalence ranges from 0.2% to 86.5%, with prevalence in women ranging from 0.3% to 91.2% and prevalence in men ranging from 0.4% to 87.7% [17]. In the United States, 15.51% of older adults have been diagnosed with sarcopenia, demonstrating its magnitude of being a public health burden [18]. Therefore, early identification and intervention are the key factors for achieving improved sarcopenia outcomes. According to the European Working Group on Sarcopenia in Older People (EWGSOP), a sarcopenia diagnosis requires the measurements of muscle mass, strength, and function [6].

Although many factors lead to sarcopenia, the 2 crucial factors that can be controlled in older adults are inadequate nutritional intake and physical inactivity [19,20]. Older adults tend to have anabolic resistance, defined as “a blunted stimulation of muscle protein synthesis (MPS) to common anabolic stimuli in SMM” [21]. Therefore, increasing protein-dense food ingestion and habitual physical activity are frontline strategies to support muscle mass, performance, and health [21]. The Society for Sarcopenia, Cachexia, and Wasting Disease provided protein recommendations for treating and preventing sarcopenia at a minimum of 1.0 to 1.5 g/kg body weight per day with exercise [22]. The protein quality is also critical in age-related SMM anabolism. Research on how protein-rich whole foods (eg, lean red meat) can enhance MPS over supplementation in older adults is rising [23]. Recent data suggest that a moderate 113 g (30 g of protein) serving of animal protein (eg, lean beef) can increase MPS by approximately 50% [24]. Therefore, the per-meal anabolic threshold recommendation is 25 to 30 g of protein [23-25]. Unfortunately, older adults’ protein needs are usually not met. Independent older adults answered the 2005-2014 National Health and Nutrition Examination Survey (NHANES) [26], revealing that up to 46% are not meeting the protein intake recommendation.

Physical activity directly impacts muscle quality and quantity [27]. Inactivity in older adults can promote sarcopenia development [28,29], whereas physical activity increases muscle strength [30,31] and mass [32,33]. Therefore, physical activity is vital to lower sarcopenia prevalence [34-36]. Specifically, resistance training and balance exercises are considered the best for sarcopenia prevention [27,37-41]. Steps through activity trackers can help determine one’s physical activity [42]. Accomplishing 10,000 daily steps is suggested to positively influence body composition (eg, weight and body fat) and improve health parameters (eg, quality of life) [43]. Therefore, nutrition and physical activity have been seen to be essential in countering sarcopenia [44].

More interventions focusing on nutrition and lifestyle changes are essential in decreasing chronic disease and health care costs [45]. Educating and empowering individuals to change their lifestyles can be less costly than medications and invasive procedures [45]. Culinary medicine (CM) is a novel evidence-based medical field defined by combining the science of medicine with food and cooking [46]. CM differs from traditional lifestyle and nutrition interventions by attempting to empower the patient to care for themselves safely, effectively, and happily with food and beverages as a primary care technique [47]. It helps people access and eat nutrient-dense meals to prevent and treat potential chronic diseases [46]. Individuals learn and practice culinary skills while tasting new recipes [45]. Also, they can incorporate their favorite foods into their eating plan while learning how to enhance diet quality through new foods (eg, different types of vegetables) and meal preparation tips (eg, defrosting techniques) [47,48]. If executed appropriately, CM can be taught to all populations regardless of culinary skill, educational level, or socioeconomic background [45]. A CM curriculum typically includes practical applications in supermarkets and home kitchens [49]. These practical applications include basic nutrition knowledge and instruction on how to apply that knowledge to diet therapies [49]. However, limited studies report whether a web-based CM curriculum could be as effective as in-person.

Multiple randomized controlled trials report that CM significantly improved individuals’ culinary knowledge, healthy dietary patterns, and self-efficacy for healthier cooking [50-54]. Thus, highlighting CM’s potential as a nutrition intervention could lower the risk of diet-related chronic disease among older adults. However, few studies in this area include older adult participants; none exclusively focused on an older adult population, and only 6% of CM programs were taught by a qualified health professional [55]. Additionally, CM
interventions have been very heterogeneous, indicating a lack of variety in how the intervention is conducted compared with others [55]. Therefore, this study could advance our knowledge of CM and sarcopenia prevention in older adults. A web-based CM program might be an innovative strategy to improve protein intake in independent older adults at home. In addition, this program could successfully reduce barriers to protein intake, enabling older adults to enhance their diet and muscle quality. This factor could be vital because research surrounding CM within older adults is in its infancy. Therefore, our study aimed to examine how a web-based CM intervention, emphasizing convenient ways to increase lean red meat intake, could improve protein intake with the promotion of physical activity to see how this intervention could affect older adults’ muscle strength and mass.

**Methods**

**Study Design**

A 16-week, single-center, parallel-group, randomized controlled trial compared a web-based CM intervention group (CMG) with a control group (CG) on their protein intake, cooking effectiveness, muscle strength, muscle mass, and physical activity. The study was conducted at Texas Tech University Nutrition and Metabolic Health Initiative (NMHI), Lubbock, Texas. Participants were permitted to remove themselves from the trial at any time.

**Ethical Considerations**

A human study compliance review was submitted to the institutional review board at Texas Tech University, Lubbock, Texas. The study was expedited for review and received approval (IRB2021-693). Once participants were recruited and eligibility was determined, an initial appointment was set up at Texas Tech University NMHI. A research team member described the study in detail, and participants were asked to sign a consent form stating willingness to participate. The participants’ information collected for the study was deidentified, given a code number, and kept on the researchers’ computer at Texas Tech University NMHI. The research team offered the participants the vofit 4 watch (Garmin) as compensation, which they used to complete the study.

**Recruitment, Screening, and Participants**

Flyers, newsletters, and word of mouth were essential for recruitment. When participants agreed to enroll in the study, they filled out an initial screening questionnaire to help determine whether they met the eligibility criteria. The inclusion criteria involved individuals who are aged 65 years or older, able to cook for themselves, physically active (eg, need for equipment for assistance), and able to use a computer and mobile device. The exclusion criteria included individuals aged <65 years; those with limited mobility (eg, need for equipment for assistance), cognitive dysfunction (eg, dementia), a heart pacemaker, or type 1 or type 2 diabetes with insulin use; current smokers; those with some form of amputation; those who unable to use a computer and mobile device or unable or unwilling to wear the vofit 4 watch (Garmin) for the duration of the study; and those undergoing or had recently undergone a severe medical procedure or diagnosis.

Participants were recruited and enrolled from June 2022 to August 2022, with data collection completed in December 2022. If a participant dropped out of the study, a new participant would replace and be allotted to the same group as the participant they replaced. A total of 52 older adults, including both men and women, met the study’s eligibility criteria. Assessments were conducted at the prestudy, weekly, and poststudy time points.

**Intervention Design and Study Procedures**

**Prestudy Visit**

Before their visit, participants were told to refrain from exercising for 48 hours, taking alcohol for 12 hours, and wearing clothes with any metals. Informed consent was obtained before starting the assessments. The assessments included completing 4 questionnaires: Community Healthy Activities Model Program for Seniors (CHAMPS), Dietary Screener Questionnaire (DSQ), protein questionnaire, and cooking effectiveness questionnaire. Afterward, grip strength, height, and weight were measured. Then, the participants were scanned by dual-energy x-ray absorptiometry (DXA). After completing their scan, they were given a vofit 4 watch (Garmin). Lastly, the participants were randomized to either CMG or CG and provided their study’s subject code (eg, Beef Study 01), grip strength and DXA results, and exercise handouts. Both groups were advised to consume 25 to 30 g of protein during every meal, and all questions were answered. A follow-up email was sent providing a sample of a 2-week workout plan based on the exercise recommendation handouts and reminders of the study protocol.

**Weekly Interventions**

The CMG received weekly web-based cooking demonstrations with a recipe handout and biweekly nutrition education video on general nutrition information based on the Nutrition Care Manual content from the Academy of Nutrition and Dietetics [56], all provided by email at the beginning of each week. Meanwhile, the CG just received the recipe handout by email. Therefore, this intervention was developed to show how effective the hands-on and visual intervention provided to the CMG is compared with just general reading of a recipe with no further education provided to the CG. In addition, at the end of each week, both groups received their weekly protein and cooking effectiveness questionnaires.

A total of 20 recipes focusing on lean ground beef were provided for this study. Before starting the study, the research team tested each recipe and adjusted it as needed based on visual, flavor, and dish size. Then, the cooking demonstration was recorded once the recipe was approved for the study. For weeks 1 and 2, three recipes were sent to the participants. For the remainder of the study, 1 recipe was sent weekly. In addition, educational videos on a specific nutrition topic were sent every 2 weeks. These topics provided the participants with further nutrition education, which is essential regarding their diet outside of protein.
Poststudy Visit
After their 16th week, the participants had their final data collected. At the end of the visit, the primary researcher shared the pre- and poststudy DXA and grip strength results with the participant and answered any questions.

Outcome Measurements

Questionnaires
The following outcomes were measured: weekly activity level through CHAMPS, the diet through the DSQ, protein intake through a protein questionnaire, cooking confidence and attitude using a pre- and poststudy cooking effectiveness questionnaire, and intervention compliance through weekly cooking effectiveness.

CHAMPS is a 41-item questionnaire [57] that assesses the weekly frequency and duration of various lifestyle physical activities that are appropriate for older adults. The DSQ was developed for the 2009-2010 NHANES [58]. It is a 30-item questionnaire that assesses the frequency of consumption of selected foods and drinks in the past month, such as intakes of fruits and vegetables, red and processed meat, dairy or calcium products, added sugars, and whole grains or fiber. The protein questionnaire is a modified version of the rapid self-administered dietary protein food frequency questionnaire, which contains 37 items evaluating the weekly intake of different types of meat, dairy products, eggs, and beans [59].

Lastly, the pre- and poststudy cooking effectiveness questionnaires measured participants’ cooking confidence, attitudes, and challenges or barriers. In addition, the weekly cooking effectiveness reported each group’s compliance toward their intervention. The prestudy cooking effectiveness questionnaire includes 14 items, the weekly cooking effectiveness questionnaire includes 5 items, and the poststudy cooking effectiveness questionnaire includes 33 items.

Anthropometrics
Height was measured using a Charder HM: 200P stadiometer (Charder Electronic Co Ltd) to the nearest half inch. Body weight was measured by a Brecknell MS-1000 wheelchair scale (Brecknell) to the nearest 0.5 lbs.

Muscle Quality
Lean body and fat mass were measured using a Norland XR-800 DXA (Swissray International, Inc) to the nearest gram. Muscle strength was measured by a Camry Digital Hand Dynamometer (Camry Scale) to the nearest kilogram for dominant and nondominant hands. Steps were measured by the vívofit 4 watch (Garmin).

Statistical Analysis
The study was powered to identify pre- to poststudy changes between the groups. A similar study [60] was used to develop the necessary sample and effect size using the G*power software (version 3.1.9.6; Heinrich Heine University Düsseldorf). Calculations were made for a total sample of 52 participants (26 participants per group) to obtain a statistical difference in muscle strength and mass between the groups, assuming an α of 5%, effect size of 0.72, power of 80%, and 10% inflation for dropouts. Data were imported to SPSS (version 29; IBM Corp) for analysis. DXA measuring muscle and fat mass was the study’s primary outcome measure. Secondary outcomes included protein intake in grams, muscle strength in kilograms, average daily steps, frequency of physical activity in minutes per week, height in inches, and weight in kilograms.

Participants were randomized to the CMG or the CG by block randomization using 2 blocks with 26 codes. On the basis of the assigned participant’s study code, the primary researcher enrolled the participants into their group at the end of their initial visit. Therefore, the allocation was not concealed. The analysis assessed the effect of the intervention with the completers. Any missing data were replaced with the last observation carried forward before analyses of all measurements via single imputation. Participants were excluded from data analysis if they did not complete over 50% of their weekly questionnaires or, after enrollment, met an exclusion criterion.

Results are presented as mean (SD), mean (95% CI), ranges, or frequencies. P<.05 was considered statistically significant. Linear mixed models were used to assess the differences in protein intake between the groups at the end of the intervention. The model included the fixed effects of time, intervention, and time-by-intervention interaction. Participants were modeled as a random effect to account for the repeated measures design. When a significant main effect was observed, post hoc analyses were conducted and the Tukey-Kramer method was used to adjust for multiple comparisons. Within-group muscle mass and strength differences, as well as physical activity and diet quality differences, were estimated using an independent samples (1-tailed) t test for variables measured before and after the study.

Study Population
In total, 64 participants expressed interest in the study. Of these, 8 (13%) were excluded during web-based or telephone screening due to failing to meet the inclusion criteria or losing contact. A total of 56 participants were eligible for inclusion and were randomized: 29 to the CMG and 27 to the CG. A total of 25 participants in the CMG, compared with 24 in the CG, completed the 16-week weekly questionnaires and both study visits. Of the eligible 56 participants, 7 (13%) withdrew or dropped out before the completion of the study. Of the 7 participants, 6 (86%) dropped out due to medical reasons unrelated to the study, and 1 participant (14%) dropped out due to family reasons. Of the 56 participants, 2 (4%) participants had to be excluded from the data analysis because 1 participant had bariatric surgery during the study and the other completed less than 50% of their weekly questionnaires. Therefore, a total of 49 participants were included for the data analysis (CMG: 24/29, 83%; CG: 23/27, 85%). See the CONSORT (Consolidated Standards of Reporting Trials) study flow diagram (Figure 1) for the study details.
Figure 1. Participants’ CONSORT (Consolidated Standards of Reporting Trials) flow diagram.

The prestudy characteristics of the groups are presented in Table 1. The study included a greater proportion of female (38/47, 81%) and White (44/47, 94%) participants. The mean age, weight, and BMI of the participants in the CMG were 71.4 (SD 5.2) years, 76.6 (SD 17.4) kg, and 28.0 (SD 6.0) kg/m$^2$, respectively. In the CG, they were slightly older (mean 73.2, SD 5.8 years) but had lower weight (mean 69.4, SD 15.0 kg) and BMI (mean 26.1, SD 5.0 kg/m$^2$). The CG was found to be more physically active than the CMG. Regarding diet, the CG consumed more fiber, calcium, dairy, vegetables, and fruit than the CMG. Meanwhile, the CMG consumed more daily added sugar than the CG. However, both groups consumed the same amount of daily whole grains.
### Table 1. Prestudy participant characteristics in body composition, physical activity, and diet components (n=47).

<sup>a</sup>Randomized controlled trial (June 2022 to August 2022; Texas Tech University Nutrition and Metabolic Health Initiative) evaluating the effect of a web-based culinary medicine intervention on protein intake, cooking effectiveness, muscle strength, muscle mass, and physical activity in an older adult population aged 65 years and older.

<sup>b</sup>CMG: culinary medicine intervention group.

<sup>c</sup>CG: control group.

<sup>d</sup>N/A: not applicable.

**Muscle Mass and Strength Outcomes**

There was no between-group difference in the muscle mass change from the prestudy visit (P=.88; Table 2). Using the EWGSOP sarcopenia diagnosis [61], 21% (5/24) of the CMG and 26% (6/23) of the CG had low muscle mass at the prestudy visit. At the poststudy visit, 21% (5/24) of the CMG and 22% (5/23) of the CG had low muscle mass.
Table 2. Mean muscle mass and strength of participants at the pre- and poststudy visits (n=47).

<sup>a</sup>The independent samples t test was used to compare between-group differences at the poststudy visit.
<sup>b</sup>CMG: culinary medicine intervention group.
<sup>c</sup>CG: control group.
<sup>d</sup>P value refers to between-group differences by the independent samples t test.
<sup>e</sup>Not available.

Similar results were seen for muscle strength. There was no between-group difference in the muscle strength change from the prestudy visit (dominant: P=.92 and nondominant: P=.72). When comparing the classification of muscle strength for the dominant hand, the CMG was considered 29% (7/24) weak, 67% (16/24) normal, and 4% (1/24) strong at the prestudy visit. At the poststudy visit, the CMG was considered 33% (8/24) weak, 46% (11/24) normal, and 21% (5/24) strong. The CG was considered 13% (3/24) weak, 83% (19/24) normal, and 4% (1/24) strong at the prestudy visit. At the poststudy visit, the CG was considered 13% (3/24) weak, 74% (17/24) normal, and 13% (3/24) strong.

When comparing the classification of muscle strength for the nondominant hand, the CMG was considered 42% (10/24) weak, 54% (13/24) normal, and 4% (1/24) strong at the prestudy visit. At the poststudy visit, the CMG was considered 38% (9/24) weak, 50% (12/24) normal, and 13% (3/24) strong. On the other hand, the CG was considered 30% (7/23) weak, 65% (15/23) normal, and 4% (1/23) strong at the prestudy visit. At the poststudy visit, the CG was considered 30% (7/23) weak, 57% (13/23) normal, and 13% (3/23) strong.

Per the EWGSOP sarcopenia diagnosis [61], 38% (9/24) of the CMG and 30% (7/23) of the CG could be diagnosed with probable sarcopenia. In comparison, 8% (2/24) of the CMG and 9% (2/23) of the CG could be diagnosed with sarcopenia at the prestudy visit. At the poststudy visit, 33% (8/24) of the CMG and 17% (4/23) of the CG could be diagnosed with probable sarcopenia, whereas 8% (2/24) of the CMG and 9% (2/23) of the CG could be diagnosed with sarcopenia at the poststudy visit.

**Protein Intake and Diet Quality**

Figure 2 reveals the mean (SD) daily protein intake in grams for each week of the study for each group. A nonsignificant time-by-intervention interaction was observed for daily protein intake (Figure 2 and Table 3; P=.08). There was also no statistically significant difference in protein intake between the interventions (P=.50). However, a statistically significant time effect was observed (P≤.001). Post hoc testing showed that daily protein intake was significantly higher at weeks 1 to 16 versus week 0 (P<.05) in the cohort. At week 16, protein intake was 16.9 (95% CI 5.77-27.97) g higher than that at the prestudy visit.
Figure 2. Mean (SD) daily protein intake in grams for each week of the study for each group. CM: culinary medicine; CN: control.

Table 3. Dietary intake of participants at the pre- and poststudy visits (N=47).

<sup>a</sup>Linear mixed-effects model analysis was used to compare between-group differences after the study for protein, whereas an independent samples t test was used for the remaining variables.

<sup>b</sup>CMG: culinary medicine intervention group.

<sup>c</sup>CG: control group.

<sup>d</sup>P value refers to linear mixed-effects model analysis of between-group differences over time (timetreatment interaction).

Each group was evaluated to see how many participants met their protein needs (1.0-1.2 g/kg body mass per day). In the CG, 39% (9/23) participants did not meet their needs, 26% (6/23) did meet their needs, and 35% (8/23) exceeded their needs during the study. In the CMG, 58% (14/24) participants did not meet their needs, 8% (2/24) did meet their needs, and 33% (8/24) exceeded their needs during the study. Additionally, in all the completed protein questionnaires, the CMG and the CG had blank answers for 15.4% (63/408) and 12.5% (49/391) of their questions, respectively. When evaluating the daily intake for each dietary component from the DSQ (Table 3), the components stayed close to the same when comparing pre- with poststudy results.

**Cooking Effectiveness**

For the CMG, participants reported watching 82.8% (318/384) of the intervention videos. The primary reason reported on why they did not watch the videos was “not interested in watching” (21/56, 38%). Additional reasons included personal reasons, traveling or vacation, or they did not receive the video. For the CG, participants reported that they read 94.8% (349/368) of the recipes sent to them. The primary reason why the participants did not read the recipe was “busy” (5/13, 39%). Additional reasons included personal and medical reasons, laziness, uninterest, not receiving the video, and having their spouse read it.
When examining whether both groups cooked the recipe learned through web-based videos or just by reading the recipe, the CMG cooked more recipes than the CG (64.8%, 249/384, vs 62.5%, 230/368). Based on the questionnaires with responses outside of “N/A,” the CMG and CG did not cook primarily because of “holiday, traveling, or vacation” (CMG: 20%, 25/125, and CG: 26.5%, 35/132). See Table 4 for the remaining reasons. Barriers or complications that were reported from both groups when either watching the videos or preparing the recipe included borrowing ingredients from a neighbor; recipe serving size being too big; confusion toward either the ingredients or methods; changing or not including ingredients to meet taste or diet preference; finding certain ingredients at the store; too much spice or ingredient in the recipe for their palette; standing for an extended period was challenging; difficulties in scheduling time and energy to shop, prepare, or cook; or taking more initiative to prepare recipe themselves.

<sup>a</sup>CMG: culinary medicine intervention group.  
<sup>b</sup>CG: control group.

At the end of the study, both groups were asked about the main challenges or barriers to maintaining their protein intake (Tables 5 and 6). Meanwhile, the CMG participants were asked how the CM videos specifically helped clarify managing their protein intake (Table 7) and what the most memorable thing they recalled after watching the video or what their favorite part of the CM videos was. All CMG participants were reported having no technical difficulties accessing and watching the videos.

Discussion

Principal Findings

To the authors’ knowledge, a study has yet to be performed with CM explicitly targeting the older adult population to enhance their protein intake. However, a statistically significant time effect was observed ($P \leq 0.001$). Furthermore, post hoc testing showed that daily protein intake was significantly higher at weeks 1 to 16 versus week 0 ($P < 0.05$). At week 16, protein intake was 16.9 (95% CI 5.77-27.97) g higher than that at the prestudy visit. This result indicates that protein intake increased in the cohort with the information provided to both groups. Nevertheless, there was no additive effect of the CMG over what the CG received because no between-group differences were observed for any primary or secondary outcomes. Insufficient consistent protein intake, low physical activity, adherence to the intervention, and accuracy of the questionnaires could explain the results. Also, participants’ ethnicity, average age, gender, and BMI were similar in both groups and affected the diversity of the study’s population; therefore, the outcomes were not tested against them because there was no vast difference to indicate a relationship. Given the limited representation of men in the cohort, the results cannot be generalized to men, Hispanic participants, and African American participants.

The accuracy of each group’s protein questionnaire could play a factor because they were self-administered. Self-administered questionnaires are more susceptible to item nonresponse [62]. The CMG and the CG had blank answers for 15.4% (63/408) and 12.5% (49/391) of their questions, respectively, suggesting that their intake could have been higher and explained how their muscle mass was overall maintained. Additionally, the participants were not asked to change their diet outside their protein intake. The DSQ reported that participants’ diets did remain the same.

Comparison With Prior Work

Before the study started, both groups were recommended to consume 25 to 30 g of protein per meal in addition to daily physical activity. These recommendations are similar to Paddon-Jones and Rasmussen’s [63] findings, reporting that approximately 25 to 30 g of protein per meal is a valuable strategy for maintaining muscle mass in older adults. This strategy would mean that the participants would have to eat approximately 75 to 90 g of protein daily. The CMG met this range from weeks 6 to 15, but the CG met this range during weeks 4, 11, and 12. Specifically, 39% (9/23) of the CG and 58% (14/24) of the CMG did not meet their needs (1.0-1.2 g/kg body weight per day). The 2005-2014 NHANES [26] reported that 31% to 50% of older adults did not meet their protein recommendations. Our population was in this range. Therefore, these results could also explain why muscle mass did not
significantly increase between the groups. However, the estimated average requirement for 51 to 70 years is 0.66 g/kg/d, and the recommended dietary intake is 0.8 g/kg/d for all adults over 18 years old, including older adults [64]. Therefore, in the context of adequate energy intake, muscle mass was maintained in this cohort if their protein intake was consistent with these levels.

Grip strength has been used in research to determine overall body strength [65,66]. However, there were no between-group differences in muscle strength change from the pretest visit. Kim et al [67] found no association between the amount and change (increase or decrease) in daily total protein intake with the incidence or prevention of low muscle strength, which was similar to our results. Additionally, a longitudinal study [68] indicated that 25 to 30 g of protein per meal is associated with greater muscle strength in older adults. However, this recommended intake did not consistently happen in our study, and participants did not meet their calculated needs, which could affect their muscle strength. Physical activity also did not impact muscle strength. Similar results were seen with Ramsey et al [69], who also saw no association between the number of steps and handgrip strength.

When looking at their steps, current evidence suggests that healthy older adults should meet approximately 7000 to 10,000 steps per day [70]. However, our study showed that 67% (16/24) of the CMG and 57% (13/23) of the CG did not meet this range. Also, Park et al [34] reported that individuals who walked at least 7000 to 8000 steps daily likely have muscle mass above the sarcopenia threshold. Because only 33% of the CMG and 44% of the CG met this threshold, it is unsurprising that their lack of steps may have impacted our results.

Lastly, the dropout rates were similar, 14% (4/29) in the CMG and 11% (3/27) in the CG. This rate is lower than the reported average of 20% to 49%, which is commonly seen in dietary clinical trials [71]. In the CMG, 10% (3/29) of participants dropped out due to medical reasons, whereas 3% (1/29) dropped out due to family reasons. In the CG, all the participants dropped out due to medical reasons. These are all common reasons for dropouts in clinical trials [72]. The dropouts were not related to the study, and no adverse effects were reported throughout the study.

Strengths and Limitations

Strength

This study is the first to evaluate CM’s effect on enhancing protein intake and muscle quality in older adults, which brings a new aspect to existing CM research. Furthermore, this study allowed us to see if the intervention program improved their knowledge, awareness, and attitude toward protein intake within 4 months. In addition, the feedback from the participants can be applied to future studies.

A registered dietitian (RD), fully trained and qualified with years of experience, developed the whole program with assistance from those with expertise in food service and kinesiology. In addition, an RD implemented the intervention and provided advice if participants needed clarification about their intervention.

Our study had an overall dropout rate and data exclusion of 16% (9/56), limiting attrition bias. Additionally, there was a high response rate to the weekly questionnaires, with 84.6% (345/408) for the CMG versus 87.5% (342/391) for the CG, and the response rate goal for most research was approximately 60% [73]. This high response rate was credited to weekly adherence checks and effective accountability in recording their weekly questionnaires. Lastly, this intervention was low-cost and could be easily replicated and enhanced for future research.

Limitations

Although exercise recommendation handouts were given in this study, the main intervention has limitations with a focus on diet and nutrition education. A more comprehensive approach including digital CM education, exercise training sessions, and dietary supplementation would have allowed for a more adequate comparison and expectation of significant differences in muscle quality outcomes. Additionally, the result of this study may not be representative of the general population because the majority were female (38/47, 81%) and White (44/47, 94%), and their ages were similar. Therefore, this study would benefit from seeing its effect on those who lack cooking confidence and skills in addition to a more diverse population setting. In addition, there may be recall and social desirability biases as the questionnaires were self-reported, and the participants knew that the research team was reading the responses. This factor could be lessened through the interview-administered questionnaires. Finally, the protein questionnaire results may not be accurate because of the blank questions.

Some participants reported that they could not cook a recipe because they were on Weight Watchers or had self-proclaimed dietary restrictions (eg, no bread or pasta). This situation was seen in 15.2% (19/125) of the CMG and 2.3% (3/132) of the CG. Also, participants reported that some recipes could have been better for a different season (eg, chili in the winter instead of during the summer). They also voiced concern about some recipes needing smaller portions because they live alone. Additionally, because this intervention was performed in summer, fall, and the beginning of winter, the seasonal changes can explain why participants did not partake in some weeks of the study. For example, the participants did not cook their recipes because of holidays, traveling, or vacations (CMG: 20%, 25/125, and CG 26.5%, 35/132). Another example is that the colder weather and traveling could have impacted the results of the steps because most of the questions asked were about outdoor and in-house activities.

Conclusions and Future Direction

To the authors’ knowledge, this study is the first to examine the outcomes of CM in the form of web-based cooking demonstrations and nutrition education to enhance protein intake and muscle quality in older adults. The results reveal insufficient evidence because no between-group differences were observed for primary or secondary outcomes. However, most of the intervention group reported that the cooking demonstrations helped them prepare and cook recipes at home, providing more confidence in the kitchen, and its learning was feasible for them.
In the future, it would be valuable to further investigate the factors that could have affected this study. In developing and implementing this study, exercise training sessions and a dietary supplement could be included. Additionally, the research study design could include RDs, chefs, exercise physiologists, health coaches, or psychologists. The staff would be essential in creating the study protocol, kitchen equipment checklist, consent forms, scripts, and questions. During recruitment, it would be ideal to obtain a broad age range with an equal gender and ethnicity ratio to help reciprocate the general population. The recipes should consider the season, 1-person portion size, time, cost, and mild flavors. A protein food diary could help keep track of protein intake during the week and help answer the protein questionnaire accurately.

It could be interesting to incorporate muscle biopsy and biomarkers, such as vitamin $B_{12}$, folate, and creatinine, to evaluate muscle mass further and see if this intervention impacts or could explain why muscle mass outcomes were nonsignificant due to predispositions. However, there are challenges in successfully performing a muscle biopsy in older men and women who are frail or have low body mass [74], so that would be a concern to consider. For biomarkers, no specific recommendations, references, or cutoff values are available to assess muscle mass or quality. Therefore, the biomarkers could be used to notice any significant change within a short time duration. Overall, given the current concern of sarcopenia, these concepts could enhance this intervention further with the information gathered in this study to impact public health.

Abstract

Background: The increasing use of social media platforms has given rise to an unprecedented surge in user-generated content, with millions of individuals publicly sharing their thoughts, experiences, and health-related information. Social media can serve as a useful means to study and understand public health. Twitter (subsequently rebranded as “X”) is one such social media platform that has proven to be a valuable source of rich information for both the general public and health officials. We conducted the first study applying Twitter data mining to autism screening.

Objective: This study used Twitter as the primary source of data to study the behavioral characteristics and real-time emotional projections of individuals identifying with autism spectrum disorder (ASD). We aimed to improve the rigor of ASD analytics research by using the digital footprint of an individual to study the linguistic patterns of individuals with ASD.

Methods: We developed a machine learning model to distinguish individuals with autism from their neurotypical peers based on the textual patterns from their public communications on Twitter. We collected 6,515,470 tweets from users’ self-identification with autism using “#ActuallyAutistic” and a separate control group to identify linguistic markers associated with ASD traits. To construct the data set, we targeted English-language tweets using the search query “#ActuallyAutistic” posted from January 1, 2014, to December 31, 2022. From these tweets, we identified unique users who used keywords such as “autism” OR “autistic” OR “neurodiverse” in their profile description and collected all the tweets from their timeline. To build the control group data set, we formulated a search query excluding the hashtag, “-#ActuallyAutistic,” and collected 1000 tweets per day during the same time period. We trained a word2vec model and an attention-based, bidirectional long short-term memory model to validate the performance of per-tweet and per-profile classification models. We also illustrate the utility of the data set through common natural language processing tasks such as sentiment analysis and topic modeling.

Results: Our tweet classifier reached a 73% accuracy, a 0.728 area under the receiver operating characteristic curve score, and an 0.71 $F_1$-score using word2vec representations fed into a logistic regression model, while the user profile classifier achieved an 0.78 area under the receiver operating characteristic curve score and an $F_1$-score of 0.805 using an attention-based, bidirectional long short-term memory model. This is a promising start, demonstrating the potential for effective digital phenotyping studies and large-scale intervention using text data mined from social media.

Conclusions: Textual differences in social media communications can help researchers and clinicians conduct symptomatology studies in natural settings.

KEYWORDS
ASD; autism spectrum disorder; machine learning; natural language processing; public health; sentiment analysis; social media analysis; Twitter
Introduction

Autism spectrum disorder (ASD) is a developmental disability causing physical, cognitive, and behavioral changes and affecting millions of individuals. A core complexity of ASD lies in its dynamic symptom profile that changes with age, often leading to the misattribution of behavioral characteristics to other conditions such as anxiety, obsessive-compulsive disorder, and attention-deficit/hyperactivity disorder [1,2]. Yet there are limitations on the availability of standard tests [3], leading to misdiagnosis or delayed treatments [4], putting patients at risk of developing depression or suicidal tendencies [5]. Social media has become a useful means for real-time public health monitoring, offering insights into individuals’ thoughts, emotions, behaviors, and daily struggles and symptomatology related to health issues. Such nonclinical data hold considerable potential for clinicians and researchers to extract meaningful insights through a less intrusive approach. This digital footprint can be analyzed to study the behavioral symptoms of ASD and other mental health disorders [6].

In recent years, social media has emerged as a promising tool for mining behavioral and observational data. The collection of digital data from social media, wearable devices, and smartphones holds potential for improving health care. Research in mental health, such as identifying depression and mood changes [7-13] and real-time mapping of natural disasters [14,15] or infectious disease spread and its effect on emotional health [16-23] has greatly benefited from such “digital phenotyping” studies. Among social media platforms, Twitter (subsequently rebranded as “X”), known for its concise microblogging nature with tweets limited to 280 characters, has emerged as a valuable source of personalized data, boasting an active monthly user base of around 450 million individuals [24].

ASD has been the subject of multiple clinical trials, reviews, and epidemiological studies conducted using behavioral features such as eye gaze [25], prosody [26], asynchronous body movement [27], facial expressions [28,29], mobile phone data [30-33], or even electroencephalograms [34]. However, only a handful of studies have used social analytical tools [35-38], especially Twitter [39-41], for investigating ASD. In addition, other social networking sites such as Reddit [42-45], Facebook [46], Instagram [47,48], Flickr [49], and Sina Weibo [50] have also provided a valuable source of data for detecting and studying mental health conditions, substance abuse, and risky behaviors. Using these previous works as inspiration, we curated a novel, extensive Twitter data set to study various aspects of social communication that differentiate people with autism from their neurotypical peers on a larger scale than previous work.

Our goal was to examine communication patterns and social cues indicative of emotional states to identify distinctive textual features associated with ASD. The methods outlined in this study could potentially aid researchers and clinicians to understand and analyze linguistic features associated with ASD, enabling the research community to build precision health tools for identifying and monitoring early symptoms, understanding specific behavioral traits, uncovering hidden patterns, proposing a tailored clinical treatment plan or personalized interventions, and offering support within communities. However, it should be noted that this research serves as a supplementary resource for clinicians, aiming to showcase how social media can aid in developing risk assessments, custom treatment plans, and targeted interventions based on the patient’s individual traits, communication style, and lifestyle. Additionally, the methods that we explore in this feasibility study could assist in designing more accessible and user-friendly technologies tailored to the sensory needs of individuals with ASD.

Methods

Overview

Here, we describe the data set curation process (Figure 1), preprocessing steps, and a series of analyses on the curated data. We started by analyzing the sentiments and topics within the data set to discover some qualitative insights. We then performed per-tweet and per-user classifications of ASD to understand the linguistic differences between the users in the ASD and control groups.
Figure 1. Pipeline for the creation of the novel Twitter (subsequently rebranded as “X”) autism data set. API: application programming interface; VADER: Valence Aware Dictionary for Sentiment Reasoning.

Data Collection

In recent years, hashtags such as #MeToo, #BlackLivesMatter, and #StopAsianHate have played significant roles in promoting social movements and campaigns, including those aimed at raising awareness about specific societal issues. Within the ASD community, popular hashtags such as #AutismMom and #AutismParent have represented the perspectives of neurotypical parents, significantly influencing research and policies in this domain. However, these advocacy groups often overshadow adults with autism, creating a gap in their representation within decision-making processes. To address this issue, a paradigm shift occurred in the autism rights movement through the hashtag “#ActuallyAutistic” [51,52]. This movement has emphasized understanding the experiences, challenges, and perspectives of individuals on the autism spectrum, redirecting attention toward them rather than solely focusing on caregivers.

Using the hashtag as the criteria for our corpus selection, we extracted Twitter conversations of users self-identifying with ASD to study the differences in their linguistic patterns. Our data extraction involved using snscreape (JustAnotherArchivist) [53], a Python-based library allowing social media scraping without requiring personal Twitter application programming interface keys and providing powerful search functionality to help filter tweets based on various conditions, such as date-time, language, or location. We targeted English-language tweets using “#ActuallyAutistic” posted from January 1, 2014, to December 31, 2022. To identify users self-identifying with ASD, we searched for keywords such as “autism,” “autistic,”
or “neurodiverse” within their profile descriptions (bios). Additionally, we considered usernames and tweet contents for users who used these keywords solely in their usernames.

Finally, we extracted all the tweets from the timelines of these users to construct the autism data set, which consists of 3,137,952 tweets from 17,323 individuals. Associated metadata such as username, account created, friend count, and date of tweets posted were also extracted and could be used for statistical or network analysis.

To build a tweet classifier for individuals with ASD and their neurotypical peers, we collected a sample of random tweets as part of the control group. To achieve this, we formulated a search query excluding the hashtag “#ActuallyAutistic,” using the advanced query searching operators and methods provided by Dr Igor Brigadir [54]. However, this approach carries the risk of data leakage, whereby users who have not posted any autism-related content may possess autism-related keywords in their profile description or username. To avoid this, we screened users who had any such keywords in their profile description or usernames, or who were also present in the autism data set, and subsequently removed them from the sample. We collected 1000 control tweets per day during the same time period to obtain a total of 3,377,518 tweets across 171,273 individual users.

**Data Labeling**

To train a supervised machine learning model effectively, labeled data that associate each data point with a respective class are crucial. We automatically labeled the tweets from the autism data set as belonging to the class “autism,” assigned label 1. All other tweets from the control data set were labeled as belonging to the class “control group,” assigned label 0. However, it is important to clarify that these tweet labels were used temporarily for classification purposes and were not permanently stored in the data set. It is important to note that obtaining ground-truth labels can be a costly and time-consuming process, and the performance of machine learning models is often found to decrease with a decrease in labeled data set size. Weak supervision approaches leverage partially accurate or noisy sources for annotations, which can be more efficient than manual labeling.

**Data Preprocessing**

Working with raw, unstructured Twitter data is challenging because the conversational text contains too many noisy elements, such as punctuation, abbreviations, emojis, and other stray characters. Thus, before using such data for model training, it is necessary to clean and preprocess the data, which is an essential step for any natural language processing task. We started by removing the usage of any profane language in the tweets, such as cursing or swear words, using a Python library called better-profanity [55], which is designed to flag inappropriate words using string comparison and mask them using special characters (the default setting uses “*”). While profane language can sometimes be highly emotive and help in understanding the sentiments of a text, we chose to censor any such words while classifying the tweets, as such words can be used by any individual and might not help in classification tasks. However, we considered the contribution of profane language through sentiment analysis and observed that the polarity of the sentiments was almost similar when using clean and uncensored tweets.

We then tokenized the text into words; removed any nonalphanumeric characters, hyperlinks, user mentions, and HTML tags; and converted the word tokens into lowercase to avoid any confusion and data redundancy. We removed stop words to avoid adding noise and complexity to the features with no meaningful information. To further simplify the input space and normalize the vocabulary, we applied stemming and lemmatization. We also removed any hashtags or a list of keywords related to ASD such as “actuallyautistic,” “autism,” “autistic,” “autismacceptance,” “autismawareness,” “askingautistics,” “askingautistic,” “neurodiversity,” “neurodivergent,” “allautistics,” “adhd,” “mentalhealth,” “asd,” “diagnosis,” “autistics,” “autismpride,” and “autismspeaks,” which could introduce bias and lead to model overfitting.

**Sentiment Labeling**

We compared the sentiments of tweets posted by individuals with ASD against those from the control group in order to understand the subjective characteristics and emotional polarity around the topic. Initially, we conducted sentiment analysis on the original raw data set, which contained profanity. Additionally, we wanted to explore how profane language can affect the sentiments of the tweets, and thus we also conducted sentiment analysis on a pseudoclean data set after removing any profane words. Sentiment analysis commonly involves 2 approaches: machine learning and lexical. We used the Valence Aware Dictionary for Sentiment Reasoning (VADER) [56], a lexical approach specifically attuned to sentiments expressed in social media or microblogs like Twitter, to analyze the sentiments of the curated data set. VADER has been explicitly trained on social media data sets (such as social media posts or New York Times editorials) and requires no training data. VADER applies a set of rules and heuristics to the sentiment scores of the individual words to determine the overall sentiment of the sentence and returns a dictionary of negative, neutral, positive, and overall (normalized) sentiment scores for the sentence.

**Topic Modeling**

The objective of our topic modeling analysis was to investigate whether there exist specific themes and semantic patterns that are frequently discussed in relation to ASD and can offer insights beneficial for clinicians and policymakers. Topic modeling is an unsupervised learning technique used to uncover concealed topics and coherent themes within textual data. We used the Top2Vec [57] algorithm, which offers a dynamic approach to discovering topics within a corpus of text data by making use of the spatial proximity of the words.

**Tweet-Level Classification**

Our initial focus involved training a model specifically designed to predict ASD based on the content within individual tweets. To build this tweet classifier, we identified unique users from both the ASD and control data sets, allocating an 85:15 split for training and testing purposes. Data splitting by user rather than by tweet avoids data leakage, where a user’s tweets might scatter across both training and testing sets, potentially leading
to overfitting by the model due to learning user-specific patterns. The tweets, with no profanity, were preprocessed as defined in the previous section and formed the training and test sets. The categorical labels, representing whether a tweet belonged to a user in the ASD or control group, were used as the basis for model training and evaluation. Additionally, the training data set underwent an 85:15 split, separating it into training and validation subsets, which was used to fine-tune the model and adjust hyperparameters.

For text-to-numeric vectorization, we used 2 approaches: a bag-of-words term frequency–inverse document frequency (TF-IDF) method and word2vec embeddings. We started by training TF-IDF feature representation using various classical machine learning algorithms: support vector machines, naive Bayes, logistic regression, and XGBoost (extreme gradient boosting), using 5-fold cross-validation and accuracy as the primary evaluation metric to identify the best classification method. We then trained the word2vec model using the best-identified algorithm for better feature representation. This approach captures both semantic and syntactic similarities among words, and we assessed its efficacy using a more comprehensive array of evaluation metrics.

User Profile Classification

Our subsequent task involved training a model to predict ASD by considering all tweets from an individual user’s timeline. To ensure a more representative data set and prevent potential model overfitting, we isolated unique users who had shared a minimum of 5 tweets and split them into an 80:20 ratio for training and testing. The preprocessed tweets from each user were then grouped together to form an individual document. For model training, we used an attention-based, bidirectional long short-term memory (Bi-LSTM) model vectorized with a randomly initialized, self-trained embedding layer. As the tweets vary in their lengths and raw text cannot be directly represented as dense vectors in the way that images can, we used padding and an extra “unknown” token during tokenization to achieve the fixed length input and represent any unseen tokens.

Ethical Considerations

While social media data can help with public health analysis by offering a less intrusive and real-time monitoring approach for disease symptomatology and public sentiments, it also poses ethical challenges by exposing the users to harm or the potential leaking of personally identifiable information. First, this study was approved by all ethics-related regulatory bodies at the University of Hawaii. The study has been approved by the University of Hawaii Institutional Review Board (2023-00248) under an expedited review procedure, and the user information was deidentified. We also ran the request through University of Hawaii institutional data governance review to approve this study, where it was determined that the study is exempt from further data governance review due to the inherently public nature of the study data. We also took additional measures not required by the Institutional Review Board. Specifically, we encrypted user IDs, reducing the chances of user reidentification. We also anonymized any user mentions or personal information, such as email addresses, contained within the tweets. These steps were aligned with the ethical considerations outlined in various research studies on social media analysis [58-60].

The public nature of such data can often overshadow the participants’ consent, leaving them unaware or unsure of the inclusion of their data in the research. Williams et al [61] observed that 84% of respondents were not at all or only slightly concerned when using the Twitter posts for university research. However, this leaves a considerable portion of the population who remains concerned. In most cases, it is impractical to obtain consent for large-scale social media analytics research, leaving the responsibility to researchers to safeguard participant data.

The purpose of analyzing social media data is not to provide an immediate intervention but rather to uncover patterns to refine accuracy and help clinicians comprehend the needs of the specific population being studied. With these considerations in mind and to promote interdisciplinary research, the fully anonymized data set can be made available to researchers upon request following a set of protocols to ensure ethicality: we require researchers who request the data set to sign a data use agreement that forbids the researchers from sharing our data set with others and to attest that the data will remain confidential. The Data Use Agreement also forbids attempting to reidentify users represented in the data set.

Results

Data Records

The autism subset, collected from 17,323 self-reported individuals with autism, contains 3,137,952 tweets. The control subset, collected from 171,273 users, consists of 3,377,518 tweets. The combined data set contains the following columns: user ID (a unique value assigned to each Twitter account), profile description (a short summary of the account posted by the user), account created (date-time when the account was created), friends count (number of accounts the user follows), followers count (number of accounts the user is being followed by), tweet date (date-time when the tweet was posted), tweet ID (a unique ID assigned to each tweet), tweet text (original tweet), a list of hashtags present in each tweet, number of replies (number of times the tweet has been replied to), number of retweets (number of times the tweet was retweeted), number of likes the tweet got, and source from where the tweet was posted (web, mobile device, or app). While we focused on using tweet text as the primary source of data, other supporting metadata could be used in the future for network analysis or statistical studies.

Exploratory Data Analysis

The data set’s columns for hashtags and locations were found to contain the highest number of missing values during our analysis. While not all tweets are accompanied by hashtags or location details, users possess the liberty to input any desired location on their profiles. Our analysis revealed that a large portion of users either did not provide their actual location or had inconsistencies in their location entries. Among the top 20 location values identified, most were variations of “United Kingdom,” such as “UK,” “London, England,” “England, United Kingdom,” and “South East, England.” However, other entries...
were less informative and included phrases such as “Picnic party” and “My parent’s basement.” Due to the majority of the missing data and to safeguard users’ personal information, we opted to exclude the location column from the data set before using it to train any machine learning algorithms.

Further analysis of the yearly distribution of tweets revealed a rising trend in discussions related to ASD across the years. This trend suggests that individuals on the autism spectrum are increasingly embracing social media platforms, potentially opening up numerous employment prospects and serving as an effective channel to educate the public about developmental delays. Additionally, sharing behavioral symptoms through social engagement could be beneficial to others to build better community support. This increased social involvement may hold significance not only in social science [62] but also in human-computer interaction research [63], offering insights to design more inclusive and efficient digital environments.

**Sentiment Analysis**

The VADER sentiments of most of the ASD and control group tweets were found to be positive and neutral, respectively, as shown in Table 1.

This was supported by another interesting observation: tweets from individuals with ASD comprised a higher character count compared to those from the control group (Figure 2). The histograms depicting the word counts in tweets from both groups follow similar distributions but with a substantial difference in their means. This disparity strongly suggests varying linguistic patterns between these 2 groups.

### Topic Modeling

Using just the ASD data set, multiple topics were discovered, and the word clouds of a few topics are shown in Multimedia Appendix 1.

As it can be seen, the majority of topics were related to behavioral and emotional symptoms such as “hyperactivity,” “fidgeting,” “depressed,” “anxiety,” “trembling,” and “overwhelmed.” Interestingly, a considerable number of documents also focused on terms such as “vaccine,” “therapy,” “misdiagnosis,” and “cats.” These findings may be attributed to the frequent misdiagnosis or delayed diagnosis of ASD, prompting individuals to seek therapy, support, and guidance. The presence of vaccine-related discussions likely stems from misinformation and its negative impact on individuals affected by ASD. However, given the time frame in which the data set was collected, it is also possible that these tweets are related to COVID-19 vaccines. Last, multiple studies [64,65] have found that children with autism are more at ease with cats due to their nonintrusive nature, lack of prolonged eye contact, and their ability to alleviate stress and interpret emotional cues.

Deriving specific topics from the control group’s Twitter conversations was challenging given their scattered and diverse nature. Most of these discussions centered around internet personalities, random conversations, specific days of the week, or special occasions such as birthdays and anniversaries. Interestingly, some broader topics related to animals surfaced in these conversations, but not as specifically focused as observed in autistic user conversations—specifically mentioning cats. Some of these posts also displayed the use of emotional words, suggesting that pets or animals may provide therapeutic benefits.

### Technical Validation

The performance metrics for tweet classification are shown in Tables 2 and 3. Table 2 displays the results from TF-IDF feature representations across several classical machine learning models, while Table 3 displays the results using word2vec feature vectors trained with logistic regression. While the TF-IDF vectorization yielded similar accuracy using different machine learning algorithms for tweet classification, logistic regression was chosen as the best predictor due to its superior performance and shorter training time. The results of the word2vec model were found to be consistent with the semantic similarities of the words. For instance, “autism” exhibited higher cosine similarity to terms such as “Aspergers,” “neurotypical,” and “autism spectrum condition,” indicating the model’s proficiency in capturing semantic relationships between words.

Table 4 displays the results for user classification. Although there is a class imbalance in the number of users with ASD versus controls, the attention-based LSTM model still seems to yield better measures, with $F_1$-scores of 0.7 and 0.9 on the “autism” and “control group” classes, respectively, and an AUC score of 0.78.

Discussion

Overview

The profound shift in society’s reliance on social media for information, in contrast to traditional news sources, along with the immense volume of generated data, has resulted in an increased focus on the use of natural language processing for text analytics. While research tools using facial expressions [6,66-75] and eye gazing for phenotyping ASD [76,77] are consistently reliable, there exists a current deficiency in standardizing precise methods for assessing deficits in social interaction. Therefore, linguistic and behavioral markers extracted from Twitter conversations can serve as valuable resources to investigate textual variations and social dynamics in naturalistic settings. In this study, we demonstrated the potential of leveraging data mining techniques to learn about ASD and related topics from social media platforms such as Twitter. The F<sub>1</sub>-scores of 0.71 in tweet classification and 0.80 in user classification signify substantial semantic distinctions in messages posted by individuals with and without ASD. Tweets by individuals with autism showed a higher frequency of emotional language, corroborated by the word2vec model’s stronger semantic associations among such words, reinforcing the model’s predictive capability. This finding, coupled with previous studies using computer vision models [76,78], suggests that social phenotypical behavior could be used to support effective ASD screening strategies and facilitate early detection. We also want to emphasize that the National Institutes of Health is actively funding research works [79,80] using data from electronic health records, social media, and mobile devices with novel artificial intelligence–based tools to improve public health surveillance and precision diagnostics, keeping in mind ethical and other societal considerations. We would also like to highlight that any social media analytics research should always be supported by ethical considerations and user privacy.

Limitations

There are certain limitations to consider in this study. While we focused on individuals who self-identified as autistic, there is no clinical validation for their diagnosis. Annotations from clinical experts or crowdsourcing can help. Furthermore, there is a possibility of data leakage, where the identified users may not be autistic but instead could be family members, parents, caregivers, or advocacy organizations belonging to a different study population and still using the hashtags. However, the frequency of this type of leakage is predicted to be rare due to the negative social connotations of using #ActuallyAutistic without a diagnosis. There might also be a possibility of some data leakage of an individual with autism falling into the control group, but with ASD having a prevalence rate of <3%, the model performance should not degrade by more than 3% if an individual who chose not to self-identify themselves with ASD falls into the control group cohort. The predictive power of social media is not to be used at an individual level but at a broader cross-sectional level, possibly combined with self-reported questionnaires for enhanced accuracy in neurological studies.
In addition, the sentiment polarity obtained through VADER may lack accuracy compared to human-labeled sentiments, as human sentiments are influenced by various factors such as surroundings and politics, making reliable labeling challenging. Moreover, this study only considered the English language, potentially missing out on information from other countries or languages that could aid the model in making better predictions. This also raises concerns about the lack of diversity in the data [81], where only English-speaking users from higher socioeconomic groups or younger adults are represented in the dataset, as they comprise a larger portion of Twitter users.

**Future Work**

This study presents several opportunities for future research, including using pretrained large language models such as Bidirectional Encoder Representations from Transformers and Generative Pre-trained Transformers for text classification, topic modeling, and feature extraction. Another interesting avenue is the integration of text data with additional data modalities such as audio and video, which could also be mined from social media. In addition, incorporating auxiliary information into textual features may further improve the effectiveness of machine learning models. Lastly, as the Centers for Disease Control and Prevention have reported that boys are 4 times more likely to receive an ASD diagnosis than girls [82], gender-stratified analysis using crowdsourcing or other metadata analysis techniques may also hold promise for more precise screening practices.

Abstract

Background: Work-related stress is associated with poor job performance and negative health outcomes. Changing health behaviors through corporate wellness programs can improve physical and mental health and help employees manage stress. This project sought to pilot the potential addition of brief coaching and biofeedback to an 8-week web-based self-help program to improve employee stress using the multiphase optimization strategy.

Objective: This study aims to determine which candidate components will be tested in a later optimization phase and at what dose they will be tested, examine the feasibility and acceptability of delivering the different components, investigate whether the outcomes can be feasibly measured, and review evidence to build a conceptual model before the optimization phase.

Methods: The study was positioned within the preparation phase of the multiphase optimization strategy. It is a 2×2×2×2 design with 4 components: 2 types of health coaching and 2 types of biofeedback. All components were tested by turning them on or off. A total of 16 adult office workers (mean age 40, SD 14.3 years; n=15 women) completed an 8-week self-paced web-based stress management and health behavior change program and were randomly assigned to 1 of the 16 conditions, created from a combination of the 4 candidate components. Assessments included web analytics, surveys, and interviews regarding program recommendations, likes, and dislikes.

Results: Findings from the interviews provided suggestions to improve the intervention (eg, separating wellness from stress content) and trial conduct (eg, streamlining the onboarding process). On average, participants logged into the wellness program 83 times (range 36-291), with 75% (12/16) participant retention and 67% (8/12) survey completion. There were no reported problems with coaching or obtaining data from interviews or apps. The interview findings suggested potential mediators to include and assess in a future conceptual model.

Conclusions: The results provided areas to improve the intervention content and trial methods. Instead of progressing to the next scheduled large-scale optimization phase, our plan to iterate through a second preparation phase after making changes to the protocol, apps, and corporate coaching partner.

Introduction

Background
Work is one of the major contributors to chronic stress. Work-related stress is experienced by most employees and is related to poor job performance and lower job satisfaction [1,2]. Chronic stress, a common outcome of workplace stress, is a critical risk factor for a variety of negative health outcomes [1,3] and is linked to the development of cardiovascular disease and depression [4-6]. Meta-analytic findings from a study conducted among >80,000 employees demonstrated an increase in coronary heart disease risk for those experiencing work stress (risk ratio 1.16) [7]. There are considerable costs to the employer from unmanaged high stress, resulting in performance decreases and absenteeism [8]. These costs can be ameliorated through employer-funded health and wellness programs [9,10], which can also serve as feasible strategies for chronic disease prevention [11].

There are numerous psychological, social, and physiological benefits of engaging in positive behaviors such as physical activity and healthy eating [12-14]. It is well established that regular engagement in positive health behaviors (eg, exercise and diet) is associated with lower stress [15-17]. Despite the potential benefits, only a few individuals meet recommendations, missing out on these benefits [18,19]. Individuals spend as much as half of their waking hours working, and the workplace offers an opportunity to promote health, including stress management. Behavior change interventions target exercise and diet in the workplace can improve health behaviors [20-24]. Evidence from a review of 23 studies indicates that workplace interventions can improve physical and mental health outcomes [25].

Internet-based interventions represent a scalable approach to health promotion. High rates of internet use and the convenience of accessing content 24 hours a day allow intervention to reach participants, whether they are at work or home [26]. Web-based self-help interventions are structured such that the participants can complete these at their own pace and do not require direct contact with an interventionist. A review of 23 web-based self-help interventions reported significant weight loss across studies [27]. Workplace health and wellness programs are often multifaceted [28]; web-based self-help approaches may be particularly useful for delivering program components such as health information or behavior change strategies designed to help individuals learn about new behaviors and plan their behavior change efforts.

Behavior change techniques (BCTs) represent the active ingredients of an intervention [29]. BCTs are used to target the hypothesized mechanism of action to help individuals change their behaviors. For example, goal setting and self-monitoring are among the most common BCTs in physical activity and diet interventions [30]. These BCTs target and seek to improve individuals’ confidence and ability to self-regulate their behavior. These types of BCTs are suitable for internet-based delivery, given the ease of use and accessibility of websites and apps.

Individual health and wellness coaching can be an effective way to promote behavior change for a variety of health behaviors [31-33]. Motivational interviewing is a person-centered coaching approach to enhance clients’ intrinsic motivation for change [34]. Motivational interviewing is a heart- and mindset approach to coaching that aims to embody compassion, acceptance, partnership, and evocation with the client [34]. There are 4 processes and 4 communication skills to support the spirit of motivational interviewing. The 4 processes (ie, engaging, focusing, evoking, and planning) are designed to guide clients from a state of ambivalence toward a state of willingness to make a healthy change. The 4 communication skills (ie, open-ended questions, affirmations, reflections, and summaries) are fundamental to reflective listening and are ways to demonstrate that spirit. Motivational interviewing–based interventions have consistently been shown to be effective across numerous health behaviors (eg, diet, exercise, and oral health) [35]. Even brief motivational interviewing–based interventions can be effective in improving diet and exercise [36]. Brief motivational interviewing coaching may be a scalable approach for providing health coaching in workplace interventions. Furthermore, individual-level coaching represents a common strategy that multifaceted health promotion programs use in the workplace [28]. A recent meta-analysis revealed that physical activity interventions highlighted biofeedback as 1 of the 4 BCTs related to the effective initiation of physical activity [37]. Heart rate variability (HRV) is a reliable means of acutely and indirectly measuring stress through the autonomic nervous system [38,39]. It has also been used as an index of physical and emotional health [40-42]. HRV biofeedback (HRV-BF) is a noninvasive method for delivering HRV data in real time to the desired user [43,44]. HRV-BF has been shown to be effective across different settings for improving HRV and other psychological and physiological outcomes [45,46]. HRV-BF has been shown to be effective in the workplace [47,48] and may help promote self-awareness and allow individuals to better regulate their psychological and physiological states [49]. HRV-BF may be a beneficial tool alongside behavioral intervention components to promote awareness and self-regulation.

We partnered with CoreHealth, a company that supplies corporate health and wellness coaches with an web platform to deliver a variety of wellness tools and interventions, including coaching, to their clients. This project sought to pilot the potential addition of brief coaching and HRV-BF to an 8-week web-based self-help program using the multiphase optimization strategy (MOST [50]).

MOST: Preparation Phase
MOST will be used to pilot this study, to optimize, and evaluate the efficacy of the stress management and health behavior change intervention to improve workers’ stress and well-being. MOST is a 3-phase framework that aims to develop interventions that are effective, efficient, economical, and scalable [50]. The 3 phases include preparation (ie, selecting which intervention and at what level components are feasible to examine), optimization (ie, determining the optimized package of components via an optimization randomized controlled trial), and evaluation (ie, evaluating the efficacy of the optimized...
package through an evaluation randomized controlled trial). The factorial design of MOST in the optimization phase will allow us to examine the effect of adding intervention components to a standard 8-week behavior change program. This paper reports the first phase of MOST, the preparation phase, using the reporting recommendations by Landoll et al [51], with the following four study objectives:

1. Determine which candidate components will be tested in a later optimization phase and at what dose they will be tested
2. Examine the feasibility and acceptability of delivering the different components
3. Investigate whether the outcomes can be feasibly measured
4. Review evidence to build a conceptual model before the optimization phase.

**Methods**

**Design Overview**

This study is registered with ClinicalTrials.gov (NCT05150574). In this phase, the components are first tested with a few participants to identify implementation problems and refine them to ensure acceptability and feasibility. The proposed future optimization phase will use a $2^4$ ($2 \times 2 \times 2 \times 2$) factorial experiment to test all combinations of the 4 candidate components by turning them “on” or “off,” resulting in 16 different conditions in total (Table 1).

\(^a\)All participants will have access to the content on CoreHealth, and they will be randomized to receive 1 of the 16 conditions.  
\(^b\)HRV: heart rate variability.

For this study, we recruited 16 participants, 1 per condition. There are four candidate coaching components being delivered, with a fifth untested component that all participants will receive the following:

1. **Daily resting HRV biofeedback:** the participants will be asked to record regular HRV measurements in the morning before eating or drinking.
2. **Momentary HRV biofeedback:** throughout the workday, the participants will be asked to take in-the-moment HRV measurements, with the option of performing a mindfulness activity to manage elevated stress.
3. **Health coaching and behavior change initiation:** the participants will receive one 15-minute wellness coaching session at the start of week 1 of their program.

4. **Health coaching and practice with feedback coaching:** the participants will receive one 15-minute wellness coaching follow-up session in either week 2 or week 4.
5. **Web-based behavior change program (all participants receive):** this is an 8-week web-based program that provides the participants with access to 8 weekly behavior change and stress management modules. The platform also contains information on a variety of health behaviors.

**Ethical Considerations**

This study received ethics approval from the Brock University Research Ethics Board (REB #20-367) before recruitment. Prospective participants were emailed information about the study, and those interested were directed to a link to complete the eligibility questionnaire via Qualtrics (Qualtrics International...
Inc). Eligible participants provided informed consent on Qualtrics before scheduling an onboarding meeting with study staff. The health coach also provided informed consent to be interviewed. All data were electronic, deidentified, and stored on the institutional servers of the corresponding authors. There was no compensation for participating in this study. Generative artificial intelligence was not used in any part of the manuscript writing.

**Participants and Procedure**

A total of 16 participants were recruited for the study. The eligibility criteria included being an adult aged ≥18 years, being able to read and comprehend English, having an Apple iPhone 8 or newer version (iOS 14 or newer) or an Android (operating 7.0 or newer), having a self-reported BMI <40 kg/m², and reporting at least a moderate amount of daily job stress. We recruited potential participants through email blasts and word of mouth from companies primarily comprising office workers. Interested participants were directed to a web link to determine their eligibility and to provide informed consent. The participants were contacted to schedule a 30-minute onboarding phone call to discuss study procedures and help them set up and learn about the study apps. Following the onboarding call, the participants were asked to complete the baseline survey and record baseline HRV for 7 days before starting the 8-week study. For the first 3 days, HRV was measured when the participants woke up in the morning, to be averaged as before and after the program to assess change, whereas for the following 4 days, they were to get accustomed to taking different HRV readings. If requested, the participants were sent reminders to record their baseline HRV readings.

At the end of 8 weeks, the participants were interviewed to discuss likes and dislikes and suggested improvements to the study. At the end of the interview, they were asked to complete a poststudy survey and record 3 more poststudy HRV readings. Furthermore, the wellness coach was interviewed at the end of the study. All interviews were conducted via Microsoft Teams (Microsoft Corp). Interviews were recorded, and written transcripts of the interviews were created. In response to ongoing participant feedback, we made a deviation to the study protocol, in which we received research ethics approval, and conducted a 15-minute interview approximately halfway through the 8-week program. This was sparked by a few participant emails regarding the onboarding process and the early technical issues. We chose to interview the participants about these challenges while the issues were fresh in their mind rather than waiting for another 4 weeks to ask questions at the poststudy interview.

**Candidate Intervention Components**

There are 5 components being delivered. Four of the components will be tested and examined as part of a future factorial experiment: (1) daily resting HRV biofeedback, (2) momentary HRV biofeedback, (3) behavioral initiation coaching, and (4) practice with feedback coaching. The fifth is a constant component with all the participants receiving an 8-week behavior change and stress management program.

**HRV Biofeedback**

Light Heart is a mobile phone app (CoreHealth) that was recently designed and developed by CoreHealth to be used as a supplementary tool in their web-based platform to provide HRV biofeedback (BCT 2.6 biofeedback). Research assessing the concurrent validity of the app in assessing pulse intervals against a gold-standard electrocardiogram (BioAmp FE132, ADInstruments) is currently being reviewed. The results demonstrated a strong positive linear correlation (r=0.99, P<0.001) between the Light Heart app and the electrocardiogram. The app was designed to measure and provide HRV biofeedback through photoplethysmography to detect changes in blood flow through the skin. All the participants were asked to download the app to measure their HRV. The participants were then asked to connect to this app via a mobile access code created through the CoreHealth platform. The participants could obtain an HRV reading by opening the app, selecting “take reading,” placing their finger over their rear phone camera, and flashing for 60 seconds. The participants were given a visual prompt if they were moving their fingers too much to obtain a clear reading.

Because HRV metrics are complex to understand (eg, SD of the normal sinus beats [sdNN; ms]), the participants view a user friendly HRV index. The proprietary index uses a 0 to 100 scale to graphically represent an individual’s HRV, with higher scores indicating poorer HRV. To assess their baseline HRV, the participants were instructed to find a quiet, distraction-free place to sit and measure their HRV when they first wake up in the morning and before they eat or drink. There are two forms of HRV biofeedback being tested: (1) momentary and (2) daily resting.

Those receiving **momentary HRV biofeedback** were instructed to use the app to record in-the-moment HRV measurements throughout the day when they experienced elevated stress. Higher HRV scores indicated elevated stress. In these instances, the participants were recommended to take a few minutes to perform a mindfulness or meditation activity, following 1 of the videos provided on the CoreHealth platform. Following the activity, the participants were prompted to take another HRV measurement to determine whether their HRV improved after performing the stress management activities.

Those receiving **daily resting HRV biofeedback** were asked to regularly obtain HRV measurements each morning, similar to recording their baseline HRV. In this way, a regular morning measurement may be an indicator of improved HRV over time as a result of making healthy changes known to impact HRV (eg, improved cardiorespiratory fitness, sleep quality, and mindfulness).

**Health Coaching: Behavioral Initiation and Practice With Feedback (BCT 3.1, Social Support-Unspecified)**

All coaching for this study was conducted through CoreHealth’s videoconferencing tool or via telephone. The wellness coach was trained in a communication style called motivational interviewing. Motivational interviewing is a person-centered collaborative counseling style that helps clients strengthen their autonomous motivation and commitment to change [34].
Coaching at 2 different points in the intervention was tested: behavioral initiation coaching and practice with feedback coaching. In this study, those who received coaching components received motivational interviewing–based health and wellness coaching. Consistent with the spirit of motivational interviewing and standard practice for many of CoreHealth’s clients, the participants were given the autonomy to choose the behavior they wished to change. Those receiving behavioral initiation coaching received one 15-minute behavioral coaching session to start week 1 of their program. In this session, the participants established their commitment to change, decided on a health behavior change goal, and were asked to create an action plan and schedule and track their progress using CoreHealth. Those receiving practice with feedback coaching received a follow-up 15-minute session. In this session, clients discussed their level of success in achieving their goals, revised their goals as necessary, and discussed potential barriers to achieving their goals. For this preparation phase, we investigated the 2 different time points to deliver the follow-up coaching at either 2 or 4 weeks after the initiation of counseling to determine which was more acceptable to the coaches to facilitate behavior change.

Web-Based Behavior Change Program
The CoreHealth wellness platform was used to deliver the 8-week web-based behavior change program. In consultation with CoreHealth, BCTs used in the current 8-week period consisted of prompts (eg, email reminders to check-in; BCT 7.1 [29]); goal setting, action planning, and self-monitoring tasks (eg, prompting to create a goal and then providing a calendar to schedule and track participants’ behavior; BCT 1.1, 1.3, 1.4, and 2.3); instruction on how to perform a behavior (eg, videos on how to meditate and examples of different types of exercise; BCT 4.1 and 6.1); reframing (eg, suggesting new perspectives to view barriers; BCT 13.2); providing health-related information (eg, text, video, infographics, or others such as recipes and guidelines; BCT 5.1, 5.3, and 5.6); and confidence ruler (motivational interviewing technique 11 [52]). Refer to Table 2 for a breakdown of the intervention content by week. Furthermore, the participants had access to modular health information and videos on the platform. Health information covered a variety of health and wellness behaviors. A total of 5 wellness areas were included on the study platform in consultation with CoreHealth, chosen based on their association to HRV (physical activity, sleep, meditation and mindfulness, diet, and stress management [53]). The intervention content was based on existing CoreHealth behavioral and stress management programming. The participants were asked to download the CoreHealth app, which provided the same features as the web platform but in an app form.

\(^a\)HRV: heart rate variability.

Analysis

Descriptive statistics were computed using SPSS software (IBM Corp). The 6-phase method proposed by Braun and Clarke [63] was used to inductively analyze the interview data. Interview data were transcribed verbatim. A total of 2 raters read through the responses to become familiar with the data; main codes and subcodes were identified, using reflexive thematic analysis and then exemplar quotations for each code were selected.

Results

Sample Characteristics

A total of 16 adults consented to participate and were randomized to each of the 16 study conditions. The sample consisted of 15 women and 1 man (mean age 40.9, SD 14.3 years). All the participants worked full-time and had a mean BMI of 24.03 (SD 4.75) and mean job stress of 2.66 (SD 0.5). Regarding race, of the 16 participants, 15 (94%) identified as being White and 1 (6%) as being Southeast Asian. Of the 16 participants, 15 (94%) were married or living as married and 1 (6%) did not respond. Of the 16 participants, 11 (69%) reported having a bachelor degree or college diploma, 3 (19%) reported having postgraduate degrees, and 2 (12%) did not respond.

Participant Retention

A total of 4 (25%) of the 16 participants dropped out of the study before completing the 8-week program. Reasons for study dropout included pregnancy (1/16, 6%), life stress unrelated to the study (2/16, 12%), and no stated reason (1/16, 6%). Of the 12 participants who completed the program, 8 (75%) completed the poststudy follow-up assessment. Regarding item-level missing data from complete surveys, there was 8.3% missing survey data in the prestudy measures and 15.6% missing survey data in the poststudy measures.

Participant Engagement and Treatment Fidelity

A total of 12 (75%) out of the 16 participants completed the entire 8-week program, 1 (6%) completed 7 weeks, and 3 (19%) completed ≤3 weeks. Participants logged into the web-based CoreHealth platform an average of 83 times during the study (SD 63.8; range 36-291 log-ins). The CoreHealth program log-ins by group were as follows: daily resting HRV (mean 110.1), momentary HRV feedback (mean 70.7), initiation...
coaching (mean 64.4), and feedback coaching (mean 90.6). Among the 12 participants initially randomized to a condition that required the use of Light Heart throughout the program, the average number of HRV readings during the 8-week program was 12.55 (range 0-39), suggesting that the participants recorded an HRV reading with an average of 1.80 readings per week. Of the 4 (25%) participants not randomized to use the Light Heart app during their 8-week program duration, 3 (75%) did not use Light Heart and 1 (25%) used it once during the program. All the participants received the coaching they were randomized to. The average acceptability score was 3.9 (SD 0.66), and the average feasibility score was 3.78 (SD 0.91).

**Trial Conduct Interview Findings**

Although more participants found the trial onboarding process helpful, there were few suggestions for improving the trial methods (Table 5). The most frequently reported code within the trial conduct was the usefulness of the onboarding process (9/16, 56%). However, 4 of the participants reported that the onboarding process could be improved. For example, providing videos in addition to showing how to use the apps in the onboarding call would help participants proceed with the trial when they went on their own. In total, 2 of the participants found that the program length of 8 weeks was sufficient, whereas 4 of the participants mentioned that a shorter program would better fit their behavior change efforts. Informal feedback from CoreHealth staff suggested that it might be difficult to manage the backend for 16 conditions and suggested fewer conditions moving forward.

### Table 5. Participant interview findings related to trial conduct.

</tr>
</tbody>
</table>

aHRT denotes participant number.

**CoreHealth Interview Findings**

There were 8 positive and 4 negative codes associated with the use of the CoreHealth platform (Table 6). A total of 6 different BCTs were coded 17 times as being positive for the program, which included prompts, self-monitoring and planning, instruction on how to perform a behavior, reframing, health-related information, and a confidence ruler. Participants noted that they enjoyed the platform features such as a weekly outlook of the self-paced modules. They also liked the health-related information on mindfulness and stress management, particularly the 10-minute videos (although 3 suggested having shorter video options available). However, the action planning feature of the weekly program drew critical feedback (n=10). Although some did not find any benefit in setting an action plan, others found that it required too much writing and that completing the action plan became repetitious as there was no function to copy the plan details from the previous week. The overall usability of the platform interface received both positive n=5 and negative reactions n=11. Most usability issues surrounded updating the user interface, including streamlining the action planning function. Additional instructions for navigating the platform were suggested 3 times for improving the user experience (eg, how-to-use videos).

\(^a\)BCT: behavior change technique.

Light Heart Interview Findings

There were 8 possible codes regarding Light Heart from the interviews (2 likes and 6 dislikes; Table 7). There were both positive n=6 and negative n=8 feedback about the usability of the app. Participants across both the daily resting and momentary HRV components generally liked the look and feel of the app. Feedback about technical issues did not differ across participants receiving either HRV component as the issues were not component specific. Technical issues of poor signal quality, failed access codes early in the program, and elevated light temperature on some Android phones muted enthusiasm for the app in a few participants. Some participants noted that additional instructions about using and troubleshooting the app would enhance app usability. Suggestions included providing more detailed in-app explanations for failed readings owing to poor

(page number not for citation purposes)
signal quality and providing more demo videos on how to use the app (eg, finger placement based on the phone and number of phone cameras).

The participants generally enjoyed recording their HRV readings to obtain biofeedback (11/16, 69%), which primed them to think about managing their stress or health and wellness goals. One participant remarked about obtaining their HRV as follows:

*There was a day I felt pretty stressed out so I tested using the HRV and then I did a breathing exercise. I tested again and it had improved. It’s validating to see those numbers. It makes you feel better to measure again and see that it worked.* [HRT104]

One participant who was randomized to using both types of HRV-BF remarked, “the best usage for HRV is really [pre-post] biofeedback,” suggesting a preference for momentary HRV (HRT108). All participants had access to both types of readings: pre- and postfeedback readings used in the momentary HRV condition and daily resting readings. This confused participants, regardless of the condition, who were uncertain about which type of reading they should record and when.

Participant feedback on both the initiation and feedback coaching components were similar. The participants overwhelmingly liked the coaching style n=11 and reported benefiting from the coach using different behavior change strategies (ie, n=17: goal setting, social support, and providing information; Table 8). One participant felt that the supportive coach helped with their ability to cope with stress, whereas another felt that the added accountability helped keep them on track with their goals. There were no negative responses regarding the BCTs used by the counselors. However, 1 participant did not like the motivational interviewing–based counseling style, suggesting that they wanted the coach to be more directive in providing exercise during the session. A total of 4 respondents suggested that 15-minute sessions were not long enough for coaching to facilitate health behavior changes. Coaching was conducted web-based through the CoreHealth platform, and there were 4 mentions of difficulty in knowing where and how to access videoconferencing.

*aBCT: behavior change technique.

Interview With the Wellness Coach

Overall, the coach was satisfied with the coaching and found that using the spirit of motivational interviewing was beneficial to bridge the gap and allowed the participants to connect to them as a coach. The coach stated that “Motivational interviewing is definitely one that I use a lot.” Although 15 minutes is the standard length of counseling for most low-risk clients, they mentioned that “15 minutes is a tight time frame to be able to really utilize a lot of motivational interviewing tools.” They also suggested that stress and health behavior change content should be separated and introduced at different time points. The coach mentioned that the study’s setup and participants receiving different conditions was a bit confusing. They mentioned the following:

_The communication was probably the hardest part is being able to get in touch with the participants and make sure that they’re on track...I’m used to being that person that goes and holds their hand and helps them along the entire way._

This seemed particularly the case for those receiving feedback counseling but not initiation counseling, where the first communication between the coach and participant occurred part-way through the program. The coach also echoed the challenges that were heard from participants in connecting Light Heart to CoreHealth to view their HRV-BF in CoreHealth as follows:

_I think that’s the main thing is making sure people are utilizing it [Light Heart] properly. And then because, I mean, when people did use it, I received the information in CoreHealth. So, if the information is there, it’s really easy to be able to coach on. It’s just making sure that they see their end._

Discussion

Principal Findings

We conducted this study to assess participants’ perceptions of different levels of the intervention components to be tested in a future optimization stage. There were many positive perceptions about the intervention components; however, interviews with participants and the coach revealed areas of strength and improvement.

In general, participants expressed more positive than negative reactions toward the onboarding process, consistent with the quantitative acceptability scores. Although some participants found it easy to learn the CoreHealth site and study apps, others suggested that additional resources were needed to help individuals engage with the technology as they started the program (eg, instructional videos). There were also mixed
responses regarding the length of the 8-week program. Although some felt that it was right, others found it too long. Previous literature has suggested that sequentially initiating changes to multiple behaviors (ie, 4 weeks of health behavior change followed by 4 weeks of stress management) may be more effective than having participants concurrently initiate changes in multiple behaviors at the same time [63]. This, combined with the feedback from participants and the coach to separate the stress management content from the health behavior change content, will result in a disaggregation of the content into 2 separate 4-week modules. Notably, there were no differences between delivering feedback coaching at either 2 or 4 weeks. Moving forward, coaching will be delivered at the 4-week time point to align with the updated structure of delivering two 4-week modules.

In reporting what they found helpful about the 8-week program, participants frequently mentioned 6 different BCTs. These responses are an indication of treatment receipt fidelity—that participants received the BCTs on the CoreHealth platform as intended [66]. One exception was the action planning content, which participants found cumbersome to use. The quality of how interventions were implemented using technology could impact the amount of time it took to complete a task [67]. Asking participants to set weekly action plans that were time-consuming may have negatively affected their experience. We plan to work with developers to simplify the action planning script to improve the user experience because health information technology systems that are easy to navigate are more likely to be used [68,69]. We also plan to work with developers to improve the process of connecting the Light Heart and CoreHealth apps to the CoreHealth Web platform through their mobile access codes.

Participants enjoyed the look and feel of the Light Heart app and reported important benefits in obtaining HRV. There were 3 noted areas for improvement related to our integration of the app within this study. First, incorporating the HRV function from Light Heart into the broader CoreHealth app would enhance usability and ease the burden of having to switch between using 2 different apps. Combining the 2 apps would also alleviate the second challenge, which is the difficulty of connecting the apps through mobile phone codes. Third, providing additional instructional resources may help alleviate other challenges that participants experienced when first learning to use the app (eg, finger placement). We believe that making these adjustments will improve the usability and acceptability of the study’s apps.

Despite these challenges, participants reported the benefits of using Light Heart to obtain HRV-BF. Biofeedback has been shown to reduce stress and improve well-being [70]. Consistent with these findings, 1 participant in the momentary HRV-BF group explicitly noted that the biofeedback improved their mindfulness and physical feeling. Biofeedback is a form of self-monitoring. Regular self-monitoring can prime individuals to think about their behavior change goals, particularly for those who do not regularly self-monitor [71]. One participant in the daily resting HRV-BF group suggested that taking regular readings served as a regular reminder of their behavior change goals. These self-reported benefits from the 2 HRV-BF conditions provide an anecdotal indication that the participants received their HRV-BF condition and obtained the hypothesized effects as intended.

One of the key activities of the preparation phase is to pilot the candidate components and gather evidence to build a conceptual model before the optimization phase [50,51]. The initial intervention components and levels were determined in consultation with CoreHealth staff based on their affordability and scalability because they align with their current standard practices. Participants’ feedback on the candidate components provided insight into potential mediators to include and assess in a future conceptual model. For example, feedback about HRV-BF did not substantially differ between the daily resting and momentary components, and the findings pointed to increased awareness of current HRV as a potential mediator. The participants suggested that using different BCTs during coaching helped them track and achieve their wellness goals. This may suggest self-regulatory efficacy in managing one’s health behaviors as a potential mediator of coaching components. We plan to review the candidate components and mediators to develop a conceptual model before the next phase of this project.

Strengths
A notable strengths of the study was using a multimethod approach used in this preparation phase and adhering to the MOST framework. For example, obtaining user feedback answers calls to include participants in developing and refining health technology [68]. MOST is a progressive framework for the development and optimization of behavioral treatments. Framing this study using MOST provided clear benchmarks for this study’s objectives and a clear path to progress to the next stage of research. Research can be more impactful and have better patient outcomes when key stakeholders are meaningfully engaged [72,73]. One final strength was the partnered approach used to execute this study. Throughout this project, we had a close working relationship with the CoreHealth staff, which allowed for the quick resolution of technological challenges as they arose. For example, we were able to find a quick solution to the challenge of mobile phone codes not working properly at the beginning of the study. Partnered research also increases the likelihood that the findings will be put into practice [74]. The findings from this study will result in changes that are implemented by our research partner. Two such examples include adjusting the action plan widget and adjusting how users navigate between the 2 types of HRV-BF readings in the Light Heart app.

Limitations
One possible limitation of conducting research with multiple partners was the continued reliance on all partners to perform their roles to ensure the ongoing success of a project. We had exceptional buy-ins from both CoreHealth and our corporate coaching partner throughout this study. However, owing to the economic impact of the COVID-19 pandemic, our coaching partner is no longer able to deliver health coaching. This possibility was anticipated at the onset of our research with CoreHealth, which indicated that they work with other health coaching companies that can be approached to run the next...
phase of the study. Another limitation was that the interview questions may not have been sensitive enough to distinguish between similar HRV-BFs or coaching components. One aim of preparation studies is to gain insight into the delivery of candidate components and different conditions. Future preparation phase research should seek more nuanced feedback about the receptivity of the different component combinations in the individual conditions. Another limitation of this study was the dropout rate, which was higher than anticipated, yielding fewer participant responses to our poststudy assessments. These adherence rates are consistent with other lifestyle intervention trials reporting up to 70% attrition, depending on the length of the follow-up [75-77]. Multiple participants received each of the 4 candidate components; however, 4 (25%) of the 16 conditions did not receive participant feedback and went unpiloted because of dropout.

MOST is a structured framework for developing efficient behavior change interventions. This preparation study will result in improved onboarding and app usability. Given that there were unpiloted conditions, proposed changes based on user feedback, and changes in corporate wellness providers, we plan to reiterate through the preparation phase before proceeding to the optimization phase. Strong partnerships with a commitment to make user-centered adjustments will allow us to keep progressing through the different phases of MOST.

Abstract

Background: Accurate head circumference (HC) measurement is essential when assessing neonates and infants. Tape measure HC measurements are prone to errors, particularly when performed by parents/guardians, due to individual differences in head shape, hair style and texture, subject cooperation, and examiner techniques, including tape measure placement and tautness. There is, therefore, the need for a more reliable method.

Objective: The primary objective of this study was to evaluate the validity, reliability, and consistency of HC app measurement compared to the current standard of practice, serving as a proof-of-concept for use by health care professionals.

Methods: We recruited infants attending the neurosurgery clinic, and parents/guardians were approached and consented to participate in the study. Along with the standard head circumference measurement, measurements were taken with the head circumference app (HC app) developed in-house, and we also collected baseline medical history and characteristics. For the statistical analysis, we used RStudio (version 4.1.1). In summary, we analyzed covariance and intraclass correlation coefficient (ICC) to compare the measurement’s within-rater and interrater reliability. The F test was used to analyze the variance between measurements and the Bland-Altman agreement, t test, and correlation coefficients were used to compare the tape measurement to the measures taken by the HC app. We also used nonvalidated questionnaires to explore parental or guardians’ experiences, assess their views on app utility, and collect feedback.

Results: The total number of recruited patients was 37. Comparison between the app measurements and the measurements with a tape measure showed poor reliability (ICC=0.177) and wide within-app variations (ICC=0.341). The agreement between the measurements done by parents/guardians and the tape measurements done by the researcher was good (ICC=0.901). Parental/guardian feedback was overall very positive, with most of the parents/guardians reporting that the app was easy to use (n=31, 84%) and that they are happy to use the app in an unsupervised setting, provided that they are assured of the measurement quality.

Conclusions: We developed this project as a proof-of-concept study, and as such, the app has shown great potential to be used both in a clinical setting and by parents/guardians in their own homes.

**Introduction**

Accurate head circumference (HC) measurement is essential when assessing neonates and infants. HC outside the normal range may indicate a brain development disorder, hydrocephalus, or an intracranial mass lesion. The growth pattern of HC, determined from serial measurements, provides valuable clinical information; for example, changes in HC are used to help determine whether hydrocephalus needs treatment and is predictive of neurodevelopmental outcomes [1].

The importance of HC measurement is recognized worldwide. The World Health Organization advises HC measurements just after birth (although measurements taken within the first 24 hours can be unreliable due to moulding), at the 8-week check, and any time thereafter if there are concerns about the child’s head growth, weight gain, development, or general health. It is also advisable for HC measurement to be performed at any pediatric review in the first 2 years of life. An accurate HC measurement is essential when clinically evaluating a neonate or infant. It monitors slow or excessive growth, assesses the impact of illness and treatment, and identifies those at higher risk of neurodevelopmental disorders [2]. HC should be measured at extremes of body weight (either below the 0.4th centile or above the 99.6th centile) or if there is rapid weight gain [3].

HC is the widest circumference of the head measured using a tape measure. Typically, this is performed by health care workers. With the increasing use of telephone and remote review clinics as a substitute for face-to-face appointments, community measurement of HC is more frequently used to help guide clinical management in various clinical specialties, such as neurosurgery, neonatology, and pediatrics. Parents and caregivers can be taught to measure the HC using tape, but its accuracy and reliability are sometimes insufficient for making clinical decisions. Many caregivers need more confidence to perform HC measurements themselves because of the technical challenges in performing the measurement and the potentially severe implications of erroneous measurements. Often, HC measurements must be checked by a health care professional, necessitating additional health visitor home visits or trips to the general practitioner.

HC measured with a tape measure is also prone to errors due to individual differences in head shape, hairstyles and texture, patient cooperation, and examiner techniques, including tape measure placement and tautness [4,5]. Measuring HC with a tape measure is often challenging due to poor cooperation in infants, particularly in a health care setting. Neonates in the neonatal intensive care unit pose significant challenges for HC measurements due to the risks associated with handling or removing them from the incubator. Many neonates require daily measurement placement and tautness [4,5]. Measuring HC with a tape measure is also prone to errors due to individual differences in head shape, hairstyles and texture, patient cooperation, and examiner techniques, including tape measure placement and tautness [4,5]. Measuring HC with a tape measure is often challenging due to poor cooperation in infants, particularly in a health care setting. Neonates in the neonatal intensive care unit pose significant challenges for HC measurements due to the risks associated with handling or removing them from the incubator. Many neonates require daily HC measurements.

The challenges of performing HC measurement with a tape measure, both in the hospital and the community, mean many missed opportunities to capture HC. Only 3% of infants presenting to Accident and Emergency had their head circumference measured within 1 year in an Australian hospital [6]. A study from a UK hospital found that HC measurement was performed sporadically in only 1 of 7 infants [7]. In summary, HC assessment is frequently missed due to difficulties measuring with a tape measure and the errors associated with this method. There is, therefore, an urgent need to improve our ability to monitor HC easily, accurately, and reliably, which would facilitate greater dependence on caregivers to perform this assessment independently.

We developed a smartphone app that measures HC using the smartphone camera and automated measurement to improve the accuracy and reliability of HC measurement. Our study’s main objective was to validate the accuracy of the HC app and prove its utility and feasibility when used by both health care workers and parents/guardians.

**Methods**

**Patient Recruitment**

Treating clinicians identified patients eligible for this study (infants <18 months of age) in a tertiary neurosurgical referral center and notified research team members with the consent of parents/guardians. Once identified, research team members approached patients’ parents/guardians to seek informed consent before their clinic appointment or at the bedside on the ward. An information sheet was used. If they chose to participate, we measured the HC during the clinic appointment or on the ward. Sample size estimation was calculated with 90% statistical power to detect a change of means by 1 and an SD of 1. This, along with 10% iteration, equaled 33 participants.

**App Development**

To successfully develop the app, we built the back end and front end of the app separately. Languages used were Python and JavaScript, and the app was built in Expo [8] using React Native [9]. The app’s back end used an algorithm to recognize a reference object and provide a measurement according to the object. Technically, the algorithm consists of a couple of parts. One part includes the foreground and contour recognition code, which recognizes the oval object and then measures the pixel points around its contour. Another part of the algorithm detects the reference object and recognizes the scale in comparison. They both fuse using Python to measure according to the identified contour points of both objects and the introduced scale of the known object sizes, providing a measurement within the scale. Points were manually inputted to clarify the top, bottom, and outermost lateral edges of the baby’s head. This was introduced as an additional measure to align with the already recognized contour and provide a more accurate measurement.

The algorithm was tested to match an SD of 0.5 cm between measurements. This SD target was selected to mirror the accepted variation in tape measurements, aiming for consistency...
and reliability while minimizing bias and variability associated with traditional methods [10].

We used a phantom baby model to test the accuracy of our measurement model (Figure 1). Instructions for parents/guardians are shown in Figure 2.

Figure 1. Head circumference app measurement sequence.
Ethical Considerations

Our regional research ethics committee (East of England-Cambridge East Research Ethics Committee) reviewed our study, and Health Regulatory Authority approval was obtained on June 6, 2022 (22/EE/0109). All parents/guardians of patients eligible to participate were approached with information about the study and given sufficient time for consideration of their participation. Informed consent in English was signed before any study-related procedures were undertaken. The data collected as part of the study were anonymized and deidentified. No patient identifiable data were collected as part of this study. Study participants and parents/guardians did not receive any compensation for their participation.

Study Objectives

After the successful trial on a life-size baby model (3B Scientific W17001 Baby Care Model), we developed a trial protocol and a study. The rationale of our study was to validate the HC app in a clinical setting and to review its usability by parents/guardians in the community.

The primary objective was to assess the technical validity (ie, accuracy and precision) and user reliability (ie, consistency of measurements across different raters) of the HC app compared to standard tape measure methods. We also set multiple secondary objectives; these include evaluating user satisfaction with the HC app and comparing the reliability of HC measurements between health care professionals and parents/guardians using both tape and the app.

Baseline and Study Data Collection

All participants had a medical history, clinical examination, and routine investigation details taken from their medical notes. The study phone did not retain any patient information. A nonvalidated questionnaire was used to capture parental or guardian feedback. Public and patient involvement feedback was sought in the design of the questionnaires for parental or guardian feedback. A complete list of questions can be found in Multimedia Appendix 1. HC measurements, as part of the study, were performed using a tape measure along the widest circumference of the baby’s head. Parents/guardians were instructed by a health care professional competent in HC measurement before the measurements were taken. They were also supervised during the procedure by a health care professional who was part of the study team. A specific set of instructions for using the app was prepared to be shown to the parents before they attempted to use the application. The instructions were developed with the help of a patient and a public representative group during the study development phase.
Statistical Analysis

In this study, we introduce a novel measurement method, which requires comprehensive evaluation to ascertain its properties. Reliability, validity, and reproducibility are key criteria in measurement science. We adopt the COSMIN (COncensus-based Standards for the selection of health Measurement INstruments) initiative standards, a widely recognized authority in clinical measurement quality [11] (Figure 2), to guide our assessment. In recent years, COSMIN has become a well-recognized organization [12], and consensus definitions can convey a unified message. COSMIN has also been dedicated to improving clinical measurement, including creating guidance and resources for measurement quality. That is why we decided to be guided by their definitions in exploring our novel measurement method’s reliability, consistency, and validity.

Guided by the COSMIN initiative, reliability is defined as the degree to which the measurement is free from measurement errors and includes a subsection of internal consistency (the degree of interrelatedness), reliability (the proportion of total variance due to true variance), and measurement error (systemic random error) [11,13]. To address this domain, we analyzed covariance, intraclass correlation coefficient (ICC), and Cohen Kappa and generated the interrater and within-rater reliability and variance. The ICC is between 0 and 1, where values below 0.5 indicate poor reliability, those between 0.5 and 0.75 indicate moderate reliability, those between 0.75 and 0.9 indicate good reliability, and any value above 0.9 indicates excellent reliability [14].

The COSMIN initiative also defines validity as the degree to which a measurement instrument measures the construct and its purpose to measure. The main subsections of this include content validity, criterion validity, and construct validity. Content validity ensures that the content of a measuring tool adequately reflects the given facts. Construct validity is defined as the degree to which the scores of a measurement instrument are consistent and includes structural validity, which is the degree of reflection of dimensionality, and hypotheses testing, which is synonymous with construct validity. Criterion validity shows how adequate the measurement is based on a “gold standard” [11,13]. For comparisons of agreements between the measures in this study, we used the correlation coefficients and the Bland-Altman method. The Bland-Altman plot analysis is a simple way to evaluate a bias between the mean differences and estimate an agreement interval. This interval encompasses 95% of the differences of the second method compared to the first one [15].

For the statistical analysis, we used RStudio (version 4.1.1). In summary, we analyzed covariance and ICC to compare the measurement’s within-rater and interrater reliability. The F test was used to analyze the variance between measurements and the Bland-Altman agreement, t test, and correlation coefficients were used to compare the tape measurement to the measures taken by the HC app.

Results

Demographics

We recruited 37 patients (23 male and 14 female), with a median age of 9 (IQR 4-16) months.

Normal means distribution was indicated visually with a histogram (Figure 3); however, the Shapiro-Wilk normality test with a $W=0.777$ and $P<.001$ showed a deviation from the normal distribution of means.
Comparison of HC App Measurements Versus Tape Measurements

A 2-sample t test was used to compare the mean values of all the tape measurements with HC app–based measurements. There was a statistically significant difference between the measurements ($P < .001$). The variance in the population means was found to be equal ($F_{5,30} = 0.92134; P = .81$).

We then calculated the limits of agreement between the 2 measures using the Bland-Altman plot. The upper limits of agreement were determined to be within a range of 0.706 to 21.472, revealing significant variability in the data points (Figure 4). These were scattered across the field away from the 0 lines, indicating a weak agreement between the 2 methods. We then assessed the ICC for the measurements, which showed a value of 0.177, which is less than 0.5, indicating inferior reliability of the HC app measurements in comparison to the measurements taken by a tape measure.
Comparison of Measurements Within the App (Interrater Reliability)

We compared the HC app’s performance between different raters (researchers and parents/guardians) by calculating the ICC, which yielded a value of 0.341. The limits of agreement, determined using Bland-Altman plots, were also high (lower limit –16.696 and upper limit 20.252), with a mean difference of 11.089 and with a significant scatter of the values. These results show poor agreement between the rater evaluations. (Figure 5). We then performed an $F$ test to assess whether the variance between the 2 groups was equal. This resulted in $F_{35,71}=0.302$ and $P<.001$, indicating a difference in the variance of the measurements between the groups. The same analysis was also performed comparing the consequential researcher measurements, showing similar results ($F_{3,33}=1.994; P=.04$). The standard error of the mean (SEM) between the measurements done by parents/guardians and the researcher measurements was 0.979 and 0.921, respectively. Cohen Kappa was calculated at 0.435, showing a fair agreement between the measures.

Figure 4. Bland-Altman plot; limits of agreement and variability assessment between app measurements and tape measurements.

Figure 5. Bland-Altman plot; limits of agreement and variability assessment between different app measurements.
Comparison Between Parent/Guardian and Health Care Professional Tape Measurement

We also compared the interrater reliability between the measurements taken with a tape measure. The parents/guardians measured the HC under direct supervision and guidance. The ICC was 0.901, indicating good method reliability with very few lines above the 0 line in the plot and a mean difference of 0.5, comparable to other evidence in the literature [16]. The SEM for the medical professional measurements was 0.88, while the SEM for the parent/guardian measurements was 0.97. Cohen Kappa was set at 0.93, showing near-perfect agreement (Figure 6).

Figure 6. Bland-Altman plot; limits of agreement and variability assessment between parent/guardian and health care professional app measurements.

User Feedback

The survey results showed favorable opinions from parents/guardians, with the majority of them being happy to use the HC app in a nonsupervised setting. Most parents/guardians (n=31, 84%) answered that the HC app was easy or extremely easy to use, and 33 (89%) responded that they were very confident in using the HC app after reviewing the instructions (Figures S1 and S2 in Multimedia Appendix 1). The app instructions, created using public and patient involvement feedback, were also valued by the parents (Figure S4 in Multimedia Appendix 1). Once again, the vast majority (n=32, 87%) were either satisfied (n=14) or very satisfied (n=18) with the HC app (Figure S3 in Multimedia Appendix 1). Free-text comments from several parents/guardians described that they found the concept of using the HC app appealing and were happy to be presented with the opportunity to use it. Most parents were also happy to use the app even at home if available (Figure S5 in Multimedia Appendix 1). Furthermore, they indicated that they would be very likely to use the HC app provided that the app’s measurements and reliability improve.

Discussion

Principal Findings

We developed a smartphone app that measures HC using the smartphone camera and automated measurement. Our HC app is less accurate in its current iteration than the standard tape measure. Interrater reliability using the app was poor, but there was no significant difference in the variability between the operators. Parents/guardians also valued the convenience of using the app and the ease of performing the measurements, highlighting the potential of this technology once modified to improve accuracy.

The idea for our HC app was conceived during the COVID-19 pandemic lockdown in 2020, when disruption to health care services significantly reduced face-to-face appointments between patients and health care providers. Parents/guardians can measure HC using tape, but this requires some teaching and is prone to errors. Many parents/guardians express anxiety about assessments typically carried out by health care professionals being delegated to them and used in making clinical decisions. We, therefore, recognized the opportunity to create an automated method for HC measurement that is simple and easy to use and eliminates the errors associated with tape measure placement and patient cooperation.

Smartphone (and wearable) technology plays an ever-increasing role in public health and health care delivery, increasing the ability of health care workers to monitor patients remotely and empowering patients to track their health care metrics. The potential of technology to benefit health care is recognized by the World Health Organization, which introduced the term “mHealth” [16] to denote “medical and public health practice supported by mobile devices, such as mobile phones, patient monitoring devices, personal digital assistants (PDAs), and other wireless devices” [16]. Mobile communication allows remote assessments with results that can be transferred distantly via mobile devices. In this landscape, we feel that replacing the tape measure with a smartphone equivalent is inevitable.

The current version of our HC app requires a reference object and manually placed input points to indicate the top, bottom,
and lateral edges of the baby’s head. The high reproducibility of measurements taken by the same person indicates the ease and reliability of this method. The relatively poor accuracy of our HC app is likely due to confounders such as the photo’s angle and distance and the type of reference object used. Using a bright-colored reference object (eg, a bottle cap) gave us a more accurate reading. However, we recognize that this choice of reference object may also relate to some inaccuracies, making the app less user-friendly and contributing to the difficulties in obtaining the perfect conditions for the photo. Thus, we intend to continue to develop the HC app using newer smartphone technology, such as light detection and ranging (LIDAR), which will improve the accuracy of the measurements, eliminate the need for a reference object, and make the app more user-friendly.

This technology is highly advanced, and mobile LIDAR is already incorporated into most modern phones. Since 2020, Apple Inc has introduced a LIDAR sensor in some iPhone and iPad models, namely iPhone 12 Pro, iPhone 12 Pro Max, iPhone 13 Pro, iPhone 13 Pro Max, iPad Pro 2020, and iPad Pro 2021 (as of March 2022) [17]. Dimension can easily be measured between 2 points in the LIDAR 3D point cloud, providing accurate measurements of various objects. This technology is already used in other fields [18,19]. Thus, we are confident that this technology can be reliably used to improve the measurement accuracy and usability of the app.

Feedback from parents/guardians about the HC app revealed that they are confident in using the HC app and value the ability to track HC themselves in the convenience of their homes. They appreciated the ease of performing the measurements and performing them without fear of waking a sleeping infant. Overall, we received positive feedback from both the public and patient panel groups we consulted in preparation for our proof-of-concept study as well as during the trial itself. Many parents gave both written and verbal feedback with ideas and suggestions for how to improve the app’s utility. Most parents suggested features they would like to see, which shows good community engagement, reassuring that the concept can easily reach the target auditorium. Most of the parents were very welcoming to the technological solution we proposed. They expressed their interest in using it in the privacy of their homes after improvements to the app. However, reassurance is needed that the measurements are accurate and reproducible, which is something to be aware of when the final version of the app is distributed. We will keep that in mind in the development of future studies following the development of the final app to increase the adoption in the community.

Importantly, our study confirms that parent/guardian measurements using a tape measure are reliable with an excellent correlation (ICC=0.901) and agreement (kappa=0.93) between health care professionals and parents/guardians. Although our findings are similar to those previously reported by Sullivan et al [4] and support empowering parents/guardians to perform these measurements, these measurements were done under the direct supervision of a health care professional with an additional helping hand during the measurements. Having this in mind, translating these results may provide false reassurance regarding the reliability of parental measurements done at home without supervision. The only thing we can do to manage erroneous measures is to provide sufficient training and guidance to parents/guardians. This does not eliminate errors, but it offers a certain degree of reassurance. The gold standard measure, nevertheless, will remain the one measured by a health care professional. In contrast, the HC app, once improved, has the potential to introduce a sustainable, uniform, and reproducible means of measurement, which can be applied consistently across settings, providing equal reliability.

Limitations
To facilitate recruitment and combined measurements by both health care professionals and parents/guardians within a reasonable time frame, measurements were performed in the clinic rather than at home. A researcher supervised measurements; however, once instructions were given, no further help was provided, as our intention was for the HC app to be reliably used by parents/guardians independently at home. Our study design, therefore, only partially validates the HC app use in the home environment independent of health care professionals. We plan to explore this with future iterations of our HC app. Another important limitation to report is associated with the Shapiro-Wilk normality test. As the data set increases in size, the test can pick up very small variations, which can result in a higher likelihood of rejecting the null hypothesis [20].

Conclusions
Our HC app has demonstrated proof-of-concept for parent/guardian HC measurement using smartphone technology. The feedback collected from parents/guardians confirmed that the technology is easy to use, giving them the confidence to perform the measurement independently. Overall, parents/guardians were interested in this technological solution and were eager to give both written and verbal feedback during the study. This, along with the clinical proof-of-concept, reassured us that the technology is feasible, prompting us to initiate plans to improve the versions of our HC app.

Abstract

Background: Self-help eHealth interventions provide automated support to change health behaviors without any further human assistance. The main advantage of self-help eHealth interventions is that they have the potential to lower the workload of health care professionals. However, one disadvantage is that they generally have a lower uptake. Possibly, the absence of a relationship with a health care professional (referred to as the working alliance) could lead to negative expectations that hinder the uptake of self-help interventions. The Unified Theory of Acceptance and Use of Technology (UTAUT) identifies which expectations predict use intention. As there has been no previous research exploring how expectations affect the adoption of both self-help and human-supported eHealth interventions, this study is the first to investigate the impact of expectations on the uptake of both kinds of eHealth interventions.

Objective: This study investigated the intention to use a self-help eHealth intervention compared to a human-supported eHealth intervention and the expectations that moderate this relationship.

Methods: A total of 146 participants were randomly assigned to 1 of 2 conditions (human-supported or self-help eHealth interventions). Participants evaluated screenshots of a human-supported or self-help app–based stress intervention. We measured intention to use the intervention-expected working alliance and the UTAUT constructs: performance expectancy, effort expectancy, and social influence.

Results: Use intention did not differ significantly between the 2 conditions (t₁₄₂=−1.133; P=.26). Performance expectancy (F₁,₁₄₀=69.269; P<.001), effort expectancy (F₁,₁₄₀=3.961; P=.049), social influence (F₁,₁₄₀=90.025; P<.001), and expected working alliance (F₁,₁₄₀=26.435; P<.001) were positively related to use intention regardless of condition. The interaction analysis showed that performance expectancy (F₁,₁₄₀=4.363; P=.04) and effort expectancy (F₁,₁₄₀=4.102; P=.045) more strongly influenced use intention in the self-help condition compared to the human-supported condition.

Conclusions: As we found no difference in use intention, our results suggest that we could expect an equal uptake of self-help eHealth interventions and human-supported ones. However, attention should be paid to people who have doubts about the intervention’s helpfulness or ease of use. For those people, providing additional human support would be beneficial to ensure uptake. Screening user expectations could help health care professionals optimize self-help eHealth intervention uptake in practice.
eHealth provides the opportunity to provide remote or automated health care support through digital tools [1]. eHealth is becoming increasingly relevant, for example, because of the physical restrictions during the recent COVID-19 outbreak [2]. During this pandemic, the demand for health care support increased too. Especially vulnerable groups experienced increased mental health difficulties [3,4], which require professional support. However, health care professionals already have a high workload and pressure [5] and, in some cases, even experience an additional workload from using eHealth [6]. Self-help eHealth interventions might provide a potential solution to these problems. Self-help eHealth interventions are defined as interventions in which automated support instead of human assistance is provided [1]. As this means that no human professionals are involved, self-help eHealth interventions are easier and cheaper to widely implement [1].

Despite these advantages, self-help interventions generally deal with low levels of adherence [7-10] and low uptake [11,12]. People generally show a higher intention to start with lifestyle changes using an intervention with additional human assistance compared to a self-help intervention [13]. While there has been extensive research on the factors contributing to nonadherence, there is a notable gap in our understanding when it comes to expectations that influence whether individuals will choose to use an intervention before starting. This information is important, as a growing number of eHealth tools are being developed and proven to be effective but hardly used [14,15]. Therefore, the aim of this study is to investigate whether there is a difference in use intentions between self-help and human-supported eHealth interventions and if user expectations influence the intention to use the intervention. If we know what expectations drive people’s intention to either use self-help or human-supported eHealth interventions, we could predict and even influence their actual uptake [16].

A possible explanation for the low use intention of self-help interventions could be the lack of a relationship with a health care professional [17]. This so-called working alliance, the degree to which a health care professional and patient is involved in a useful and collaborative working relationship [18], is an important predictor of intervention adherence and effectiveness [19,20]. People are more engaged with the intervention and motivated to work on their goals when they feel supported. This effect is not exclusive to face-to-face settings; it is also evident when internet-based human assistance is involved in the use of eHealth interventions [21,22]. It is even shown to be present in self-help eHealth interventions with automated support, using, for example, a human avatar [23-25]. Thus, people can form relationships not only with other people but also with technology [26]. Therefore, we predict that people’s expectations toward a potential future working alliance when using an eHealth intervention will influence their intention to use that intervention.

Other important expectations that may influence the use intention of human-supported and self-help eHealth interventions can be found within the Unified Theory of Acceptance and Use of Technology (UTAUT) [16]. According to this model, 3 different types of expectations explain people’s intention to start with an eHealth intervention. These UTAUT expectations are (1) performance expectancy: the extent to which someone expects that the eHealth intervention will be helpful in reaching their goals; (2) effort expectancy: the extent to which someone expects that the eHealth intervention will be easy to use; and (3) social influence: the extent to which someone expects that important others believe one should use the eHealth intervention [16]. Although the UTAUT model has been used to explain people’s intention to use eHealth in general [27,28], to our knowledge, no studies have used this model to investigate differences in people’s intention to use either human-supported or self-help eHealth interventions.

In this study, we aim to investigate (1) whether there is a difference in use intention between human-supported and self-help eHealth interventions, (2) whether the expected working alliance predicts the use intention of human-supported and self-help eHealth interventions, and (3) what UTAUT constructs predict the use intention of human-supported and self-help eHealth interventions.

**Methods**

**Design and Sample**

In an experiment, people were presented with a sham stress management app. In this app, people would either be supported by a human coach or by an automated coach. We decided to use a student sample, as they experience high levels of stress and could therefore benefit from an eHealth stress intervention [29], especially given their increased need for support during the COVID-19 pandemic [3,4]. They were asked to evaluate the screenshots of the app and measure their use intention, the 3 UTAUT constructs (performance expectancy, effort expectancy, and social influence), and their expected working alliance. We used a randomized between-participants design with 2 experimental conditions (human-supported or self-help eHealth interventions). Healthy participants aged 18 years or older, who had a sufficient level of grasp in English, were recruited on the campus of Leiden University with internet-based and offline flyers. Power calculations [30] identified a minimum sample size of 119 to detect a medium effect ($\beta^2=0.15$) with an $\alpha$ of .05, based on a linear multiple regression with 3 predictors.
Procedure and Manipulation
Interested participants could open the internet-based questionnaire and would be offered the internet-based consent form. After reading and agreeing to the informed consent, participants were automatically randomized into 1 of 2 experimental conditions (human-supported or self-help eHealth interventions). In both conditions, participants were instructed to evaluate a nonexistent stress management app for students called “Bye Bye Stress.” They were asked to carefully assess the screenshots of the app and give feedback to help the researchers make the app fit the needs of students. Although the design of the app and the content of the intervention were identical in both conditions, the conditions differed in the type of support that would be offered in the app. In the human-supported condition, the description of the app explained how a human coach would support the participants and provide them feedback. The screenshots of the app showed a picture of a human coach and messages with a human tone of voice (Figure 1). In the self-help condition, the description of the app explained how participants would receive automated feedback. In the screenshots, there was no picture of a human being, and the messages had a neutral tone of voice (Figure 1). All screenshots used in both conditions can be found in Multimedia Appendix 1. After this, participants were asked to complete the questionnaire.

Figure 1. Example screenshot of the app for human-supported (left) and self-help conditions (right).

Measures
Use Intention
The behavioral intention subscale of the UTAUT questionnaire [16] was used to assess use intention. The subscale consists of 3 items (eg, “I would intend to use ‘Bye Bye Stress’ in the next 6 months.”) measured on a Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree). A higher score indicates a higher intention to use the app. The scale showed a high internal consistency (Cronbach α=.953).
**Expected Working Alliance**

The expected working alliance was measured with an adjusted version of the Working Alliance Inventory–Short Revised form (WAI-SR) [31], which consists of 12 items measured on a 5-point Likert-type scale ranging from 1 (seldom) to 5 (always). Questions were adjusted to fit the context of the study by using the words “coach,” “lifestyle,” and “intervention” and being written in the future tense (eg, “The coach and I will collaborate on setting lifestyle goals.”). A higher score indicates a stronger working alliance. The adjusted version had a high internal consistency (Cronbach $\alpha=.917$).

**Performance Expectancy, Effort Expectancy, and Social Influence**

The constructs predicting behavioral intention according to the UTAUT model—performance expectancy, effort expectancy, and social influence—were measured with the corresponding UTAUT subscales [16]. Each subscale consisted of 4 items (eg, “I find 'Bye Bye Stress' useful.”), measured with a Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree). A higher score indicates a higher expectation of the app’s efficacy in helping the participant, a higher expectation toward the ease of use of the app, and a higher expectation that important others will approve the use of the app. The performance expectancy, effort expectancy, and social influence subscales all had sufficient internal consistency (Cronbach $\alpha$ of .764, .730, .792, respectively).

**Manipulation Check**

To assess whether participants carefully read the information and whether the manipulation had worked, they were asked to complete a manipulation check question (“During the intervention, I would be supported by...” followed by several options, such as “doctor” or “chatbot”).

**Analyses**

To test whether there was a difference in use intention between conditions, we ran a 2-tailed independent-sample $t$ test with use intention as the dependent variable and condition (human-supported vs self-help eHealth interventions) as the independent variable. To test whether the association between condition and use intention differed for different levels of the UTAUT constructs (performance expectancy, effort expectancy, or social influence) as a covariate in 3 separate analyses. We added use intention as dependent variable, condition as fixed factor, and each of the UTAUT constructs (performance expectancy, effort expectancy, or social influence) as a covariate in 3 separate analyses. We analyzed both the main effects of condition and the UTAUT construct, as well as their interaction effect on use intention. To further investigate the interaction patterns found in the data, we conducted 3 simple slopes analyses: the intercept and the slope were obtained for both conditions from the parameter estimates of the GLM analyses testing the association between expected working alliance and use intention.

To test whether the association between condition and use intention differed for different levels of the UTAUT constructs of performance expectancy, effort expectancy, and social influence, we conducted 3 univariate GLM analyses with interactions. We added use intention as dependent variable, condition as fixed factor, and each of the UTAUT constructs (performance expectancy, effort expectancy, or social influence) as a covariate in 3 separate analyses. We analyzed both the main effects of condition and the UTAUT construct, as well as their interaction effect on use intention. To further investigate the interaction patterns found in the data, we again conducted 3 simple slopes analyses: the intercept and the slope were obtained for both conditions from the parameter estimates of the GLM analyses testing the association between the UTAUT construct and use intention.

Statistical analyses were conducted with SPSS (version 26; IBM Corp) with a significance level set at $P \leq .05$.

**Ethical Considerations**

The study was approved by the Psychology Research Ethics Committee of Leiden University (CEP19-1125/557). Furthermore, the study was preregistered through the Center for Open Science [32]. Before the start of the study, participants were asked to sign an informed consent form. After completing all the questionnaires, they were debriefed and provided with a few examples of real internet-based stress management interventions in case they needed one. As compensation, participants received course credits.

**Results**

### Demographic Characteristics

A total of 146 students participated in our study and completed the questionnaire. Their mean age was 21.8 (SD 4.51) years, 103 (70.5%) were female, and 104 (71.2%) were of Dutch nationality (Table 1). There were no significant differences in demographic characteristics between the 2 groups.

Use Intention Per Condition

We found no significant difference in use intention between the human-supported condition and self-help condition ($t_{142}=-1.133; P=.26$; Table 2). Furthermore, we found no differences between the 2 conditions in any of the other constructs (Table 2).

Working Alliance and Use Intention

The GLM showed no significant association between condition and expected working alliance ($F_{1,140}=0.051; P=.82; \eta^2=0)$. However, we did find a significant positive association between expected working alliance and use intention ($F_{1,140}=26.435; P<.001; \eta^2=0.159$). We found no significant interaction effect of condition and expected working alliance on use intention ($F_{1,140}=0.367; P=.55; \eta^2=0.003$; Figure 2).

UTAUT Constructs and Use Intention

The GLM showed no significant association between condition and performance expectancy ($F_{1,140}=3.34; P=.07; \eta^2=0.024$). We did, however, find a significant positive association between performance expectancy and use intention ($F_{1,140}=69.269; P<.001; \eta^2=0.331$) and a significant interaction effect of condition and performance expectancy on use intention ($F_{1,140}=4.363; P=.04; \eta^2=0.030$). An increase in performance expectancy was related to a greater increase in use intention in the self-help condition compared to the human-supported condition (Figure 2).

We also found no significant association between condition and effort expectancy ($F_{1,140}=3.408; P=.07; \eta^2=0.024$). However, again, we did find a significant positive association between effort expectancy and use intention ($F_{1,140}=3.961; P=.049; \eta^2=0.028$) and a significant interaction effect of condition and effort expectancy on use intention ($F_{1,140}=4.102; P=.045; \eta^2=0.028$). An increase in effort expectancy was related to a greater increase in use intention in the self-help condition but not in the human-supported condition (Figure 2).

Again, we found no significant association between condition and social influence ($F_{1,140}=0.003; P=.96; \eta^2=0$). We did find a significant positive association between social influence and use intention ($F_{1,140}=90.025; P<.001; \eta^2=0.391$) but this time...
we found no significant interaction effect of condition and social influence on use intention ($F_{1,140}=0.020; P=.89; \eta^2=0$; Figure 2).

**Discussion**

**Overview**

In our study, we asked university students to evaluate a sham stress management app. We aimed to investigate whether there is a difference in use intention for self-help eHealth interventions compared to human-supported ones and what user expectations may influence this. We found that people were as likely to start using a self-help eHealth intervention as an eHealth intervention with human support. More than with human-supported interventions, the perception that the intervention might be ineffective or difficult to use limits the intention to start using self-help interventions. See Figure 3 for an overview of the findings.

![Overview of study findings.](image)

Although previous studies show a relatively low uptake and use intention of self-help eHealth interventions [11-13], we did not find differences in use intentions between the self-help and human-supported interventions. Possibly, the health beliefs, perceptions, and skills of our student sample might have played a role in this [33]. Not only do perceptions about the effectiveness or ease of use of an eHealth tool affect the start of an intervention but also perceptions about the risks of getting health-related problems and actually performing the health-promoting behavior [34]. Furthermore, a younger age and higher educational level are related to a higher intention to start eHealth interventions in general [13]. Our sample might therefore have been more open to using eHealth interventions and were less influenced by the presence, or lack thereof, of human support. Future research could focus on investigating the role of age and educational level on use intentions of self-help and human-supported eHealth interventions. Another explanation for the differences in findings between our and previous studies [11,12] could be the use of different outcome measures. Although the UTAUT model predicts that use intention can predict actual use, studies do show that people have difficulties translating their intentions into actual behavior [35]. The objective measure of uptake might therefore have led to different results compared to the more subjective measure of use intention we used, which would be interesting to additionally take into account. Finally, the study that did find a difference in use intention between self-help and human-supported interventions focused on interventions for mental health, such as depression [13]. It would be interesting to test if the need for social support during eHealth interventions depends on the goal of the intervention (e.g., psychological vs lifestyle improvements).

Interestingly, we found that an expected working alliance has an equally strong effect on the intention to use either a human-supported or self-help intervention. This result is in line with previous studies showing a positive effect of working alliance on intervention effectiveness and adherence, both within human-supported [21,22] and self-help eHealth interventions with automated support [23-25]. Our findings show that working alliance is not important only during an intervention but even before the intervention has started in the form of expectations. The similar effect of the expected working alliance in both conditions suggests that people not only are able to actually have relationships with technology [26] but also seem to expect building one with the technology they are about to interact with. These results would also mean that improving the expected working alliance before the start of an intervention (e.g., by designing a digital character that would welcome the user) would be a way to possibly increase the uptake of self-help eHealth interventions.
Finally, we found that performance and effort expectancy had a stronger effect on the use intention of self-help interventions compared to human-supported interventions. Not only the UTAUT model but also models such as the Health Belief model show that perceived benefits and perceived barriers affect whether people start with a health-promoting behavior, such as stress management [33]. What is new, though, is that the perceived effectiveness and ease of use of the intervention have a more pronounced impact on intention to use an intervention for interventions with an absence of human support compared to interventions where human support is available. This suggests that the perception that the intervention might be ineffective or difficult to use diminishes the intention to start using a self-help intervention but not the intention to start using a human-supported intervention. Meta-analyses show that the mere presence of a human being (even a nonprofessional) is a key ingredient in intervention effectiveness and the prevention of dropout [36-38]. Just the option of having someone available to provide procedural support (related to performance expectancy) or technical support (related to effort expectancy) seems to be enough for people to be motivated to start something new. The presence of a human coach could act as a buffer against negative expectations, which would make it easier for these people to adhere to the intervention [39]. Possibly, the mere presence of social support in the human-supported intervention could compensate for a lack of self-efficacy (the extent to which one believes in his or her own capabilities [40]) that people may feel when using a new intervention [41,42]. This could lower the perceived barriers and increase willingness to start using the intervention [33]. Exploring this further is crucial in a clinical context because individuals with limited social support tend to experience reduced adherence to health interventions and demonstrate less favorable intervention outcomes [39,43]. Even despite the relatively high use intention of self-help eHealth interventions, these results indicate that it is important to take the user’s needs and wishes into account when deciding on the level of human support to provide during an intervention.

Self-help eHealth interventions will become more and more important in health care practice. To ensure uptake of new eHealth interventions, professionals could screen the user’s expectations toward the intervention’s helpfulness and ease of use beforehand (Table 3). If the user’s expectations turn out to be low, it would be useful to incorporate some level of human support into the eHealth intervention to prevent people from dropping out even before the start of the intervention. Additionally, designers of self-help eHealth interventions could pay extra attention toward its perceived helpfulness and ease of use. Preventing negative user expectations toward the intervention’s performance or effort expectancy could help increase the uptake of self-help eHealth interventions.

Strengths and Limitations

Our study was not without limitations. For example, although the screenshots of the app were adjusted to the experiences and interests of our sample, it is plausible that the topic of stress management was not equally relevant for all students, which could also have affected use intentions. For future studies, it would be better to tailor the goal of the eHealth intervention (eg, decreasing stress or improving physical activity) to the actual interests of the individual participants to investigate if and how this affects a participant’s use intention. Second, we used a university student population to test our hypotheses. People with a younger age and higher educational level have a more favorable attitude toward eHealth interventions in general [13]. To be able to generalize our findings, future research should investigate whether the same effects are found in other populations. It would be interesting to replicate this study with a target population who would benefit the most from eHealth interventions, for example, older patients with a chronic disease, to see if their expectations toward either human or automated support have similar effects on their intention to start with such interventions.

Conclusions

In our study, we investigated what expectations drive the intention to start using self-help and human-supported eHealth interventions. The results suggest that expectations toward the intervention’s helpfulness and ease of use are especially relevant regarding the use of self-help interventions. This means that people who have doubts about the intervention’s usefulness or usability would benefit the most from additional human support. The question, however, remains whether such expectations are also relevant for actual uptake. Our study provides a basis to further investigate user expectations within a clinical sample, which will provide health care practitioners with the tools to influence the uptake of eHealth interventions.
Acknowledgments
This work was supported by the Netherlands Cardiovascular Research Initiative, an initiative with the support of the Dutch Heart Foundation, CVON2016-12 BENEFIT, ZonMw (the Netherlands Organization for Health Research and Development), and the members of the BENEFIT consortium. Furthermore, we would like to thank Yalou Schoot (master student of psychology, Leiden University) for her assistance in the practical implementation of the study procedure and for data acquisition.

Authors' Contributions
TRCR and TR contributed to study design. TRCR was responsible for data acquisition. TRCR, TR, and AWME were involved in data analysis and interpretation and drafting the manuscript. TRCR, TR, LDB, VRJ, RAK, DEA, and AWME contributed to manuscript revision. All authors gave final approval and agreed to be accountable for all aspects of the work ensuring integrity and accuracy.

Conflicts of Interest
None declared.

Abstract

Background: Chronic pain has long been a major health burden that has been addressed through numerous forms of pharmacological and nonpharmacological treatment. One of the tenets of modern medicine is to minimize risk while providing efficacy. Further, because of its noninvasive nature, virtual reality (VR) provides an attractive platform for potentially developing novel therapeutic modalities.

Objective: The purpose of this study was to determine the feasibility of a novel VR-based digital therapy for the treatment of chronic pain.

Methods: An open-label study assessed the feasibility of using virtual embodiment in VR to treat chronic pain. In total, 24 patients with chronic pain were recruited from local pain clinics and completed 8 sessions of a novel digital therapeutic that combines virtual embodiment with graded motor imagery to deliver functional rehabilitation exercises over the course of 4 weeks. Pain intensity as measured by a visual analog scale before and after each virtual embodiment training session was used as the primary outcome measure. Additionally, a battery of patient-reported pain questionnaires (Fear-Avoidance Beliefs Questionnaire, Oswestry Low Back Pain Disability Questionnaire, Pain Catastrophizing Scale, and Patient Health Questionnaire) were administered before and after 8 sessions of virtual embodiment training as exploratory outcome measures to assess if the measures are appropriate and warrant a larger randomized controlled trial.

Results: A 2-way ANOVA on session × pre- versus postvirtual embodiment training revealed that individual virtual embodiment training sessions significantly reduced the intensity of pain as measured by the visual analog scale (P<.001). Perceived disability due to lower back pain as measured by the Oswestry Low Back Pain Disability Questionnaire significantly improved (P=.003) over the 4-week course of virtual embodiment regimen. Improvement was also observed on the helplessness subscale of the Pain Catastrophizing Scale (P=.02).

Conclusions: This study provides evidence that functional rehabilitation exercises delivered in VR are safe and may have positive effects on alleviating the symptoms of chronic pain. Additionally, the virtual embodiment intervention may improve perceived disability and helplessness of patients with chronic pain after 8 sessions. The results support the justification for a larger randomized controlled trial to assess the extent to which virtual embodiment training can exert an effect on symptoms associated with chronic pain.

Introduction

Chronic pain is a major health care problem worldwide. About 20% of the US [1-3] and European [4-6] populations have been reported to experience chronic pain. Chronic pain is associated with anxiety, depression, and other psychological disorders [7-13], as well as impairment in executive functions [14] and decision-making [15]. Opioids are one of the most common treatment strategies for chronic pain despite the potential for abuse, dependence, misuse, and accidental overdose [16,17]. Chronic pain is a consequential burden on society due to impairment of personal well-being, loss of productivity, and opioid use and dependence. Opioid addiction has been declared a public health emergency by the US Health and Human Services due to the potential misuse by more than 2 million people and more than 47,000 deaths annually [18].

While the specific neural mechanisms of chronic pain are variable and elusive, it has been proposed that a maladaptive neuroplasticity in the anterior cingulate cortex (ACC) occurs, leading to the long-term potentiation in neural circuits associated with the ACC [19]. The ACC has been shown to elicit rate, spatial, and temporal coding that is specific to the anticipation of pain [20]. The ACC shares connections with the periaqueductal gray (PAG), which is the primary control center for descending pain neuromodulation. The disruption of ACC and PAG circuit activation may impair the ability of the descending pain suppression pathway to modulate pain in patients with chronic pain [21]. Long-term potentiation in the ACC may alter nociceptive processing, resulting in hyperalgesia and hyperpathic anticipation of painful events. The ACC and PAG also interact with the amygdala of the limbic system, which has been suggested to modulate pain pathways [22-27]. Through the involvement of the amygdala in pain pathways, the emotions such as stress and fear modulate pain [24,27-29].

Fear-avoidance models of pain suggest that attitudes and beliefs about pain are predictors of pain-related disability, as pain catastrophizing beliefs cause behavioral avoidance [30-37]. Pain catastrophizing has been defined as an exaggerated negative attitude toward pain experience [38]. Pain catastrophizing has been linked to the transition of acute pain into chronic pain [30,39], as well as a negative attitude toward medical procedures in patients with chronic pain [40,41]. Interventions aiming to develop adaptive psychological attitudes and strategies are suggested to reduce the level of pain catastrophizing and thus having a positive impact on patient outcomes [32,42].

Virtual reality (VR) has emerged as a novel technology for the treatment of pain, showing promise as a treatment strategy for chronic pain, burn pain, acute pain, and reducing the intensity of experimentally induced pain [43-50]. There are 2 strategies of VR that may promote analgesic effects: distraction therapy and immersiveness [47,48,51]. Distraction therapy temporarily diverts the attention of a user, which leads to reduced intensity of pain. Immersiveness, also known as embodiment, is the phenomenon by which a person identifies with and develops a sense of ownership over a body part that is not their own. Embodiment allows a user to interact with an artificial environment and receive altered visual feedback associated with the movement of a virtual avatar, which is controlled by the user's manipulation of the VR hardware. Immersiveness in VR may activate premotor and somatosensory circuitry associated with the body parts that are embodied [52]. Thus, there may be a reorganization of the sensorimotor representations within the central nervous system in a way that the perception of a painful limb is modified, resulting in people perceiving the limb as less painful [48,53-55]. Furthermore, virtual embodiment has been shown to influence pain-free range of motion in patients with unilateral chronic shoulder pain [49].

Digital rehabilitation interventions could have multidimensional, biopsychosocial effects for managing pain [56,57]. In patients with chronic neck pain using digital rehabilitation therapy, disability and range of motion was improved [58,59], suggesting that VR interventions are promising for treatment of chronic pain. Multiple sessions of Fear Avoidance Beliefs Training through a rehabilitation medical device have shown improvements in the Pain Catastrophizing Scale (PCS), along with reductions in pain intensity and mobility impairment and disability [49]. Active coping strategies, such as exercise in chronic pain, were shown to have better outcomes in pain-related disabilities compared to passive strategies such as taking medication or resting [60]. Immersiveness in VR could potentially provide the patients with a more active participation in their treatment for chronic pain.

Chronic pain is a health care problem worldwide. There is a compulsory need for alternative, noninvasive, and nonaddictive therapeutics for treating chronic pain [61]. The purpose of this study was to determine the feasibility of a novel VR-based digital therapy for the treatment of chronic pain. The safety and feasibility of an intervention through embodiment in VR to treat chronic pain was assessed. In this study, 24 patients with chronic pain received a novel VR-based functional rehabilitation program (Karuna Virtual Embodiment Training [KVET]; Karuna Labs, Inc) over the course of 4 weeks, with 2 sessions per week. Self-perceived pain intensity rating, pain catastrophizing, and self-perceived disability were measured. The measurements were anonymized for analysis. We hypothesized that gradual exposure of patients to functional rehabilitation in immersive therapy in VR can be used to help patients overcome pain-related fears and catastrophizing beliefs. We hypothesized that an immersive VR therapy would have a positive impact on patient outcomes.
Methods

Ethical Considerations
This study’s protocol was approved by Advarra’s institutional review board (reference number: Pro00026459) and conducted in accordance with the ethical standards of the Declaration of Helsinki.

Study Procedure
This trial was registered at ClinicalTrials.gov (NCT04060875). In total, 24 adult participants that were diagnosed with chronic (for 3 months or longer) lower back or chronic upper extremity pain were recruited from local pain clinics over the normal course of business. Individuals with a history of severe mental illness, including schizophrenia, bipolar disorder I or II, and posttraumatic stress disorder; a history of susceptibility to seizures per the participant’s reporting; and pregnant women were not included in this study. Interested participants received information regarding virtual embodiment training and were scheduled for an intake visit. During the intake visit, participants completed a written informed consent and then were administered initial outcome measures (patient-reported pain questionnaires). To assess potential adverse events associated with VR, the Simulator Sickness Questionnaire (SSQ) was administered to all potential participants. The SSQ helps identify the risk of nausea and dizziness in VR [62]. In this study, no patients exceeded the exclusion threshold on the SSQ, and none were excluded from participation on this basis. Qualified participants received information regarding VR therapy and were scheduled for an intake visit. During the intake visit, all recruited candidates completed a written informed consent, and baseline instruments for outcome measures were administered. All recruited participants completed this study.

Intervention
Virtual embodiment sessions were administered on an HTC Vive (HTC Corporation) VR head-mounted display (110° field of view, 1080 x 1200 pixels/eye, and 90 Hz refresh). The HTC Vive hand controllers and Vive trackers were used to provide an immersive VR experience. The HTC Vive accurately tracks limb and trunk position and movement and delivers an immersive experience where a virtual avatar is controlled by manipulating the position of the hand controllers, Vive tracker, and head-mounted display.

Patients received biweekly sessions of virtual embodiment training over the course of 4 weeks. Visual analog scale (VAS) was administered before each session to obtain an indication of baseline pain intensity levels. Patients were then administered virtual embodiment training. Virtual embodiment training sessions progressed from 20 minutes in the initial session to 45 minutes in later sessions. Following each virtual embodiment training session, the VAS was readministered to determine whether individual sessions provide reductions in self-perceived pain intensity. KVET consists of exercises in an embodied VR experience that are designed based on the principles of graded motor imagery (GMI). In this study, patients with upper-extremity chronic pain engaged in the 4 virtual embodiment training modules: laterality, motor imagery, “mirroring,” and predictive coding. Laterality training consisted of movements mirrored from one side to the other by an avatar in VR. In the motor imagery module, the participant experienced a first-person perspective view of virtual avatar limbs moving while being instructed to imagine the movement is happening in his or her own body. In the mirroring module, a participant’s healthy limb is used to produce movements that appear to be occurring in the painful limb. In the predictive coding module, participants were surrounded by floating orbs in a virtual environment (Figure 1). The orbs were placed at random locations within arm’s reach of the participant. Participants were instructed to reach and grab the orbs promoting upper-extremity movement. A description of rehabilitation exercises administered in KVET for patients with chronic low back pain has been previously published [49].
**Measures**

Self-perceived pain intensity served as the primary outcome measure and was evaluated before and after each virtual embodiment training session using a VAS for pain. Participants were asked to denote pain using a 10-cm line with the left end representing no pain and the right indicating the worst possible pain. Participants would then check off the region of the line they believed accurately represented their current pain. The distance between the left most part of the 10-cm line and the participants check mark was then measured using a standard ruler. This instrument is standard for tracking pain [63]. A 2-way ANOVA on session (1-8) was used to assess differences in VAS score as a function of session and clinical intervention.

To assess the appropriateness of outcome measures on a larger scale, exploratory outcome measures were administered for pain, physical functioning, mental functioning, and disability. Patient-reported pain questionnaires were administered before the first session of virtual embodiment training and after the last session. The validated instruments included the Fear-Avoidance Beliefs Questionnaire (FABQ), Oswestry Low Back Pain Disability Questionnaire (ODI), PCS, and the Patient Health Questionnaire. The FABQ is a questionnaire measuring the effect that pain has on daily life activities [64]. The ODI, frequently used in research of physical therapy efficacy for treatment of lower back pain [65,66], was applied to the subset of participants whose diagnoses included low back pain. The PCS includes 3 subset scales: rumination, magnification, and helplessness [67]. Due to the ordinal nature of subjective pain questionnaires and the likeliness of nonnormal distribution, a Wilcoxon signed rank test was used to assess the difference in the subjective pain questionnaire score before and after clinical intervention.

**Results**

**Self-Perceived Pain Intensity**

Self-perceived pain intensity as measured by the VAS improved as a function of individual virtual embodiment training sessions. A 2-way ANOVA on session (1-8) x pre- versus posttraining on the VAS revealed a significant main effect of KVET therapy sessions ($F_{1,8}=14.246; P<.001; \text{Cohen } d=0.504$). There was no significant main effect of the number of sessions ($P=.85$).

**Patient-Reported Pain Questionnaires**

Pre- and posttraining FABQ work and physical activity scores were recorded for 14 participants. A Wilcoxon signed rank test revealed no significant difference between pre- and post-KVET scores for FABQ-work ($Z=-0.629; P=.57$; mean pretest score 26.14, SD 13.04; mean posttest score 24.86, SD 13.07) nor FABQ-physical activity ($Z=-1.480; P=.15$; mean pretest score 15.07, SD 7.08; mean posttest score 13.21, SD 7.16).

Pre- and posttraining Patient Health Questionnaire scores of the 4-week course were recorded for 10 participants. A Wilcoxon signed rank test revealed no significant difference between pre- and post-KVET scores ($Z=1.262; P=.23$).

Pre- and posttraining ODI scores for the 4-week course were recorded for the population of participants experiencing low back pain. A Wilcoxon signed rank test revealed a significant improvement on how patients rated their disability associated with low back pain after KVET ($Z=-2.819; P=.003$; mean pretest score 23.07, SD 9.42; mean posttest score 19.73, SD 6.99). A post hoc measurement of effect size revealed a medium treatment effect of KVET (Cohen $d=0.401$).
Pre- and posttraining PCS scores for the 4-week course were recorded for 15 participants. A Wilcoxon signed rank test revealed a significant improvement of pain catastrophizing in the helplessness category (Z=-2.254; P=.02; mean pretest score 11.60, SD 6.62; mean posttest score 9.13, SD 5.10). A post hoc measurement of effect size revealed a medium treatment effect of KVET (Cohen d=0.418). No significant difference was observed for PCS rumination (Z=0.605; P=.59; mean pretest score 8.80, SD 4.75; mean posttest score 9.33, SD 3.83), magnification (Z=-0.247; P=.84; mean pretest score 5.27, SD 2.02; mean posttest score 5.13, SD 3.09), or total (Z=-1.224; P=.24; mean pretest score 25.60, SD 11.48; mean posttest score 23.60, SD 11.02). These results suggest that 8 sessions of KVET are an effective treatment for improving the feeling of helplessness associated with chronic pain and allows a person to experience that they can influence pain and movement.

We analyzed the magnitude of change in scores before and after training to assess the degree to which patients with chronic pain improved on pain intensity before and after each session, low back pain disability rating before and after 8 KVET sessions, and the sense of helplessness in dealing with pain before and after 8 KVET sessions. The magnitude was defined as the amount of reduction between pre- and posttraining scores. Figure 2 displays scatter plots of the magnitude of change of the pre-(x-axis) and posttraining (y-axis) scores. A Pearson product correlation analysis revealed a significant correlation for VAS (r=-0.41; P<.001), PCS helplessness (r=-0.64; P=0.01), and ODI (r=-0.69; P=.003).

**Discussion**

**Principal Findings**

This study aimed to assess the feasibility and safety of a novel digital therapy that delivers functional rehabilitation through virtual embodiment in VR. Patient-reported exploratory measures were administered to assess the effectiveness of virtual embodiment training as a viable nonpharmacological, noninvasive treatment of pain. Pain intensity, as measured by the VAS, showed statistically significant reductions after each individual KVET session but no improvement session over session. Disability, as measured by the ODI, and pain catastrophizing all improved as a function of a 4-week virtual embodiment training.

In this experiment, pain intensity was reduced after the intervention using embodiment in VR. The effect size was similar to that reported in magnetic neural stimulation for chronic pain in spinal cord injury [68] and acceptance and commitment therapy to treat chronic pain [69], suggesting that this protocol is a promising intervention for patients with chronic pain. The use of VR in interventions has been previously proposed to be an interesting nonpharmacological alternative for treating chronic pain [70]. VR technology is rapidly advancing due to the introduction of headsets such as Oculus Rift (Meta) and HTC Vive. The recent advances in handheld controllers, cameras, and body trackers have enabled first-person body experience in VR. Embodiment (sometimes referred to as immersiveness) is the process by which a person identifies with and develops a sense of ownership over a body part that is not their own. In this experiment, virtual embodiment, the first-person perception of sensory feedback of the actions of an avatar, was used. Using VR, it is possible to display movements that are not possible for the patient in physical reality and modify the movement to appear more understated or exaggerated. When a person experiences embodiment, sensorimotor representation in the central nervous system of the painful limb is suggested to go through a reorganization. This modification in the representation and thus the perception of a painful limb allows people to perceive the limb less painful [48,53-55]. Although the sense of embodiment was not measured in this feasibility study, the reduction in the pain intensity observed in this study before and after each intervention session could be due to the embodiment protocol used, as embodiment has the potential to shift the perception of pain to less intense and less threatening.

The reduction of pain in this experiment could also be partially due to the specific exercises used. Exercises used in this study’s intervention through KVET were designed based on the principles of GMI. GMI is a biopsychosocial approach to physical therapy aiming for a gradual reintroduction of motor actions and was developed as a systematic approach to ready
subjects with severe chronic pain to engage their sensorimotor pathways related to their painful bodily regions. In a meta-analysis of 6 randomized control trials, GMI was found to produce substantial pain reduction in chronic pain conditions of the upper limbs, more efficiently than usual physiotherapy [71]. GMI consists of 3 stages: (1) 
*lateral* *testing*, in which the participant identifies whether a limb is the right or left limb; (2) *motor imagery*, in which the participant imagines the movement of his or her affected limb while engaging motor pathways to “feel” as though they are actually moving; and (3) *mirror therapy*, or the mirror visual feedback (MVF) [72]. In this experiment, MVF was incorporated into the VR experience for treating chronic pain. Initially developed to treat phantom limb pain, MVF is a dynamic therapy that uses a mirror image of an unaffected contralateral limb to visually represent the function and motion of an affected or impaired limb. MVF has been shown effective in treating complex regional pain syndrome in randomized control trials, which found clinically significant reduction in pain above conventional physical therapy techniques [73]. The application of MVF through the virtual embodiment could have reinforced its effectiveness in this study. However, although pain intensity was reduced after each session, there was no change in pain intensity over the course of 4 weeks.

Previously, GMI and similar interventions that aim for cortical remapping for neuroadaptive changes in chronic lower back pain have found short-term benefits on pain intensity and disability while long-term effects are yet to be confirmed [74]. The VR intervention in this experiment was designed based on GMI, suggesting that GMI through VR shows similar short-term benefits. Alternatively, the lack of reduction in the pain intensity over the course of 4 weeks could also be due to the number of sessions. Perhaps more durable improvements in pain intensity requires more sessions for attaining adaptive neuroplasticity in chronic pain. Future studies with more frequent sessions or longer interventions using VR could clarify the lack of long-term effects in this study.

In this study, the disability component of the ODI and the helplessness subscale of the PCS were reduced over the course of 4-week intervention, suggesting that the virtual embodiment protocol used was effective in improving psychological measures. Moreover, the observed effect size of reduction in disability was similar in magnitude to that reported for other nonsurgical treatments for chronic pain such as acupuncture, behavioral therapy, and exercise [75], suggesting that 8 sessions of KVET is an effective treatment for chronic low back pain disability. Similarly, the helplessness was also reduced over the course of the 4-week immersiveness intervention, suggesting that 8 sessions of KVET are an effective treatment for improving the feeling of helplessness associated with chronic pain. Previously, digital rehabilitation therapy has been shown to reduce disability while increasing the range of motion in patients with chronic cervical neck pain [58]. Digital rehabilitation therapy was suggested to alter the activation of pain pathways in the central nervous system [76] with 2 approaches of distraction and immersiveness [48,51]. In this experiment, through the embodiment, the gradual exposure of patients could have helped the patients overcome learned behaviors and fear avoidance due to chronic pain. The immersiveness in a VR setting could be especially pertinent for individuals with chronic pain who experience reduced motivation for volitional movement. Previously, similar rehabilitation sessions of Fear Avoidance Beliefs Training have shown improvements in pain catastrophizing, pain-related mobility impairment, and pain intensity and disability [49]. Moreover, in this experiment, there was a negative correlation between the change over the course of 4 weeks in pain intensity and helplessness as well as pain intensity and disability, suggesting that the patients with the most severe pain may benefit the most from KVET therapy on psychological measures related to chronic pain. The immersive VR experience could have allowed the person to gain a sense of control and belief that they can influence the pain and improve movement. With improved movement, in turn, the brain could have dampened the threat response to movement. Thus, over time, adaptive neural pathways are established, allowing the patients to be desensitized to pain associated with movement.

Although this study provides evidence for safety and the benefits of a 4-week virtual embodiment training for chronic pain, there were also limits. Notably, the lack of a control group is an important limitation of this study. Further studies are to be carried with a control group who is following the standard of care for chronic pain. Additionally, this study did not have a follow-up measure, hence the long-term efficiency and effects of the treatment are not known.

Finally, in this experiment, all 24 patients completed all planned sessions during the 4-week virtual embodiment training without adverse events, suggesting that when designed correctly, VR therapies that combine pain relief and movement may provide nonpharmacological, noninvasive, and nonaddiction modalities for treating chronic pain. This study’s results support the justification for a larger randomized controlled trial to assess the extent to which virtual embodiment training can exert an effect on symptoms associated with chronic pain. VR may be ubiquitous in homes within the near future, this could introduce the possibility of engaging in neurorehabilitation from the convenience of the home, with data from sessions accessible by prescribing clinicians. Further research is needed to explore the potential use and effects of VR for managing chronic pain.

**Conclusion**

This experiment showed that the gradual exposure of patients to functional rehabilitation through a rehabilitation medical device provided cognitive retraining, improving pain intensity after each session as well as pain-related disability and helplessness over the course of 4 weeks. When designed correctly, VR therapies that combine pain relief and movement may provide nonpharmacological, noninvasive, and nonaddiction modalities for treating chronic pain.

Contactless Monitoring System Versus Gold Standard for Respiratory Rate Monitoring in Emergency Department Patients: Pilot Comparison Study

Abstract

Background: Respiratory rate is a crucial indicator of disease severity yet is the most neglected vital sign. Subtle changes in respiratory rate may be the first sign of clinical deterioration in a variety of disease states. Current methods of respiratory rate monitoring are labor-intensive and sensitive to motion artifacts, which often leads to inaccurate readings or underreporting; therefore, new methods of respiratory monitoring are needed. The PulsON 440 (P440; TSDR Ultra Wideband Radios and Radars) radar module is a contactless sensor that uses an ultrawideband impulse radar to detect respiratory rate. It has previously demonstrated accuracy in a laboratory setting and may be a useful alternative for contactless respiratory monitoring in clinical settings; however, it has not yet been validated in a clinical setting.

Objective: The goal of this study was to (1) compare the P440 radar module to gold standard manual respiratory rate monitoring and standard of care telemetry respiratory monitoring through transthoracic impedance plethysmography and (2) compare the P440 radar to gold standard measurements of respiratory rate in subgroups based on sex and disease state.

Methods: This was a pilot study of adults aged 18 years or older being monitored in the emergency department. Participants were monitored with the P440 radar module for 2 hours and had gold standard (manual respiratory counting) and standard of care (telemetry) respiratory rates recorded at 15-minute intervals during that time. Respiratory rates between the P440, gold standard, and standard telemetry were compared using Bland-Altman plots and intraclass correlation coefficients.

Results: A total of 14 participants were enrolled in the study. The P440 and gold standard Bland-Altman analysis showed a bias of −0.76 (−11.16 to 9.65) and an intraclass correlation coefficient of 0.38 (95% CI 0.06-0.60). The P440 and gold standard had the best agreement at normal physiologic respiratory rates. There was no change in agreement between the P440 and the gold standard when grouped by admitting diagnosis or sex.

Conclusions: Although the P440 did not have statistically significant agreement with gold standard respiratory rate monitoring, it did show a trend of increased agreement in the normal physiologic range, overestimating at low respiratory rates, and underestimating at high respiratory rates. This trend is important for adjusting future models to be able to accurately detect respiratory rates. Once validated, the contactless respiratory monitor provides a unique solution for monitoring patients in a variety of settings.

cardiopulmonary monitoring; contactless monitor; radar; respiratory rate; vital signs

Introduction

Respiratory rate is a fundamental vital sign that serves as an indicator of physiologic function [1]. Changes in respiratory rate are often one of the first indicators of severe illness and clinical deterioration in a variety of disease states, such as sepsis, metabolic acidosis, respiratory distress, and drug toxicities [2,3]. Early identification of clinical decline by recognition of changes in respiratory rate is associated with improved outcomes, such as decreased intensive care unit admissions, decreased length of stay, and improved functional outcomes in patients [4]. However, respiratory rate is often considered a “neglected vital sign” due to inconsistent documentation [5]. There are 2 techniques currently used to measure respiratory rate. The gold standard for determining respiratory rate is manual counting. The current standard of care in hospital facilities and emergency departments (EDs) is transthoracic impedance plethysmography, which measures chest wall movement through cardiac telemetry electrodes. However, both techniques have several limitations. Manual counting is labor-intensive, needs to be done by visually examining the patient, and cannot practically be continuous for long periods of time [6,7]. Transthoracic impedance plethysmography is susceptible to inaccurate readings, as any aberrant movement of the patient makes the monitoring ineffective [8,9].

The development of technologies that accurately and effectively monitor respiratory rates is important to improve the care of patients. Additionally, with the widespread use of telemedicine, digital health interventions that can be used in outpatient settings or settings where a patient cannot be closely monitored are increasingly needed. One such technology is a contactless sensor system that uses an ultrawideband impulse radar–based contactless respiratory monitor PulseON 440 (P440) capable of detecting subtle movements in participants (eg, as the chest wall rises). The P440 works by sending an electromagnetic wave with a transmitter antenna, the reflections of which are caught by the receiver antenna. The device uses 2-way time of flight ranging to measure the distance between the radar and a target. In addition, this radar is a coherent radio transceiver that allows the energy in each transmitted pulse to be summed, improving the signal-to-noise ratio of received transmissions. This monitor has demonstrated high accuracy in laboratory testing, is less than 2 cm in size, and can perform scanning at rates up to 125 Hz at distances up to 30 meters [10]. The monitor operates at approximately 50 μW, which is considered a very low power transmission. For comparison, a standard incandescent lightbulb operates at 60 W. Its capability to detect small movements with extreme accuracy makes this device optimally suited to measuring respiratory rate.

As new technologies are being developed, it is important to compare them to current gold standards to assess whether these technologies are both accurate and practical for clinical use. This study aimed to pilot-test the P440 radar in a cohort of ED patients to (1) compare the performance of the P440 radar to the gold standard (manual counting) and to the standard of care (transthoracic impedance plethysmography) in a clinical setting and (2) compare performance in subgroups of interest (patients with cardiopulmonary diagnoses and by sex).

Methods

Recruitment

This pilot study was performed at a large, academic, tertiary-care, level-one trauma center in central Massachusetts that treats approximately 135,000 patients per year. A convenience sample was enrolled during the study period (June 2019-February 2020). Eligible participants were aged 18 years or older, were being monitored by cardiac telemetry for respiratory rate in the ED, and were able to provide informed consent. Individuals were excluded if they were pregnant or were prisoners, as these populations are routinely excluded in this phase of research. Participants were screened for eligibility through the ED electronic medical record and approached for consent after discussion with the treating ED clinical providers.

Study Design

Once the participant consented to participate, basic demographic and relevant clinical information were obtained from the electronic health record. A total of 3 P440 radar units were placed in a triangulated formation in the participant room for a 2-hour period (Figure 1). During the 2-hour period, the gold standard respiratory rate (manual counting) and the standard of care respiratory rate (transthoracic impedance plethysmography) were recorded at 15-minute intervals. Relevant clinical data (including medications given during the study period and significant events) were recorded.
**Hardware**

The main study device was the P440, which used radar technology to calculate respiratory rate. Data were collected using application programming interfaces. The Raspberry Pi3 (Raspberry Pi Foundation) interfaced with the P440 (programed in C language) and stored all collected data on a microSD card. Each radar unit consisted of the P440 module, an absorber, a Raspberry Pi unit, and a hard disk (Figure 2). All components were assembled in a 3D-printed box. Details of the radar have already been published elsewhere [10].

PulsON 440 Data Cleaning, Processing, and Fusion

The radar data were collected from all 3 devices in raw radargram format. The files were marked with Uniplexed Information Computing System (UNIX) timestamps and were synchronized in order to have the same event observed by all 3 radars for the same time windows. Raw radargrams contained information about participant movement as well as reflections from all the static clutter present in the environment (eg, walls, stretchers, and medical furniture). The first step in cleaning the raw data involved removing the static clutter [11]. A background subtraction technique was used to get rid of the clutter. The mean of the first 100 scans where there were no participants was subtracted from each window of 30 seconds. A bandpass filter was applied to remove direct current and high-frequency noise from the radargrams.

The system leveraged the different vantage points of the radars in 3 different positions in the room to observe the respiratory motion of the participant. As the orientation of the participant was not known and in a dynamic environment, we applied an independent component analysis (ICA) to find out which radar had the best respiratory signal [12].

Each radar signal and radargram were then filtered by an equiripple finite impulse response filter at cutoffs analogous to the normal breathing range from 6 to 30 breaths per minute. The location of the participant being monitored was extracted using a localization algorithm along with trilateration and Kalman filtering [13,14]. From each radar, the system focused on 50 range bins (45 cm) centered at the participants’ location bin. The focused range bin forms 50 individual time series of 30 seconds for a particular window. The 2D signal with 50 timeseries was then collapsed to a 1D signal using a sum-aligned function. The function found the timeseries that had the highest root-mean-square energy in that window and used it as a reference to align the remaining 49 timeseries with itself. After alignment, the function was summed to generate the global sum-aligned 1D signal, which preserved the breathing motion.

The ICA was applied to all 3 radars in 1D time series. The ICA output 3 independent components, which underwent a fast Fourier transform (FFT). The component with the strongest FFT peak was selected as the most dominant radar signal. We applied 2 different frequency detection methods to further identify the respiration rate from the selected radar—FFT and zero-crossing rate [10].

Statistical Analysis

Descriptive statistics were calculated for basic demographic and clinical information. We compared the respiratory rate measured by the P440 with the gold standard (manual) respiratory rate by the Bland-Altman plot method using GraphPad Prism (version 9; GraphPad Software). This approach used the means and differences between the pairs of readings to calculate the mean difference (bias) and the upper and lower limits of agreement [15,16]. We considered an acceptable upper and lower limit of agreement to be –2 to 2 breaths per minute. We subsequently calculated the intraclass correlation coefficient (ICC) for the 2 methods of measurement. We then repeated this procedure for the gold standard (manual) and standard of care (transthoracic impedance plethysmography) respiratory rates. The Bland-Altman plot method was also used to compare respiratory rate differences found between the P440 and gold standard in participants based on sex and the presence of a cardiopulmonary diagnosis.

Ethical Considerations

The study was approved by the University of Massachusetts Chan Medical School Institutional Review Board (protocol number H00016885). All participants provided informed consent. Study data were deidentified. Participants were not remunerated.

Results

Participant Data

A total of 14 participants were enrolled in the study. The demographics of the study participants are detailed in Table 1. The study population was comprised of 57% (8/14) male candidates with an average age of 58 years.

### Comparison of Respiratory Rate Measurements

The P440 and gold standard Bland-Altman analyses showed a bias of –0.76. The upper limit of agreement was 9.65, and the lower limit of agreement was –11.16 (Figure 3A). At lower respiratory rates, the bias was more positive, indicating a higher measured respiratory rate by the P440 than the gold standard. At higher respiratory rates, the bias was more negative, indicating a lower measured respiratory rate by the P440 than the gold standard. About 34% (30/88) of the differences in measurements were within the prespecified clinically significant limits of agreement of –2 to 2. The P440 and gold standard respiratory rates did not have a statistically significant correlation. The ICC was 0.38 (95% CI 0.06-0.60). The mean absolute error between the P440 and gold standard respiratory rates was an average of 3.89 (range 1.55-8.51).

The standard of care and the gold standard Bland-Altman analysis showed a bias of 0.69. The upper limit of agreement was 8.18, and the lower limit of agreement was –6.81 (Figure 3B). Around 59% (52/88) of the differences in measurements were within the prespecified clinically significant limits of agreement of –2 to 2. The gold standard and standard of care respiratory measurements did have a statistically significant correlation. The ICC was 0.82 (95% CI 0.72-0.88).
Subgroup Analyses

Participants grouped by cardiopulmonary chief concern plotted on a Bland-Altman analysis showed a bias of $-2.39$ (Figure 4). The upper limit of agreement was $7.89$, and the lower limit of agreement was $-12.67$. Participants without a cardiopulmonary chief concern showed a Bland-Altman bias of $1.21$ with an upper limit of agreement of $10.49$ and a lower limit of agreement of $-8.08$. While there was no clear trend for the cardiopulmonary chief concerns, the noncardiopulmonary chief concern measurements followed a similar trend to the overall Bland-Altman, with the bias being more positive at lower respiratory rates and more negative at higher respiratory rates.

There was not a statistically significant correlation for either the cardiopulmonary or noncardiopulmonary chief concerns. The ICC was $0.21$ ($-0.41$ to $0.56$) and $0.42$ ($-0.09$ to $0.69$) respectively.

When grouped by sex, the Bland-Altman analysis had a bias of $-0.41$ ($-11.56$ to $10.70$) for male candidates and a bias of $-1.52$ ($-10.05$ to $6.881$) for female candidates (Figure 5). The overall trend for male candidates was also positive at lower respiratory rates and negative at higher respiratory rate; however, there was no clear trend for the female candidates. There was no statistically significant correlation for either the male or female candidates. The ICC for male candidates was $0.45$ ($0.08$-$0.67$) and for female candidates was $-0.40$ ($-2.13$-$0.47$).
Figure 4. Bland-Altman plot of (A) cardiopulmonary and (B) noncardiopulmonary chief complaint.
Discussion

Overview

Although overall there was no statistically significant correlation, the P440 agreed best within the physiologically normal respiratory range. There was less agreement at both increased and decreased respiratory rates as the P440 was underestimated at higher respiratory rates and overestimated at lower respiratory rates. One possible reason for not achieving statistical agreement is that fewer participants had episodes of bradypnea (slow respiratory rate) or tachypnea (high respiratory rate) during the study period and therefore the measurements were more prone to error. Additionally, the ED is a busy environment, and there were many events that could have affected the accurate measurement of respiratory rate, including patient movement, patient clothing or obstruction by blankets, people entering and exiting the room, and the need for bedside procedures. Understanding this trend is important to adjust future respiratory models to be more accurate in the abnormal ranges. However, further validation will be needed before it is able to be used in clinical settings.

There have been other recent studies using an ultrawideband to detect respiratory rates [17,18]. He et al [17] used a combination of a 3D depth camera and ultrawideband radar to use localization with the radar technology to detect respiratory rate in an experimental lab setting. However, the results were limited when movement (such as a person walking) interfered with the respiratory signal. Lauteslager et al [18] also used a ultrawideband radar to detect respiratory rates in a variety of controlled clinical settings. The radar was able to accurately detect respiratory rate; however, the study excluded time periods of irregular respiratory patterns, apnea, and high-motion artifacts. While lab and controlled patient scenarios are important for the initial testing of a monitor, it is also necessary...
to understand how the device performs in real-world settings where there is unplanned motion and noise. Additionally, studying the device in a variety of clinical scenarios, such as patients with invasive mechanical ventilation, may help overcome some of the real-world barriers and understand the setting in which the device best performs. By piloting the P440 in the ED, we were able to gather a better understanding of how the device will perform in an uncontrolled setting.

There are several limitations to this study. First, this was a small study. This was designed to be a pilot study, and therefore a convenience sample was obtained during the enrollment period. Future studies will aim to recruit additional participants in order to validate the P440. Additionally, there are difficulties inherent in measuring respiratory rates that may have affected the accuracy of the P440. Gold standard respiratory rate monitoring requires direct observation that may not only affect a participant’s breathing pattern but also necessitate close proximity, which can cause interference with the monitor. Motion artifacts are also known to cause inaccuracies in respiratory monitoring, which is similarly seen in the standard of care telemetry monitoring that is currently used in practice.

Future iterations of the contactless monitoring system will focus on improving the respiratory rate algorithm. To achieve this, we plan to investigate the Eulerian phase magnification of the radargram signal in order to extract meaningful features [19]. The Eulerian phase magnification approach was first introduced for video magnification; however, its use for human motion estimation was limited by privacy concerns. Using the ultrawideband radar with this approach may provide a convenient, nonrestrictive, and unobtrusive means to detect motion, especially in noisy conditions like the ED. Our next step is to build a 1D radar signal magnification pipeline using the Eulerian phase-based magnification algorithm’s complex Gabor wavelet pyramid [20,21]. Different spatial wavelengths of the Gabor pyramid will give us different 1D signals from which we will get FFT peaks and zero-crossing rates as features. Using these informative features, we plan to fit a regression model to better estimate the respiratory rate. The motivation behind using a motion magnification-based algorithm is to leverage the amplification of subtle motions in a dynamic environment that might be difficult to observe by conventional temporal models. Additionally, by using machine learning models, we can get a better respiratory rate estimate by generalizing across different settings as well as diverse demographics.

Overall, the contactless radar respiratory monitor provides a unique solution to monitor patients in places that previously presented challenges, such as low-acuity outpatient settings, waiting rooms, and the home. The ability to monitor changes in respiratory rate accurately and continuously in these settings can help detect clinical deterioration without having direct contact with the person. This has become increasingly important, especially during the COVID-19 pandemic and with the increase in hospital crowding and long ED wait times.

Conclusions
This pilot study has provided important preliminary data that will be used to inform the development of future iterations of the P440 respiratory rate model. Once validated, the device can be miniaturized and used in a variety of settings to provide continuous respiratory monitoring that can be remotely accessed to detect clinical changes in a variety of disease states and improve the care of patients.

Abstract

Background: Circumcision as a common elective pediatric surgery worldwide is a stressful and anxiety-inducing experience for parents and children. Although current perioperative interventions proved effective, such as reducing preoperative anxiety, there are limited holistic solutions using mobile apps.

Objective: This paper aims to describe the development and primary evaluation of an intelligent customer-driven smartphone-based app program (ICory-Circumcision) to enhance health outcomes among children undergoing circumcision and their family caregivers.

Methods: Based on the review of the literature and previous studies, Bandura’s self-efficacy theory was adopted as the conceptual framework. A multidisciplinary team was built to identify the content and develop the apps. Semistructured interviews were conducted to evaluate the ICory-Circumcision.

Results: The ICory-Circumcision study was carried out from March 2019 to January 2020 and comprised 2 mobile apps, BuddyCare app and Triumf Health mobile game app. The former provides a day-by-day perioperative guide for parents whose children are undergoing circumcision, while the latter provides emotional support and distraction to children. In total, 6 participants were recruited to use the apps and interviewed to evaluate the program. In total, 4 main categories and 10 subcategories were generated from content analysis.

Conclusions: ICory-Circumcision seemed to lean toward being useful. Revisions to ICory-Circumcision are necessary to enhance its contents and features before advancing to the randomized controlled trial.

Introduction

Background

Male circumcision is a surgery to remove the foreskin of the penis [1]. It is one of the most common day pediatric surgeries worldwide, with an estimated 30% incidence of circumcised males, of which two-thirds were Muslim [2,3]. Singapore’s male circumcision prevalence is about 15% [4]. Male circumcision is commonly performed in Singapore between ages 8 and 11 years often for religious reasons [3]. With Muslims comprising 14.7% of Singapore’s population [5], circumcision is likely common in Singapore.

While global and local trends can be ascribed to mainly religious or cultural reasons [6], it is also expected to rise due to growing evidence of health benefits such as up to 73% protection against acquiring HIV [7,8] and reduced risks of urinary tract infections [4]. Voluntary medical male circumcision may save US $16.5 billion by 2025 from averted HIV treatment and associated costs [8].

Rising preferences for elective male circumcision may also be explained by low complication rates of 0% to 30% in male circumcision [9] and benefits of elective day surgeries such as reduced hospital-acquired infection risks, financial burdens, and disruptions to daily commitments like school [10]. With shifts in male circumcision being done as elective surgeries, parents have to assume heavier parenting roles as their involvement in perioperative care increases [11]. These tasks include managing their child’s preoperative fasting and postoperative wound. Despite the advantages of elective male circumcision, surgeries, even minor ones, are still stressful and anxiety-inducing periods for both parents and children [12,13]. The unfamiliarity of settings and perioperative care and fear of their child’s death are reasons for parental preoperative anxiety [11,14]. In fact, parents of children who undergo day surgery have been found to experience higher parental preoperative anxiety than parents of hospitalized children [15]. This could be due to increased responsibilities and inadequate time to adjust to unfamiliar settings [11]. High parental preoperative anxiety often results in unfavorable somatic symptoms such as insomnia that can hinder parents’ everyday functions and impact work productivity [16]. Parental preoperative anxiety and lack of knowledge can incur unnecessary costs for families and hospitals through unnecessary visits to the emergency department after male circumcision [13,17]. Furthermore, parental preoperative anxiety affects children’s emotional responses and increases children’s preoperative anxiety, as children heavily depend on their parents, especially during foreign events like surgery [11,18,19]. Up to 84% of children undergoing male circumcision had experienced fear or worry, suggesting children’s preoperative anxiety is prevalent in pediatric male circumcision [20]. Children’s preoperative anxiety has been correlated with consequences such as increased postoperative pain, sleep-related problems, and hindered recovery [21-23]. Children’s preoperative anxiety also causes prolonged induction and further use of sedatives and requires additional nursing staff, incurring more costs for families and hospitals [13,24-26].

These combined findings suggested the need for a more comprehensive and effective solution to decrease children’s preoperative anxiety. This study aimed to develop an intelligent customer-driven solution for pediatric surgery care on the improvement of outcomes of parents and their primary school-aged children undergoing circumcision (ICory-Circumcision) and examine the feasibility of the program.

Review of Current Circumcision Clinical Practice in Singapore

Figure 1 shows the current pediatric circumcision routine care in the Singapore health system. At one of Singapore’s tertiary hospitals, about 12% of children who underwent male circumcision reverted to the emergency department before scheduled follow-up appointments [27]. However, only 2% of these children had postoperative problems that warranted medical intervention, while the remaining 10% did not require specialist care and, therefore, were avoidable [27]. As seen, parents’ lack of postoperative knowledge and communication with health care professionals (HCPs) led to what could have been affordable costs. Additionally, parents in Singapore have expressed the desire for information provision through mobile apps [14]. Current practices of providing surgery-related information for male circumcision are through verbal or written mediums. Technological-based solutions have yet to be incorporated. Therefore, incorporating ICory-Circumcision into pediatric male circumcision settings in Singapore could potentially save resources for families and hospitals.
Review of Literature and Findings From Previous Studies

Parents and children undergoing elective surgeries experience stress and negative emotions [28]. As a result, studies have been conducted to explore their needs. Parents desire emotional support and perioperative information, involvement in their child’s perioperative care, and building good collaboration with HCPs [29-33]. Studies have shown that providing information helped decrease parental preoperative anxiety and encouraged parents’ participation in their children’s care [28,32,34]. Parents wished to know surgery indications, medications and fasting instructions, involvement in the operating theater, and pain and wound management [35-37]. Their strong desire for such information could be attributable to their major roles in assimilating information to their children [38]. Parents also hoped for such information to be individualized and disseminated to them via web-based mobile apps or literature [14,29,36]. They also preferred if postoperative information was given before surgery instead of just before discharge [39].

Children desire preparational information and tend to seek help from parents when they experience pain [40,41]. The majority of the children experience moderate to severe pain during the postoperative period despite their parents’ involvement in care [40]. This could suggest that pain was undertreated [33]. This further highlights the need to provide education on pain management to parents. Children desired parental presence and more distraction techniques to be used by their parents for pain management [41]. Parents also wished to monitor their children’s pain in addition to the strategies [31]. Finally, children hoped for more communication between parents and nurses to assist with postoperative pain [42].

Various technological-based interventions have been developed and aimed at parents of children undergoing elective surgeries. Videos aimed at educating parents about their children’s surgery have been used in several studies. However, the contents of the studies varied rather widely. Chow et al [43] conducted a systematic review and found that videos that included both preoperative and postoperative information were more effective. Two such studies focused on perioperative education; however, only one study showed a decrease in parental preoperative anxiety, while the other showed no significant changes [17,44]. The video contents of 2 studies were about the surgery day [45,46]. Chartrand et al [45] aimed to educate parents about the experience in the recovery room, and it improved parents’ knowledge but not anxiety. Berghmans et al [46] aimed at modeling a hospital tour for parents and children, but no significant changes in parental anxiety. Other studies focused on different surgery periods such as informed consent and postoperative pain management [47,48]. Two studies examined the effects of web-based preparation programs for parents and children undergoing elective surgeries, and both were effective in reducing parental preoperative anxiety [49,50]. Both interventions had elements of surgery-related educational modules for both parents and children. Two studies examined the effects of web-based preparation programs for parents and children undergoing elective surgeries, and both were effective in reducing parental preoperative anxiety [49,50]. Both interventions had elements of surgery-related educational modules for both parents and children. Two studies examined the effects of web-based preparation programs for parents and children undergoing elective surgeries, and both were effective in reducing parental preoperative anxiety [49,50]. Both interventions had elements of surgery-related educational modules for both parents and children. Two studies examined the effects of web-based preparation programs for parents and children undergoing elective surgeries, and both were effective in reducing parental preoperative anxiety [49,50].

Children’s preoperative anxiety decreased in Fortier and Kain’s study [49] but did not in Wright et al’s study [50]. SMS text messages and mobile apps were also used in several recent studies in pediatric surgery settings [51-55]. Four studies used SMS text messages to convey perioperative education to parents of children undergoing elective surgeries [51-53,56]. These studies allowed real-time communication with HCPs via SMS text message or phone call. The programs were able to decrease parental preoperative anxiety, increase parental knowledge, reduce children’s preoperative anxiety, and improve parent satisfaction, which resulted in neither operation cancellations nor visits to the emergency department. While those 4 studies had no intraoperative texts, Kwan et al [57] examined the effectiveness of sending intraoperative texts, and it was effective in reducing parental anxiety. Ji et al [54], on the other hand, developed an app that uses drawings to explain procedures to parents, which resulted in reduced parental preoperative anxiety and improvement in parental satisfaction. Bailey et al [55] tested the effects of an educational video app on perioperative information and parents’ role in the operating theater.
Several studies have examined the effectiveness of mobile game apps on children’s preoperative anxiety [58-61]. These 4 studies used game apps that were available in app stores and were selected based on age appropriateness. There was a significant reduction in children’s preoperative anxiety after the children played the games in 3 studies. In addition, Cumino et al [58] also showed that a combination of strategies (parental leaflet+mobile game) was more effective in lowering the prevalence of anxiety in the operating room. Marechal et al [61] showed no significant difference in children and parental anxiety. A few studies also used mobile apps to prepare children for surgery [62-64]. All 3 studies aimed to simulate the operating room but through different presentations in the apps: medical clowning video, multimedia app presenting hospital procedures in stages and accompanying videos, and photographs and cartoons. All 3 studies led to a significant decrease in children’s preoperative anxiety. Fernandes et al [63] also showed decreased parental state anxiety.

Our review of the literature showed that perioperative needs of parents and children undergoing elective surgeries have been extensively researched, and as a result, many interventions have been developed to address their needs. However, there is a lack of technological-based interventions targeted at parent’s self-efficacy in children’s perioperative care. There is also a dearth of studies using mobile app–based education for parents, and none were conducted in Singapore.

### Methods

#### Content Development and Theoretical Framework

Taking all the gathered information into consideration, Bandura’s self-efficacy theory and interrelationships between self-efficacy, anxiety, knowledge, and satisfaction were adopted as the theoretical and conceptual framework to guide the development of ICory-Circumcision and methodology of this study (Figure 2).

**Figure 2.** Theoretical framework used for the study.

Bandura posited that self-efficacy is derived from the integration of information from 4 sources of self-efficacy, namely, enactive mastery experience, vicarious experience, verbal persuasion, and emotional and physiological states [65]. Enactive mastery experience refers to parents’ prior experiences in taking care of children throughout the perioperative period, and it is the most influential source of self-efficacy. Vicarious experience was gained by observation and modeling, as it offers parents chances to judge their abilities against a reference point to master tasks [65]. Verbal persuasion refers to persuasive information parents receive from others to enhance parental self-efficacy. Emotional and physiological states influence self-efficacy as a person’s functions are affected [65].

Parental self-efficacy has been shown to negatively correlate with anxiety and child distress and positively correlate to child cooperation [66,67]. High parental preoperative anxiety has been positively correlated with children’s preoperative anxiety, while children’s preoperative anxiety has been positively correlated with higher postoperative pain [68-70]. Additionally, parental preoperative anxiety has been reported to increase the likelihood of surgical cancellations due to lower compliance with fasting instructions [70]. Based on Bandura’s theory, anxious parents could lower parental self-efficacy and subsequently affect children’s perioperative outcomes such as children’s preoperative anxiety and postoperative pain [71]. Parental preoperative anxiety has been shown to be positively correlated to the need for information, thus further reinforcing the need to develop interventions to provide the information parents require [72].

### ICory-Circumcision Components in Relation to Self-Efficacy Theory

The Template for Intervention Description and Replication (TIDierR) checklist and guide was also recommended to be
used in the process of intervention development [73]. The components of ICory-Circumcision in relation to the self-efficacy theory are depicted in Figure 3.

**Figure 3.** ICory-Circumcision components in relation to self-efficacy theory.

### Qualitative Evaluation of the ICory-Circumcision Program

A self-developed interview guide for field test of BuddyCare and TriumfHealth apps (Multimedia Appendix 1) was used to guide the semistructured interviews to explore the perceptions of the strengths, weaknesses, and the use of ICory-Circumcision from parents, children, and HCPs who used ICory-Circumcision. The qualitative data obtained from process evaluation were analyzed using inductive content analysis [74,75]. The analysis was done in 3 phases: preparation, organizing, and reporting [74], while steps were taken to achieve trustworthiness [76].

### Ethical Considerations

Ethics approval (2019/00582) and amendment approval were obtained from the National Health Group Domain Specific Review Board before the commencement of the study. All research team investigators obtained the Collaborative Institutional Training Initiative certificate. Informed consent was obtained from the children’s parents, while assent was taken from the children. All potential participants were given information about the study using the participant information sheet to inform them about the study’s aim, potential benefits, risks, and responsibilities. Voluntary participation, the right to withdraw, and confidentiality were highlighted. Informed consent was not obtained from the HCPs who were interviewed as they were part of the study team. All data from questionnaires were entered electronically into the study hospital’s REDCap (Research Electronic Data Capture; National University Hospital) database, and the data were exported as nonidentifiable data into SPSS (IBM Corp) for data analysis. Only identified study team members with intranet access were able to enter, monitor, and export data. The audio recordings of the interview will be deleted from the audio recorder and stored in the principal investigator’s password-protected computer in the office of Alice Lee Centre for Nursing Studies. All physical records such as consent forms and questionnaires were stored in a locked cupboard at the Department of Pediatric Surgery in National University Hospital. The documents and electronic data will be destroyed after 6 years upon closure of the study by the Domain Specific Review Board. A brand-new SIM card was purchased for the study phone, and it will be disabled and destroyed at the end of the study as well. In addition, no identifiable information was entered in ICory-Circumcision’s apps; instead, pseudonyms and precreated emails were used. This ensured that no participant identifiers were captured by the apps’ companies to protect the participants’ privacy and data confidentiality. No compensation in terms of material or financial benefits was provided to the research participants who participated in this program.

### Results

This study was carried out from March 2019 to January 2020 and comprised 2 mobile apps.

#### BuddyCare Mobile App for Parents

One of the eventual products was the BuddyCare mobile app that provides a comprehensive day-by-day perioperative guide for parents regarding their children’s surgery with an interface to communicate with HCPs. Parents were able to select the surgery date and time on the app, and then, the contents were arranged according to each participant’s timeline. The timeline of BuddyCare contents can be found in Multimedia Appendix 2. Two educational topics on the app were selected in accordance with the parental and children’s needs in the literature review and surgery pathway, one is circumcision-related information, including an overview of...
circumcision, tips on how to explain the surgery to their children, and what to expect about anesthesia; another one is caring for children, including pain management techniques (eg, emotional support, breathing techniques, positive reinforcement, and distraction), preoperative instructions (eg, fasting instructions), and wound management (eg, how to clean and when to bring their child to the emergency department; Figures 4 and 5). Positive quotes are refreshed periodically as emotional support to motivate the parents throughout the perioperative process (Multimedia Appendix 3). With the messaging function, participants are able to communicate with HCPs by sending SMS text messages through the messaging tab (Multimedia Appendix 4). The HCPs in the study team will be able to access the SMS text messages via a BuddyCare dashboard, and they can reply to the participant through this dashboard.

Figure 4. Screenshot of BuddyCare overview.
Another product was the Triumf Health mobile game app that provides emotional support and distraction to children. The game allowed the children to customize their own characters and save Triumfland city from a diseased monster by finding one’s inner superpowers. The child was able to control their character to venture around Triumfland and gain points through completing quests in order to help the town doctor to eradicate the disease monster. One important aspect of the game was providing general surgery information to the child (Figure 6). The child could access the topics at any time on their own volition, and the information about each topic was displayed in levels to cater to the child’s reading and comprehension ability. To illustrate, once the child accessed the information in level 1, the information would be presented, and the app would prompt the child to ask if he understood the information. If the child says no, a short summary of the information from level 1 will be presented in short simple sentences. The app also rendered various psychological support to the children such as pain and mood. If the child responded with unfavorable answers such as severe pain or a negative emotion, the game provided appropriate words of encouragement to the child (Multimedia Appendix 5). The abovementioned features of the app made Triumf Health game user experience personalized and dynamic. Further gameplay, that is, accessing the educational module, entertainment games, and other elements of the intervention, was determined by the in-game choices made by the player. Furthermore, the provision of psychological support is dynamically dependent on the patient’s individual progress and in-game progress.
The Qualitative Evaluation on ICory-Circumcision

In total, 6 participants (2 boys who were going to take male circumcision, 2 of their parents, and 2 HCPs) were recruited to use the apps and were required to share their perceptions about the apps. An interview guide was developed and followed (Multimedia Appendix 1). In total, 4 main categories and 10 subcategories were generated from content analysis and presented in Textbox 1.
Textbox 1. Categories and subcategories.

**Strengths of ICory-Circumcision**
- BuddyCare content is useful
  - Comprehensive (n=3) and easy to understand (n=1)
  - Learning experience for parents (n=3)
  - Useful especially for parents with no experience (n=2)
- Mobile apps as useful platform
  - Convenient (n=2) and appropriate for the modern era (n=2)
  - BuddyCare supports routine care (n=4)
- Reasons for liking the Triumf Health game app
  - Follow-up on child’s postoperative status (n=1)
  - Enjoyed the game and its features (n=1)

**Factors for dissatisfaction in ICory-Circumcision**
- Reasons for disliking the Triumf Health game app
  - Boring (n=3) and frustrating (n=1)
  - Children preferred other means of distraction (n=4)
- Communication issues
  - Delayed and unsatisfied response in BuddyCare (n=1)
  - Inconvenience of BuddyCare dashboard (n=1) and difficulty in using (n=1)

**Outcomes of using ICory-Circumcision**
- Opinions of BuddyCare on perioperative outcomes
  - Reduction in parental and child anxiety (n=2)
  - Improved parental confidence in taking care of the child (n=1)
- Opinions of Triumf Health on perioperative outcomes
  - Minimal help in managing preoperative anxiety (n=3)
  - No help with coping with postoperative pain (n=1) versus little help (n=1)

**Suggestions for improvement**
- BuddyCare content suggestions
  - Less words (n=1)
  - Different languages for important information (n=1)
  - More visuals (n=2) versus sufficient visuals (n=1)
- BuddyCare technical aspects
  - Reduce reminders (n=1) versus adequate reminders (n=1)
  - Making a dashboard app (n=1)
- Fidelity of ICory-Circumcision
  - Training for health care professionals (n=2)
  - Intervention delivery suggestions (n=2)
**Discussion**

**Main Findings**

The principal aim of the program was to develop an intelligence solution to increase parental self-efficacy and decrease parental and children’s preoperative anxiety. Parents generally expressed positive reactions toward the BuddyCare app. They found BuddyCare to be comprehensive, convenient, and useful, and they would highly recommend it to other parents. Triumph Health app was useful in follow-up postoperative pain and emotional care for children. These findings align with the aims of ICory-Circumcision and the HCPs’ views. Participants also found ICory-Circumcision to be a good resource that complements routine care, which is similar to another study [49].

Feedback on Triumph Health and BuddyCare should be taken and revise ICory-Circumcision as an intervention. Based on the mixed reactions from the qualitative interview, it may suggest that ICory-Circumcision may not be individualized enough for participants. For example, more visuals such as videos could be added into BuddyCare, but they could be placed in a different tab, which allows parents the liberty to access that section or not. This is to cater to the different levels of comfort each parent has with seeing pictures of open wounds. For Triumph Health, the number of words could be reduced, and the mechanics of the game could be reviewed with the team in Finland to see if it could be better improved to suit the needs of the children in Singapore.

Lack knowledge of pain management strategies and wound management techniques could affect the development of parental self-efficacy and increase negative emotions [29,72]. Studies showed that providing information about their children’s surgery to parents could reduce parental preoperative anxiety and showed an increase in parental self-efficacy [28,55,77]. Past experiences could have contributed to the high parental self-efficacy. Bandura [65] suggested that mastery experiences have the strongest influence on self-efficacy out of the 4 sources, and if caregivers had previous caregiving experience, they had high parental self-efficacy. On the contrary, parents would have higher anxiety when they have the first surgical experience due to medical reasons, which could impede the self-efficacy gained from physiological and affective states [65]. Therefore, providing adequate knowledge to parents is an efficient way to improve health-related outcomes.

Mobile apps are ubiquitous among parents and children, possibly due to the convenience brought by their easy accessibility [78-80]. The infiltration of mobile apps into pediatric settings is clear with the advent of mobile apps aimed at helping children with different health conditions [81,82]. Therefore, the number of mobile resources HCPs have access to has greatly expanded, improving efficiency and productivity [83]. Evidently, mobile apps have tremendous potential as a platform for information delivery.

As there are limited interventional studies presenting the development process, this study will contribute to the body of literature about intervention development [84]. This informs readers about the possible challenges that one can encounter should they decide to embark on similar intervention development [73]. This study also provided insights into the feasibility of ICory-Circumcision and the study’s methodology, which could improve the main trial’s processes and prove the effects of ICory-Circumcision. If the effects are then proved, it could potentially save nurses’ time, as nurses are heavily involved in providing education to parents and children about surgery [17,34]. Although our qualitative evaluation of ICory-Circumcision involved various users, including children, parents, and HCPs, the sample size was small due to the limited time for an honors student’s project and the COVID-19 pandemic occurrence in November 2019.

**Conclusions**

This paper detailed the development of a holistic technology–based intervention for parents and their children undergoing elective circumcision and examined its preliminary feasibility and evaluation. The qualitative evaluation identified strengths, weaknesses, and suggestions for improvement concerning ICory-Circumcision, suggesting its potential usefulness for parents and children in perioperative outcomes. Prior to proceeding with the randomized controlled trial, revisions to ICory-Circumcision to enhance its contents and features are recommended.

**Acknowledgments**

The authors wish to thank the clinicians, administrators, and those who have directly and indirectly contributed their expertise or public opinion to the development of this program. This study would not have been possible without the support of the National University of Singapore, Singapore General Hospital, National University Hospital, and Buddy Healthcare. Abstract

Background: The increasing prevalence of nonalcoholic fatty liver disease (NAFLD) in China presents a significant public health concern. Traditional ultrasound, commonly used for fatty liver screening, often lacks the ability to accurately quantify steatosis, leading to insufficient follow-up for patients with moderate-to-severe steatosis. Transient elastography (TE) provides a more quantitative diagnosis of steatosis and fibrosis, closely aligning with biopsy results. Moreover, machine learning (ML) technology holds promise for developing more precise diagnostic models for NAFLD using a variety of laboratory indicators.

Objective: This study aims to develop a novel ML-based diagnostic model leveraging TE results for staging hepatic steatosis. The objective was to streamline the model’s input features, creating a cost-effective and user-friendly tool to distinguish patients with NAFLD requiring follow-up. This innovative approach merges TE and ML to enhance diagnostic accuracy and efficiency in NAFLD assessment.

Methods: The study involved a comprehensive analysis of health examination records from Suzhou Municipal Hospital, spanning from March to May 2023. Patient data and questionnaire responses were meticulously inputted into Microsoft Excel 2019, followed by thorough data cleaning and model development using Python 3.7, with libraries scikit-learn and numpy to ensure data accuracy. A cohort comprising 978 residents with complete medical records and TE results was included for analysis. Various classification models, including logistic regression (LR), k-nearest neighbor (KNN), support vector machine (SVM), random forest (RF), light gradient boosting machine (LightGBM), and extreme gradient boosting (XGBoost), were constructed and evaluated based on the area under the receiver operating characteristic curve (AUROC).

Results: Among the 916 patients included in the study, 273 were diagnosed with moderate-to-severe NAFLD. The concordance rate between traditional ultrasound and TE for detecting moderate-to-severe NAFLD was 84.6% (231/273). The AUROC values for the RF, LightGBM, XGBoost, SVM, KNN, and LR models were 0.91, 0.86, 0.83, 0.88, 0.77, and 0.81, respectively. These models achieved accuracy rates of 84%, 81%, 78%, 81%, 76%, and 77%, respectively. Notably, the RF model exhibited the best performance. A simplified RF model was developed with an AUROC of 0.88, featuring 62% sensitivity and 90% specificity. This simplified model used 6 key features: waist circumference, BMI, fasting plasma glucose, uric acid, total bilirubin, and high-sensitivity C-reactive protein. This approach offers a cost-effective and user-friendly tool while streamlining feature acquisition for training purposes.

Conclusions: The study introduces a groundbreaking, cost-effective ML algorithm that leverages health examination data for identifying moderate-to-severe NAFLD. This model has the potential to significantly impact public health by enabling targeted...
investigations and interventions for NAFLD. By integrating TE and ML technologies, the study showcases innovative approaches to advancing NAFLD diagnostics.

NAFLD; artificial intelligence; public health; transient elastography; diagnosis

**Introduction**

Nonalcoholic fatty liver disease (NAFLD) stands as the foremost chronic liver condition, impacting approximately 1.7 billion individuals worldwide. NAFLD manifests as a multifaceted chronic liver disorder marked by an excessive buildup of fat within liver tissue. As hepatic steatosis advances, it exacerbates the onset and progression of hepatitis and fibrosis, while heightening the likelihood of liver cancer. Furthermore, numerous studies provide compelling evidence linking NAFLD closely with metabolic disorders such as obesity, diabetes, and hypertension, significantly elevating the risk of cardiovascular disease [1]. A recent meta-analysis revealed that the prevalence of NAFLD in Asian countries mirrors that of Western nations. Notably, China exhibits the highest prevalence, incidence, and yearly mortality associated with NAFLD in Asia. If this trend persists, projections suggest that by 2030, the total NAFLD population in China will soar to 314.58 million. Consequently, China will emerge as the global leader in both patients with NAFLD and liver-related fatalities [2]. Given that the majority of NAFLD cases are asymptomatic, early diagnosis holds significant clinical importance. Furthermore, precise quantification of liver fat content and clarification of hepatic steatosis severity are crucial for determining appropriate clinical interventions, assessing disease progression, and evaluating treatment efficacy. Hepatic steatosis is typically categorized into minimal (<5%), mild (5%-33%), moderate (33%-66%), and severe (≥66%) levels [3]. Patients exhibiting moderate-to-severe steatosis necessitate more intensive intervention and follow-up. Enhanced detection of individuals at high risk and early diagnosis can substantially aid in the diagnosis, treatment, and prevention of NAFLD.

Ultrasound is widely acknowledged as the preferred method for screening hepatic steatosis due to its cost-effectiveness, safety, convenience, and efficacy [4]. The characteristic ultrasound findings of fatty liver are either homogeneous or heterogeneous enhancement of liver echogenicity, along with liver enlargement and diminished visualization of intrahepatic ductal structures. However, the accuracy of ultrasound in diagnosing the disease is heavily reliant on the skill and expertise of the operator [5]. Studies have consistently found that ultrasound is highly operator dependent and lacks the capability to precisely determine the extent of hepatic steatosis or distinguish between steatosis and fibrosis, as both conditions lead to heightened liver echogenicity. Consequently, ultrasound is predominantly used for screening fatty liver disease (FLD) [6]. However, it is not recommended for tasks requiring accurate diagnosis and severity grading of early-stage fatty liver, liver transplantation assessments, or evaluation of short-term drug therapies.

At present, liver biopsy stands as the gold standard for diagnosing FLD and evaluating the severity of hepatic steatosis. However, its utility for dynamic monitoring of disease progression and efficacy assessment is limited by factors such as poor patient acceptance and high cost. Additionally, liver biopsy entails inherent risks of complications including invasiveness, bleeding, and infection. Moreover, it is prone to subjective evaluation bias and sampling errors, further impeding its effectiveness as a monitoring tool [7]. Currently, the noninvasive preliminary assessment of hepatic steatosis and the quantitative dynamic evaluation of hepatic fat content represent focal points in current research efforts. Techniques such as transient elastography (TE), computed tomography, and magnetic resonance imaging (MRI) have all been validated for the quantitative diagnosis of steatosis, with MRI demonstrating superior accuracy [6]. However, the high cost, poor patient acceptance, and lengthy examination times associated with biopsy, MRI, and computed tomography render them impractical for large-scale population screening. Consequently, obtaining sufficient sample data in outpatient services worldwide remains challenging. Controlled attenuation parameters in TE represent a quantitative diagnostic approach tailored for detecting steatosis graded as S1, S2, and S3, as well as fibrosis graded as F1, F2, F3, and F4. A meta-analysis has determined that controlled attenuation parameters exhibit good sensitivity and specificity for grading steatosis [7]. Additionally, a prospective study that used TE to assess disease progression in patients with NAFLD indicated that liver stiffness measurements (LSMs) can effectively monitor the degree of liver fibrosis in this patient population [8]. The study indicated that TE can serve as a comprehensive diagnostic tool for both hepatic steatosis and liver fibrosis. It also offers a rapid and noninvasive method to assess liver fibrosis in patients with diverse chronic liver diseases, encompassing chronic hepatitis C, chronic hepatitis B, and NAFLD. Moreover, TE shows promise in predicting complications associated with advanced compensated chronic liver disease [4,9]. However, the widespread adoption of TE in population-based health screenings faces obstacles, particularly in China, where TE is primarily used for evaluating patients with FLD in general hospital settings. There are persistent challenges concerning inadequate ultrasound equipment and insufficient specialized training for physicians in primary health services that require attention. Consequently, there is a pressing need for the development of more cost-effective and efficient methods to identify individuals in the population with FLD who warrant intervention and follow-up, particularly those reaching the threshold of needing medical attention (S≥S2).

Machine learning (ML) offers a promising avenue to tackle these challenges. ML, a branch of computer science, uses algorithms to discern patterns within extensive data sets and predict diverse outcomes [10]. Evolving from pattern recognition
and computational learning, ML uses computers to analyze interactions between variables, encompassing both nonlinear and complex relationships, while minimizing errors between predicted and actual outcomes. ML not only enhances predictive accuracy but also has the capacity to identify latent variables that might not be directly observable but can be inferred from other variables. Currently, various ML techniques, including logistic regression (LR), random forest (RF), artificial neural networks (ANNs), k-nearest neighbors (KNNs), support vector machine (SVM), and extreme gradient boosting (XGBoost), are being used in disease prediction with significantly higher accuracy compared with classical methods [11]. Previous studies have used clinical data to diagnose patients with NAFLD, often relying on traditional ultrasound results for FLD diagnosis [12,13]. Given the challenges posed by the unsatisfactory diagnostic accuracy of traditional ultrasound in FLD screening and its inability to provide early warnings for patients requiring follow-up and more stringent interventions, there is an opportunity to leverage data from TE in population-based health examinations. These data can be used to develop a new ML model with enhanced accuracy and the capability to classify patients based on severity thresholds.

Methods

Recruitment
All clinical data for our study were sourced from health examinations conducted at 7 health examination centers across Suzhou, encompassing 3 districts of Suzhou Municipal Hospital and its 4 affiliated community hospitals. The study included individuals who underwent health examinations from March to May 2023, with exclusion criteria applied to those lacking TE test results. Among the 1753 patients who underwent TE screening, 1344 were selected during their health examination. Ultimately, a total of 978 health examination records with complete medical files were included, accessible for querying in the case system.

Ethical Considerations
All participants who agreed to partake in the annual health examination were required to complete an informed consent form. Physical examination data were collected for the Suzhou Municipal Government and Suzhou Municipal Hospital. The authors take full accountability for all aspects of the work, ensuring that any questions regarding the accuracy or integrity of the study are thoroughly investigated and resolved. All procedures adhered to the ethical standards outlined in the Helsinki Declaration and received approval from the Ethical Committee of Suzhou Municipal Hospital. The study was approved by the Ethics Committee of Suzhou Municipal Hospital (ethical approval number K-2022-034-K01).

Machine and Operational Standard
The machine used in the health examination was the FibroTouch, specifically the Transient Elastography FibroTouch (FibroTouch-FT5000; Wuxi HISKY Medical Technologies). This device assesses the degree of hepatic fibrosis by measuring LSM through vibration-controlled instantaneous elastography. Hepatic steatosis is quantitatively evaluated by measuring the attenuation of ultrasound signals in the liver, known as the ultrasound attenuation parameter (UAP). To address detection errors in patients with obesity, the FibroTouch automatically adjusts the probe based on the thickness of subcutaneous fat following precise positioning and depth measurement. This adjustment ensures comparable diagnostic accuracy to FibroScan [14].

FibroTouch measurements were conducted by experienced and certified physicians, each having performed over 500 examinations. Following the manufacturer’s instructions, patients assumed a supine position with the right hand placed behind the head to facilitate the expansion of the intercostal space. An image-guided probe was carefully chosen to scan the region between the seventh and ninth intercostal spaces, avoiding cysts and blood vessels in the liver. The probe was maintained in a vertical position relative to the skin surface, with pressure applied within the appropriate range (Figure 1). Detection commenced once the M waveform intensity was uniformly distributed and the A waveform appeared linear. In this study, the representative measurement of FibroTouch was determined by calculating the median value of the 10 acceptable LSMs in kilopascals (kPa) and UAPs in decibels per meter (dB/m), along with their respective IQRs. LSM and UAP measurements were deemed reliable only if 10 successful measurements were obtained, with an IQR-to-median ratio of 30% and a success rate of at least 60% [15].
Figure 1. A simplified schematic diagram of TE testing showing an image-guided probe selected to detect the region through the intercostal space. ROI: region of interest; TE: transient elastography.

Statistical Analysis

When collecting data, we initially searched for the patient’s medical number to ensure that the accessed data did not contain any identifiable patient information. To enhance data quality and mitigate the impact of erroneous data on the model, we developed a comprehensive set of logic algorithms to systematically check for logical errors within the health examination data records. These checks included identifying unit errors, magnitude errors, format errors, and so forth. Any identified errors were then manually corrected following prompts from the algorithm. Additionally, to detect potential hidden errors arising from data entry issues, we generated scatterplots (Figure 2) to identify outliers, which were subsequently monitored and reviewed manually on a case-by-case basis. A professional medical doctor, with over 15 years of experience in the field, assessed the reasonableness of outliers. It is notable that some outliers exhibited values that were theoretically unlikely, such as low-density lipoprotein-cholesterol (LDL-C) levels exceeding 300 mmol/L. We conducted thorough verification of these unreasonable values and subsequently corrected or excluded data entries found to be erroneous due to researchers’ data entry mistakes or other factors.

Figure 2. Scatterplots for outlier detection. HDL-C: high-density lipoprotein-cholesterol; LDL-C: low-density lipoprotein-cholesterol; TC: total cholesterol.

In the lifestyle characteristics section, dietary information was omitted from the model. This decision was based on the understanding that many older individuals were unable to accurately report their daily food intake, while younger individuals often experienced irregular eating habits. Additionally, in terms of prevalence, conditions with low case numbers such as chronic obstructive pulmonary disease (n=5), myocardial infarction (n=28), and stroke (n=23) were excluded from the model. Osteoporosis was also excluded because bone mineral density assessments were not included in the health examination protocol, making it difficult to ascertain the presence of osteoporosis in the majority of patients undergoing
health examinations. Furthermore, 56 patients were excluded due to data disorder errors. Specifically, variables such as red blood cell count, neutrophil count, white blood cell count, and lymphocyte count were mistakenly entered as percentages of red blood cells, neutrophils, white blood cells, and lymphocytes, respectively.

**Characteristic Processing**

**Exercise**

The PARs-3 (Physical Activity Rating Scale-3) is a commonly used exercise measurement scale in China [16]. In previous studies, the scale’s internal consistency and reliability were 0.86 and 0.82, respectively. The scale contains 3 dimensions, namely, time, intensity, and frequency of exercise. A score of 20 or higher on this scale is indicative of moderate physical activity, which equates to engaging in at least 150 minutes of moderate exercise per week. To simplify the analysis, moderate physical activity was categorized into 2 groups: individuals who participate in at least 150 minutes of moderate exercise per week versus those who engage in less than 150 minutes weekly.

**Smoking and Drinking**

The health examination records included information on the variety of wine, volume of drinking, and alcohol percentage consumed per day. We calculated alcohol intake using the following equation: alcohol intake (g) = volume of drinking (mL) × alcohol percentage (% vol/vol) × 0.8 (g/mL). Patients with alcohol intake above the recommended limits (male ≥ 30 g/day; female ≥ 20 g/day) were excluded. However, individuals with an alcohol intake of 0 were included in the analysis. We categorized alcohol intake into 2 groups: those with an alcohol intake of 0 and those with an intake greater than 0, treating them as 2-categorical variables. Similarly, we classified patients into 2 groups based on smoking history: those who had never smoked and those with a history of smoking, also treated as 2-categorical variables.

**Metabolic Disease**

In contrast to previous studies where diastolic and systolic blood pressures were often analyzed as features, we chose not to include them. We believed that the blood pressure measurements of patients undergoing health examinations could be biased due to various factors such as changes in peak blood pressure, medication usage, and clinical hypertension. Similarly, random blood glucose levels are strongly influenced by diet. Instead, we opted to use fasting plasma glucose (FPG), postprandial plasma glucose (PPG), and hemoglobin A1c (HbA1c) as variables. Additionally, we included hypertension, hyperuricemia, diabetes, and hyperlipemia as 2-categorical variables. All remaining data were normalized for analysis.

**Educational Attainment and Financial Situation**

Individuals who have never received formal education are classified as “uneducated.” Those with less than a high school education are categorized as “low,” whereas individuals with a high school diploma or specialized education are labeled as “mid.” Education at the college level or higher is defined as “high.” Regarding income, the medical report divides income into categories including below the social minimum wage, slightly below the average social wage, slightly above the average social wage, and significantly above the average wage. Individuals earning below the social minimum wage were categorized as “poor,” whereas those earning significantly above the average wage were classified as “rich.” Those with incomes falling between these extremes were categorized as “average.”

**Enrollment of Participants**

We screened individuals who ultimately met the diagnostic criteria for NAFLD based on the American Association for the Study of Liver Diseases (AASLD) Practice Guidance [17]. Cases with conditions known to substantially impact TE results, such as liver cancer and ascites, were excluded from the study. Similarly, individuals with conditions known to affect blood biochemistry analysis, such as infections and long-term glucocorticoid use, were excluded. Figure 3 presents a flowchart illustrating the enrollment process of patients.
Figure 3. Flowchart of patient enrollment and diagnostic standards of NAFLD from the AASLD Practice Guidance. AASLD: American Association for the Study of Liver Diseases; NAFLD: nonalcoholic fatty liver disease; TE: transient elastography.

![Flowchart](image)

All the collated data of the 916 people screened are summarized in Tables 1 and 2. Table 1 summarizes the descriptive characteristics of the study population, including gender, age, educational attainment, financial situation, residence, smoking and drinking state, exercise, and metabolic disease (hypertension, hyperuricemia, diabetes, and hyperlipemia). Table 2 presents a summary of blood biochemistry analysis of the study population.

**Model Building**

To predict NAFLD with different severities, we used several classification models, including LR, KNN, SVM, RF, light gradient boosting machine (LightGBM), and XGBoost.

RF is an ensemble classification algorithm developed by Leo Breiman and Adele Cutler in 1999. It operates by constructing a multitude of decision trees during the training phase and outputs the mode of the classes (classification) or the mean prediction (regression) of the individual trees. RF is widely used for classification, regression, and other tasks. Each decision tree in the RF is built independently by applying the general technique of bootstrap aggregating (bagging), where random samples are selected for the training set. RF determines the final result by aggregating the predictions of all individual trees through a simple majority vote. It has demonstrated high accuracy across various fields, including medical diagnosis. Additionally, RF is frequently used for feature selection in data science workflows. One of the reasons for its popularity in feature selection is due to the tree-based strategies used by RF. These strategies naturally rank features based on how effectively they improve the purity of the nodes in the decision trees. Features that result in the greatest decrease in impurity are typically encountered at the beginning of the trees, while those with the least decrease in impurity are found toward the end of the trees [11]. By selectively pruning trees below a certain node, a subset of the most important features can be derived.
LR is a type of discrete choice model that falls under multivariate analysis. It is extensively used in various fields such as sociology, biostatistics, clinical medicine, quantitative psychology, econometrics, and marketing. LR is often used for empirical analysis and is commonly used for comparison with ML studies [18]. This method offers several advantages, including high power and accuracy, making it a popular choice for modeling binary or categorical outcomes.

ANNs, a family of statistical learning algorithms, draw inspiration from biological neural networks. ANNs have demonstrated remarkable power in nonlinear modeling and have been proven for accurate predictions in many fields, including clinical decision support [19]. The operation of an ANN is akin to a biological neuron, where signals are received through dendrites. In ANNs, this process is replicated with an input layer that feeds into several hidden layers, ultimately leading to an output layer. Each layer consists of numerous perceptrons interconnected by adjustable weights. During training, the ANN iteratively adjusts these weights using a data set, aligning inputs with their desired outputs. This iterative learning process allows the ANN to refine its predictive capabilities over time.

The KNN classification algorithm is among the simplest methods in data mining classification techniques. KNN operates by searching the pattern space for k-training tuples that are nearest to the unknown tuple being classified. These tuples collectively form the KNN classifier for the unknown tuple. The concept of “nearest” is determined by a distance metric, such as the Euclidean distance, which measures the proximity between data points. One potential limitation of KNN classifiers is that they assign equal weight to all attributes based on distance, regardless of their relevance. Consequently, KNN classifiers may suffer from poor accuracy when confronted with noise or irrelevant attributes in the data.

XGBoost is a significantly enhanced implementation of the gradient-boosting supervised ML technique, known for its speed and performance. It shares similarities with RFs but uses a more regularized model formulation to control overfitting. XGBoost operates as a tree ensemble model, which involves the summation of predictions derived from a specific set of classification and regression trees. This regularization technique helps improve the overall performance of the model by mitigating overfitting issues. XGBoost is versatile and can be applied to both classification and regression tasks.

LightGBM is a gradient-boosting framework that uses decision trees as the base learner, similar to XGBoost. However, LightGBM is optimized for efficiency and performance, offering several advantages, including faster training speed and lower memory usage. Additionally, LightGBM supports single-computer multithreading, multicomputer parallel computing, and graphics processing unit training, and has the ability to handle large-scale data.

After cleaning the data, we constructed models (RF and LightGBM) to eliminate irrelevant features such as gender, urea, creatinine, and total cholesterol. The final model incorporated the following features: age, education, finance, alcohol intake, smoking, hypertension, hyperuricemia, diabetes, hyperlipemia, BMI, waist circumference, HbA1c, FPG, PPG, total bilirubin (TBil), uric acid (UA), triglyceride (TG), high-density lipoprotein-cholesterol (HDL-C), LDL-C, alanine transaminase (ALT), aspartate transaminase (AST), γ-glutamyl transpeptidase (γ-GT), high-sensitivity C-reactive protein (hs-CRP), platelets, and hemoglobin (HGB).

Analysis Tools
The basic patient information and paper questionnaire responses were manually entered by a researcher using Microsoft Excel 2019 as the information entry software. Data cleaning, model construction, and area under the curve chart output were performed using Python 3.7 (Python Foundation), with the packages scikit-learn and numpy. The editor used for this purpose was PyCharm (JetBrains). The flowchart was drawn using MyDraw (Nevron Software).

Results
Overview of Data Comparison
First, we compared the diagnostic rates of traditional ultrasound with TE and found that traditional ultrasound achieved a high diagnostic rate of 84.6% (231/273) in patients with TE-rated moderate-to-severe steatosis (S2≥S2), which is consistent with previous reports on the accuracy of ultrasound diagnosis [20]. The comparison of hepatic steatosis stages produced by TE and traditional ultrasound results is shown in Table 3.

Model Performance Comparison

Finally, the model incorporated the following features: age, education, finance, alcohol intake, smoking, hypertension, hyperuricemia, diabetes, hyperlipemia, BMI, waist circumference, HbA\textsubscript{1c}, FPG, PPG, TBil, UA, TG, HDL-C, LDL-C, ALT, AST, \(\gamma\)-GT, hs-CRP, platelets, and HGB. The features incorporated into the final model are presented in Table 4. We compared the study population with moderate-to-severe steatosis with those without it.
Table 4. Features that were incorporated into the final model and significantly contribute to moderate-to-severe steatosis.

$^b$S2: moderate steatosis.

Table 5 presents the performance of the classification models. The area under the receiver operating characteristic curve (AUROC) for RF, LightGBM, XGBoost, SVM, KNN, and LR was 0.91, 0.86, 0.83, 0.88, 0.77, and 0.81, respectively. Additionally, the accuracy for RF, LightGBM, XGBoost, SVM, KNN, and LR was 84%, 81%, 78%, 81%, 76%, and 77%, respectively. Figure 4 displays the AUROC obtained on the test set of the moderate-to-severe fatty liver cohort using the final features.

Model Simplification and Visualization

Furthermore, we attempted to build a more concise model. We repeated the process randomly 5 times, each time selecting the top 15 scored features to create a Venn diagram (Figure 5), resulting in a total of 11 filtered features. We ranked the importance of these 11 features and plotted them on a scree plot (Figure 6). The plot demonstrated a substantial change between FPG and ALT, leading us to choose the first 6 features as inputs, excluding PPG. We made this decision based on the fact that the PPG test takes 2 hours and is not typically performed in most population health examinations.
To our surprise, the 6-feature RF model maintained accuracy while simplifying the feature acquisition for training. Table 6 displays the performance of the 11-feature RF model and the 6-feature RF model. The AUROC of the RF (11 features) model is 0.90, with a sensitivity of 0.61 and specificity of 0.94, maintaining the same accuracy as the RF model before simplification. Meanwhile, the performance of the RF (6 features) model showed an acceptable decrease compared with the others, with an AUROC of 0.88, accuracy of 0.82, sensitivity of 0.62, and specificity of 0.90. Figure 7 provides a summary of the ROC curves for the 2 simplified RF models.

Figure 8 presents box plots depicting the distribution of the 6 features. We can clearly see that there is a significant difference (Table 4) in the features between the 2 groups, which again demonstrates the high importance of the 6 features. To present our models more intuitively, Figure 9 showcases an example tree from the dense RF tree used for classification in the analysis.

**Figure 9.** Example tree from the dense RF tree used for classification in the analysis.
User-Friendliness and Cost-Effectiveness

In Suzhou, FPG, UA, and TBil can be tested through blood biochemistry analysis, hs-CRP can be tested through CRP analysis, and BMI and waist circumference are easy to obtain. Our decision tree clearly shows the eigenvalues and prediction accuracy of each node, which is convenient to use in clinical practice. Therefore, we aimed for a simplified decision tree model that can be widely applicable and generalized.

Waist circumference and BMI can be measured during routine physical examinations at a negligible cost. Blood biochemistry analysis costs approximately 168 yuan (US $23.6) per person, while CRP analysis costs around 35 yuan (US $5) per person. The total cost is approximately 203 yuan (US $28.5) per person. As blood biochemistry analysis and CRP analysis are routine checkup items in health examinations, our algorithm does not require additional testing items. Additionally, residents of Suzhou over the age of 40 years have free access to all of these tests once a year, making our model cost-effective.

TE screening, as a noninvasive quantitative assessment of liver fat deposition, poses challenges in determining its feasibility for widespread implementation in densely populated cities such as Suzhou (with >15 million residents), primarily due to the additional expense involved.

Discussion

Principal Findings

We used ML to differentiate the severity of NAFLD by incorporating body circumference, lifestyle, and blood indicators. The optimal results demonstrated that a 6-feature RF model could achieve an area under the curve of 88% (with 62% sensitivity and 90% specificity). The 6 features of the RF model were waist circumference, BMI, FPG, UA, TBil, and hs-CRP. The total cost of the indicator tests involved in the RF model was approximately 203 yuan (US $28.5) per person. By contrast, TE, as a noninvasive quantitative assessment of liver fat deposition, currently costs 260 yuan (US $36.5) per person. Compared with the cost of the indicator tests, TE incurs an additional expense of approximately 57 yuan (US $8) per person. Moreover, the Suzhou government offers free annual health examinations to residents over 40 years old within their jurisdiction. Consequently, people in Suzhou, with the assistance of our model, can obtain an almost free evaluation of NAFLD.

Therefore, we ultimately decided to use the RF model composed of these 6 features, as it not only serves as a routine component of health examinations but also has the advantages of being inexpensive and easily obtainable. In addition, we considered that some variables such as systolic blood pressure, diastolic blood pressure, and random blood glucose, which are included in similar studies, may be variable and unreliable. Therefore, we excluded these features to ensure that our model remains stringent and stable.

Metabolic associated FLD is a newer diagnosis; however, NAFLD was still used in this study. This decision was made because in the 43 patients we excluded who met the criteria for alcohol intake (30 g/day for men and 20 g/day for women), the diagnosis of FLD was significantly higher than in the rest of the cohort. Additionally, we considered that the grading data referenced by TE were generated from biopsies of patients with NAFLD, and the inclusion of patients with FLD who exceeded the alcohol intake limit would have led to less rigorous results. In the model, we included 4 metabolic diseases (hypertension, diabetes, hyperuricemia, and dyslipidemia) as 2-categorical variables. Although all 4 diseases showed a correlation with FLD, their importance was deemed lesser compared with features such as waist circumference and BMI.

Models presented in previous studies are typically stratified by age, with age demonstrating a high correlation in the final constructed model. It has been observed that from 2010 to 2018, the annual incidence of NAFLD was higher among those under 60 years of age (4.7%; 95% CI 4.0%-5.5%) than among those
over 60 years of age (2.4%; 95% CI 2.1%-2.8%). Additionally, the prevalence of NAFLD is parallel with the rising trend of obesity in China, increasing from approximately 2% in 2000 to 7% in 2014 [21]. Therefore, we believe that the high prevalence across all age groups is highly correlated with changes in lifestyle habits of the population. Consequently, BMI and waist circumference were heavily weighted in our model across all age groups. However, despite their potential significance, lifestyle variables such as smoking, alcohol intake, and physical activity showed low importance compared with the ones we ultimately used, and did not significantly improve the final accuracy. Additionally, a portion of the patients who participated in the TE examination had already been diagnosed with FLD and had undergone lifestyle adjustments.

In economically developed regions such as eastern China, the prevalence of FLD is higher. For example, the prevalence of NAFLD in Shanghai is 38.17% [22]. Ultrasound screening used in population-based health examinations does not allow for a clear diagnosis of FLD grading, and therefore, does not identify patients who need stricter lifestyle control and follow-up. Additionally, there is still a lack of awareness and perception of NAFLD as a chronic disease with serious consequences among the public. Surveys conducted in the 2000s reported that only 31% of the general population in China was aware of NAFLD [23]. If our results are appended to the health examination reports, it may catch people’s attention. Our next plan is to perform TE testing on patients with a model diagnosis of moderate-to-severe NAFLD, and we hope to screen out more patients who need follow-up through the combination of ML and TE examinations. At the same time, TE has the advantage of being less costly and more readily available compared with MRI and biopsy, allowing us to obtain more data to refine our model. We welcome the use of our model for validation. We hope that the use of ML to construct easy-to-use classification models for targeted population screening can be generalized.

Limitations
Our study has some limitations that should be addressed. First, while our model demonstrated a high specificity, the sensitivity was comparatively lower. This could be attributed to the complexity of our input data, indicating a potential need for higher-dimensional inputs. Second, although we used TE results to classify moderate-to-severe NAFLD along with other categories, it is important to acknowledge that TE itself may not be 100% accurate, necessitating liver biopsy as the gold standard. Incorrect classification could diminish the accuracy of our predictions. It is essential to test the model in real health examinations.

In addition, the clinical data in this study encompassed all age groups above 20 years old. Residents aged 40 years and above can avail themselves of free health examinations provided by the government, wherein related indicators can be included in the examinations to facilitate and reduce the cost of data acquisition. The population composition and dietary habits exhibit good representativeness in the East China region. The relevant research findings also show no obvious preference. However, residents aged 40 years and above generally have more chronic diseases and may be taking medications such as lipid-lowering drugs, which can influence the importance of lipid and other indicators in different age groups. These characteristics may play a significant role in the development of fatty liver, but they have not shown sufficient importance in the application of our model across a broader age range. The accuracy of using these indicators may vary across different age groups. Therefore, if the relevant conclusions of this study are widely promoted, they will require more representative data support to ensure applicability across diverse age demographics.

Finally, it is important to note that while TE offers improved precision and accuracy, studies suggest that obesity increases the risk of TE examination failure [24,25]. Additionally, research indicates that the presence of ascites can lead to failures in ultrasound examinations [25]. These potential failures underscore the need to consider alternative testing strategies when dealing with patients with obesity or ascites, ensuring comprehensive assessment and accurate diagnosis.

Conclusions
NAFLD has indeed emerged as a significant health burden in China. Unfortunately, many Chinese individuals pay little attention to the disease and are hesitant to undergo expensive tests such as MRI or TE. The proposed cost-effective algorithm using ML to identify moderate-to-severe NAFLD by screening health examination data is promising. This approach has the potential to address the limitations of ultrasound in staging hepatic steatosis and overcome the high cost and low accessibility of TE through the use of artificial intelligence.

Abstract

Background: To address the anticipated rise in mental health symptoms experienced at the population level during the COVID-19 pandemic, the Ontario government provided 2 therapist-assisted internet-delivered cognitive behavioral therapy (iCBT) programs to adults free of charge at the point of service.

Objective: The study aims to explore the facilitators of and barriers to implementing iCBT at the population level in Ontario, Canada, from the perspective of patients and therapists to better understand how therapist-assisted iCBT programs can be effectively implemented at the population level and inform strategies for enhancing service delivery and integration into the health care system.

Methods: Using a convenience sampling methodology, semistructured interviews were conducted with 10 therapists who delivered iCBT and 20 patients who received iCBT through either of the publicly funded programs to explore their perspectives of the program. Interview data were analyzed using inductive thematic analysis to generate themes.

Results: Six salient themes were identified. Facilitators included the therapist-assisted nature of the program; the ease of registration and the lack of cost; and the feasibility of completing the psychoeducational modules given the online and self-paced nature of the program. Barriers included challenges with the online remote modality for developing the therapeutic alliance; the program’s generalized nature, which limited customization to individual needs; and a lack of formal integration between the iCBT program and the health care system.

Conclusions: Although the program was generally well-received by patients and therapists due to its accessibility and feasibility, the digital format of the program presented both benefits and unique challenges. Strategies for improving the quality of service delivery include opportunities for synchronous communication between therapists and patients, options for increased customization, and the formal integration of iCBT into a broader stepped-care model that centralizes patient referrals between care providers and promotes continuity of care.

Introduction
The COVID-19 pandemic presented a significant challenge to the mental health of Canadians [1]. Studies have drawn attention to the negative impact of the pandemic on population-level mental health, highlighting increased levels of self-reported symptoms of depression and anxiety among Canadian adults [2-4]. Research conducted throughout the pandemic demonstrated barriers to accessing in-person mental health care in Canada, which occurred in the context of existing challenges, including lengthy wait times, limited availability of services in rural areas, high cost of services, a shortage of mental health professionals, stigma, and a lack of integration of mental health care services [5]. Due to the shortage of trained mental health professionals in Canada, the current workforce is unable to adequately meet the demands of one-on-one in-person psychotherapy [6]. Therefore, other solutions are required.

Digital mental health interventions, such as internet-delivered cognitive behavioral therapy (iCBT), are promising because they may address many of these barriers to care by providing increased reach at a lower cost than other modalities, subsequently improving access to evidence-based mental health treatment for depression and anxiety [7]. iCBT involves structured and predefined psychotherapeutic content organized in online modules. Patients are assigned homework to consolidate their learning, and brief therapist support is typically provided via secure in-app messaging and calls [8]. Randomized controlled trials have provided evidence in support of the effectiveness of iCBT across psychiatric disorders [9,10]. For example, a meta-analysis of transdiagnostic iCBT found medium to large controlled effect sizes for depression and anxiety outcomes (g=0.79 to 0.82) [11]. The treatment has also been successfully implemented in routine care settings in countries such as Australia, Sweden, Denmark, and Norway [12]. Despite its apparent efficacy and efforts to reduce barriers, iCBT programs face difficulties in maintaining user engagement, which is evident by limited uptake and high dropout rates [13]. Dropout in digital mental health therapies has been a long-standing issue, with dropout rates being typically lower in study trials compared with real-world implementations and routine care [14]. For example, some studies report that just more than half of patients complete a full course of iCBT [15]. A meta-analysis of 7313 participants across 40 studies found a dropout rate of 57%, with higher rates of dropout for iCBT programs for depression without support (74%) and lower rates for those with therapeutic support (28%) [16]. Real-world iCBT implementations in Australia and the United Kingdom (eg, This Way Up, MindSpot, and Improving Access to Psychological Therapies) show dropout rates ranging from 29% to 64% [17-19]. Future work should focus on identifying participants who will most likely benefit from iCBT and adhere to treatment protocols.

In addition, studies have shown that iCBT is a cost-effective way to improve accessibility to care, particularly for patients who face geographic and mobility limitations, such as those who live in remote or rural areas [20]. Moreover, Health Quality Ontario has suggested that the few publicly funded psychotherapy services in Ontario are not equitably distributed across the province, such as in rural areas in Northern Ontario where there are fewer psychiatrists [21], and cannot meet the needs of patients with mental health concerns [9]. Indeed, there is strong evidence that there is income-based inequity in access to mental health services, especially for psychologists who tend to be concentrated in private practice under the existing 2-tiered mental health care system in Canada [22,23]. Mental health services provided by general practitioners and psychiatrists can be billed through provincial and territorial health insurance plans; however, services offered by allied health professionals, such as psychologists, cannot. Estimates suggest that while two-thirds of Canadians can access mental health services through private employer benefits, the remaining one-third must access services through limited publicly funded services, pay out-of-pocket, or forgo seeking care [24]. Therefore, leveraging digital health technology can increase patient access to evidence-based psychotherapy, regardless of whether or not there is a pandemic.

To address the anticipated rise in mental health symptoms experienced at the population level, the Ontario government rapidly expanded digital mental health service offerings in May 2020 [25]. This included therapist-assisted iCBT, a form of guided iCBT where licensed mental health professionals provide regular support for patients by monitoring their symptoms, offering regular check-ins, and giving feedback on their homework assignments. This form of iCBT can be contrasted to coach-assisted iCBT, where nonregulated mental health workers are trained to provide support to patients throughout the program, or self-guided iCBT, where patients access a series of modules independently.

While publicly funded iCBT has been successfully implemented in Ontario during the pandemic by 2 service providers (ie, privately owned Canadian companies in the mental health and wellness sector), patient and therapist perceptions around its implementation have yet to be explored. Research on the experience of patients and therapists with publicly funded iCBT in other jurisdictions highlights accessibility, convenience, and the role of therapist support [26,27]. While these findings provide valuable insights, it is important to acknowledge potential differences that cultural factors, health care systems, and program variations may influence. Furthermore, few studies have examined the uptake and experience of publicly funded iCBT programs in Canada [28]. Therefore, the study objectives were to explore, from the perspectives of patients who accessed the iCBT program in Ontario and the therapists who provided the service, the facilitators and barriers related to iCBT delivery during the pandemic, and the proposed recommendations to address such barriers. The findings can inform future policy and funding decisions by providing insight into whether and
how the service should be expanded and better integrated into the mental health care system.

Methods

Study Setting

This study aimed to investigate the therapist-assisted iCBT program funded by the Ontario government during the COVID-19 pandemic to residents and offered in both English and French [25]. The 10- to 12-week program was promoted to individuals experiencing mild to moderate depressive or anxiety symptoms. The program could be accessed through self-referral or clinician referral to 1 of 2 service providers. Both service providers offered programs that adhered to the general principles of iCBT programs, which include a comprehensive intake assessment to identify primary mental health concerns, cognitive behavioral therapy techniques, and ongoing access to communication with a regulated mental health professional [29]. Both programs were based on the same principles but differed in their intake assessment process and method of communication between the therapist and patient. Program A (LifeWorks AbilitiCBT) offered a 5- to 7-minute online intake questionnaire, followed by a mandatory remote synchronous intake assessment with a therapist to identify the patient’s mental health needs and to develop a protocol tailored for the patient’s primary mental health concern [30]. Program B (Mind Beacon TAI CB T) used a 30-minute online intake questionnaire to achieve the same aims [31]. Both programs had a secure in-app messaging system for communication between patients and therapists, through which therapists could send messages to clients derived from a bank of predetermined messages. However, only program A offered optional synchronous phone or video calls that could be scheduled if needed throughout the program. Program A provided most patients with 10 content modules, irrespective of their specific mental health needs. One exception was for patients with posttraumatic stress disorder or trauma, who were provided with 2 additional modules for a total of 12 modules and an estimated completion time of 10 weeks. Program B provided patients with an average of 7 to 16 playlists (synonymous with modules), with additional playlists of content provided depending on the individual- or condition-specific needs, for an overall average completion time of 12 weeks. Despite the slight programmatic differences, it is reasonable to argue that the barriers to and facilitators of uptake and engagement in iCBT are unlikely to differ significantly between the 2 programs, both of which were implemented in the same context and aim to provide accessible and convenient iCBT interventions using online platforms and secure messaging system for patient-therapist communication. By conducting a combined analysis, a larger data set can be obtained, enabling a broader perspective on barriers and facilitators to iCBT implementation at the population level and the identification of overarching themes that go beyond program-specific differences. By focusing on common factors among programs, the study findings can provide valuable insights for the development and improvement of implementing iCBT programs across contexts.

Study Design

In this qualitative study, the research coordinator (MN) and 2 research assistants (BNK and ST) conducted semistructured, emergent interviews [32] with patients and therapists to gain a thorough understanding of their perspectives and experiences using or delivering iCBT. All interviewers had prior experience conducting semistructured interviews and received training prior to data collection. The study design and interview guides were developed based on input from multiple stakeholders, including patient advisors, psychiatrists, and experts in qualitative research. Furthermore, the interview guides were pilot-tested among the research team. The initial interview questions aimed to elicit contextual information, understand acceptance and satisfaction with the program, identify barriers and facilitators in using or delivering iCBT, and gather feedback on refining the service for future offerings. The interviews also focused on gaining insight into program completion and communication between therapists and patients. Follow-up questions were then tailored to participants’ responses to the initial questions in keeping with the emergent interview design. Finally, to ensure the relevance of the questions, separate interview guides were developed for patients and therapists (see Multimedia Appendix 1).

Recruitment and Data Collection

The 2 service providers assisted with recruitment by sending emails and in-app messages on behalf of the research team to the therapists and patients enrolled in the program. Both service providers sent recruitment emails to all therapists on an internal listserv and in-app message prompts through the platform to reach all users with access to the program on a weekly basis between September and November 2021. During the recruitment period, 39 patients (20 in program A and 19 in program B) and 29 therapists (17 in program A and 12 in program B) contacted the research team via email expressing interest in the study. Between October and December of 2021, 30 interviews were conducted with 20 patients (10 in program A, 9 in program B, and 1 in both program A and program B) and 10 therapists (5 in program A and 5 in program B). Interviews were conducted until data saturation was reached. The interviews were conducted between the interviewer and interviewee who had no relationship established prior to study commencement via audio call using Microsoft Teams and lasted approximately 45 minutes. Inclusion criteria for patients included being 18 years or older, having mild to moderate depression- or anxiety-related symptoms at the time of registration with the iCBT program, and having accessed the publicly funded program during the COVID-19 pandemic (between May 2020 and December 2021). The inclusion criteria for therapists included being a health care professional who delivered the iCBT program from either provider during the COVID-19 pandemic.

Data Analysis

The interviews were audio recorded, transcribed verbatim, and analyzed using inductive thematic content analysis, allowing for the emergence of themes and patterns directly from the data [33]. Transcripts were not returned to participants for comment.
or correction, nor did participants provide feedback on the findings. MN, RF, ST, and VK all contributed to the data coding and analysis process, which involved iteratively reading and rereading the transcripts to identify meaningful patterns and themes. This data-driven approach ensured that the analysis was grounded in the participants’ experiences and perspectives. To ensure rigorous methodology, the research team engaged in multiple meetings to develop consensus and refine the emergent themes.

To analyze the data, the researchers first independently reviewed the transcripts and created initial codes. Together, they then confirmed the structure of the codes and looked for potential themes. Once themes were identified, they were named and defined, using exemplar quotes to illustrate key points. All research team members reviewed and provided input on the themes and their interpretations. The themes and codes were related back to the study objectives during paper preparation. To ensure rigor and trustworthiness, the researchers engaged in reflexivity and debriefing with peers throughout the analysis.

Ethical Considerations

The study received ethical approval from the Women’s College Hospital Ethics Assessment Process for Quality Improvement Projects (REB # 2021-0057-E). All participants provided written and verbal consent before participating in the semistructured interview, during which the research objectives were described. Participants were made aware that the interviewers were unbiased third-party evaluators of the program. All participants were compensated via a $25 CAD electronic gift card to their choice of one of several major retailers. The data has been de-identified.

Results

Demographics

Table 1 displays the demographic characteristics of the patient interviewees. Of the 20 patients, most (n=13, 65%) were between the ages of 20 to 50 years; 55% (n=11) of patients were female and 40% (n=8) of patients were male. Regarding ethnicity, 70% (n=14) of the patients identified as White, while 30% (n=6) of patients identified as belonging to a racialized minority group. Notably, 80% (n=16) of patients completed 10 or more modules or playlists, meaning that they completed most of the program content without dropping out prematurely. A total of 25% (n=5) of patients had an average comfort with technology, while 30% (n=6) and 45% (n=9) of patients reported advanced and expert comfort with technology, respectively. Furthermore, all patients were self-referred to the program. Many patients heard about the program through a self-directed web-based search (n=9, 45%) or via their social network (n=9, 45%), while only 10% (n=2) of patients heard about the program via advertisements.

Table 2 displays the demographic characteristics of the therapist interviewees. Of the 10 therapist interviewees, most were (n=6, 60%) between the ages of 20 to 35 years, with a higher proportion of female therapists (n=9, 90%). Most therapists were licensed social workers (n=8, 80%), while the remaining 20% (n=2) were registered psychotherapists. Half (n=5, 50%) of all therapists had been delivering iCBT for less than 6 months. Most therapists (n=6, 60%) had 5 years or less of experience in their current profession.

Facilitators of iCBT included the therapist-assisted nature of the program, the ease at which the service could be registered for and accessed on an ongoing basis due to a lack of cost, and the feasibility of completing the psychotherapeutic content given the online and self-paced nature of the program. However, the study identified 3 barriers to the program’s implementation: challenges with the online delivery of the program for the therapeutic alliance; the program’s generalized nature, which limited customization to individual needs; and a lack of formal integration between the iCBT program and the health care system.

*iCBT: internet-delivered cognitive behavioral therapy.*

**Facilitators of iCBT**

**The Therapist-Assisted Nature of the Program**

Patients valued the therapist-assisted nature of the iCBT program, with many reporting satisfaction with being able to connect with a mental health professional. Personal communication with and feedback from therapists were essential in supporting patients’ engagement with the program and creating accountability for completing the program content, as they regularly checked in on patient progress.

I was really busy and I kind of left it unattended, and then [my therapist] just told me...don’t give up, find the time even though it might be busy, just take time aside and keep going, you’re almost done. I think if she wouldn’t be there or she wouldn’t send me that message, I would probably [have] just dropped it. [Patient 24, program A]

I will get occasional emails, “Your therapist has checked in”...it’s almost like a cue that, “Are you on track with your lessons?” Because I think if you leave people to their own devices, sometimes they’ll just fall off...the only accountability is to yourself. [Patient 7, program B]

In addition, the presence of a therapist allowed patients to feel connected to another human despite the online nature of the program. Patients felt supported knowing that an individual cared about their progress, read their messages, and reviewed their work.

I think I also don’t want to just feel so clinically cold about it either...that I just do my thing, and hopefully something will come of it. It’s nice for me to know that there’s somebody checking in...you feel like somebody cares. I kind of like the messaging, I think that without it, it’s a little sterile. [Patient 7, program B]

I felt like somebody was actually listening to me. I wasn’t just going through a computer program. [Patient 24, program A]

As several patients noted, the presence of a therapist was perceived as the most valuable component of the program.

I felt the material that I was working on was helpful, but the therapist was most helpful for what was there...I don’t think it would have been of any value to me personally without a therapist involved...For me that was one of the biggest things, was just to have someone to lean on a little bit. [Patient 13, program B]

That’s the best part...the conversation with the therapist. [Patient 2, program A]

However, as 1 therapist noted, not all patients take advantage of the ability to engage with a therapist.

Several patients appreciated the asynchronous communication modality, which allowed for a more accessible introduction to mental health treatment for those reluctant to engage in traditional therapy formats.

It makes you not quite so vulnerable as one-on-one counselling either on the phone or face-to-face, for somebody who is new to it or may have been reluctant in the past, I think that was the initial appeal for me, was that there was that kind of buffer...having that initial message from your e-therapist...was a very gentle introduction to therapy. [Patient 11, program B]
Other patients similarly noted that they felt more comfortable openly expressing personal topics through messaging as opposed to face-to-face or over the phone (patient 7, program B).

**The Accessibility of Registering for the Program**

The iCBT program was found to be accessible for patients due to its free and immediate availability. Many patients interviewed were willing to enroll in the iCBT program because it was available almost immediately with no waiting period.

*As soon as I finished my [intake assessment], I got the email almost immediately...within a week, I had a therapist send me an email to set up our initial interview.* [Patient 28, program A]

The lack of cost enabled individuals experiencing financial difficulties to participate, as well as those who were on waitlists or could not afford mental health services. As 1 therapist noted, the low barrier to entry is especially important because “so many people are looking for support...on waitlists...having to pay out of pocket, [and] are feeling they can’t find anyone to talk to...This is a great base for them to get that step in the door to build that confidence to be able to get more support” (therapist 4, program A). For example, 1 patient noted that they were interested in pursuing traditional CBT but did not have the resources to do so. The program being offered free of charge reduced the barrier to engagement.

*Doctors thought that CBT was the appropriate therapy for me, and so...I would go through an evaluation, and then it was a horrendous cost which I couldn’t afford...The cost is prohibitive.* [Patient 26, program A]

For many patients, money is a factor in their ability to access mental health services. As 1 patient stated, “I would have had to look at my benefits to see if something else was covered, but when I read that [it was free], I knew that it was not going to be a financial burden on me.” (patient 13, program B). However, some therapists expressed concern that the free service made it noncommittal and may contribute to patient withdrawal or inactivity.

**The Feasibility of Completing the Psychotherapeutic Content of the Program**

Furthermore, the online nature of the program also allowed for easy access from home or mobile devices, making it more feasible.

*It was the most practical thing ever. Everybody sits on their phone and scrolls through Instagram and Facebook and stuff, so having the module accessible on my phone was amazing because I was able to do that at any point in time throughout my day.* [Patient 28, program A]

One patient noted that they had to travel outside the home to receive the services, they would not have been able to participate (patient 26, program A). Indeed, the accessibility of the program was appealing to many patients who were not generally available during business hours. For example, 1 patient noted that the online delivery “makes the service much more accessible because people who are busy or working...it makes it more feasible to access the program compared with having to go into a doctor’s office” (patient 6, program A). This was especially important for patients who did not feel comfortable leaving their homes during the pandemic or lacked access to transportation. As 1 therapist noted, the program makes it easier for patients to access mental health support because it reduces the effort required to attend in-person therapy, a step which may compound the existing difficulties for patients experiencing challenges with their mental health.

Patients also appreciated the ability to work at their own pace and revisit their worksheets following the completion of the program. Patients similarly were satisfied with always having the program available.

*I really enjoyed the immediate accessibility of it...just having the reassurance that it is immediately at hand is oftentimes, sometimes all you need.* [Patient 11, program B]

Other patients noted the unique ability to spread out their therapy over time and work at their own pace.

*I would just get up and walk away or maybe go for a walk and come back and you can’t do that in traditional therapies.* [Patient 26, program A]

As 1 therapist noted, “I feel like one of the strengths is that it’s there when people need it, I think we are not telling people, ‘You have to be here on this particular day for your session’. We are saying, ‘It’s open. When you need it, it’s right there’” (therapist 19, program B). Furthermore, patients appreciated the absence of time pressure associated with traditional therapy sessions.

*I can take time to read the modules. I would never have that luxury to take time and reflect on modules in [a] therapy session...This relaxation of time and availability of resources makes the mental health service delivery much more effective.* [Patient 5, program A and program B]

**Barriers to iCBT**

**Challenges With the Online Modality**

Although therapists recognized the importance of developing a therapeutic alliance with their patients, some noted challenges in establishing rapport and communicating with patients online. Some therapists found it difficult to connect with patients due to the primarily asynchronous nature of communication and the limitations of the messaging platform. For example, 1 therapist noted that “it’s not the same as talking over the phone or in person...you have to wait for them to respond so that can be kind of difficult if they don’t respond...[Also]...it’s not a chat service so it can be hard to maintain a streamlined conversation that you would in person or on the phone because we are supposed to limit our interaction to one to two business days” (therapist 4, program A).

*It can be difficult sometimes to build that connection and build that therapeutic relationship when you’re just a voice, or you’re just words on a screen talking to somebody, and you’re not in person getting to build more of that physical or that non-verbal connection.*
as well. So, being online and virtual is definitely very
different in terms of how you have to build that
relationship as opposed to how you could do it if you
were sitting right in front of the person...it just
requires a little bit of extra thought into how to
develop that relationship when you’re not in person
with a patient. [Therapist 8, program A]

Therapists were required to refine their skills in connecting with
patients through a digital modality.

Despite the reported challenges, some patients said that they
were able to develop a strong therapeutic alliance with their
therapist online. One patient provided evidence for the ability
to develop the therapeutic alliance online, as they stated that
“my therapist and I have such a great relationship” (patient 28,
program A), while another shared that “I felt understood [and]
heard...[the therapist] listened to me...” (patient 26, program
A). However, a few patients would have preferred to speak to
their therapist over the phone after completing each module.
For example, 1 patient stated that they would have preferred to
verbally speak to their therapist about their feelings after
completing each module, as is their preferred mode of
communication: “I would like to express it verbally rather than
writing it.” (patient 2, program A)

Limited Opportunities for Customization

According to the feedback gathered, patients and providers of
the iCBT program felt that it needed more opportunities for
customization. They suggested that tailored protocols, feedback,
and guidance would enhance the program. While some degree
of customization was available through the chat functionality
and the ability to add worksheets, tools, or readings, some
therapists noted that more needs to be done to make the program
more customized to patient needs.

I think the chat functionality, and the ability to add
in worksheets or tools or readings at a whim...gives
a lot of flexibility, and I think CBT requires more
flexibility than is given...we offer reflections, and we
ask questions, and sometimes go a little deeper than
just what the material presents. [Therapist 20,
program B]

However, therapists also noted limited options for them to
customize the program for their patients, such as the inability
to change the patient’s protocol after treatment has started in
program B.

I don’t like the fact that when I have assigned a
patient a protocol, let’s say, depression, and then we
have worked together; and then, maybe, depression
is not really the thing I should have assigned this
person...but I cannot really change the heading of the
treatment. [Therapist 19, program B]

Patients also expressed that the lack of tailoring made the
program feel “superficial” and not customized to their needs
(patient 1, program A). For some patients, the lack of tailoring
made them feel “a little boxed into the format” and that the
content was “not...necessarily customized for what I [they]
needed” (patient 7, program B). Others suggested that given
the broad nature of the content, it was not necessarily relatable.

They suggested the option for “patient-specific” content based
on the patient’s needs (patient 28, program A). One therapist
noted that patients have expressed challenges due to the lack of
personalization, recognizing that the content has been created
in bulk and is not personalized, termed “bulk-therapy” (therapist
10, program B). As 1 therapist stated, many of the messages
they sent to their patients were obtained from a bank of
prewritten messages, which they would send to their patients
after changing the name in the message.

You’re sending messages, but the messages are really
short or they’re kind of formulaic...you also need to
have the ability to connect with an individual.  
[Therapist 9, program A]

Lack of Formal Integration With the Health Care System

The iCBT program was noted to lack formal integration with
the health care system by patients and therapists, who expressed
a desire for the program to be integrated with other mental health
programs and resources. The program currently does not allow
therapists to make formal referrals for patients; instead, they
can only suggest additional resources, which places the onus
on patients to seek other services. Therapists emphasized the
need for integration of services, especially given the siloed
nature of different services.

We don’t really refer. We make suggestions. We say
oh, call this program, or I hear this hospital has an
outpatient so-and-so, or you can try so-and-so...I
know what referrals are. You fill it in, you phone and
you fax it, you confirm, you do handover, and you
send case notes. That’s a referral. That’s a solid
connection with an appointment usually by the time
you’re done for the patient. We don’t do any of that,
and we say to the patient it’s all on you. [Therapist,
program A]

The therapists also suggested that iCBT could be used as a triage
process to ensure that patients are matched to the right level of
care.

If we’re connected to other mental health agencies,
then we can all be able to communicate in a way
that’s easy...If this isn’t what would be the best
program...we can continue to help you...it’s easy and
there’s a feeling that people are really being taken
care of. [Therapist 9, program A]

They suggested that social workers were in an ideal position to
refer patients to other services, but the existing infrastructure
does not allow for this.

I would encourage them to reach out to their family
doctor [and] provide some resources...and then, I
just hope that that’s what’s going to happen...It would
be great to have a partnership where the person will
have continuity of work, if we could refer them rather
than just give them resources for them to self-refer.
[Therapist 8, program A]

Patients and therapists both felt that patients might still require
additional support after completing the iCBT program and
desired the ability to stay connected with their therapist on an
Discussion

The study of patient and therapist perceptions of 2 free publicly funded iCBT programs implemented in Ontario during the COVID-19 pandemic revealed that while several aspects of the program were well-received and facilitated access to care, there were several barriers and missed opportunities. Patients and therapists reported that the following facilitators: (1) the therapist-assisted nature of the program, which enhanced participation, (2) the ease of registration and access, and (3) the online self-paced nature of the program, which increased the feasibility of completing the psychotherapeutic content. However, the study identified three barriers: (1) challenges with the online delivery of the program for developing a therapeutic alliance; (2) the program’s generalized nature, which limited customization to individual needs; and (3) a lack of formal integration between the iCBT program and the health care system.

The findings regarding the facilitators to implementation are largely consistent with what has been reported in the literature. Many patients who were highly engaged with the program felt supported by their therapist and had adequate contact with them, which aligns with previous studies [35]. Furthermore, meta-analyses have found that guided iCBT is more effective than unguided iCBT [36], suggesting that communication with a therapist is one of the active components contributing to the effectiveness of iCBT. Another strength of the program implementation was removing many of the financial, logistical, and emotional barriers for patients. For several clients, the asynchronous communication modality was appreciated as it reduced the barriers associated with stigma for those who were reluctant to engage in traditional therapy formats, many for the first time. These findings are consistent with the literature that posits a key advantage of iCBT is in reducing stigma and, thereby, improving service access [37,38]. Moreover, the absence of a waitlist in both iCBT programs ensured that clients could receive timely access to care, which is crucial given that waitlists are a large barrier to mental health care in Ontario. Across Canada, the average wait time for first-time community mental health services from 2019 to 2020 was nearly 1 month [39]. Last, many patients expressed that the self-paced format of the program allowed them to work through the program at a preferred pace that worked well for their schedule, allowing them to integrate the program into their lives feasibly. These findings are consistent with previous studies of the attitudes of therapists and patients regarding online treatment, for which they positively perceived the ability to perform assignments at the patient’s own time and pace [40,41].

When asked about barriers, some therapists acknowledged challenges in developing the therapeutic alliance with patients; findings that are consistent with other studies in Ontario during the pandemic, where mental health care providers expressed concerns that digital care impeded the therapeutic relationship [42]. However, these findings are contrary to previous studies that found a positive alliance that is similar to face-to-face psychotherapy [43] and with a similar relationship between therapeutic alliance and patient outcomes [44]. Indeed, previous qualitative studies have suggested that the treatment format may act as both a facilitator and barrier to engagement for different individuals [45-49]. While therapists noted that some degree of customization was possible, patients desired more tailored protocols, feedback, and guidance, and some patients expressed that the program felt superficial and not relatable. These findings are aligned with previous qualitative studies on iCBT, where patients desired more flexibility for the therapist to adjust the therapeutic content to their individual difficulties or life situations [50]. While greater customization and therapist involvement may increase effectiveness, there may be a tradeoff of increased costs and, thereby, reduced reach. The most significant finding was that there was a missed opportunity in formally integrating iCBT into the health care system during its implementation, hindering the continuity of care for patients. Furthermore, participants emphasized the need for therapists to provide direct referrals for patients to other services. Understanding for whom specific interventions are most beneficial remains a challenge, particularly for low-intensity interventions such as iCBT [36,51-53]. Last, patients desire continuous support post-iCBT; including necessary follow-up mechanisms and resources for relapse prevention. The frustration experienced by patients who lose access to their therapist has also been reported in qualitative experiences of patients engaging in iCBT [50]. Overall, integrating iCBT with existing services may ensure that adequate treatment options are provided to those for whom iCBT is inappropriate, as well as facilitate the provision of additional support when necessary.

While many iCBT programs have high rates of dropouts or noncompleters [54], the findings provide insight into what works for the minority of patients who are highly engaged with the program. Knowledge and understanding about the patient experience are limited for those with low engagement or who prematurely dropped out of the program. Additionally, despite efforts to reach nonusers, defined as individuals who discontinued treatment after completing the intake assessment but prior to any treatment or were deemed ineligible for the program, no one volunteered to participate in qualitative interviews. Furthermore, the results are not generalizable to all patients and therapists, given the limited variation of sample characteristics and that only those who were interested in sharing their experiences with iCBT chose to participate in the evaluation. Moreover, while the intent of the study was to assess implementation, the interview guide did not include questions to assess users’ perspectives on the perceived impact of the program on their mental health. However, a key strength of this study is that, unlike other real-world implementations of iCBT programs that have been evaluated by those involved in the program development and implementation, the present evaluation was conducted by a neutral third-party evaluation team contracted by the program funder.

The study’s findings have implications for policy, practice, and research. Participants proposed a stepped-care model, wherein...
the iCBT program could serve as a triage mechanism to ensure that patients are matched with the appropriate level of care. Given the low barriers to access, the program can reach a large segment of the population and provide an entry point into other clinical services that may be more appropriate or act as an introduction to more intensive therapy for patients on waitlists for more specialized services. In clinical practice, iCBT may be used as an introduction to psychotherapy for those who are unsure about traditional CBT, to help prepare clients for more intensive psychotherapy, or when used as a companion to traditional CBT as a booster program following discharge. At the outset of the program implementation, the primary objective was to ensure timely and scalable implementation of iCBT with low barriers to care and broad reach. Understandably, initial decisions regarding the scope and design did not consider how the program could be better integrated into the mental health care system for continuity of care. Policy decisions have since been made based on preliminary findings from a pragmatic evaluation of this program to shift from a low-access model to a prescriptive service offering that requires a referral and is integrated into the Ontario Structured Psychotherapy program, coordinated by 10 partner hospitals across the province [55].

The findings also suggest that iCBT programs could benefit from more personalized approaches to treatment. For example, therapists may benefit from training to be more specific and tailored in their patient feedback rather than using generic responses that may be perceived as disingenuous. To ensure effective support and authenticity in iCBT therapy, further research is needed to determine how therapists can convey these qualities despite the limited communication opportunities in primarily asynchronous care, given the varied patient perceptions of support. In addition, as proposed by Cavanagh et al [56], it may be necessary to reconceptualize the therapeutic alliance in the context of iCBT, given the unique treatment modality, which may guide how therapists are trained to support patients within the context of the program. Furthermore, identifying individuals for whom less therapist interaction is necessary for therapeutic benefit can help allocate more resources for those who may need more frequent interaction and possible modifications to the program structure. However, the discrepancy between the quantitative studies with larger samples and patient experiences reported in qualitative studies suggests that while many patients who do not complete the program report missing face-to-face meetings and synchronous support [46], this may not make a clinical difference. Regardless, future large-scale investigations should examine how iCBT programs can be adjusted to reduce dropout rates for those less satisfied with the treatment format. To enable reaching out to individuals who have dropped out and are no longer actively using the platform, funders should require that vendors provide clients with the option to be contacted outside of the iCBT platform for research purposes by including an additional consent clause during the enrollment process and maintain additional contact details. This is necessary for future research that aims to examine the perspectives of clients who dropped out or disengaged from the program, as they are difficult to reach. Last, the study aims to support an emerging research culture evaluating mobile apps beyond traditional market research done by vendors, wherein therapeutic apps are held to the same standards as other therapeutic interventions, such as drugs, medical devices, or psychotherapy.

In conclusion, our study provides valuable insights into the benefits and limitations of iCBT programs. While the convenience and accessibility of iCBT programs have the potential to be transformative for the treatment of mental health disorders, there is still work to be done to address the concerns of patients and therapists regarding limitations to digital care, customization, and integration with the health care system. Future research should focus on developing more personalized approaches to iCBT treatment, as well as finding ways to better integrate iCBT programs into the existing mental health system.

Acknowledgments

The authors would like to express their gratitude to the research participants who took the time to share their perspectives and experiences, without whom this research would not be possible. The authors also greatly appreciate the funding provided by the Ontario Ministry of Health to carry out this research. The study funder was not involved in the design of the study and the collection, analysis, or interpretation of data.

Authors’ Contributions

ST participated in the coordination of the study; collected, analyzed, and interpreted the data; and drafted the manuscript. OB, RL, MN, ST, and BNK led in the conception of the study design. BNK, OB, and MN revised the manuscript. BNK and MN oversaw the coordination of the study and contributed to data collection. MN, RF, and VK also analyzed the data. AO, MK, BBA, and MLC supported the conception of the study design. All authors read and approved the final manuscript submitted for publication.

Abstract

Background: Young sexual minority men (YSMM) engage in cardiometabolic risk behaviors (eg, substance use) at higher rates than their heterosexual counterparts. Theory and previous research suggest that these risk behaviors may stem, in part, from exposure to minority stress (ie, discrimination based on sexual identity and other identities such as race).

Objective: This pilot study examined the feasibility and acceptability of a virtual 2-day daily diary study that examined daily experiences with discrimination, cardiometabolic risk behaviors (ie, sleep, physical activity, and substance use behaviors), and patterns of physiological stress and inflammation among YSMM aged 18 to 35 years.

Methods: Participants (n=20) were recruited from the greater New York metropolitan area and engaged in a 2-day daily diary protocol wherein they provided web-based consent, took a web-based baseline survey, and then, starting the next day, provided 3 saliva samples a day for 2 consecutive days to measure salivary cortisol, engaged in 3 daily diaries per day, and provided 1 blood spot sample via the finger prick method to measure high-sensitivity C-reactive protein. At follow-up, participants were interviewed via videoconferencing to ascertain their experiences and feelings related to the study protocol. Qualitative analyses explored the feasibility and acceptability of the study protocol, and exploratory quantitative analyses explored the descriptive statistics and Pearson correlations among the main study variables of interest.

Results: The retention rate was high (19/20, 95%) in our study sample. Qualitative analyses demonstrated that participants were willing to engage in similar, longer-term studies (eg, studies that include both week and weekend days) in the future and suggested the feasibility and acceptability of our study protocol among YSMM. However, participants noted several areas for improvement (eg, redundancy of survey items and difficulty pricking one’s finger) that should be considered in future research. Preliminary quantitative analyses revealed a moderate negative correlation between everyday discrimination and mean cortisol levels ($r = -0.51; P = .03$). Furthermore, descriptive analyses suggest that that daily cortisol curves differ across races or ethnicities among YSMM. White and other-identified YSMM experiences the highest cortisol awakening response (mean 0.39, SD 0.21 µg/dL for White participants; mean 0.34, SD 0.34 µg/dL for others) with the steepest decline around bedtime (mean 0.05, SD 0.04 µg/dL for White participants; mean 0.09, SD 0.13 µg/dL for others) followed by a lower cortisol awakening response (mean 0.31, SD 0.11 µg/dL for Hispanic participants; mean 0.23, SD 0.15 µg/dL for Black participants) and a slower decline around bedtime (mean 0.10, SD 0.09 µg/dL for Hispanic participants; mean 0.03, SD 0.02 µg/dL for Black participants) among Hispanic and Black YSMM.

Conclusions: Overall, the results suggest that similar study protocols are feasible and acceptable among YSMM. Future research should highlight the pathways through which cardiovascular disease risk may arise among YSMM using longer-term study designs and more diverse study samples.
Introduction

Background
Cardiovascular disease (CVD) is the leading cause of death and disability in the United States [1], and young sexual minority men (YSMM) have disproportionately high rates of CVD compared with their heterosexual counterparts [2]. Emerging evidence implicates stress from racial and sexual orientation discrimination as a significant social determinant of cardiovascular risk among young sexual minorities (aged 18-35 years) [3-5]. Moreover, research shows that CVD risk accumulates early in life, and as such, prevention interventions should focus on addressing risk factors in young adulthood [6]. However, evidence suggests that disparities exist in early CVD risk, such that sexual minorities are more likely to experience CVD at an earlier age than heterosexual individuals, in part because of exposure to minority stress (eg, sexual orientation-related discrimination) [7]. Although research has demonstrated that sexual minority men are more likely to experience excess CVD risk related to factors such as tobacco use, illicit drug use, and poor mental health [8], there is a critical lack of research aimed at understanding the mechanistic links between minority stress and CVD risk, particularly for YSMM. Thus, this study aimed to examine the feasibility and acceptability of an internet-based daily diary protocol aimed at measuring the mechanistic links between minority stress, CVD risk behaviors, and health among YSMM between the ages of 18 and 35 years.

Theoretical Model
This study was guided by sexual minority stress theory, which posits that sexual minority individuals are exposed to a number of distal stressors related to the negative social valuation of minority identities, resulting in stress exposure beyond the level that people generally experience [9]. Distal minority stressors refer to external discrimination or prejudice events that are targeted toward an individual owing to their minority identity (eg, sexual orientation discrimination) [9]. However, over time, individuals may internalize minority stress, which may, in turn, increase the likelihood of dysregulated physiological stress and poorer health behaviors (eg, substance use) [10-13], which are linked to an increased risk of subclinical CVD [14-17]. Evidence suggests that exposure to sexual minority stressors can lead to physiological changes that over time can lead to an increased risk of CVD [3,18-20]. For instance, Lewis et al [3] posit a causal pathway between discrimination and CVD risk such that exposure to discrimination leads to emotional or affective dysregulation, which, in turn, can lead to physiological dysregulation (eg, inflammation) and poor health coping behaviors (eg, substance use). Over time, this may overburden the physiological stress system and lead to cardiovascular risks. Indeed, these authors found evidence to suggest that expectations of racism are associated with increased carotid intima-media thickening measurements, a measure of increased risk of subclinical CVD, among Black women [3].

Experiences of sexual minority stress among racial or ethnic minorities are not equal and are framed by individual cultural realities and contexts. Intersectionality theory posits that the possession of multiple marginalized identities intertwines at the individual level and is reflective of structural-level power inequities and inequality, influencing health behavior and outcomes across the life course [21]. In particular, the intersection of race- and sexual orientation–based discrimination may be detrimental to health. Indeed, many studies have documented the deleterious effects of discrimination among racial or ethnic minorities, including dysregulated cortisol rhythms, elevated C-reactive protein (CRP), and heightened ambulatory blood pressure [19,22]. These important biological outcomes influence vascular inflammation, atherosclerosis, stroke, and other cardiovascular risk factors [23-25]. In addition, there are health behaviors along the posited causal pathway between discrimination and CVD risk including substance use, diet, and physical activity, which are important mechanisms to study and understand [3,26]. Nevertheless, the mechanisms linking discrimination and cardiovascular factors in racially diverse populations remain underexplored [4]. Conducting this research is vitally important, considering the heightened rates of both stress from discrimination and subclinical CVD among these potentially vulnerable populations [3,8].

The COVID-19 pandemic has provided us with a unique opportunity to conduct our study on the web. Thus, the current investigation reports on the feasibility and acceptability of conducting a study to understand 2 key pathways linking sexual minority and racial or ethnic discrimination to CVD risk, health behaviors (ie, substance use and physical activity), and physiological dysregulation (stress reactivity) completely virtually.

Study Objectives
The aims of this study were as follows: (1) to assess the feasibility and acceptability of a virtual daily diary study protocol (measured via qualitative debrief interviews), including the collection of biologics and ActiGraph technology; and (2) to explore preliminary associations between discrimination, substance use, sleep, physical activity, physiological stress, and inflammation among YSMM (measured via surveys, ActiGraph technology, and biologics, respectively).

Methods
Setting and Participants
This single-site pilot study recruited YSMM between the ages of 18 and 35 years from the New York tristate area. Eligibility criteria included (1) identification as cisgender male; (2) between the ages of 18 and 35 years, inclusive, at the time of screening; (3) identification as a sexual minority; (4) having no
known heart conditions, diabetes, or high blood pressure; and (5) willingness to provide informed consent. Participants were identified via online and offline techniques, including posts to listservs and flyers posted on campuses around the New York metropolitan area (eg, New York University). The recruitment materials included information about the study, contact information for the principal investigator’s laboratory, and a link to a web-based screening survey via Qualtrics.

Ethical Considerations

Interested participants filled out a web-based screening survey, which ascertained relevant sociodemographic information, such as age, biological sex, gender identity, sexual orientation, race, and ethnicity. Eligible participants were contacted by trained research assistants (RAs) to schedule a baseline meeting via Zoom to confirm eligibility, provide more information about the study (eg, study protocol and duration of study), and provide electronic informed consent. The participants were renumerated with up to US $95 for completion of the study protocol. The full details of the full study protocol are detailed below. This study was approved by the Institutional Review Board of New York University (FY2021-5355).

Procedure

Baseline

Participants who were screened eligible through the web-based screening survey were emailed by trained RAs to schedule a baseline meeting via Zoom. During this baseline visit, participants were given detailed information about the full study design, which included a baseline survey to be taken on the web via Qualtrics, a 2-day daily diary period that included biological specimen collection (see 2-Day Diary Period section), and a 30- to 45-minute follow-up and debrief interview via Zoom after completion of the baseline survey and the 2-day protocol. Participants who agreed to participate and who provided electronic informed consent were then sent a link to a Qualtrics survey to be taken within the proceeding 24-hour period as well as electronic copies of step-by-step instructions for saliva collection, HemaSpot collection, and Actigraphy use. Actigraphy was chosen for the purposes of this study because research demonstrates that it provides reliable estimates of sleep patterns in relation to polysomnography [27]. The baseline Zoom meeting took an average of 30-45 minutes, and the baseline survey took approximately 45 minutes to complete. Furthermore, participants who provided informed consent were mailed a study kit with materials needed to complete the 2-day diary period via the United Parcel Service (UPS). The study kit contained saliva collection aids for the 2-day period, a HemaSpot collection device, an Actigraphy watch, and printed copies of instructions for each section of the protocol.

Two-Day Diary Period

Within 48 hours of completing the baseline, RAs mailed study kits to participants’ homes via UPS overnight shipping. These study kits contained (1) a charged Actigraphy GT9X Link watch ready to start data collection immediately; (2) 2 Ziploc bags with 3 saliva collection tubes and 3 saliva collection aids per bag; (3) a HemaSpot blood spot collection device with an absorbent sheet, 2 gauze packs, 2 alcohol swabs, 2 safety lancets, and 2 bandages; (4) printed out instructions for the saliva collection procedure, HemaSpot blood spot collection procedure, and wearing the Actigraphy, as well as a sheet to record when the Actigraph was placed on one’s wrist and when it was taken off, if applicable; (5) supplies for returning the study kit including a small plastic bag with a humidity indicator card and 2 desiccant packets for the HemaSpot device, a cold pack (which they were instructed to freeze immediately upon receiving the kit), a silver insulated bubble mailer, and a brown paper shipping envelope; and (6) a prepaid shipping label to return the Actigraphy, saliva samples, and HemaSpot kits back to the laboratory. Participants were instructed to start the 2-day protocol the day after receiving their study kit.

Over the 2-day study period, participants were instructed to wear the Actigraphy watch on their nondominant wrist consecutively, even when showering and sleeping, over the 2-day period. Furthermore, participants provided 3 saliva samples per day, a blood spot sample, and took 3 surveys each day via Qualtrics. The first 2 of these surveys, termed “momentary diaries” took 2-3 minutes to complete and asked participants to fill out relevant information related to saliva samples, mood, and experiences. The last survey of the day, termed the “nightly diary,” took about 10 to 15 minutes to complete and asked the same “momentary diary” questions as well as more detailed questions about their experiences throughout the day. Surveys were sent via email to participants at 6:00 AM, 6:30 AM, and 8 PM each day over a 2-day period, and they were instructed to take the surveys immediately after providing their saliva samples upon wakeup, 30 to 45 minutes after waking up, and around bedtime.

For the 2-day saliva collection period, participants were asked to provide 3 saliva samples per day via the passive drool method. The first saliva sample was taken immediately upon waking, the second saliva sample was taken 30-45 minutes after waking, and the third saliva sample was taken before bedtime. This procedure was repeated for 2 consecutive days. Participants were instructed to avoid brushing their teeth, eating, and drinking liquids high in sugar or acidity (eg, coffee) 30 minutes before taking their saliva samples. Participants were instructed to allow saliva to pool in their mouth and then use a saliva collection aid to collect 1 mL of saliva in the collection vial. The participants were also instructed to freeze their samples immediately after collection.

For the HemaSpot blood spot collection procedure, participants were instructed to provide a blood spot sample on the afternoon of the second day of the 2-day study period. Participants were instructed to wash their hands before beginning the finger prick procedure. Then, participants spread the absorbent sheet provided in the study kit on a table or countertop and placed gauze, alcohol swabs, safety lancets, and bandages on the sheet in close reach. When the participants were ready to start the procedure, they were instructed to open the pouch containing the HemaSpot device (which must be used within a few minutes of opening). They were then instructed to prepare a safety lancet for use by twisting the cap until it popped out. Participants then selected their ring or middle finger from their nondominant hand and selected a place to the side of the finger pad (avoiding their fingernail). Participants then wiped their finger with an
During this interview, the RAs described the purpose of the to schedule their 15 to 20 minute debrief interviews via Zoom.

Downloaded. Then, the RAs contacted the participants via email or too little blood). Furthermore, ActiGraph data were present) and blood spot samples (eg, if there was too much blood). RAs processed the saliva and blood spot samples by examining the features of the saliva (eg, denoting whether phlegm or blood was present) and blood spot samples (eg, if there was too much or too little blood). Furthermore, ActiGraph data were downloaded. Then, the RAs contacted the participants via email to schedule their 15 to 20 minute debrief interviews via Zoom.

During this interview, the RAs described the purpose of the study and followed a semistructured interview guide to ascertain participants’ experiences with the study design, collecting saliva and blood spot samples, wearing an ActiGraph, and filling out diary surveys each day. After the completion of this interview, participants were compensated according to their compliance with the study protocol (see the Financial Incentive Structure section above) through an electronic Visa gift card via GiftBit.

The RAs took notes on participants’ responses to the follow-up interview questions (see Figure 1). The interview guide was structured to gather information pertaining to the feasibility and acceptability of the study protocol among the YSMM. In particular, we asked participants about their experiences with the RAs, saliva samples, ActiGraph watch, and HemaSpot collection device. We also asked participants to describe whether the study caused any stress or confusion, and if they had any areas of improvement to increase their willingness to engage in future research with similar designs.

Financial Incentive Structure

In this study, a financial incentive structure was used to promote retention. Participants were compensated with US $10 for completion of the baseline survey. For wearing the ActiGraph and returning the ActiGraph, participants were compensated with US $15. To provide and return saliva samples, the participants were compensated with US $15. For providing and returning the blood spot sample, participants were compensated with US $15. Furthermore, the participants were provided with US $10 for completing the follow-up interview. Finally, if participants completed each component of the study, they received a US $30 bonus. Thus, the participants could earn up to US $95 for the completion of this study.

Qualitative Data

Procedure

Participants were instructed to mail their study kits to the laboratory the day after completing the 2-day study protocol by placing the frozen HemaSpot device in a small plastic bag with a humidity indicator card and the 2 desiccant packets. They were instructed to place the 6 saliva collection tubes and ActiGraph along with the sealed HemaSpot device in a silver-insulated bubble mailer with a frozen cold pack. Afterward, participants placed the silver-insulated bubble mailer into the brown paper silver envelope and were instructed to affix the prepaid return label to the envelope and drop it off at UPS to be sent back to the laboratory via overnight shipping.

After receiving the returned study kit back to the laboratory, RAs processed the saliva and blood spot samples by examining the features of the saliva (eg, denoting whether phlegm or blood was present) and blood spot samples (eg, if there was too much or too little blood). Furthermore, ActiGraph data were downloaded. Then, the RAs contacted the participants via email to schedule their 15 to 20 minute debrief interviews via Zoom. During this interview, the RAs described the purpose of the study and followed a semistructured interview guide to ascertain participants’ experiences with the study design, collecting saliva and blood spot samples, wearing an ActiGraph, and filling out diary surveys each day. After the completion of this interview, participants were compensated according to their compliance with the study protocol (see the Financial Incentive Structure section above) through an electronic Visa gift card via GiftBit.

The RAs took notes on participants’ responses to the follow-up interview questions (see Figure 1). The interview guide was structured to gather information pertaining to the feasibility and acceptability of the study protocol among the YSMM. In particular, we asked participants about their experiences with the RAs, saliva samples, ActiGraph watch, and HemaSpot collection device. We also asked participants to describe whether the study caused any stress or confusion, and if they had any areas of improvement to increase their willingness to engage in future research with similar designs.

Qualitative Analysis Plan to Assess Feasibility and Acceptability

A deductive directed content analysis approach was used to code the interview notes [28]. This approach uses prior theory and research to create an initial coding scheme consisting of overarching themes—in this case, our initial predetermined themes were feasibility and acceptability as well as potential areas of improvement. Three coders met to discuss the predetermined themes and then one coder applied the themes to the transcripts. The 3 coders met throughout the duration of the qualitative analysis to discuss themes and resolve any discrepancies in coding. After reading the transcripts, subthemes for each overarching theme were deduced from the interview notes to determine a finalized coding scheme organized by the themes of feasibility, acceptability, and areas for improvement. Debrief notes were analyzed using Atlas.ti qualitative software [29].
Quantitative Data to Explore Preliminary Associations

Baseline Survey
The baseline survey was conducted on the web using Qualtrics. Participants were assigned a unique participant ID and required to enter the ID to access each survey. The baseline survey asked questions pertaining to sociodemographics (eg, date of birth, race and ethnicity, education level, yearly income), family history of cardiovascular-related illness or disease, and general weekly exercise patterns (ie, the Global Physical Activity Questionnaire [30]). We then administered a series of scales related to experiences with stress (eg, Adverse Childhood Experiences Scale [31], Perceived Stress Scale [32]), discrimination (Everyday Discrimination Scale [EDS] [33], Major Experiences of Discrimination Scale [33]), substance use (Alcohol, Smoking, and Substance Use Involvement Screening [34]), and mental health (eg, Center for Epidemiologic Studies Depression Scale [35]). The baseline survey took an average of 45 minutes to an hour to complete.

Momentary Diaries
Momentary diaries were taken by participants twice per day over a 2-day period (once upon waking and once 30-45 min after waking) via Qualtrics. Participants were asked several questions related to their saliva samples (eg, what time they provided the sample and caffeine consumption) and questions pertaining to their current mood, stress, recent experiences of racial and sexual orientation discrimination, and substance use. Each momentary survey was sent to the participants via a secure Qualtrics link. The survey took an average of 2-3 minutes to complete.

Nightly Diaries
Nightly diaries were taken by participants once per day over a 2-day period (before bedtime) using Qualtrics. Nightly diaries contained the same questions as the momentary diary and included modified scales to assess experiences of mood (Positive and Negative Affect Schedule [36]), depressive symptoms (Center for Epidemiologic Studies Depression Scale), and discrimination (EDS). Nightly diaries were sent to the participants via Qualtrics via email.

Salivary Cortisol
Participants provided 3 saliva samples per day over the course of 2 consecutive days to assess diurnal cortisol [37]. They were instructed to provide samples upon awakening, 30 minutes after awakening, around lunchtime, and around bedtime. The participants were also instructed to take a brief diary survey after providing each saliva sample. After participants collected their first 3 saliva samples, they received a link to an additional “momentary” diary survey via text message or email, which took about 2 minutes to complete. This momentary survey assessed variables associated with cortisol (eg, caffeine consumption) as well as other psychosocial variables (eg, current mood). Finally, after each bedtime saliva sample, participants received a link via text message or email, depending on their preference, to a longer “nightly” diary survey. To increase adherence to sample collection and surveys, participants received text message reminders to provide their samples, which also contained the appropriate survey link.

High-Sensitivity CRP
The Center for Studies in Demography and Ecology Biodemography Lab analyzed serum high-sensitivity CRP (hsCRP) values using an enzyme-linked immunosorbent assay as described in detail elsewhere [38]. Microliter plates were coated with anti-CRP antibodies to measure CRP concentrations within serum samples and stored at −20 °C. This method has been validated for population health research as a robust method for detecting low concentrations of CRP [38-40]. hsCRP values were arranged into 3 categories according to clinical risk for CVD assigned by the American Heart Association and Centers for Disease Control and Prevention to create a nominal outcome variable for calculation: low (<1.00 mg/L), average (1.00-3.00 mg/L), and high (>3.00 mg/L) [41,42]. The categories described the results in terms of clinical significance, as CVD risk increases with higher CRP concentrations. Previous studies using CRP in heart disease have demonstrated this clinical significance using categorical CVD risk [43-45].

Other Covariates

Overview
BMI was calculated using a standard formula based on the participants’ height and weight (kg/m²), each of which was self-reported. Values were sorted into 2 categories: underweight or normal weight (<25.00) and overweight or obese (≥25.00). Furthermore, we also ascertained information pertaining to smoking status (never, former, and current), substance use (measured at baseline via Alcohol, Smoking, and Substance Use Involvement Screening and nightly diaries), and family history of CVD (yes or no).

Quantitative Analysis
First, sociodemographic and clinical characteristics were explored in our study sample (eg, means with SDs and frequencies). We then explored retention and feasibility through an examination of study dropout, loss to follow-up, and completion rates of each of the study components (ie, salivary samples, HemaSpot blood spot samples, momentary diaries, and nightly diaries). Finally, Pearson correlation coefficients were used to explore associations among our main independent variables (discrimination as measured by EDS), the dependent variable (hsCRP), and our mediators (sleep, physical activity, and physiological stress as measured by salivary cortisol). Time-varying variables (ie, sleep, physical activity, and cortisol) were averaged across the study period for each participant. Baseline discrimination (as measured by EDS) was used for the purpose of the correlations. Average daily cortisol curves were also examined and stratified by race and ethnicity using the profile plot command in Stata (version 18; StataCorp) [46].

Results

Sample Characteristics
Figure 2 displays an overview of the number of participants who were screened, ineligible, enrolled, and analyzed. Sociodemographic and clinical characteristics of the 19 YSMM who participated in the study are presented in Table 1. On
average, the participants were aged 24.37 (SD 5.46) years. With respect to racial or ethnic identity, 39% (7/19) identified as non-Hispanic white, whereas the remaining identified as Hispanic (3/19, 16%), Black (3/19, 16%), or another racial or ethnic identity. Most participants identified as gay or bisexual (8/19, 42%), and the remaining identified as having another sexual identity. Concerning health characteristics, most participants reported an average BMI (10/19, 53%) and no family history of CVD (16/19, 84%). The average hsCRP among participants was 0.20 (SD 0.17), and participants slept an average of 313.18 (SD 90.25) minutes per night and expended an average of 1.52 (SD 0.36) metabolic equivalent of tasks (METs) per day.

Table 2 presents the retention and feasibility measures. Overall, 20 YSMM enrolled in this study. Of these 20 YSMM, 1 participant was lost to follow-up after the informed consent meeting, and 2 participants were lost to follow-up after completion of the study protocol (ie, they did not participate in the follow-up interviews but completed all other parts of the study protocol). Of the 19 YSMM who engaged in the study protocol, 100% (n=19) sent back their HemaSpot samples (ie, blood spots) and all 6 of their saliva samples (3 saliva samples per day for 2 consecutive days). With respect to the momentary diaries, 89% (17/19) completed 4 out of the 4 momentary diaries (2 momentary diaries/d for 2 days). The remaining participants completed either 2 (5%; n=1) or 1 (5%; n=1) of the momentary diaries over the 2-day period. In contrast, 1 participant did not complete any nightly diaries over the 2-day period. However, of the remaining 18 participants, 94% (n=16) completed 2 out of the 2 nightly diaries over the study period, and the remaining 6% (n=2) completed 1.

**Feasibility and Acceptability**

Overall, 17 (89\%) participants completed the follow-up qualitative interviews. Within each overarching prespecified theme of “feasibility,” “acceptability,” and “areas for improvement,” we found several subthemes. The overarching themes and subthemes, as well as their definitions and excerpts, are presented in Table 3. For feasibility, we found two subthemes: (1) informative onboarding experience and easy communication with RAs, and (2) easy protocol to follow. Most participants (14/17, 82\%) reported that their onboarding experience (including informed consent and a detailed step-by-step protocol) was informative and that they were able to answer all of their questions. Several participants noted that the documents that were emailed (and hard copies mailed) to them during the onboarding call were clear and laid out the study protocol in a helpful and step-by-step manner. Furthermore, participants noted that the RAs were easy to communicate with and were available to answer any questions they may have had over the study protocol period, thus reducing any confusion or hesitancy when it came to completing the study’s steps. Furthermore, 76\% (13/17) reported that the study protocol was easy to follow with little to no issues arising, especially with the instruction documents that were sent to the participant (eg, for the ActiGraph, HemaSpot, and saliva samples).

With respect to acceptability, we found three subthemes: (1) appropriate financial incentive structure, (2) desire to participate beyond financial incentives, (3) changed perceptions of mood or discrimination, and (4) willingness to participate in long-term studies with a similar protocol. First, 53\% (9/17) reported that the financial incentive payment structure increased their willingness to complete the study and all steps in the protocol. These participants noted the importance of being compensated fairly for their time, especially because this protocol required the collection of biological samples (ie, saliva and blood). Furthermore, these participants also noted that they appreciated the breakdown of the payments—in other words, they appreciated being compensated for each component of the study separately rather than a lump contingent on completion of the entire protocol at the end of the study period. However, 41\% (7/17) of the participants described internal and altruistic motivations for participation, which motivated them to complete the study regardless of the financial incentives attached to it. These participants described an interest in the scientific process, as well as wanting to contribute to their community’s health by getting involved in health-related research. Moreover, 47\% (8/17) reported positive experiences directly because of participation, including a better sense of mood and becoming more aware of experiences of discrimination. These participants noted reflecting on their experiences over the course of the day (eg, nightly diaries) required them to become more mindful of their feelings and moods throughout the day and to become more aware of their surroundings. Furthermore, these individuals were able to better capture experiences with discrimination and microaggressions and reflect on their subsequent moods. Finally, 100\% (n=17) of the participants reported willingness to participate in long-term studies (eg, 30 days of data collection) using a similar protocol. In particular, participants felt that a long-term study would be more reflective of their day-to-day stressors and experiences. However, 2 of these participants noted that while they would be willing to participate in a longer-term study, they preferred that the study surveys (eg, baseline and nightly) be shorter in duration.

<tr>
<td>Protocol easy to follow</td>
<td>Participant was able to comprehend and follow the study instructions with little to no problems</td>
<td>• “[The protocol was a] good experience, not very invasive. Labeled tubes and collection aid were helpful. Instructions were clear and helped.” (Asian, bisexual, 21 y) • “Everything was very clear. Explanation of the blood spot sample was especially helpful.” (Asian, gay, 28 y)</td>
</tr>
<tr>
<td><strong>Acceptability of intervention</strong></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Appropriate financial incentive structure</td>
<td>Descriptions of being motivated to engage in the study due to the financial incentive structure and feeling that the financial incentive structure was appropriate for the time given</td>
<td>• “The incentive did help my willingness [to participate] and the breakup of the payments helped.” (Hispanic, bisexual, 25) • “[The financial incentive structure] made me want to ensure I completed all the steps, but it was not very hard so I would have done it either way. But the payments definitely helped.” (White, bisexual, 30 y)</td>
</tr>
<tr>
<td>Desire to participate beyond financial incentives</td>
<td>Feelings and motivations of external reasons for participating in the study (eg, wanting to progress science)</td>
<td>• “From an academic perspective, I was interested in the study regardless. Realistically, I would be taking opportunity to be doing the study anyway.” (Black Hispanic, gay, 31 y) • “[The financial incentive structure] did not really affect my participation, would have still done without compensation.” (Black, gay, 31 y)</td>
</tr>
<tr>
<td>Changed perceptions of mood and discrimination</td>
<td>Increased awareness of one’s experiences with discrimination and mood throughout the day</td>
<td>• “It made me a bit more aware of my surroundings and did notice more [discriminatory] experiences once I was asked.” (Hispanic, gay, 18 y) • “[I became] more sensitive to attuning to [discrimination]. Many of these things I encounter on a regular basis, but it became more salient when calling my attention to it.” (Black Hispanic, gay, 31 y)</td>
</tr>
<tr>
<td>Willingness to participate in longer-terms studies</td>
<td>Expressing interest and desire to participate in studies similar to this on a longer-term basis (eg, 30 d)</td>
<td>• “Yeah, it would be good to participate [in a longer term study] because I felt like study duration was very short. A longer study would be more insightful.” (Black Hispanic, gay, 24 y) • “Absolutely [I would participate in a longer-term study]. I have participated in longitudinal studies before and recognize the challenge that goes into them.” (Black Hispanic, gay, 31 y)</td>
</tr>
</tbody>
</table>

**Areas for improvement**
Although participants overall had positive feedback with respect to the study design and their experiences with participation, there were several areas that they noted for improvement: (1) experiences with day-to-day stress unrelated to the study, (2) protocol-related criticisms related to the study procedures, and (3) stress directly resulting from the study protocol.

To be honest, it was a stressful experience. It was also hard to write the time on the tube. (Black Hispanic, gay, 24 y)

Certain parts of the study caused me stress, such as the blood spot sample. (Asian, bisexual, 19 y)

No stress related to the study. Logistical planning was needed to make sure I was waking up and going to bed at a relatively set time. But it was not stressful, just extra planning in terms of how I would navigate my time. (Black Hispanic, gay, 31 y)

I stressed during the 2-day study due to personal relationships. The study didn’t cause any anxiety, and I thought the structure was helpful and allowed me to plan things out. (Asian, bisexual, 21)

The surveys were long and felt frustrating. I felt the wording was ambiguous and that the questions assumed participants were affected by other people’s feelings. (White, bisexual, 21 y)

It was a good experience during the day, but at night after doing the blood sample it was a little bit exhausting and it was a lot of questions, etc. (Hispanic, gay, 18 y)

Certain parts of the study caused me stress, such as the blood spot sample. (Asian, bisexual, 19 y)

To be honest, it was a stressful experience, it was simple to give saliva, etc. but I was uncomfortable with storing the saliva in the freezer. It was hard to use the saliva tube and straw, but at the end of the day it was a good experience. It was also hard to write the time on the tube. (Black Hispanic, gay, 24 y)

Preliminary Exploration of Hypothesized Pathway

Correlations between main independent variable (discrimination), dependent variable (hsCRP), and the mediators (salivary cortisol, sleep, and physical activity) are presented in Table 4. Furthermore, Table 5 displays the average cortisol parameters by race, and Figure 3 displays the average cortisol curves over the 2-day period stratified by race or ethnicity. It is important to note that out of the 19 YSMM included in these analyses, 2 participants did not wear their ActiGraph watch over the 2-day period and thus were not included in the actigraphy measures. There was a moderate negative association between everyday discrimination and mean cortisol such that greater experiences of discrimination were associated with lower daily cortisol, on average. Moreover, we also observed a moderate, positive association between daily physical activity, on average (as measured by METs) and hsCRP such that greater levels of average physical activity were associated with higher hsCRP, on average. No other correlations were significant in our study sample. With respect to the average cortisol curves over the 2-day period (Figure 3), White YSMM experienced the strongest...
cortisol awakening response (CAR; ie, the spike in cortisol that occurs in healthy individuals 30-45 min after waking), which steeply declined throughout the day, whereas Black YSMM’s cortisol started out lower and exhibited a weaker CAR and declined throughout the day.

Discussion

Principal Findings

This pilot study found evidence for the feasibility and acceptability of a virtual daily diary protocol and explored preliminary associations between discrimination, cardiometabolic health behaviors, and inflammation among YSMM. Of the 19 participants who completed more than just the baseline survey, 100% (n=19) returned their HemaSpot and saliva samples, and 89% (n=17) completed all momentary measures.

Although some participants mentioned some areas for improvement, such as having to take extra time to plan ahead to ensure that they were able to complete the required steps and experiencing stress directly related to the study (e.g., needle anxiety, having to produce saliva samples 3 times a day), 100% of the participants reported a willingness to participate in longer-term studies using a similar protocol. Such valuable findings greatly contribute to the literature by demonstrating the feasibility and acceptability of a fully virtual protocol with a component of collecting biological specimens. Our findings expand on current research that highlights the specific challenges of conducting a fully virtual protocol [47,48].

For instance, Feigelson et al [47] examined the feasibility of an at-home study involving cross-sectional survey data and stool collection and found that there is a need for significant personal contact and carefully timed follow-up to ensure participant willingness. In our study, only 2 individuals did not participate in follow-up interviews. However, they completed all the other parts of the study protocol. In addition, the subthemes found in the qualitative analysis regarded the informative nature of the onboarding experience, easy communication process with the RAs, and the fact that the protocol was easy to follow. Furthermore, some of the challenges encountered by the participants were concurrent with previous research that has described remote protocols. For instance, in-home sample collection and the inconvenience of fitting the protocol timeframe with participant schedules have been highlighted in previous studies [47,48]. In the current protocol, some of the participants mentioned that due to various forms of daily stress unrelated to the study, they had to dedicate time to ensure they would be able to complete the steps in the specified time frame. In addition, although 76% (13/17) of the participants reported that the study protocol was easy to follow, 24% (4/17) reported experiencing stress when collecting biospecimens. It was not clear if the experiences of stress outside the study protocol would still be a barrier if participants were to come to the laboratory to complete the study.

Furthermore, a notable finding of our protocol was that 47% (8/17) of participants reported better perceived mood and awareness of discriminatory experiences as a direct result of their participation in the study. The participants highlighted that the momentary diary prompts led them to reflect on their experiences throughout the day. As previously described in the study’s theoretical model, there is a pressing need for studies to take an intersectional approach and consider the unique experiences of stress among sexual minority individuals by racial/ethnic and sexual/gender status and by culture and context.
Although not a direct aim of our protocol, such results and reports greatly contribute to and expand on the current literature by highlighting the need for protocols and intervention development to take an intersectional approach, especially ones using ecologic momentary data collection. In addition, as mentioned above, 100% of the participants reported a willingness to participate in a longer-duray protocol with components similar to the current one. This was because participants believed that a longer-term study would better reflect their everyday stressors and experiences. Future research aimed at understanding key minority stressors and their effects on health behaviors should consider expanding the study duration to best capture individuals’ overall experiences. Similar study designs with longer durations have shown acceptance among sexual minority populations [49]. For example, one ecologic momentary assessment study examining tobacco, alcohol, and drug use in relation to daily discrimination experiences among 50 sexual and gender minorities found that participants completed an average of 68% of the 6 prompts sent to them daily over a period of 14 days [49]. Furthermore, in a daily diary study examining minority stress and daily mood among racially diverse sexual minority youth (n=94) over a 21-day period, participants responded to 83% of the daily diary prompts sent to them per day [50]. By capturing day-to-day experiences over a longer duration (eg, a 14- or 30-day period), researchers could not only improve generalizability and power but also capture variation in experiences of minority stress and cardiovascular risk behaviors across both week and weekend days. Our preliminary descriptive findings also shed light on potential differences across racial or ethnic groups in the YSMM, which necessitates further exploration. For instance, we examined average daily cortisol curves across race or ethnicity and found evidence suggesting that Black YSMM may experience a more dysregulated cortisol curve compared with White YSMM. In particular, we found that Black YSMM experienced a less pronounced CAR and a slower decline throughout the day compared with White YSMM. CAR represents a brief period, typically 30 to 45 minutes after waking, where an individual experiences increased cortisol activity and is recognized as an important marker of the hypothalamic-pituitary-adrenal axis as it aids an individual in their transition from sleep to wake [51]. Typically, however, individuals experience a steady decline in cortisol activity throughout the day, with the lowest levels recorded around bedtime (ie, daily cortisol curves) [52]. Research has generally found that individuals with steeper cortisol curves (ie, cortisol that declines at a faster rate) are associated with better overall health outcomes compared with individuals with more blunted cortisol curves (ie, cortisol that declines at a slower rate) [52]. Although we were underpowered to detect significant differences within daily cortisol curves among our study sample (n=19), our descriptive findings shed light on potential differences across race or ethnicity among YSMM that warrant further exploration with larger, more diverse study samples.

Although our preliminary study highlights the feasibility and acceptability of a fully remote protocol examining momentary, daily, and biological measures, there are several limitations that should be considered. First, our sample consisted of YSMM who resided in the New York tristate area, and thus may not be generalizable to the wider population of YSMM in the United States. Second, our study sample was small, which also affected our ability to detect significant differences in our key measures of interest (eg, daily cortisol curves and CRP). To the best of our knowledge, this is the first study to integrate momentary assessment data and biologics using a fully remote protocol. Third, our study was, in part, disrupted by the COVID-19 lockdown, which may have impacted participants’ ability to fully engage with the protocol and may also have impacted participants’ daily cardiovascular health behavior patterns (eg, participants may not be walking or traveling as much as they used to pre-pandemic). Fourth, we may have missed important information within our surveys that could affect cardiovascular health, such as dietary patterns. Fifth, although the overarching literature supports the use of wearables, such as the ActiGraph, to measure sleep, it may not have wholly captured sleep patterns over the course of 2 days in comparison with gold standards, such as polysomnography [27,53]. Thus, it is important to carefully examine the updated literature when determining the best wearable device for capturing sleep patterns. Sixth, given that our pilot study only spanned a period of 2 days, our actigraphy measures (ie, sleep and physical activity) may not have reliably captured daily sleep and physical activity patterns among our sample of YSMM and we did not include data on napping in these analyses. Thus, future research should use longer collection periods to capture sleep and physical activity patterns more comprehensively among diverse samples of YSMM. For instance, research has found that a period of at least 3-5 days is necessary to capture accurate information pertaining to sleep [27]. Despite these limitations, the strengths of this study lie in its diverse sample of YSMM and its rigorous design that integrates surveys and biological metrics. By demonstrating the feasibility and acceptability of a fully remote protocol combining ecological momentary assessment and biological measures, our results pave the way for future work aimed at developing culturally tailored just-in-time interventions that might be delivered virtually. Such interventions should consider minority stressors and their influence on health behaviors and adverse outcomes throughout their lifespan. Doing so could lessen the mental and physical burden at the intersection of multiple minoritized identities as well as reduce inequities in the health care system.

Conclusions

Overall, the fully virtual protocol for assessing CVD among emerging adult sexual minorities was acceptable, indicating that it can be used in the future for similar work and with a larger time period and sample size. Furthermore, preliminary descriptive results suggest that there may be key racial or ethnic differences among YSMM in key cardiovascular health features (ie, daily cortisol curves) that warrant further research.

Abstract

Background: In the coming years, telemedicine will play a key role in health care. Especially in rural areas with weak infrastructure, telemedicine could be crucial to providing adequate and personalized medical care.

Objective: We investigated the acceptance and preferences of telemedicine among cardiologists, internists, and general practitioners. In addition, we aimed to identify knowledge, explore factors that influence the decision to adopt or reject this technology, and create starting points for demand-oriented further research.

Methods: We conducted a web-based survey between May 2021 and February 2022. The 34-item questionnaire covered a wide range of questions regarding knowledge, acceptance, and use of telemedicine in cardiology care. Participants (cardiologists, internists, and general practitioners) were contacted through their professional email addresses, through a QR code published in a regional health journal, and through X (formerly known as Twitter). After exclusion of questionnaires with missed values, multidimensional scaling and k-means clustering were performed. Participants were divided into 3 clusters (C1, C2, and C3) based on their attitudes toward telecardiology. C1 uses telemedicine for personal health and clinical practice; C2 shows reluctance; C3 uses telemedicine mainly clinically.

Results: We contacted 929 physicians. Of those 12.1% (112/929) completed the questionnaires. Participants were 56% male (54/97), 29% female (28/97), and 2% (2/97) diverse (median age 50 years). About 16% (18/112) of the respondents currently use telemedicine daily, 14.3% (16/112) 3-4 times a week, and 43% (48/112) did not use telemedicine at all. Overall, 35.1% (34/97) rated their knowledge of telemedicine as very good or good. Most of the respondents replied that telemedicine could support cardiology care in monitoring of blood pressure and electrocardiograms (57/97, 58.8%, both), consultation (57/97, 58.8%), and extending follow-up time (59/97, 60.8%). Reported barriers to implementation were mostly administration (26/97, 26.8%), inadequate reimbursement (25/97, 25.8%), and the purchase of technology equipment (23/97, 23.7%). Attitudes toward telemedicine in clinical practice were closely related to the number of patients being treated per annual quarter: C3 (median 1350, IQR 1000-1500) versus C1 (median 750, IQR 300-1200) and C2 (median 500, IQR 105-825). The differences between clinical caseloads of C1-C3 members were significant: C1 versus C2 (P=.03), C1 versus C3 (P=.02), and C2 versus C3 (P<.001). Most participants (87/112, 77.7%) would like to expand telemedicine approaches in the future. In the field of cardiology, the participants reported a high suitability of telemedicine. The willingness to train in telemedicine is high to very high for > 50% of the participants.
Conclusions: Our results indicate generally moderate use but positive attitudes toward telemedicine among participating physicians with a higher clinical caseload. The lack of a structural framework seems to be a barrier to the effective implementation of telecardiology.

Introduction
As the burden of patients with cardiovascular diseases (CVDs) is increasing [1], regions with an aging population, such as the German federal state of Brandenburg, are particularly affected. Demographic changes concern not only the patient population but also health care professionals (HCPs). The average age of physicians in the state of Brandenburg is 54.4 years. In the next 5-10 years, the number of physicians will decrease by one third, crucially impacting medical care in the sparsely populated states of Germany. There are already 683 inhabitants per contract physician in the state of Brandenburg [2]. At the same time, the digital transformation is radically changing health care delivery [3]. In rural areas, telemedicine could help to initiate treatment faster and might have a positive impact on quality of life [4]. In cardiology, telemedicine can be used in various ways, including remote patient monitoring, remote visits, and telecardiology consultations [5]. In patients with chronic heart failure, telemedical interventions were associated with optimized medical therapy, a significant reduction in hospital readmissions, and an improvement in quality of life [4,6,7]. As reported in other medical domains, telemedicine not only potentially extends the reach to underserved populations but also enhances opportunities to provide care within usual inpatient and outpatient settings [8]. Not to be underestimated for a future-proof and sustainable health care system, there are also first indications that telemedicine could make a significant contribution to reducing the carbon footprint of health care [9]. Yet, current data on the acceptance of telemedicine by HCPs in cardiology are lacking. Furthermore, the investigation of differences in telemedicine acceptance between urban and rural areas is a research priority. Thus, we aimed to assess the acceptance of telemedicine among cardiologists, internists, and general practitioners in Berlin and Brandenburg. In addition, we aimed to identify knowledge and explore factors that influence the decision to adopt or reject this technology. To create starting points for demand-oriented further research, we wanted to identify user types in the use of telemedicine.

Methods

Ethical Considerations
The study was approved by the local ethics committee of the Brandenburg Medical School (E-01-20210304). Data processing was based on the informed consent of the participants in the study. Participation in the study was not remunerated. Personal data were only collected from the participants to be able to process any requests in accordance with current law. These data were deleted after the end of the study. No other personal data were collected.

Questionnaire and Procedure
The authors developed a web-based survey that was pretested and validated among cardiologists (n=5) and general practitioners (n=5). The final 34-item questionnaire covered a wide range of questions regarding knowledge, acceptance, and use of telemedicine in cardiology care. Physicians were asked to participate in the survey if they met the following inclusion criteria: (1) working in inpatient or outpatient cardiology care, (2) working in the states of Brandenburg or Berlin, and (3) providing informed consent. Consequently, physicians who did not meet these criteria were excluded. Furthermore, questionnaires were excluded if less than half of the questions were answered. Participants were contacted through their professional email addresses, through a QR code published in a regional health journal, and through X (formerly known as Twitter). Data were collected between May 28, 2021, and February 28, 2022, using the web-based survey application “LimeSurvey” [10], embedded in the domain [11].

Data Analysis and Statistics
The statistical analysis was conducted in several steps. First, questionnaire data were analyzed using descriptive statistics, including quantities, percentages, median scores, and ranges for ordinal variables. An exploratory quantitative analysis was performed to identify factors determining telecardiology use. To create a data matrix for the analysis, qualitatively recorded participants’ attitudes toward telecardiology as reported in the survey were recoded from left to right according to the direction of the hypothesis of positive attitudes, for example, the response options in relation to the a priori hypothesis that “Would you like to use telemedicine more often?” which ranged from the positive to the negative scale. The answers “yes, totally,” “yes,” “no,” and “no at all” were coded as “5,” “4,” “2,” and “1,” respectively. The undefined “I don’t know” response option was coded with an intermediate value of “3.” Recoding was undertaken for the characteristics indicated by the age groups, the clinical location, gender, medical specialty, and type of practice. The interval-scaled variable “number of patients” (quarterly) was recoded. To ensure sample homogeneity, participants who did not use telemedicine were not included in the analysis.

To classify survey participants based on their attitudes toward telecardiology, multidimensional scaling (MDS) and subsequent k-means clustering were used. MDS aims to represent input proximities (typically dissimilarities) between objects by means of fitted distances in a low-dimensional space [12]. It therefore
visualizes the level of dissimilarity among cases in a data set. Since we were interested in scaling the participants and not attitudes, the dissimilarity measure was applied across columns of the data matrix. Then, nonmetric MDS was applied to the dissimilarity matrix to obtain the coordinates of the sample in a representative low-dimensional space. The algorithm used for the MDS calculation was “Scaling by Majorizing a Convex Function” (SMACOF [13]). Starting with any initial configuration, the algorithm iteratively transforms proximities to estimated proximities (disparities) for calculating the configuration of the items in the context of the coordinates. This continues until the squared differences between the disparities and distances are minimized. These differences reflect a model’s (mis)fit, expressed by the Stress-1 index, which ideally has a value of 0; a value higher than 0.2 indicates a bad representation [14]. However, the larger the number of points (ie, participants in this study), the more difficult it is to map these into a low-dimensional space. This means that the Stress-1 index may become unacceptably high. For this reason, the Stress-1 index was criticized by Borg et al [15], who developed permutation tests for MDS solutions [16], whereas a significant test result ($P<.05$) allows to reject the H0, hypothesizing that the stress and, subsequently, the configuration are obtained from a random permutation of dissimilarities. As with other dimension-reducing methods, however, the final decision for an MDS solution should not be made based on these indices but on their interpretability [17].

To create a classification of participants based on their attitudes toward telecardiology, k-means clustering was applied to the mapped sample [18]. Clustering consists of grouping objects that are, in some sense, similar to each other. The k-means is a nonhierarchical clustering method commonly used in data mining [19]. The algorithm starts with a collection of $s$ objects, where each object is a point in a q-dimensional space, and a given number of clusters, $K$, that is subjective and specified in advance by the user. However, to determine $K$, we also relied on the total Within Sum of Squares (WSS) index. The k-means groups the “$s$” objects into $Ks$ clusters to minimize the objective function given by the sum of distances between the points and the centers of their clusters. The k-means arrives at a solution in which objects within each cluster are as close to each other as possible and as far from objects in other clusters as possible. Finally, the chi-square test and the Kruskal-Wallis nonparametric test [20] (due to nonnormal data distribution), followed by the posthoc analysis using the Conover-Iman test with Holm’s correction [21], were applied to examine the difference in selected variables between each cluster. A value of $P<.05$ was considered statistically significant.

All data analyses and graphics were done within the R environment (R Core Team). To run MDS, SMACOF [13], ggpubr [22], magrittr [23], and dplyr [24] packages were used. The k-means clustering was done based on stats (version 3.6.2 [25]) and factoextra [26] packages. To run Conover Test with Holm’s correction, the package connover.test [27] was used.

**Results**

**Overview**
A total of 929 physicians were contacted, of whom 112 (12.1%) responded to the questionnaires. Of which, 15 (13.4%) participants were excluded from the analysis because less than half of the questions were answered.

**Sample Characteristics**
The data for this survey were obtained from 97 physicians. Most participants—48.5% (47/97) were cardiologists, 15.5% (15/97) were internists, 12.4% (12/97) were general practitioners, and 23.7% (23/97) were not yet specialists at the time of the survey or their status was not reported at the time of the survey (Table 1). Most respondents, 56.7% (55/97), were aged between 40 and 59 years and worked in the state of Brandenburg (69/97 71%) in medium-sized cities (40/97, 41%) (Table 1). Additionally, more than half of the participants were men (54/97, 55.7%). The ratio of respondents from the participants practicing inpatient and outpatient care was 48% versus 42% (10% with no response), with most participants in outpatient care working in a single practice. Position types, hospital characteristics according to the number of beds, and patients treated per physician per quarter are shown in Table 1.
Table 1. Demographic data and characteristics of the participants.

Telemedicine: Knowledge and Use

Overall, 64.9% (63/97) of respondents rated their knowledge of telemedicine as satisfactory, poor, or very poor, whereas 35.1% (34/97) rated their knowledge as very good or good (Table 2). The frequency of current telemedicine use is shown in Table 2, with 16% (18/112) of the respondents currently using telemedicine daily, 14.3% (16/112) using it 3-4 times a week, and 43% (48/112) reporting no use at all. However, 45.4% (44/97) answered that they would like to use telemedicine more often in the future. Overall, 52.6% (51/97) of the physicians surveyed indicated that there were barriers to the use of telemedicine. The top 3 barriers to the implementation of telemedicine, according to respondents, were administration (26/97, 26.8%), inadequate reimbursement (25/97, 25.8%), and the purchase of technology equipment (23/97, 23.7%).

**Implementation of Telecardiology**

Most of the respondents replied that telemedicine could support cardiology care in the monitoring of blood pressure and electrocardiograms (57/97, 58.8%, both), consultation (57/97, 58.8%), and extending follow-up time (59/97, 60.8%) (Table 3). When asked which communication partners they should exchange through telemedicine, 80.4% (78/97) responded “physician-to-patient,” 72.2% (70/97) responded “physician-to-physician,” and 51.5% (50/97) responded “physician-to-assistant or other participants” (multiple replies were possible). According to the respondents, the diseases or conditions that are particularly suitable for telemedicine care include “cardiac arrhythmias” (78/97, 80.4%), “monitoring of various diseases and conditions” (75/97, 77.3%), and “therapy” (74/97, 76.3%) (Table 3).

Telecardiology User Groups

The exclusion of the cases with missed values yielded a data matrix of 53 cases. Figure 1 shows a 2D MDS solution for the distribution of survey participants. The Stress-1 index was borderline (stress 0.20). However, the permutation test indicated a well-fitting model \((P<.001)\). Considering the fact that the next step of the analysis involved more detailed clustering using k-means, the 2D solution was sufficient and more complex solutions were not examined. Determining the cluster numbers with the WSS index resulted in a 3-cluster solution. The application of this solution for the segmentation of the study participants using k-means showed that all 3 clusters were localized and ordered according to the axes of the MDS diagram. Cluster 1 (C1, n=19) and cluster 2 (C2, n=21) were in the lower left and right quadrants, and cluster 3 (C3, n=13) was in the upper right quadrant of the diagram. Table 4 shows that physicians assigned to group C1 used telemedicine privately to improve their personal health, yet not only in their clinical practice. Physicians in group C2 showed reluctant attitudes toward telemedicine. Members of group C3 use telemedicine for clinical activities and not for their personal health. Attitudes toward telemedicine in clinical activities were closely related to the number of patients being treated. This could be confirmed by a higher patients’ number per annual quarter (median 1350, IQR 1000-1500) treated by C3 members compared with the corresponding numbers indicated by members of C1 (median 750, IQR 300-1200) and C2 (median 500, IQR 105-825). These differences were statistically significant with C1 versus C2 \((P=.03)\), C1 versus C3 \((P=.02)\), and C2 versus C3 \((P<.001)\). The comparison of other characteristics did not have any statistical significance.
Figure 1. Segmentation of survey participants in a 2D group space. Numbers are identification numbers of participants. Cluster 1 (C1, n=19) and cluster 2 (C2, n=21) are in the lower left and right quadrants, and cluster 3 (C3, n=13) is in the upper right quadrant of the diagram. Telecardiology user groups were identified through cluster analysis of a web-based survey conducted between May 2021 and February 2022 to assess telemedicine knowledge, acceptance, and use. Analysis of 53 cases reveals 3 distinct clusters (C1, C2, and C3) based on use behavior: C1 uses telemedicine for personal health and clinical practice; C2 shows reluctance; and C3 uses telemedicine mainly clinically. Statistically significant differences were observed: C1 versus C2 (P=.03), C1 versus C3 (P=.02), and C2 versus C3 (P<.001).

**Discussion**

Cardiologists, internists, and general practitioners consider the overall use of telecardiology to be acceptable; two-thirds of respondents would like to use telemedicine in their daily practice. However, most physicians rate their knowledge as “satisfactory” or worse, and less than a third were using telemedicine at the time of the survey. Barriers to telemedicine adoption, such as “limited knowledge,” “administrative burden,” “purchase of technology,” and “inadequate reimbursement,” were clearly identified by both specialists and generalists. Direct communication with patients is preferred to information exchange with colleagues. In the exploratory analysis, we found 3 potential telecardiology user groups, which differ regarding the number of patients treated per quarter: The more patients treated, the higher the telemedicine acceptance rate. The results provide information on how telemedicine can support cardiology care from the physicians’ perspective.

In 2021, a number of changes were introduced for telemedicine in Germany, such as the mandatory electronic patient record, an increasing number of prescribable digital health applications,
and video consultations for nonphysician therapists. The study TIM-HF II [7] has shown the world that telemedical interventional management can reduce mortality. Since January 2022, remote patient monitoring of patients with heart failure has been reimbursed by the statutory health insurance funds in Germany [28]. In addition to the reimbursement of costs, however, the expansion of telemedicine in the real world is the central topic of the implementation process that is now beginning. Yet, it is surprising that despite the successful study and the establishment of telemedicine infrastructure for cardiology care in the federal states of Brandenburg and Berlin, telemedicine acceptance among physicians in routine cardiology care is still heterogeneous. Considering further large-scale research activity on telehealth for prevention in hypertension care in this region [29], there seems to be a wide evidence-based practice gap for telemedicine in cardiology care [30]. Our results support this conclusion, as knowledge of telemedicine has been reported as low by the participants in this survey. Based on the design of our questionnaire as a web-based survey, we recommend high-quality training programs that reflect the multidimensionality of knowledge barriers by addressing the economic, organizational, and behavioral framework conditions of digital health implementation [31]. Furthermore, our results indicate that bureaucratic and infrastructural barriers hamper telemedicine implementation. These barriers were also identified in a similar study on telemedicine in rheumatology care, conducted before the COVID-19 outbreak [32]. This suggests the reported barriers to effective use of telemedicine have remained in Germany despite the pandemic and a massive digital health uptake globally.

COVID-19 has demonstrated the importance and acceptance of contactless approaches to medical care and, particularly, cardiology care [33-35]. Also, gold standard adherence measures in telemedical interventions need to be established so that study outcomes are more comparable [35]. As the survey was published in May 2021, it is not derivable from our data whether the willingness to use telecardiology has changed. Only a minority of the surveyed physicians currently use telemedicine, although two-thirds would like to implement telemedicine into their clinical routine.

It seems that the participants foreshadow and recognize a benefit that has already been described in the literature [7,36] but which does not yet seem measurable in its daily representatives due to poor global implementation of telemedicine. Due to that lack of everyday application, it seems understandable that most physicians regard their knowledge of telemedicine as poor.

As physicians reported barriers to the use of telemedicine, the structural framework for effective implementation of telecardiology is not yet in place. Significant administrative burdens and inadequate reimbursement structures prevented the physicians surveyed from using telemedicine. The greatest barrier seems to be physicians’ limited knowledge about “how to use telemedicine.” This underlines the need for clearly defined use cases for telemedicine in cardiology as well as the timely introduction of low-threshold training offers. Overall, this seems to reflect that the potential of telemedicine is not being fully reached. Further research should define use cases as well as specific interventions and evaluate the effects on patients’ outcomes and health and economic implications. Those seem particularly important because our data suggest that in the current health care system, only what is paid for is done. An increasingly aging society with an increasingly scarce resource of highly specialized doctors is catalyzing the need for enrollment in telecardiology under the aspects that PerplexityAI has already summarized: “telecardiology has the potential (…) to improve patient engagement and save time and money for patients and health care providers” [1]. Further research may therefore provide individualized patient- and clinician-adapted telemedicine options and triage mechanisms to select patients for either digital or analog consultations as appropriate. Based on our data, participants accept telemedicine and support its expansion if framework conditions such as reimbursement, the removal of existing usability barriers, and specialized training are optimized. The authors see this as a call to the health care system to create a framework for the use of telecardiology to optimize the use of an increasingly scarce resource with increasing demands and workloads. The provision of high-quality cardiology care using telemedicine will require urgent research, as well as the removal of existing barriers and training for specialists and generalists.

Due to the design of our questionnaire as a web-based survey, we assume a positive selection bias for physicians who are already interested in digitalization, telemedicine, or telecardiology. In addition to digital invitations to participate, participants were also recruited by an analog magazine report about the research project in the “KV-intern,” which was delivered to every physician registered with the Medical Association Brandenburg (Kassenärztliche Vereinigung Brandenburg). Either way, internet access and at least a certain level of digital expertise were required for participation. As the average age of the participants is comparable to the average age of physicians in Brandenburg [2], the group of participants surveyed nevertheless appears to be representative.

At this point, we have only explored the perspectives of physicians on telemedicine in cardiology. There is an urgent need to investigate the patients’ perspective on telemedicine implementation in cardiology care.

In summary, our results indicate low use but high acceptance among participating physicians. Although potential users report general willingness and the potential benefits of telemedicine, self-reported knowledge is limited. The lack of a structural framework seems to be a barrier to the effective implementation of telecardiology.

Acknowledgments
The authors would like to thank Prof Heiner Gembris for reviewing and advising on the web-based questionnaire. Abstract

Background: Access to health care services is a critical determinant of population health and well-being. Measuring spatial accessibility to health services is essential for understanding health care distribution and addressing potential inequities.

Objective: In this study, we developed a geoprocessing toolbox including Python script tools for the ArcGIS Pro environment to measure the spatial accessibility of health services using both classic and enhanced versions of the 2-step floating catchment area method.

Methods: Each of our tools incorporated both distance buffers and travel time catchments to calculate accessibility scores based on users’ choices. Additionally, we developed a separate tool to create travel time catchments that is compatible with both locally available network data sets and ArcGIS Online data sources. We conducted a case study focusing on the accessibility of hemodialysis services in the state of Tennessee using the 4 versions of the accessibility tools. Notably, the calculation of the target population considered age as a significant nonspatial factor influencing hemodialysis service accessibility. Weighted populations were calculated using end-stage renal disease incidence rates in different age groups.

Results: The implemented tools are made accessible through ArcGIS Online for free use by the research community. The case study revealed disparities in the accessibility of hemodialysis services, with urban areas demonstrating higher scores compared to rural and suburban regions.

Conclusions: These geoprocessing tools can serve as valuable decision-support resources for health care providers, organizations, and policy makers to improve equitable access to health care services. This comprehensive approach to measuring spatial accessibility can empower health care stakeholders to address health care distribution challenges effectively.

Introduction

The role of geography in understanding and addressing population health and health inequities is hardly deniable [1-3]. Access to health care is a critical indicator of health care system performance and directly impacts population health and disease burden [4,5]. Improving access to primary care, for instance, has been proven to lead to improved health outcomes and decreased potentially avoidable hospitalizations [6,7]. The concept of access plays a significant role in health services and policy research, including both spatial and nonspatial

https://formative.jmir.org/2024/1/e51727
dimensions. Nonspatial access refers to the factors unrelated to geography that influence access, such as affordability, timeliness, accommodation, acceptability, and awareness [8]. Spatial access, on the other hand, involves the geographic elements that influence the availability and accessibility of health care providers and services [9]. The calculation of spatial accessibility involves considering three key factors: (1) supply, (2) demand, and (3) mobility. Supply relates to the infrastructure’s locations (eg, health care providers); demand refers to the locations of individuals who are expected to use the infrastructure (eg, patients); and mobility considers the travel costs between demand and supply locations (eg, driving time) [10]. Identifying areas with limited spatial accessibility enables planners and policy makers to understand the distribution of health service locations and reveal and address spatial inequities [11].

Various methods have been used to evaluate spatial accessibility, including gravity models [12], regional availability models [13], and kernel density models [14]. Among the gravity models, the 2-step floating catchment area (2SFCA) method, initially introduced by Radke and Mu [15] and modified by Luo and Wang [16], has been widely used in the literature for measuring spatial accessibility. The 2SFCA approach measures spatial accessibility through a 2-step procedure based on the interaction between supply and demand within a certain catchment as a ratio of provider-to-population [16]. However, the 2SFCA technique has certain limitations. Locations outside the catchment area are entirely out of access, while population locations within the catchment area are assumed to have equal access to health care providers [17]. To overcome these limitations, Luo and Qi [18] proposed an enhanced version of the 2SFCA method known as the enhanced 2SFCA (E2SFCA) method. This enhanced approach differentiates accessibility within a catchment (usually 3 catchments) by incorporating multiple travel time zones and assigning weights based on a decay function within each catchment [18].

Although the advancements in geographic information system (GIS) technology have made the implementation of the 2SFCA-based models more feasible, researchers with limited GIS expertise still face challenges in gathering, preprocessing, analyzing required data sets, and implementing the model. However, GIS software like ArcGIS provides powerful tools, including model builders and Python programming tools, that enable developers to automate data processing by creating custom geoprocessing toolboxes. In this study, our objective is to develop and share Python script tools for implementing 2SFCA and E2SFCA methods in ArcGIS Pro (Esri). Each toolbox was developed in 2 ways: using a distance buffer and travel time (driving time or walking time) in catchment areas. Additionally, we will present a case study assessing the accessibility of hemodialysis services in the state of Tennessee to include an important nonspatial factor in the accessibility score.

### Methods

#### Theoretical Framework and Conceptual Explanations

A total of 4 geoprocessing tools were developed to work in ArcGIS Pro software based on 2SFCA [16] and E2SFCA [18] approaches with the following names:

1. 2SFCA01: 2SFCA with buffer distance catchments
2. E2SFCA01: E2SFCA with buffer distance catchments
3. 2SFCA02: 2SFCA with travel time catchments
4. E2SFCA02: E2SFCA with travel time catchments

After presenting the theoretical background of the 2SFCA and E2SFCA approaches, the development framework for each tool will be presented.

#### Models’ Theory

##### Theoretical Background of 2SFCA

The 2SFCA method assesses the relationship between resource availability and demand population distribution in 2 steps, resulting in an access score for each demand area.

**Step 1:** For each facility location (j), identify all demand locations (k) that fall within a specified catchment area (d<sub>j</sub>) from the facility. The provider-to-demand ratio (R<sub>j</sub>) within the catchment area is calculated using equation 1:

\[
R_j = \frac{P_k}{\sum_{j} S_{kj}}
\]

where P<sub>k</sub> represents the population at demand location k within catchment area j (d<sub>j</sub> ≤ d<sub>i</sub>), S<sub>ij</sub> is the capacity or number of providers at location j, and d<sub>ij</sub> is the distance (or travel time) between k and j.

**Step 2:** For each demand location i, search for all facility locations (j) within the specified catchment area (d<sub>i</sub>) from location i, and calculate the summed provider-to-demand ratios (R<sub>i</sub>) obtained in step 1 using equation 2:

\[
R_i = \sum_{j} \frac{P_k}{\sum_{j} S_{kj}}
\]

In equation 2, \(\bullet\) represents the accessibility at demand location i based on the 2SFCA method. R<sub>j</sub> denotes the provider-to-demand ratio at facility location j that falls within the catchment area of the demand location i (ie, d<sub>ij</sub> ≤ d<sub>i</sub>), and d<sub>ij</sub> is the distance (or travel time) between i and j.

##### Theoretical Background of E2SFCA

The classic 2SFCA relies on a dichotomous distance decay function, assuming that individuals within catchment areas have equal access to services, while those outside catchment areas have no access at all. To overcome the distance decay limitation of the classic 2SFCA, we also used the E2SFCA procedure introduced by Luo and Qi [18] as follows:

**Step 1:** For each facility location (j), 3 distance or travel time catchment areas are created, including zone 1: 0-5 miles (0-8 km); zone 2: 5-10 miles (8-16 km); and zone 3: 10-15 miles (16-24 km) or minutes. Search all demand locations (k) that have no access at all.
were within the zones \(D_r\) for location \(j\) and compute the weighted provider-to-demand ratio \(R_j\) using equation 3:

\[
R_j = \frac{P_k}{S_j} \cdot \frac{1}{d_{kj}} \cdot W_r
\]

where \(P_k\) is part of the demand \(k\) falling within the catchment \(j\) \((d_{kj} D_r)\), \(S_j\) is the capacity or number of providers at facility \(j\), \(d_{kj}\) the distance (or travel time) between \(k\) and \(j\), and \(D_r\) is the \(r^{th}\) catchment zone \((r \in \{1,2,3\})\) within the catchment. \(W_r\) is the distance weight for the \(r^{th}\) zone calculated from the Gaussian function capturing the distance decay of access to the facility \(j\).

Step 2: For each demand location \(i\), search all facility locations \((j)\) within the distance (or travel time) threshold of the location \(i\), and summed up the provider-to-population ratios \(R_j\) (calculated in step 1) as follows:

\[
\text{Accessibility at } i = \sum_{j} R_j \cdot \frac{1}{d_{ij}}
\]

where \(\bullet\) represents the accessibility at the demand location \(i\), \(R_j\) is the provider-to-demand ratio at facility location \(j\) that falls within the catchment of demand location \(i\) \((i.e., d_{ij} D_r)\), and \(d_{ij}\) is the distance (or travel time) between \(i\) and \(j\). The same distance weights derived from the Gaussian function used in step 1 are applied to each zone to account for the distance decay.

**Tool Frameworks**

**Overview**

The accessibility tools in this study use 2 spatial data sets as input, provider and population data, and 1 output data set, as described in the following paragraphs. The framework for developing each tool is described in their respective subsections.

**Provider Data**

These are point data showing the location of health service providers (eg, hospitals) and contain an ID field and a capacity field. The capacity field is a numeric field including the number of providers (eg, number of physicians) or the number of resources (eg, number of hospital beds).

**Population Data**

These are polygon data that contain the geographical areas where the accessibility score is supposed to be calculated (eg, census tracts) and contain an ID and population field. The population field is a numerical field that represents the demand for service. It could be the total population of a census tract or the number of women, children, or older adults.

**Output Feature Class**

This polygon feature class is exactly similar to the population input feature class, with 1 added field named “final index.” This field demonstrates the accessibility score of service providers in the input regions.

**Framework for Developing 2SFCA01**

Figure 1A shows the simplified procedure used to develop the 2SFCA01 tool. Some preprocessing steps, including duplicating the input data file and creating temporary fields, have been done for each input. Then, in step 1, using the input parameters from the user, the output is created, named “Step 1 output.” This feature class is similar to input provider data, with a new field named provider to demand representing the ratio of providers to the demand population in the catchment of each provider facility. Step 2 is relatively straightforward and uses the same buffer size as step 1 to sum up the provider-to-demand values calculated in step 1 for each population area.

Figure 2A shows the screenshot of the 2SFCA01 tool. Users can easily select the input data and fields using combo boxes. As the value of the accessibility score is usually very small, the “per capita” parameter multiplies the score with a user-defined value.
Figure 1. Flowchart diagram for creating (A) 2-step floating catchment area (2SFCA) and (B) enhanced 2-step floating catchment area (E2SFCA01) spatial accessibility tools.

Figure 2. Screenshots of the accessibility tools with distance buffer catchments: (A) 2-step floating catchment areas with buffer distance catchments (2SFCA01) and (B) enhanced 2-step floating catchment areas with buffer distance catchments (E2SFCA01).

Framework for Developing E2SFCA01

The procedure to create the E2SFCA01 tool is similar to the 2SFCA01 tool (Figure 1B). As in this model, 3 catchments are necessary for each step, and more parameters from users are required to be defined (circle shapes). The calculated values for each catchment size are combined using user-defined weights. In this tool, the output file not only includes the final index...
value but also includes the accessibility values for each of the 3 catchment sizes.

Figure 2B shows a screenshot of the toolbox. The default values for distance values are 5, 10, and 15 miles (8, 16, and 24 km) and weights: 1, 0.68, and 0.22, respectively. These default weight sets for distance decay were derived from the original study that developed the model [18], but users should choose the proper weights regarding the purpose and context of the study.

(a)

**Framework for Developing 2SFCA02**

The accessibility tools developed with travel time catchments need 2 separate tools to conduct the analysis. The first user should create travel time catchment data for input data using a tool that we developed named “create travel time catchment areas” and then calculate the accessibility index using the 2SFCA02 tool. In order to run the “create travel time catchment areas” tool, users have 2 options. First, if they have a network data set for their study area, they can use it in this tool to create the necessary catchments. If not, they can select ArcGIS Online resources to capture the driving or walking time catchment areas. In this way, the user should have a Network Analysis license with enough credits to use this tool. As shown in Figure 3A, in addition to provider and population data, the ID fields should be defined by the user in this tool. It is necessary to include the output of this tool in the 2SFCA02 and E2SFCA02 tools as input. A value of 10 minutes of driving time is used as the default value, but users can change it to walking distance. Also, the time, date, and direction of the travel can be customized to consider the traffic, as the catchment sizes will be smaller during rush hour than at other times of the day. Two output files, 1 for the provider and 1 for the population data, will be exported. The main 2SFCA02 tool is shown in Figure 3B. This tool has 4 input files: 2 for the provider and population data, and 2 for the travel time catchments derived from the previous step. The ID fields that are specified in the “create travel time catchment area” tool should be specified. Other features of the toolbox and the process are similar to 2SFCA01.

![Screenshot of the toolbox](image)

**Figure 3.** Screenshots of the proposed tools: (A) Create Travel Time Catchments tool, (B) the 2-step floating catchment areas with travel time catchments (2SFCA02) tool, and (C) the enhanced 2-step floating catchment areas with travel time catchments (E2SFCA02) tool.

**Framework for Developing E2SFCA02**

To use this tool, the user should use the create travel time catchment areas tool similar to adding 3 travel time values, for example, 10 minutes, 15 minutes, and 20 minutes of driving time. This will create 3 travel time rings around each provider facility and demand population point. Figure 3C demonstrates the E2SFCA02 toolbox to create accessibility.

Python scripts for all of the tools are available in Multimedia Appendix 1, and our implemented executable tools are available for download elsewhere [19].

**Ethical Considerations**

This study and the development of the presented tool did not involve data that requires ethical oversight. The case study in this manuscript used publicly available data focusing on dialysis center locations and population age distribution at the census tract level. This secondary analysis of aggregated, open-source data is exempt from institutional review board review, in accordance with the Federal Policy for the Protection of Human Subjects (45 CFR 46).
Results

Case Study: Access to Hemodialysis Services in the State of Tennessee

To demonstrate the practicality of the proposed tools in real-world scenarios, we aimed to assess the accessibility of hemodialysis services in different areas of the state of Tennessee.

Hemodialysis is a crucial treatment for individuals with end-stage kidney disease (ESKD), as it eliminates waste products and extra fluid from the blood when the kidneys can no longer do this on their own. Without this treatment, people with ESKD would quickly develop life-threatening complications. This is why the geographical accessibility of hemodialysis services is a critical issue. A study showed that patients living 60 minutes away from a hemodialysis center not only run an increased risk of mortality but also have a significantly lower quality of life compared with patients living 15 minutes or less away [20].

Input Data Sets

Provider Data

The address and location of hemodialysis centers and the number of machines in each center have been extracted from the Centers for Medicare and Medicaid Services [21]. The address data for the 192 hemodialysis centers have been geocoded into coordinates using the ArcGIS world geocoding service. The resulting shapefile includes ID and capacity (number of machines) fields imported to ArcGIS Pro software.

Population Data

The shapefile of census tracts in the state of Tennessee and their total population has been downloaded from the US Census Bureau website [22]. The state of Tennessee includes 1701 census tracts with an average population of 3981 (SD 1646) people. To have a better proxy of target demand, we adjusted the total population with the age distribution of each census tract. Researchers can adjust the target population based on demand and health care needs [23]. We derived the incidence rates of ESKD for various age groups from the 2020 report by the US Department of Health and Human Services [24]. According to the report, the incidence rate of ESKD among individuals aged between 0 and 12 years is 11 cases per million, whereas it is 2080 cases per million for those aged 75 years or older. Table 1 details the age-adjusted demand for ESKD health care services for each census tract, calculated using the following formula: Age-adjusted demand = (N\(_{0-12}\) × 1) + (N\(_{18-44}\) × 7) + (N\(_{45-64}\) × 51) + (N\(_{65-74}\) × 106) + (N\(_{≥75}\) × 189) where N\(_{a-b}\) represents the number of individuals in the census tract aged a to b years.

The shapefile of census tracts in Tennessee, including GeoID as an ID field and age-adjusted demand as a population field, was imported into ArcGIS Pro software. Figure 4 demonstrates the location of hemodialysis centers and the population density of census tracts in Tennessee.

Table 1. End-stage kidney disease (ESKD) incidence rate in different age groups of the US population and calculated weighted demand values.
Figure 4. The locations and distribution of hemodialysis centers in Tennessee; 1 mile=1.6 km.

Mobility

To measure the accessibility indexes, we used a distance buffer size of 15 miles (24 km) for the 2SFCA01 tool and 5, 10, and 15 miles (8, 16, and 24 km) for E2SFCA01. Also, for the 2SFCA02 tool, we used 30 minutes’ drive-time catchments and 10, 20, and 30 minutes for the E2SFCA tool. The distance decay sets of 1, 0.68, and 0.22 have been used for weighting each catchment in enhanced versions. The resulting accessibility index for each tool was symbolized in a geographical map using natural break classification (Figure 5).

As depicted in Figure 5, each tool generates distinct accessibility scores in the state of Tennessee, although the overall trends remain largely consistent. Rural and suburban areas generally exhibit lower access scores compared to urban areas, where a concentration of hemodialysis centers is observed. The 2SFCA tool’s findings reveal that in areas with high access for every 100,000 people, there are between 12.9 and 27.7 dialysis machines available within a 15-mile (24-km) radius or from 15.7 to 21.2 machines accessible within a 30-minute travel time. Conversely, in regions with low access, the availability of these resources is nearly nonexistent. Interpreting the results from the E2SFCA tool is not straightforward due to its weighted measurement approach. Notably, it is evident that areas represented by white, indicating a lack of health care resources within the distance thresholds, should be prioritized for informed resource allocation efforts [25].

Figure 5. Access to hemodialysis centers in Tennessee using the following tools: (A) 2-step floating catchment areas with buffer distance catchments (2SFCA01), (B) enhanced 2-step floating catchment areas with buffer distance catchments (E2SFCA01), (C) 2-step floating catchment areas with travel time catchments (2SFCA02), and (D) enhanced 2-step floating catchment areas with travel time catchments (E2SFCA2); 1 mile=1.6 km.
We could not identify any peer-reviewed studies presenting a comprehensive spatial accessibility toolbox in ArcGIS. However, there have been a few attempts documented in the gray literature. One such effort was made by Langford et al [28], who shared a tool named USW-FCA2 on ResearchGate using an E2SFCA model. Their tool requires a network data set for the study area and a Network Analysis license in ArcMap. In comparison, our toolbox offers significantly more functionalities and options that cater to the specific needs of the target users. Additionally, some studies have used spatial accessibility tools on alternative platforms. Saxon et al [29] developed an open software environment based on the Python-based PySaL package for measuring spatial accessibility. They calculated travel costs by incorporating precomputed origin-destination distance matrices for all US census tracts and census blocks in the 20 major cities.

In the case study, we demonstrated the integration of a nonspatial factor, age, with spatial accessibility. Age is an important determinant of health care demand, and regions with older populations tend to have a higher demand for health services [10]. The procedure used in the case study to adjust the age of the demand population can be extended to consider other factors such as ethnic groups or disease distributions. The resulting geographical maps revealed disparities in access to hemodialysis services across the state of Tennessee. Urban areas, where hemodialysis centers are concentrated, generally exhibited higher accessibility scores. However, areas in the southern parts of the state displayed lower accessibility scores, indicating a need for attention and prioritization in resource allocation.

This study does have limitations to consider. The developed tools are designed specifically for ArcGIS Pro, which may limit their usability for researchers using other software platforms like QGIS. However, future studies could explore the adaptation of these tools to different GIS software to ensure broader accessibility and usability for researchers across various platforms.

**Conclusion**

In conclusion, the developed tools for measuring the accessibility of health care resources offer valuable benefits to researchers across various domains. For large-scale analyses, such as country-level assessments, the 2SFCA01 and E2SFCA01 tools provide fast analysis with basic software requirements, making them accessible and efficient options. Additionally, the 2SFCA02 and E2SFCA02 tools offer a more realistic measure of accessibility by incorporating travel time catchments that consider traffic and transportation modes. Among these tools, the E2SFCA02 tool stands out as a powerful option as it considers both distance decay and uses travel time catchments, providing a comprehensive approach to measuring health care accessibility. Overall, these tools empower policy makers and researchers to gain valuable insights into identifying underserved areas and formulating effective resource allocation strategies. By assessing spatial disparities in health care access, these tools contribute to improving equity and enhancing health care service delivery. In the future, we will use and evaluate the outputs of this study for various health resource allocation projects.
including primary care providers and cancer care services (eg, radiotherapy). Furthermore, we will explore the impact of nonspatial factors such as ethnicity, income levels, and different social determinants of health to better understand their contributions to health care accessibility.

Acknowledgments
This study did not receive any specific grants from funding agencies in the public, commercial, or not-for-profit sectors.

Data Availability
The data sets generated during and/or analyzed during this study are available through Arcgis’ website [19].

Authors’ Contributions
SH authored the manuscript and conducted the data analysis. DLS conceptualized, reviewed, and edited the content. AS-N conceptualized and supervised the study, participated in writing, and managed fund acquisition.

Conflicts of Interest
None declared.

Abstract

Background: Online mindfulness based cognitive therapy (eMBCT) has been shown to reduce psychological distress in people with cancer. However, this population has reported lack of support and asynchronous communication as barriers to eMBCT, resulting in higher nonadherence rates than with face-to-face MBCT. Using a co-creation process, we developed 2 formats of eMBCT: group, blended (combination of therapist-guided group and individual online sessions) and individual, unguided (individual, unguided online sessions only). Group, blended eMBCT offers peer support and guidance, whereas individual, unguided eMBCT offers flexibility and the possibility of large-scale implementation.

Objective: The objective of this nonrandomized feasibility study was to assess aspects of feasibility of the group, blended and individual, unguided eMBCT interventions.

Methods: Participants were people with cancer who chose between group, blended and individual, unguided eMBCT. Both intervention conditions followed the same 8-week eMBCT program, including an introductory session and a silent day (10 sessions total). All sessions for individual, unguided eMBCT occurred via the platform Minddistrict, whereas group, blended eMBCT consisted of 3 online videoconference sessions guided by a mindfulness teacher and 5 sessions via Minddistrict. We assessed the feasibility of the intervention quantitatively and qualitatively by evaluating its acceptability among participants. Additionally, we assessed limited efficacy by looking at the number of questionnaires participants completed pre- and postintervention.

Results: We included 12 participants for each eMBCT condition. Participants in group, blended eMBCT completed, on average, 9.7 of 10 sessions, compared with an average 8.3 sessions for individual, unguided eMBCT (excluding dropouts). Of the 24 participants, 13 (54%) agreed to be interviewed (5 unguided and 8 blended). Participants in both conditions reported positive experiences, including the convenience of not having to travel and the flexibility to choose when and where to participate. However, among the barriers for participation, participants in the group, blended condition reported a preference for more group sessions, and participants in the individual, unguided condition reported a lack of guidance. Additionally, for the group, blended condition, the effect sizes were small for all outcome measures (Hedges g range=0.01-0.36), except for fatigue, which had a moderate effect size (Hedges g=0.57). For the individual, unguided condition, the effect sizes were small for all outcome measures (Hedges g range=0.24-0.46), except for mindfulness skills (Hedges g=0.52) and engagement with the intervention (Hedges g=1.53).
Conclusions: Participants in this study had a positive experience with group, blended and individual, unguided eMBCT. Based on the results from this study, we will adjust the intervention prior to conducting a full-scale randomized controlled trial to evaluate effectiveness; we will add 1 group session to the group, blended eMBCT using Zoom as the platform for the group sessions; and we will send reminders to participants to complete questionnaires.

Trial Registration: ClinicalTrials.gov NCT05336916; https://clinicaltrials.gov/ct2/show/NCT05336916

Introduction

The number of people with cancer is increasing at alarming rates. It has been estimated that, by 2040, the number of people with cancer will be almost double that of 2020 [1]. Additionally, approximately 1 in 3 individuals with cancer experience severe psychological distress [2]. As a result, there is an increasing number of distressed people with cancer who could benefit from effective psycho-oncological interventions [3].

One kind of evidence-based psychological treatment for people with cancer is a mindfulness-based intervention (MBI). Mindfulness can be defined as moment-to-moment awareness, which is cultivated by purposely paying attention to the present experience without judgment [4]. Although mindfulness practices were originally developed centuries ago in the Buddhist traditions of Asia, it was not until the past couple of decades that they were implemented in health care. Different forms of MBIs (eg, mindfulness-based cognitive therapy [MBCT]) have been used across conditions [5], including cancer [6-8], and have been shown to have beneficial effects on psychological distress, quality of life, and well-being [5]. MBCT includes mindfulness components (eg, meditations, visualization exercises, movement exercises) and cognitive components from cognitive behavioral therapy (eg, identifying and reframing automatic thoughts, recognition that thoughts are not facts, habitual thoughts and behavioral patterns).

MBIs have been successfully adapted to online formats [9]. Although eHealth interventions are complex and relatively new [10], online MBIs offer multiple advantages over face-to-face interventions. For instance, online interventions are more easily accessible, more flexible in when and how participants can follow the program, and less costly [9]. A recent systematic review evaluated 9 randomized controlled trials (RCTs) and found that, although online MBIs generally have smaller effect sizes than face-to-face MBIs, they were still effective in reducing depression symptoms, anxiety, and stress, as well as improving mindfulness skills among people across different physical conditions [11]. In addition, a meta-analysis evaluated the effectiveness of different forms of online MBIs (delivered on a website or by an application) for people with cancer and found that online MBIs were effective in reducing distress, depression, and sleep disturbance and that they improved quality of life [12]. Plus, the authors of this meta-analysis concluded that online MBIs may provide unique advantage of increased accessibility and scalability. Online MBIs can offer a valuable alternative to face-to-face interventions, in particular for people with cancer who often already have to deal with frequent hospital visits, physical symptoms from the disease, and its treatment (such as intensive medical treatments and treatment-related fatigue and pain) [13].

Our research group previously conducted an RCT comparing the effectiveness and cost-effectiveness of online mindfulness-based cognitive therapy (eMBCT) and face-to-face MBCT with treatment as usual in reducing psychological distress in people with cancer (BeMind trial) [13]. The online condition in the BeMind trial consisted of an individual, 8-week, online mindfulness intervention supported by a qualified mindfulness teacher who provided feedback via email. The face-to-face condition was a prototypical 8-week group MBCT taught by a qualified mindfulness teacher.

Results from the BeMind trial showed that, in a heterogeneous sample of distressed people with cancer, both interventions were more effective at reducing psychological distress and were less costly than treatment as usual [13]. Nevertheless, nonadherence rates were higher in the individual eMBCT condition than in the group, face-to-face MBCT condition. Furthermore, qualitative analyses showed important barriers to participating in eMBCT, including insufficient peer support and asynchronous communication [14]. Additionally, mindfulness teachers had to invest more time for the individual, online condition than for the group condition, which may hamper large-scale implementation. Thus, the BeMind study showed that, although eMBCT is effective at reducing distress in people with cancer, there is room to improve the eMBCT intervention prior to implementation.

Considering the results from the BeMind trial and the social restrictions from the COVID-19 pandemic at the start of our project, we developed 2 new eHealth formats using a co-creation process. With experts in eHealth interventions, MBCT teachers, representatives from cancer patient organizations, and people with cancer, we explored how to give proper counseling, personalize the intervention, and make it more engaging. In addition, as adherence to online interventions without the guidance of a teacher (individual, unguided interventions) is often lower than intended, persuasive technology known to improve adherence, such as reminders and virtual coaches, was included [15]. By considering the different perspectives of the stakeholders, we aimed to develop a more appealing, persuasive, and participant-focused online intervention.

We developed the following 2 interventions using a co-creation process: group, blended and individual, unguided eMBCT.
Group, blended eMBCT consisted of 3 online, group sessions with a mindfulness teacher and 5 individual, teacher-assisted online sessions; this combination provided peer support and partly synchronous communication. Individual, unguided eMBCT consisted of 8 eMBCT sessions in which participants followed the intervention by themselves without teacher guidance; an unguided intervention could increase access and improve scalability at a lower cost for both participants and therapists. Both intervention conditions also included an introductory session and a silent day. We developed group, blended and individual, unguided interventions to optimize eMBCT delivery and efficacy by addressing the barriers we found in our previous study, by considering the target group needs and by constructing an online intervention that is engaging and attractive.

Although the 2 MBIs were carefully designed using a cocreation process with relevant stakeholders, aspects of their feasibility such as acceptability and preliminary efficacy needed to be established prior to conducting a full-scale RCT. In fact, pilot studies can support researchers with identifying possible challenges, weighing resources, and evaluating the feasibility of an intervention [16,17]. Moreover, pilot studies can assess preliminary efficacy of an intervention before moving on to a full-scale RCT, which involves more resources [16,17]. The objective of this pilot study was to assess the feasibility and preliminary efficacy of the group, blended and individual, unguided eMBCT interventions among people with cancer. The results from this pilot will help us improve the intervention conditions prior to testing their effectiveness in a full-scale, 3-arm RCT that will compare group, blended and individual, unguided eMBCT with care as usual [18].

Methods

Study Design and Setting

This was a mixed methods, nonrandomized feasibility study. Participants could choose to participate in either group, blended or individual, unguided eMBCT. All participants were invited to a semistructured interview postintervention. Participants were also asked to complete questionnaires before and after the intervention.

The study was conducted at the Radboudumc Center for Mindfulness in Nijmegen, The Netherlands. Although our study was not randomized, results are reported in accordance with the Consolidated Standards of Reporting Trials (CONSORT) extension for randomized pilot and feasibility trials [19], as many of the principles described apply.

Participants

Participants were eligible if they (1) were adults and had been diagnosed with cancer at any point in their life (irrespective of type or stage of cancer and time since diagnosis); (2) had internet access and were able to use a computer; and (3) had good command of the Dutch language. Participants were excluded if they (1) had participated in a mindfulness intervention before (>4 sessions); (2) had a severe psychiatric comorbidity that warranted acute treatment (ie, psychosis, mania, severe personality disorders, suicidal thoughts); (3) had dependence on drugs or alcohol; or (4) had severe cognitive impairments.

Procedure

Participants were recruited online via posts placed on websites of cancer-related organizations or patient group forums (online sites where people with cancer can hold conversations and find information), flyers and posters placed at Radboud University medical center, and social media platforms.

Interested participants contacted us via email, via phone, or by completing the contact form on the study website. After this, they received a phone call from one of the researchers to verify inclusion criteria and provide information about the study. Participants were allowed to choose their preferred intervention condition. For each eMBCT condition, a maximum of 12 participants were allowed, so once one eMBCT condition was full, participants were informed that they could only participate in the other one if they wished to be included in this study. Eligible participants were sent the written information about the study and the informed consent form by post and email. After participants signed and returned the informed consent form, they were enrolled in the study and asked to complete pre-intervention questionnaires via the secure Castor EDC system.

Within 1 week after the 8 weeks of the intervention, participants were invited to complete postintervention questionnaires and share their experiences in a semistructured interview. Participants in both conditions were allowed to have any form of medical, psychological (except for MBIs), or paramedical care they required during the study period.

See Figure 1 for the participant inclusion flow chart.
**Intervention**

**eMBCT**

The content of both eMBCT interventions was based on the MBCT program developed by Segal et al [20]. For both conditions, the intervention consisted of 8 online sessions with mindfulness meditation exercises, psychoeducation, and reflections, plus a silent day. We included psychoeducation about mindfulness for cancer and grief and adapted the moving exercises for people with cancer. Participants were asked to do home practice for 30 minutes to 45 minutes a day. Although the content of the sessions did not differ between the 2 conditions, the delivery format did; in the group, blended eMBCT, sessions 1, 5, and 8 took place as online group sessions via the videoconferencing platform Zaurus. In both conditions, participants were allowed to join with a significant other. The specific content for each session has been published elsewhere [18].

**Group, Blended eMBCT**

Group, blended eMBCT consisted of 3 videoconference group sessions lasting 2.5 hours and guided by a mindfulness teacher (sessions 1, 5, and 8). The other sessions (sessions 2, 3, 4, 6, and 7 and the silent day) were followed individually via Minddistrict. Participants were provided with written online ...
feedback on the individual sessions from their mindfulness teacher within Minddistrict. The mindfulness teachers involved in the project were health care professionals experienced in psycho-oncology who met the qualification criteria of the Association of Mindfulness Teachers based in The Netherlands and Flanders, which are in line with the 2015 UK Network for Mindfulness-Based Teachers criteria. In addition, teachers had regular peer supervision sessions led by a senior mindfulness teacher (AS).

**Individual, Unguided eMBCT**

Participants in the unguided eMBCT condition were provided the entire training through Minddistrict. They received weekly access to one of the online mindfulness sessions, which involved the same themes, exercises, and homework as those in the group, blended eMBCT condition. However, there was no mindfulness teacher involved. Participants received automated feedback instead. Participants could contact the research team for technical support.

**Feasibility Outcomes**

Aspects of feasibility were assessed based on the areas of focus suggested by Bowen et al [21], including acceptability and limited efficacy. Acceptability focuses on how the participants react to the intervention (to what extent the intervention is suitable, satisfying, and attractive) [21]. Limited efficacy intends to test the intervention in a limited way [21]. For this pilot study, limited efficacy was evaluated with the pre-intervention and post-intervention questionnaire scores (the same questionnaires will be used in the full-scale RCT).

**Acceptability of the intervention** was evaluated by how many participants chose each eMBCT condition, how many participants started the intervention, the participants’ clinical characteristics at baseline, the average number of sessions completed per condition—adherence—(through attendance lists for groups and login data in Minddistrict), and dropout rate (participants who discontinued the intervention).

In addition, acceptability was evaluated by conducting semistructured interviews postintervention. Participants from group, blended and individual, unguided eMBCT were asked program-specific questions to assess their experiences with the respective intervention condition; in addition, they were asked to express if they experienced barriers to or facilitators for group, blended and individual, unguided eMBCT (eg. Were there specific parts that were helpful/not helpful?). Questions were asked in an open way to permit participants to freely speak. Participants were interviewed via telephone within 3 months after the end of the intervention. Participant interviews were conducted by 2 researchers with previous experience in qualitative research who had not been involved in the delivery of the training (see Multimedia Appendix 1 for the complete interview guide).

**Limited efficacy** includes planned outcome measures for full-scale RCT. Consistent with the feasibility trial design [19,22], limited efficacy of the following measures of distress and secondary outcomes that will be used to evaluate the program in the full-scale trial are reported: Hospital Anxiety and Depression Scale [23], severity scale of the Fear of Cancer Recurrence Inventory-Short Form [24,25], fatigue severity subscale of the Checklist Individual Strength [26], rumination subscale of the Ruminations and Reflection Questionnaire [27], Five Facet Mindfulness Questionnaire-Short Form [28], Self-Compassion Scale-Short Form [29], Mental Health Continuum-Short Form [30], Twente Engagement with E-health Technologies Scale [31]. Detailed information about each questionnaire has been published previously [18].

**Sample Size**

There is no consensus about the optimal sample size for pilot and feasibility studies [32]. Guidance varies between 12 and 30 participants or more per trial arm [33,34]. To reach the study objectives, including sufficient feedback on the acceptability of both conditions, we aimed to include 12 participants in the individual, unguided condition and 12 participants in the group, blended condition.

**Data Analyses**

Descriptive statistics were used to characterize participant demographics, recruitment numbers, and login data. Baseline and postintervention mean scores, standard deviations, and effect sizes from all the questionnaires were calculated for both conditions using SPSS (version 27; IBM Corp). The number of sessions completed was calculated by summing the number of sessions that each participant completed. In this count, we included the introductory session and the silent day, which made a total of 10 sessions. The proportion of sessions completed in Minddistrict was represented as percentages based on each participant’s usage login data. We transformed the percentages into units to aggregate the number of sessions completed by each participant.

Interviews were transcribed verbatim and analyzed by means of an iterative process of thematic analysis in which coding categories were derived directly from the text data (inductive coding) [35]. We followed a form of data-driven thematic analysis and followed the different phases of thematic analysis as suggested by Braun and Clark [35]. First, we familiarized ourselves with the data. Second, 2 researchers independently did a first round of coding 2 interviews (1 from a participant in the group, blended intervention and 1 from a participant in the individual, unguided intervention), during which initial codes were generated. Third, codes between the 2 researchers were compared and reviewed. Fourth, the 2 researchers created a common coding map for analysis and coded the rest of the interviews. All remaining interviews were coded by one researcher and reviewed by a second. Discrepancies were discussed and resolved by consensus. Fifth, the codes from step 4 were reviewed and categorized into broader themes with a larger group. The group consisted of 3 senior researchers (AS, JP, and LK) who have extensive experience in the fields of mindfulness, cancer, and research methodology, a mindfulness teacher with more than 20 years of experience teaching different mindfulness courses (including mindfulness for people with cancer), and a PhD candidate with a background in mindfulness and clinical experience (NB). Definitions and labels for each theme and subthemes were generated. Finally, we selected vivid and compelling examples from the interviews that clearly portrayed the themes and subthemes identified.
Ethical Considerations

The Buddy feasibility trial was approved by the ethical review board, CMO Arnhem-Nijmegen (number: NL73117.091.20), prior to data collection. The study was conducted according to the principles of the Declaration of Helsinki (6th edition, 2008) and in accordance with the Medical Research Involving Human Subjects Act (WMO). All participants who joined the study signed an informed consent form prior to enrollment. Participation was free of charge and voluntary. Participants were informed that they could withdraw at any time without consequences, that their anonymity was ensured, and that there was no monetary compensation for participation.

Results

Acceptability

Enrollment took place between August 2020 and January 2021. A total of 29 participants were assessed for eligibility, of which 2 were excluded; 1 participant had previously followed an MBI, and the other participant was never diagnosed with cancer. Of the 27 eligible participants, 1 participant did not want to participate, 1 participant preferred to join a group, face-to-face MBI program, and we could not contact the other person. In total, 24 participants started the program. The first 12 eligible participants who contacted us preferred to join the group, blended condition. Therefore, subsequent eligible applicants were only offered individual, unguided eMBCT. See Figure 1 for the complete flow of participant selection procedures.

All participants were Dutch and had at least a secondary education; their mean age was 51 (SD 11.5) years, and most (21/24, 87%) were female. Participants had the following types of cancer: breast (9/21, 42%), ovarian (5/21, 24%), colon (3/21, 14%), leukemia (2/21, 10%), lymphoma (1/21, 5%), and bowel (1/21, 5%). Most participants (15/20, 75%) received treatment with curative intent. In addition, overall, it appeared that participants in the blended group had more working hours than participants in the unguided group (21 hours vs 13 hours) and were more often treated with curative intent (10/11, 90% vs 5/9, 56%), and a larger proportion was diagnosed with ovarian cancer (5/11, 46% vs 0/10, 0%). Demographic and disease characteristics of the participants for each condition are shown in Table 1.

For the group, blended condition, the mean number of sessions completed was 9.7 of 10; all participants completed at least 9 of the 10 sessions (minimum 9 sessions and maximum 10 sessions); adherence was high; and there were no dropouts.

In total, 5 of the 12 (42%) participants in the unguided, online condition dropped out. These participants completed fewer than 4 sessions: 3 participants completed 3 sessions, and 2 participants completed 1 session only. We could not contact 2 participants after they dropped out, and the other 3 reported that the program was too hard to follow because of personal circumstances. Participants in the unguided, individual condition who dropped out and completed baseline assessments (n=4) had metastatic cancer and were receiving palliative anticancer treatment. The mean number of sessions completed for the individual, unguided condition, excluding dropouts, was 8.3 of 10 (minimum 1.5 sessions and maximum 10 sessions). The mean number of sessions completed for the individual, unguided condition, including dropouts, was 6.1 of 10.

Results From the Interviews

Participation and Themes

All 24 participants were invited for semistructured interviews, and 13 (54%) agreed to participate (5 from the individual, unguided condition and 8 from the group, blended eMBCT condition). Interviews lasted between 35 minutes and 90 minutes. Responses from the semistructured interviews showed that there were overlapping as well as different barriers and facilitators for group, blended and individual, unguided eMBCT. The barriers and facilitators were organized into the following 4 emergent themes (each one with multiple subthemes): program content; program format; group, blended condition; and individual, unguided condition.

Program Content

Factors categorized as program content were the specific online program components (eg, exercises, videos, diaries) in Minddistrict that were used in both intervention conditions. Program content facilitators that participants reported included the possibility to choose different exercises that were suitable to personal needs. For instance, one participant reported:

*What I also like is that you could choose which exercises yourself (...) that’s just really nice, that bit of freedom you had.* [group, blended condition; completed 10 sessions]

In addition, participants reported that the identification with other peer participants in the videos and the normalization of their experiences through video stories were useful and made them feel less alone:

*I really liked those videos, to experience what other people thought about it—how they thought about it or how they experienced it (...) I often recognized myself in it, so that was helpful.* [individual, unguided condition; completed 7 sessions]

Reported program content barriers included too many exercises with no clear explanation about their rationale, too many forms to fill out, and reflection on emotions in diaries that were
It was sometimes quite intense to fill in your diary every day, and every week there was also another diary that you had to keep. [group, blended condition; completed 10 sessions]

Program Format

Factors categorized as program format were the arrangement of the online program that facilitated participants’ participation (e.g., structure, time, place) to both intervention conditions. Not having to travel and being able to follow the program at one’s own pace were the most reported program format facilitators. One participant reported:

I liked doing it at home so I could do it in my own time and place, and also with no travelling times. [individual, unguided condition; completed 10 sessions]

Additionally, the presentation of visual information that complemented the written and spoken exercises and having the choice of a physical booklet as an additional source and future reference were positively valued, as participants indicated:

I always really liked the information pieces with those drawings, because then I could make it visual instead of everything being spoken, then I really had an image and I really liked that. [individual, unguided condition; completed 7 sessions]

...a book you can easily pick up in addition to your exercise. I personally prefer it. [individual, unguided condition; completed 10 sessions]

However, some other participants said that they found the program structure unclear and that it was difficult to navigate. In addition, they reported that it required too much time investment and that it was difficult to follow it at home with constant interruptions of family members. For instance, one participant from the individual, unguided condition said:

I just don’t know when to schedule it. Then, I had just found a moment, and another child came downstairs and asked loudly: ‘Can I have an apple?’ Yes. Or then, the partner comes and gets some tea, and he would say... ‘Oh, sorry. I see you are doing mindfulness.’ [individual, unguided condition; completed 7 sessions]

Group, Blended Condition and Individual, Unguided Condition

There were also barriers and facilitators that were specific to the intervention conditions. Participants in the group, blended condition liked the group sessions because they had connection with others, peer support, the possibility to ask questions, and synchronicity in communication. A participant in the group, blended condition who completed 10 sessions reported that “it’s also nice to hear that other people are struggling with the same things and yes, you know, you’re suddenly not crazy anymore.”

Another participant reported that:

I was really looking forward to it when it was finally time for another group session of, oh yes, nice, just talking to people. [group, blended condition; completed 10 sessions]

Moreover, one participant emphasized that:

You know, if you have any questions, at least you can ask questions. Then, you will get an answer right away. [group, blended condition; completed 9 sessions]

Barriers that were specific to the group, blended sessions included having to be sitting for a long time during the group sessions, the intensity and length of the sessions, the infrequent number of group sessions, and the fact that they were online rather than in person. A participant commented that “and with the 3 times you only have together, that was quite short” [group, blended condition; completed 9 sessions]. Another participant, also from the group, blended condition, reported that “it’s quite a long time to sit behind a screen like that. And I wasn’t that far into my recovery yet, so I especially thought the first session was really exhausting” [completed 10 sessions]. An outstanding result was that almost all participants from the group, blended condition indicated the need to have more group sessions. They mentioned that the group sessions were not enough to get to know each other properly. One participant reported:

I was really looking forward to when it was finally time again for a group session (...) I think for me, if it had been a group session 8 times, then that would also just be very nice. [group, blended condition; completed 10 sessions]

Participants in the individual, unguided condition reported lack of peer support and lack of feedback from a therapist as barriers for participation. One participant from the individual, unguided condition reported that “the fact that there is no contact with a person or with a group and that there is also no concrete agreement that we will meet each other—even if it is only online...that made it very difficult for me to keep it up” [completed 6 sessions].

For all the barriers and facilitators for both conditions across themes and subthemes, see Table 2.
Table 2. Barriers and facilitators experienced by participants during group, blended and individual, unguided online mindfulness-based cognitive therapy (eMBCT).

| **Group, blended condition** | • Feels unsafe to share personal information with unknown recipient | • Asynchronous written feedback, this was less stimulating to some. |

**Planned Trial Outcomes**

Overall, 21 of the 24 (88%) participants completed baseline questionnaires, and 19 of the 24 (79%) participants completed posttreatment questionnaires. More specifically, most participants (11/12, 92%) in the group, blended condition completed both baseline and posttreatment questionnaires, while in the individual, unguided condition, only 7 (7/12, 58%) completed both baseline and posttreatment questionnaires. Although this study had a small sample size and tests of significance were not included, effect sizes were calculated to evaluate changes between pre- and postassessments. For the group, blended condition, the effect sizes for change before and after treatment were small for all outcome measures (Hedges $g$ range=0.01-0.36), except for fatigue, which had a moderate effect size (Hedges $g$=0.57). For the individual, unguided condition, the effect sizes for change before and after treatment were small for all outcome measures (Hedges $g$ range=0.24-0.46), except for mindfulness skills (Hedges $g$=0.52) and engagement with the intervention (Hedges $g$=1.53). Table 3 shows the baseline and postintervention scores for the planned trial outcome measures for both groups. No adverse events were reported.
participants' feedback has been mentioned as relevant in the condition in the full-scale RCT. It should be noted that, although fourth group session will be added to the group, blended and that they would have liked more. Based on these results, a condition even indicated that there were too few group sessions others, experienced good peer support, and appreciated the group component of the sessions; they felt connected with cancer need flexible psycho-oncological interventions.

We found that participants in both intervention conditions valued and individual, unguided eMBCT will be assessed.

Principal Findings

This nonrandomized study evaluated aspects of feasibility of group, blended and individual, unguided eMBCT for people with cancer. Overall, participants were positive about their experiences in both conditions. This supports the progression to a full-scale RCT in which the effectiveness of group, blended and individual, unguided eMBCT will be assessed.

We found that participants in both intervention conditions valued practicing at their own time, at any place. This flexibility of eMBCTs among people with cancer has been previously reported as a facilitator [14,36,37]. It is evident that many people with cancer need flexible psycho-oncological interventions.

Participants in the group, blended condition particularly valued the group component of the sessions; they felt connected with others, experienced good peer support, and appreciated the synchronicity in communication. People in the group, blended condition even indicated that there were too few group sessions and that they would have liked more. Based on these results, a fourth group session will be added to the group, blended condition in the full-scale RCT. It should be noted that, although participants' feedback has been mentioned as relevant in the cocreation process [10] and we obviously considered it important, it should be critically evaluated and weighed. Participants in this study reported that they preferred the group sessions, but if we were not able to offer the group, blended condition, they still accepted the individual, unguided condition. It is clear that participants saw the group as an important component, yet this does not necessarily mean that the group sessions are indeed crucial for the intervention to be effective. In fact, it was reported that human feedback was the most requested feature in a participatory design for an online intervention; however, this did not increase effectiveness, and the feedback messages were not even read all the time [38]. Hence, there might be a difference in what people say they want prior to participation, what they will actually do or use, and what is effective. Therefore, it is crucial to carefully think about how to use different kinds of input in a cocreation process [10] and we obviously considered it important, it should be critically evaluated and weighed. Participants in this study reported that they preferred the group sessions, but if we were not able to offer the group, blended condition, they still accepted the individual, unguided condition. It is clear that participants saw the group as an important component, yet this does not necessarily mean that the group sessions are indeed crucial for the intervention to be effective. In fact, it was reported that human feedback was the most requested feature in a participatory design for an online intervention; however, this did not increase effectiveness, and the feedback messages were not even read all the time [38]. Hence, there might be a difference in what people say they want prior to participation, what they will actually do or use, and what is effective. Therefore, it is crucial to carefully think about how to use different kinds of input in a cocreation process when developing online interventions.

In terms of preferences and dropouts, the first 12 participants who enrolled in this study preferred the group, blended condition, and there were no dropouts in this condition, compared with 5 participants who discontinued the intervention in the individual, unguided eMBCT. Acceptability and adherence seemed to be higher in the group, blended condition than in the individual, unguided condition. It is important to...
note that all participants who discontinued the intervention were in palliative treatment. Although we could not determine the exact reason, these preliminary insights suggest a proclivity for group, blended eMBCT and questions the acceptability of the individual, unguided eMBCT for people receiving palliative treatment. In addition, it should be considered that, although the individual, unguided condition may be easier to implement and cheaper, people with cancer may still prefer a group, blended intervention format.

Another finding is that the completion rates for the postintervention questionnaires and interviews were low, in particular for the individual, unguided group. Participants were not reminded to complete questionnaires, and no incentive to participate in the interviews was provided. In addition, people in the individual, unguided condition had no contact with a mindfulness teacher or peers throughout the intervention. It might be that these participants did not feel as engaged in the study as the people in the group, blended condition. It has been shown that the use of electronic reminders and real-time monitoring among people with cancer can contribute to a very high completion rate [39]. In the full-scale RCT, we therefore plan to include prompts, such as emails, calls, and WhatsApp messages, so participants are reminded to complete questionnaires.

**Strengths and Limitations**

In this pilot study, we included representatives from the target group as well as experts in the field of cancer, mindfulness, and eHealth to develop an effective intervention. This study highlights the importance of assessing relevant stakeholders’ opinions before developing an intervention and prior to going through the efforts of conducting a full-scale RCT. Based on the results of the cocreation process, we developed an app that is visually attractive; user friendly; low cost; and flexible in how, when, and where to participate. We developed an intervention that is in line with the participants’ needs and wishes and that considered expert opinions. It has increasingly been mentioned in the emerging field of eHealth interventions [10] that it is crucial to carefully consider and understand the target group when developing an effective online intervention. In this pilot study, we not only carefully addressed the target group’s desires and needs before the intervention but also evaluated their experiences after, to develop an optimal intervention that is acceptable to the end user.

This study also has limitations that should also be considered when interpreting its results. First, because of the nature of pilot studies, this study had a small sample size; in addition, it was nonrandomized, limiting our ability to assess limited efficacy. Second, our sample was rather homogeneous (eg, all Dutch, mostly highly educated women), and these participants were self-selected. The participants who had a choice between both conditions all chose the group, blended format. Consequently, findings cannot be generalized to all people with cancer. It may require more research to be able to apply online MBIs across people with cancer with different characteristics (eg, type of cancer, age, sex, language). Moreover, some participants who were invited for the interviews did not reply, and some declined participation, which further limits the generalizability of our results and calls for further research: More attention needs to be paid to people who are not reached or who do not choose to participate. In addition, in our study, we only assessed barriers and facilitators for the interventions among those who had already agreed to participate. Gaining more in-depth knowledge about those who declined participation in the program could have provided additional information about the acceptance of the program.

**Research Implications**

MBCTs have proven to be effective for people with cancer [7,11], and here, we showed that participants felt positively about the 2 formats of eMBCT. Although all interviewed participants considered the intervention conditions acceptable, there were differences in their experiences both between and within intervention conditions. Participants experienced the same components of an online intervention in different ways, which is in line with the findings of similar studies [14,37]. For instance, a study about an online MBI among people with cancer found that some participants found the meditations too long, whereas others liked how they enabled them to have time for themselves [37]. In our previous study, we also found that many aspects of the eMBCT (such as the treatment setting and format) were mentioned both as a facilitator and a barrier [13]. In this pilot study, we did not assess specific participants’ characteristics that might explain these differences. Exploring which type of program delivery works for whom can help to establish the best fit for individual patients, balancing effectiveness and the resources required. The subsequent full-scale RCT with a larger and more varied sample will enable us to conduct mediation and moderation analyses to help clarify some of these uncertainties.

It should be noted that participants valued the possibility of following the program at their own time and place. Being able to decide when and where to participate in online interventions among people with cancer has been reported as a positive characteristic among other pilot studies too [14,37,38]. In addition, to our knowledge, there are no studies comparing preferences of people with cancer between online, group, blended eMBCT and individual, unguided eMBCT. This highlights the importance of research on effectiveness among online MBIs for people with cancer.

**Conclusions**

The main goal of this study was to assess aspects of feasibility of group, blended and individual, unguided eMBCT for people with cancer. This study showed that both intervention conditions were positively received and could potentially be effective. The results of this investigation inform adjustments to the intervention and study process prior to conducting a full-scale RCT to evaluate its effectiveness [18].

Data Availability
The data sets generated and/or analyzed during this study are available from the corresponding author on reasonable request.

Authors’ Contributions
NB analyzed the data, interpreted the results, and wrote the first draft of the manuscript. MvK set up the cocreation process and pilot study, developed and adjusted the intervention, and collected data. AS contributed to the design of the study and the application for funding. She was involved in the cocreation process, supervision of the mindfulness teachers supporting the program, and analysis and reporting of the paper. JV analyzed the qualitative part of this study. JP contributed to the study plan and research design and was involved in coding the interview themes and subthemes. SK contributed to the study plan and research design and coconducted the cocreation sessions. LK analyzed the qualitative part of this study, supported the analysis for the quantitative part, and edited all versions of the manuscript. All authors critically reviewed and approved the final manuscript.

Conflicts of Interest
None declared.

Abstract

Background: Accurate and timely assessment of children’s developmental status is crucial for early diagnosis and intervention. More accurate and automated developmental assessments are essential due to the lack of trained health care providers and imprecise parental reporting. In various areas of development, gross motor development in toddlers is known to be predictive of subsequent childhood developments.

Objective: The purpose of this study was to develop a model to assess gross motor behavior and integrate the results to determine the overall gross motor status of toddlers. This study also aimed to identify behaviors that are important in the assessment of overall gross motor skills and detect critical moments and important body parts for the assessment of each behavior.

Methods: We used behavioral videos of toddlers aged 18-35 months. To assess gross motor development, we selected 4 behaviors (climb up the stairs, go down the stairs, throw the ball, and stand on 1 foot) that have been validated with the Korean Developmental Screening Test for Infants and Children. In the child behavior videos, we estimated each child’s position as a bounding box and extracted human keypoints within the box. In the first stage, the videos with the extracted human keypoints of each behavior were evaluated separately using a graph convolutional networks (GCN)–based algorithm. The probability values obtained for each label in the first-stage model were used as input for the second-stage model, the extreme gradient boosting (XGBoost) algorithm, to predict the overall gross motor status. For interpretability, we used gradient-weighted class activation mapping (Grad-CAM) to identify important moments and relevant body parts during the movements. The Shapley additive explanations method was used for the assessment of variable importance, to determine the movements that contributed the most to the overall developmental assessment.

Results: Behavioral videos of 4 gross motor skills were collected from 147 children, resulting in a total of 2395 videos. The stage-1 GCN model to evaluate each behavior had an area under the receiver operating characteristic curve (AUROC) of 0.79 to 0.90. Keypoint-mapping Grad-CAM visualization identified important moments in each behavior and differences in important body parts. The stage-2 XGBoost model to assess the overall gross motor status had an AUROC of 0.90. Among the 4 behaviors, “go down the stairs” contributed the most to the overall developmental assessment.

Conclusions: Using movement videos of toddlers aged 18-35 months, we developed objective and automated models to evaluate each behavior and assess each child’s overall gross motor performance. We identified the important behaviors for assessing gross motor performance and developed methods to recognize important moments and body parts while evaluating gross motor performance.
Introduction

For the continuous and proper development of children, an accurate and timely assessment of their developmental levels is essential [1]. Early diagnosis during the toddler stage allows for early intervention, which can significantly impact children’s later life outcomes [2,3]. Previous research has shown that early intervention in vulnerable populations, such as those with low birth weight and prematurity, leads to significant improvements in later childhood developments compared to those who do not receive early intervention and that these differences persist into adolescence [4,5]. Numerous studies have shown that the influence of early intervention extends beyond adolescence to adulthood, with significant socioeconomic benefits [6-8]. A recent study about the development of children exposed to lead showed that early intervention before the age of 3 years benefited their future academic performance [9].

As a result, many countries recommend the need for regular developmental screening of infants and young children, and South Korea has implemented the National Health Screening Program for Infants and Children for children under 6 years of age since 2007 [10-14]. The National Health Screening Program for Infants and Children in South Korea developed the Korean Developmental Screening Test for Infants and Children (K-DST) in 2014, which assesses gross motor, fine motor, cognitive, language, social, and self-help skills in children aged 4-71 months [15].

In various areas of development, gross motor development begins earlier than other areas of development, such as fine motor and language development, and therefore, it is possible to assess the risk of developmental delay at a younger age by monitoring gross motor development. Studies have shown that gross motor development at an early age is predictive of subsequent developments [16] and is also associated with future academic achievement [17,18].

However, a global shortage of pediatric health care providers hinders the proper developmental assessment of children. In a report published in 2016, one-third of pediatricians in the United States did not use standardized screening tools in their pediatric practice because of issues such as limited clinic hours and a shortage of medical staff to perform developmental screenings [19]. As an alternative to pediatric health care professionals, many countries, including South Korea, rely on parental reports to determine developmental milestones. However, parental reports are based on subjective opinions, and parents may respond positively even when they have observed their child’s activities only once, leading to false positives [20]. Based on these factors, there is a need for an objective, labor-free, and automated tool to assess the development of children.

Recently, there have been several studies using deep learning to assess gross motor development in children. A study reported that a deep learning model can predict cerebral palsy progression from videos of spontaneous movements taken in infancy [21]. However, this study did not use a previously validated metric such as the K-DST, which may limit the explainability and generalizability of the model. Liu et al [22] evaluated the gross motor skills of children with autism with an average age of 5 years, and Suzuki et al [23,24] assessed gross motor skills on a video-by-video basis using a deep learning model with behavioral videos of 4- to 5-year-old children. However, since these studies were conducted on children aged ≥4 years, there is a limitation in that they could not validate the model effectiveness in the <3 years age group, where early intervention is expected to be more effective.

Considering these factors, we developed an automated and accurate pediatric developmental assessment model using videos of toddlers aged 18-35 months performing gross motor movements that have been validated with the K-DST. Our 2-step model assesses each behavior and evaluates each child’s overall gross motor performance based on the performance level of each behavior. In addition, we identified behaviors that contribute to the overall gross motor skills assessment and detected critical moments and important body parts for the assessment of each behavior.

Methods

Study Design and Participants

In this study, we used behavioral videos of toddlers aged 18-35 months, when most of them could walk, perform a wide range of gross motor actions, and minimally understand the examiner’s instructions to perform the task [16,25]. We selected 4 behaviors frequently used by the K-DST to assess gross motor development in this age group: climb up the stairs, go down the stairs, throw the ball, and stand on 1 foot [15]. These 4 movements were chosen as core tasks based on existing child development guidelines and in consultation with 3 pediatricians and 15 child development experts, considering the physical and cognitive abilities of this age group [26,27]. The participant performed multiple trials for each behavior. For each of these trials, the raters watched the video and rated the performance as “bad,” “good,” or “perfect.”

We also categorized participants into “relatively slow” and “relatively fast” groups based on their overall performance: if their performance was rated as “bad” on 2 or more behaviors, we categorized them as “relatively slow”; the remaining cases were categorized as “relatively fast.”
Ethical Considerations

The data set used in this study is from our previous study and it was constructed while adhering to the ethical principles of the Declaration of Helsinki [28]. The construction of the data set was approved by the Institutional Review Board of Severance Hospital, Yonsei University College of Medicine (4-2021-0845), and the requirement for informed consent was waived due to the retrospective nature of the study. Participants of the data set were recruited from daycare centers, kindergartens, primary pediatric hospitals, and internet communities. Written informed consent for data collection and subsequent analysis was obtained from all caregivers of the participants. Participants received ₩50,000 (approximately US $38) and were provided with an intelligence scale test valued at around ₩300,000 (US $232) as compensation. To ensure the confidentiality and privacy of the participants, each study participant was deidentified via an alphanumeric code.

Experimental Setting

The videos were recorded in the presence of caregivers, examiners, and children. Depending on the behavior, a staircase or a ball was used as the apparatus. The video recordings for each child were conducted for approximately 1 hour. A camera was positioned to capture the entire body of each child. Using a frontal angle camera, the child’s behavior was recorded as an RGB (red-green-blue) video. All videos were collected using a Sony DSC-RX100 with 1920x1080 resolution and at 30 frames per second. The collected videos were rated by human raters based on the K-DST criteria, and these values were used as true labels in the stage-1 model.

Data Preprocessing

To assess the behavior of the children in the RGB videos, we estimated the position of each child as a bounding box and then extracted 17 human keypoints within the box [29]. To detect the participants, we estimated the bounding boxes using Faster-RCNN [30] with the ResNet 50 backbone in the RGB videos. HRNet was then used to detect human keypoints in the detected bounding boxes [31]. Skeleton data were generated at a rate of 30 frames per second.

Model Construction

We divided the data into training, validation, and test sets in a 6:2:2 ratio for each behavior, ensuring that data from the same individual were not allocated across multiple sets. To predict the overall gross motor performance of the children, we designed a 2-stage model. The overview of our model is shown in Figure 1. The first stage is the action evaluation stage, in which each behavior is evaluated separately using a graph convolutional networks (GCN)–based deep learning algorithm. To improve the performance of the stage-1 model, we performed transfer learning with pretrained weights. These pretrained weights are released by PYSKL and are trained with the channel-wise topology refinement graph convolution networks (CTR-GCN) model on the NTU RGB+D dataset by detecting 17 skeleton nodes with HRNet [32-34]. The CTR-GCN model is a stacked structure of 10 basic blocks, 8 of which were frozen during the training on our data. Augmentation using random flipping and scaling was applied to our training data. The training task was repeated 5 times for the same data, and 80 frames were randomly selected each time. The model training strategy of this study and the architecture of the CTR-GCN is shown in Figure 2. A total of 4 CTR-GCN models were trained to generate the predicted probabilities for the 4 gross motor skills, 1 for each behavior [35]. Although these 4 models can assess the performance of each behavior, it was necessary to integrate all 4 models to have a comprehensive assessment of the child’s gross motor development. Accordingly, to assess overall gross motor performance, the stage-2 model aggregated the outcome probability values of each label per behavior. The extreme gradient boosting (XGBoost) algorithm was used for the stage-2 model [36]. The validation process was performed using a 10-fold cross-validation strategy. The parameters used to train our models are shown in Multimedia Appendix 1.
Figure 1. An overview of the suggested 2-stage model for predicting and evaluating comprehensive gross motor performance of children. Faster-RCNN and HRNet were used to extract the skeletal joints from the 4 behavioral videos. The evaluation of each behavior in the stage-1 was performed by graph convolutional networks model separately, and Grad-CAM was used for analyzing the influence of each joint and time segment of the video. In stage-2, the XGBoost algorithm was used for overall performance evaluation, and the SHAP method was used to recognize the contribution of each behavior to the evaluation. B: behavior; C: class; CTR-GCN: channel-wise topology refinement graph convolution networks; Grad-CAM: gradient weighted class activation mapping; GMS: gross motor skills; SHAP: Shapley additive explanations; XGBoost: extreme gradient boosting.
**Figure 2.** A detailed architecture of the suggested model and CTR-GCN. We applied augmentation methods and frame sampling strategies. The pretrained weights for the CTR-GCN model were applied, and 8 basic blocks of the model were frozen during training. The Grad-CAM was generated from the gradients and feature map from the last block. The Grad-CAM was then interpolated to align with the input frames. A basic block of CTR-GCN consists of 3 CTR-GCs, which use temporal pooling to aggregate temporal features of skeleton graph sequences and pairwise subtraction and concatenation for correlation modeling between skeletal joints. C: channel dimension of the data; CTR-GCN: channel-wise topology refinement graph convolution networks; GMS: gross motor skills; Grad-CAM: gradient-weighted class activation mapping; MLP: multilayer perceptron; N: number of skeletal joints; T: temporal dimension of the data; Tanh: hyperbolic tangent function; XGBoost: extreme gradient boosting.

**Evaluation of Model Performance and Verification of Explainability**

The stage-2 model–assessed performance was compared with human panel–assessed performance on a fixed-test data set. A panel consisting of 1 pediatrician and 2 nonexperts assessed the participants’ overall gross motor status. Sensitivity and specificity for each panel were calculated.

For the interpretability of the stage-1 action evaluation model, gradient-weighted class activation mapping (Grad-CAM) was used to identify critical time points and body parts in behavioral videos [37]. To create a Grad-CAM heatmap, we obtained weights for each label through gradient calculation and extracted feature maps from the final graph convolutional layer of the CTR-GCN model. The heatmap was then generated by linearly combining the derived weights and feature maps and applying the ReLU function [38]. We then visualized the heatmap along with the original input, which is a sequence of positions of skeletal joints. To understand the influence of each body part on model decision, we determined the top-1 activated joints that had the highest Grad-CAM values per frame and grouped their frequency by body part [39]. The 17 joints were grouped as belonging to the head, left arm, right arm, left leg, and right leg [39].

In the second stage of overall performance prediction, we used the Shapley additive explanations (SHAP) method to identify the actions that contribute more to the total developmental assessment [40]. The mean absolute SHAP value was obtained to estimate the contribution of each feature to the model output.

**Statistical Analysis**

The performance of the models was evaluated using the area under the receiver operating characteristic curve (AUROC) score, which was calculated as the average of all folds and presented with SD. The optimal cutoff value for the overall gross motor skill assessment was determined based on receiver operating characteristic analysis using the Youden index. The receiver operating characteristic curve was also plotted with the average of the folds within the threshold intervals and the area between the SDs. All statistical analyses were performed in Python (version 3.6.8; Python Software Foundation) using sci-kit-learn (0.24.2 version).

**Results**

**Characteristics of Cohort Participants**

Behavioral videos of the 4 gross motor skills were collected from 141 children, of which 71 (50.4%) were boys, and 70 (49.6%) were girls. The average age of the children in this study was 29.6 (SD 4.3) months. The characteristics of the behavioral data for each gross motor skills are listed in Table 1. A total of 2502 behavioral videos were collected, with 698 (23.9%) rated as “bad,” 581 (23.2%) rated as “good,” and 1321 (52.8%) rated as “perfect.”
Table 1. Characteristics of cohort participants. The 141 participants consisted of 71 (50.4%) boys and 70 (49.6%) girls, and the average age was 29.6 (SD 4.3) months. A total of 2502 behavioral videos were collected, with 698 (23.9%) rated as “bad,” 581 (23.2%) rated as “good,” and 1321 (52.8%) rated as “perfect.” The distribution of the demographics of the population and the number of videos by label for each behavior are represented as the total number and its percentage.

Performance of the Evaluation of Each of the 4 Gross Motor Skills

Table 2 shows the results of the first-stage model. The AUROC values with each behavioral evaluation were from 0.79 to 0.90. We found that the model for the “climb up the stairs” behavior performed the best, with an AUROC score of 0.90, followed by “go down the stairs” with an AUROC score of 0.86; subsequently, the models for “throw the ball” and “stand on 1 foot” performed similarly, with AUROC scores of 0.79 and 0.80, respectively (Figure 3).

**Figure 3.** Performance scores and confusion matrices of the stage-1 gross motor skill evaluation model for 4 behaviors. The bar chart of scores is shown with error bars indicating the range between minimum and maximum scores observed in the cross-validation. The AUC scores range from 0.79 for “throw the ball” to 0.90 for “climb up the stairs.” The confusion matrices show the model’s ability to distinguish between “bad” and “good” labels. AUC: area under the curve.

**Grad-CAM on the Visualization of Human Keypoint**

Our keypoint-mapping Grad-CAM visualization showed the differences in the activated joints for each behavior and label (Figure 4). By observing the highlighted areas in the heatmap, we could identify the contribution of the joints to the evaluation of each behavior. The horizontal axis, labeled as “time,” indicates the moments of the behavioral video that contributed to the classification across the selected 80 frames of the videos. The vertical axis, labeled as “skeletal joint,” shows the critical joints related with behavior evaluation. For the “climb up the stairs” behavior, the Grad-CAM results of the behavior evaluated as “bad” showed that the Grad-CAM scores of the arms and head increased as the child falls and grabs the stairs with their hands. On the other hand, for behavior evaluated as “perfect,” the child’s legs scored consistently high as they walked up.

It was also observed that the Grad-CAM score was higher when a given task was being performed. In the Grad-CAM results for the child who was rated “bad” for “climb up the stairs,” we could observe that the moment when the child wandered and looked back to the assistant has a lower Grad-CAM value than the moment when they climbed the stairs. To compare the importance of each body part, we determined the top-1 activated joint, which is the joints with the highest Grad-CAM value per frame, and grouped the frequencies by body part. (Multimedia Appendix 2) [39].
**Figure 4.** Grad-CAM heatmap with frame-by-frame mapped keypoints for each behavior. The change of Grad-CAM values over time for 17 human keypoints was displayed as a heatmap. For each behavior, the Grad-CAM heatmap for a given participant was compared between a “perfect” and “bad” performance. The actions of the participant over time were visualized as human keypoints and shown above the heatmap. The age and gender of each child were displayed together. Grad-CAM: gradient-weighted class activation mapping.

**Overall Performance Status Prediction**

The results of the stage-2 overall performance prediction model and the human panels on a fixed-test data set are shown in Figure 5. The model had an AUC score of 0.90, and the specificity and sensitivity of the optimal cutoff points were 0.83 and 0.82, respectively. For the human panels, sensitivities of 0.90 and 0.91 and specificities of 0.59 and 0.81 were recorded by nonexperts and an expert, respectively. Comparing each of these showed that the model performed better than the nonexpert panel and was similar to the expert panel. Table 3 shows the overall results of the model.

According to the grouped SHAP value obtained from variables for each action, the action “go down the stairs” contributed the most to the prediction, with a SHAP value of 1.28 (Figure 5). The next highest values were “climb up the stairs,” “throw the ball,” and “stand on 1 foot,” with values of 0.73, 0.65, and 0.36, respectively.
Discussion

Principal Findings

In this study, we evaluated each gross motor behavior and assessed each child’s overall gross motor performance status using movement videos of toddlers aged 18-35 months. To the best of our knowledge, this study is the first to predict the overall gross motor behavior status using pediatric gross motor movement videos at ages younger than 3 years.

Several previous studies have attempted to predict pediatric development using digital phenotype data, such as detecting developmental disabilities using drag-and-drop data in games [41], identifying visual impairments using gaze patterns and facial feature data in response to visual stimuli on a smartphone, and measuring fine motor skills in children using sensor-augmented toys [42]. Suzuki et al [23,24] conducted studies that collected the behavioral videos of 4- to 5-year-old children and extracted skeletal data through OpenPose to evaluate behavioral performance on a per-video basis using a convolutional neural network and autoencoder model. Liu et al [22] proposed a method to evaluate the initial gross motor skills of children with autism with an average age of 5 years using velocities, trajectories, and angles of upper and lower limb joints based on skeleton data extracted through OpenPose. However, unlike these previous studies of gross motor skill assessments, our study focused on gross motor function in toddlers younger than the age of 3 years, which may allow us to quickly identify developmental delays in children younger than the age of 3 years for early intervention. Additionally, this study not only assessed each behavior but also built a model to evaluate the overall performance of each individual by aggregating the assessments of each behavior.

In this work, we performed action recognition using CTR-GCN on skeleton data extracted through human pose estimation with Faster-RCNN and HRNet [30,31,35]. Recently, many studies have been published on action recognition, which is broadly categorized into RGB-based methods and skeleton-based methods [43]. In this study, instead of RGB-based methods, which directly use RGB video, we used a skeleton-based method using Faster-RCNN and HRNet to estimate the location of human presence as a bounding box and extract human keypoints [30,31]. These skeleton-based methods are not only computationally efficient but also have the advantage of focusing on the child’s behavior and deidentifying the study participants by removing background information [43,44].

For human pose estimation, we used HRNet and Faster-RCNN compared to the studies by Suzuki et al [23,24] and Liu et al [22], which used OpenPose [30,31,45]. In human pose estimation, there are 2 types of methods: the bottom-up method (eg, OpenPose), where each body part is detected first and subsequently the body parts are combined, and the top-down method (eg, HRNet + Faster-RCNN), where the person is detected and then each body part is searched within the detected bounding box [29-31,45]. The HRNet method is known to be more accurate than OpenPose, and the top-down method is expected to be more accurate in detecting body parts, especially...
when there are multiple people in the video [31,32]. Since children are often filmed with their caregivers in the developmental test, the HRNet was more suitable for our study.

The types of behaviors assessed in this study have been used in the K-DST for the corresponding age group, and previous research has shown that these types of gross motor behaviors are good predictors of childhood developmental disorders, such as intellectual disability, autism spectrum disorder, and cerebral palsy [15]. Furthermore, the model we developed in this study provides more objective assessments of gross motor skills than the K-DST, which relies on parental reports and enables the assessment of gross motor skills to be automated without requiring trained pediatric health care providers.

Of the 4 behaviors evaluated, “go up the stairs” was the most accurately classified; however, in the actual model, “go down the stairs” had a higher contribution in SHAP values (Figures 2 and 4). When viewing videos of actual children’s behaviors, we found that while performing the “go down the stairs” behavior, the examiner placed the child on the stairs, and the child subsequently performed the action of going down the stairs to return to the caregiver at the bottom of the stairs without the examiner’s intervention. Other behaviors required frequent intervention by the investigator to encourage the child to perform the behavior successfully, because the children sometimes did not understand the investigator’s instructions (eg, holding up 1 leg for more than 1 second) or had a variety of alternative actions at the onset of the behavior (eg, returning to the caregiver instead of climbing the stairs).

We also aimed to validate the explainability of the model by calculating the Grad-CAM values of each joint for each behavior, frame by frame (Figure 4). This allowed us to identify specific joints that had high importance values at critical points in the child’s behavior. For example, in a video of a child performing the “stand on 1 foot” behavior, when we analyzed the Grad-CAM of each joint on a frame-by-frame basis, we could observe that the importance of the leg joints increased as the child stood on 1 leg. The importance of each joint across the videos was determined by counting the number of times each joint was the most important in a particular frame (Multimedia Appendix 2) [39]. This allowed us to identify the vital body parts for evaluating each behavior. In the case of “climb up the stairs,” for example, it was found that the values in the arm area increased when the child was performing the behavior poorly. This finding can be attributed to the child’s tendency to resort to crawling instead of standing when the child had difficulty climbing, thereby increasing the values in the arm. The analysis of Grad-CAM values per joint in the children’s behavioral videos allowed us to identify which joints were important for certain behaviors and which body parts were more deficient in each child during specific behaviors.

One limitation of this study was that we could not validate the model’s performance in different patient populations. The study used data from participants aged 18-35 months, as this is the developmental stage when children can perform a wide range of gross motor movements, such as walking and running, and can understand simple verbal instructions from the examiner. Therefore, further research is needed to determine which gross motor activities in different age groups can be used to assess gross motor development in children. In addition, because this study was limited to Korean children, we suggest that its applicability should be studied in various settings, including other ethnicities and cultural settings.

Additionally, this study did not collect long-term follow-up prognostic data on the participants, such as the subsequent occurrence of developmental delays. If prospective data had been collected on the occurrence of future developmental disabilities (eg, cerebral palsy and autism spectrum disorders), more thorough studies could have been conducted using our model. Therefore, it is necessary to consider the long-term prognosis follow-up of participants in future studies.

Conclusions
We developed a model to assess 4 behaviors using behavioral video in children aged 18-35 months and to assess each child’s overall gross motor performance. This is the first study to assess the overall gross motor behavioral status of children younger than 3 years of age using gross motor video for automated and objective prediction of child development. We also identified important behaviors during the model’s assessment of overall gross motor performance. Furthermore, we developed a method to identify important moments and key body parts during behavioral assessment using Grad-CAM. We anticipate that a more accurate and automated assessment of gross motor development will be possible with this model if more data are available in a variety of settings.

Acknowledgments
This research was supported by a grant from the R&D project funded by the National Center for Mental Health (grant MHER22A01). Funding was used toward labor costs for data collection and analysis. The funders of the study had no role in study design, data collection, data analysis, data interpretation, or writing of the report.

Data Availability
We used publicly available data from our previous research [28]. These data are available on GitHub [46].

Authors’ Contributions

Background: Mental health care provision in the United Kingdom is overwhelmed by a high demand for services. There are high rates of under-, over-, and misdiagnosis of common mental health disorders in primary care and delays in accessing secondary care. This negatively affects patient functioning and outcomes. Digital tools may offer a time-efficient avenue for the remote assessment and triage of mental health disorders that can be integrated directly into existing care pathways to support clinicians. However, despite the potential of digital tools in the field of mental health, there remain gaps in our understanding of how the intended user base, people with lived experiences of mental health concerns, perceive these technologies.

Objective: This study explores the perspectives and attitudes of individuals with lived experiences of mental health concerns on mental health apps that are designed to support self-assessment and triage.

Methods: A semistructured interview approach was used to explore the perspectives of the interviewees using 5 open-ended questions. Interviews were transcribed verbatim from audio data recordings. The average interview lasted 46 minutes (rounded to the nearest min; SD 12.93 min). A thematic analysis was conducted.

Results: Overall, 16 individuals were interviewed in this study. The average age was 42.25 (SD 15.18) years, half of the interviewees identified as women (8/16, 50%), and all were White (16/16, 100%). The thematic analysis revealed six major themes: (1) availability and accessibility, (2) quality, (3) attitudes, (4) safety, (5) impact, and (6) functionality.

Conclusions: Engaging in clear communication regarding data security and privacy policies, adopting a consent-driven approach to data sharing, and identifying gaps in the app marketplace to foster the inclusion of a range of mental health conditions and avoid oversaturation of apps for common mental health disorders (eg, depression and anxiety) were identified as priorities from interviewees’ comments. Furthermore, reputation was identified as a driver of uptake and engagement, with endorsement from a respected source (ie, health care provider, academic institution) or direct recommendation from a trusted health care professional associated with increased interest and trust. Furthermore, there was an interest in the role that co-designed digital self-assessments could play in existing care pathways, particularly in terms of facilitating informed discussions with health care professionals during appointments and by signposting individuals to the most appropriate services. In addition, interviewees discussed the potential of mental health apps to provide waiting list support to individuals awaiting treatment by providing personalized psychoeducation, self-help tips, and sources of help. However, concerns regarding the quality of care being affected because of digital delivery have been reported; therefore, frequent monitoring of patient acceptability and care outcomes is warranted.
addition, communicating the rationale and benefits of digitizing services will likely be important for securing interest and uptake from health care service users.

**Introduction**

The demand for mental health care is steadily rising [1], with mental health disorders being among the leading causes of global disease [2] and disability burden [3]. Despite the documented consequences of delays in providing support [4,5], there is inadequate service coverage and poor quality of care within most health care systems globally [6], with documented disparities between the quality of physical and mental health care [7].

In this regard, mobile and internet technologies, such as web and smartphone apps, have been identified as potential tools to improve access to care by mitigating some of the economic, geographic, and human resource constraints posed by in-person care [8]. Evidence gathered from numerous studies supports the view that the internet and mobile apps have become a source of health information, support, screening, and disease management, as well as being the entry point for referral processes with various degrees of success in implementation.

In the United Kingdom, there is an urgent need for innovative mental health technologies, as despite a lifetime prevalence of 1 in 4 adults experiencing a mental health disorder [9], many individuals who seek help face considerable barriers to effective support. First, an estimated 1 in 35 people are waiting for specialist mental health care in the United Kingdom [10], with the reported wait for specialist care often exceeding a month [4]. Patients who spend more time on waiting lists report worsening mental health symptoms [4,5]. In addition, there are reports of impairments in social or relationship domains, with some individuals reporting that their mental health deteriorated to the extent that they needed emergency care [4].

Second, there is well-documented evidence of mental health misdiagnosis. It is estimated that 90% of mental health concerns are managed entirely in primary care settings [11]. Despite this, there is frequent misidentification of common mental health disorders, such as major depressive disorder [12,13], bipolar disorder [14], and anxiety disorders [15]. There is also evidence that some general practitioners (GPs) feel their surgeries are underprepared to provide adequate mental health care [16]. A plethora of interconnected reasons may explain the misdiagnosis of mental health conditions, such as the overlapping symptom profiles of different psychiatric disorders [17], short consultations [18], and a lack of appropriate training [19]. These assessment difficulties are compounded by person-level barriers, such as difficulties in accurately communicating symptoms to health care professionals [20]. Additional barriers to diagnosis include geographic variability in resources and the availability of trained mental health care professionals.

In contrast, smartphone ownership is becoming widespread, all-time high, and the increasing number of mobile device users has created an unprecedented opportunity to develop evidence-based mobile apps for remote delivery of mental health care. There is evidence of interest from individuals with mental health concerns in digital tools designed for mental health assessments, particularly when they are integrated into care pathways, with results delivered directly to a health care professional before their appointment [5]. Individuals appear to feel more comfortable disclosing sensitive information digitally [21] than health care professionals. In addition, digital self-assessment and triage support tools may be useful in augmenting existing services by ensuring timely response and intervention to urgent cases [22,23] and signposting appropriate services outside formal health care.

However, despite the interest in and promise of mental health apps, prolonged engagement and use remains an issue [24]. This poses the question of how to design tools that are usable and useful for individuals experiencing mental health concerns. Iterative user-centric research and design are key to addressing this challenge. Indeed, work has been done to explore the opinions of apps designed for mental health concerns and disorders [25-29]. However, given the interest in digital tools intended for mental health self-assessment and triage, more work is required to understand the perspectives and acceptability of such tools designed and implemented to augment existing care pathways.

Therefore, in this study, we conducted semistructured interviews with individuals who represented potential app users: those with lived experiences of mental health concerns. The key objective of this study is to advance the understanding of potential users’ views and perspectives on mental health apps, with a specific focus on apps designed for self-assessment and triage. To this end, the semistructured interview included eight questions broadly focused on the following topics: (1) previous use and perception of mental health apps; (2) perspectives of mental health assessment apps; (3) perspectives of opportunities for integration of mental health apps, including mental health assessment apps, into traditional care; (4) perspectives of the safety and privacy aspects of mental health apps; and (5) desired app features for an ideal mental health app.
professor of neurotechnology (SB). All authors had previous experience in qualitative data analysis. JB is identified as male, and all other authors are identified as female. This study was a follow-up to a previous web-based survey study [5].

**Participants and Recruitment**

Participants from a previous web-based survey study [5] who expressed interest in participating in follow-up studies were contacted via email between April and June 2022 and invited to participate in this interview study. The email addresses collected in the prior survey study [5] used to contact potential participants for this study were stored in a locked (password-protected) Excel file, only accessible to members of the research team who were named after ethical approval. The inclusion criteria were as follows: (1) aged ≥18 years, (2) living in the United Kingdom, and (3) having to visit a health care professional after 2016 to discuss their mental health symptoms. The first 2 rounds of recruitment were blinded to the demographic characteristics. In the second and third rounds of recruitment, only participants who had identified as men or nonbinary in the survey study were contacted to increase the representation of these groups in this study sample.

**Study Procedures and Materials**

Participants were first provided with written details of the aims, methods, and requirements of this interview study via email. They were then asked to express their interests and provide consent to participate via email. Upon the expression of interest and receipt of consent, the date and time for the interview agreed with the researchers (ELF and BS). The interviews were conducted by an interviewer (ELF or BS) in the presence of an observer (ELF or BS).

All study materials, including the participant information sheet, consent form, interview guide, and debriefing, were developed in consultation with the senior author (SB) of a practicing psychiatrist. In addition, some questions in the interview guide were adapted from previous relevant literature investigating attitudes toward digital interventions for mental health [31,32]. All study materials were then further amended and finalized in consultation with members of the Cambridge University Hospitals Patient and Public Involvement panel, who have lived experiences of mental health concerns. This strategy was used to ensure the suitability and relevance of the study materials to the target population.

A semistructured interview guide was used to facilitate the conversation, which included open-ended questions to encourage participants to discuss their perceptions of digital tools (eg, applications) for mental health. The guide included eight questions (with further prompts) focusing on (1) previous use of mental health apps, (2) perceptions of mental health apps, (3) perspectives of apps for mental health assessment, (3) perspectives of receiving an indication of a mental health diagnosis from an app, (4) perspectives of information collected by a mental health assessment app being sent to a health care professional, (5) perspectives on whether apps can improve access to mental health services, (6) views on safety and privacy related to mental health apps, and (7) desired features for future mental health apps. In addition, the participants were asked (8) if they had any additional thoughts relevant to mental health and digital technologies (eg, apps). A copy of the semistructured interview script is available in Multimedia Appendix 2. The interviews were adaptive, such that only relevant questions were asked based on previous responses. The interviewer could reformulate or clarify questions during the interviews to gain a deeper understanding of the participants’ thoughts and opinions, or delve into relevant details that were mentioned in relation to the questions asked. The audio of the interview was recorded for subsequent transcription. After completion of the interview, all participants were provided with debrief via email and offered a £15 (~US $18) Highstreet voucher for their time.

**Data Collection**

Interviews were conducted between May 5, 2022, and June 22, 2022. Overall, 14 (88%) of the interviews were conducted using Zoom (Zoom Video Communications Inc) videoconferencing, 1 (6%) using Microsoft Teams videoconferencing, and 1 (6%) via telephone call. Participants were informed that they did not need to have their cameras on during the interview. Audio data were recorded for all the interviews. In total, 12 hours and 25 minutes (rounded to the nearest min) of interview audio were recorded, with the average length of the interview being 46 minutes (rounded to the nearest min; SD 12.93 min). The interviews were transcribed verbatim from audio data recordings using cloud-based AI-powered software Otter [33]. The researchers (ELF and BS) then reviewed the transcripts by listening to the audio recordings and amending the transcripts where necessary. Any unclear audio segments were labeled “unintelligible.” Interview transcripts were numbered and not connected to any identifiable information (ie, email address for recruitment and participation reimbursement). Any names or identifying information (eg, city of residence) disclosed during the interviews were removed from the transcripts. The transcripts were downloaded as PDFs and analyzed as described below.

**Data Analysis**

The data were analyzed using a bottom-up (data-driven) thematic analysis approach based on the Braun and Clarke framework [34]. A total of 2 authors (ELF and JB) analyzed all the transcripts under blinded conditions using the following process: the first interview transcription was analyzed, and initial codes were identified. The second interview was analyzed by checking for the presence of codes identified from the analysis of the first interview and adding any new codes identified. This process was continued for each interview transcript, each time adding or refining existing codes. Upon completion of the analysis, the authors were unblinded and compared their lists of identified codes. Any inconsistencies were discussed with a third author (BS or NAM-K) until consensus was reached. Once the codes were agreed upon by all authors, they were organized into themes under blinded conditions by 2 authors (ELF and JB). The resulting themes were discussed with a third author (BS and NAM-K) until a consensus was reached. Data analysis (ie, code creation and assignment, theme creation, and assignment) was performed using Google Sheets spreadsheets. A copy of the codebook organized into their respective themes is available in Multimedia Appendix 3.
Ethical Considerations
This study was approved by the University of Cambridge Human Biology Research Ethics Committee (approval number: PRE.2021.053). The participants provided informed consent electronically via email to participate in the study. In one case, a participant provided consent at the start of the interview because they had experienced difficulties in sending a complete consent form via email. On the day of the interview, the interviewer (ELF or BS) verified that participants understood the information that had been provided to them and gained verbal consent that they were happy to continue with the interview.

Results

Sociodemographic Characteristics
A total of 16 individuals were included in this study. The average age was 42.25 (SD 15.80), with 50% (n=8) of the participants identifying as women and all White (16/16, 100%). English was the native language of 87% (14/16) of the interviewees. More than 69% (n=11) had at least one undergraduate degree. A total of 43% (7/16) were single and 43% (7/16) were cohabiting. Regarding accommodation characteristics, living alone or with a partner was the most common arrangement, with 38% (n=6) living alone, 25% (n=4) living with a partner, and 19% (n=3) living with a partner or children. A total of 37% (6/16) were employed, and 62% (10/16) had a household income of less than £35,001 (approximately US $43,608) before tax.

Mental Health Characteristics
The majority (15/16, 94%) of respondents had discussed their mental health with a GP in the last 5 years, with 88% (n=14) having also seen a therapist or counselor. More than half (9/16, 56%) of the participants had also seen a psychiatrist. Mental health care visits were typically provided free of charge via the National Health Service (15/16, 94%). A total of 81% (13/16) of the interviewees were diagnosed with a mental health disorder (see Table 1 for a breakdown of the frequency of diagnoses). The most common diagnosis in the sample was major depressive disorder (13/16, 81%), followed by generalized anxiety disorder (5/16, 31%), and posttraumatic stress disorder (5/16, 31%).

Thematic Analysis
Thematic analysis revealed 6 major themes comprising 25 minor themes (Figure 1).
Availability and Accessibility

Availability and accessibility emerged as key themes in this study, with issues surrounding (1) app stores, (2) exclusion, (3) environment, (4) convenience, and (5) employee benefits emerging as important minor themes.

Regarding the first minor theme, app stores, interviewees reported that there is too much variability in what app store searches return, which could make app stores difficult to navigate and, in turn, be overwhelming for users:

> It’s overwhelming and it can be just really difficult to find what you’re looking for as well. You know, if you just put in a search term, and then you just get kind of a load of random stuff. That’s not necessarily categorized very well, I don’t think. [Transcript 5]

In addition, concerns were raised about groups of individuals with specific conditions being excluded from the adoption of a digital approach to mental health, with gaps in the market for apps for certain mental health conditions, such as neurodevelopmental disorders:

> [...] specialized things like ASD specifically, I’ve not really seen anything in terms of like apps to help with anything like that sort of helping with meltdowns and things like that. [Transcript 4]

Interviewees also noted a lack of diversification in-app offerings, expressing concerns that available apps are basic and essentially all offer the same thing:

> I think the ones that the NHS or the GP or the CPN have recommended they seem to be quite basic. I suppose cause the NHS makes them, they make it for everybody, so you can’t really fine tune it, I don’t think. [Transcript 15]

But in terms of my perception, I think, I don’t think they have a lot of options out there. I mean, there’s a broad range. I mean, you’ve got apps, that you know, under different names, but they all, they all work the same. [Transcript 13]

In terms of the second minor theme, exclusion, interviewees raised concerns related to severe or complex mental health symptoms impeding users’ ability to actively engage with a mental health app:

> I don’t think I’d have the mental abilities to read a question, understand it, put in an answer, look at my
answers, look for any pattern there might be or anything like that. I think I wouldn’t be able to do it. [Transcript 6]

In addition, with regard to exclusion, not being able to afford a potential one-off or subscription payment was raised as a concern:

I know some of them have like paid options, which sometimes can be a bit of a barrier. I’m in a position now where I can like pay for subscriptions, but in the past like when I was a university student I think that was one thing that sometimes put me off was having to pay for them. I used to use one calm, I found it was actually quite expensive and there’s like other apps that are completely free, that do the same thing. [Transcript 7]

Moreover, exclusion due to digital delivery, particularly in the elderly, those with limited digital literacy, or individuals with physical health conditions such as visual impairments or dyslexia, was raised as an important barrier:

[...] it would exclude some people who haven’t got the internet. And it would exclude a lot of older people who might have it and haven’t got a clue how to do it. So, so that would be one of the disadvantages of excluding some people [...]. [Transcript 6]

The environment was also identified as a minor theme within the availability and accessibility theme, with interviewees raising the issue of not having the right environment to complete a digital mental health assessment:

[...] when you’re in a house when everybody else is stuck at home as well you don’t get peace and quiet. You actually need to concentrate on it. [...] When you’re trying to sit down at home in a busy house doing it, you’re never guaranteed to have the time you need to actually finish the section in one go, having to start things three sometimes four times just to actually work through it. [Transcript 8]

In contrast, interviewees also reported that digital technologies are convenient and improve accessibility to mental health services:

[...] a lot of people can’t, can’t get to places. I don’t just mean COVID I mean, they haven’t got the money or it takes longer or whatever.” “But then the same things that are advantages are disadvantages. Because like people who are physically disabled, it must, it’ll be a lot easier for them to use to do things online. [Transcript 6]

as well as fitting well into modern daily routines:

I find that the good thing of them, is that you can use them, do them anytime. Can do it at your own pace and at home so you don’t have to depend on anyone to do it or, or have a scheduled time to. [Transcript 14]

Finally, regarding the role of the workplace, it was noted that engagement with mental health apps could improve if provided as an employee benefit:

Yeah, I mean, I got it free from my work. They had an agreement with them, so I feel I’ll try it anyway. [Transcript 11]

Quality
The quality theme was identified in this study, encompassing the minor themes of (1) subjectivity, (2) scientific rigor, (3) background and development, and (4) perceived value.

Interviewees mentioned the subjective nature of mental health symptoms. Because of their reported subjective nature, symptoms were deemed difficult to consolidate with the formal diagnostic labels and descriptions of mental health disorders, causing distrust regarding the validity of diagnoses:

I must say it’s all very subjective, isn’t it? Your own feelings are all what you feel and then you think just that is really what they mean? Am I feeling what they, what they mean? [Transcript 3]

Related to this aspect of subjectivity, interviewees mentioned concerns related to self-reporting of mental health symptoms in self-assessments. Some interviewees expressed that the subjective and hard-to-define nature of mental health symptoms can create a risk that users of mental health apps may unintentionally report their symptoms inaccurately:

So[...] you know the thing is people are expressing their symptoms, but they might be inaccurate symptoms. It might only be that person’s interpretation of what they’ve got. [Transcript 3]

Others have stated that app users may intentionally incorrectly report or exaggerate their symptoms to support self-diagnosis of a specific mental health disorder:

I guess there’s always the risk of people not being honest. And maybe people exaggerating symptoms or something like that. I know there’s a lot of talk at the minute, isn’t it about social media and people like self-diagnosing from social media, and I know it’s only a small percentage of people, but I guess that would be a concern. [Transcript 7]

The subjective nature of mental health symptoms and concerns related to self-reporting are both associated with potential difficulties in using digital tools for accurate mental health assessment, with interviewees reporting concerns that mental health symptoms may be difficult to capture in assessments that rely on predefined multiple-choice questions:

[...]it’s difficult if you’re, what you’re experiencing doesn’t fit in with the responses that have been configured. [Transcript 1]

I’d be concerned about using the app on its own to do a mental health assessment just because I think it can lack nuance sometimes. [Transcript 16]

One potential method, offered by an interviewee, to address the challenges of subjectivity outlined here was to allow for clinician-facilitated symptom reporting, wherein the app user and clinician could collaboratively complete the mental health assessment. This collaboration would allow the user to provide...
details of their symptoms or experiences, which the clinician can use as a basis to answer the questions within the assessment:

"[...] the GP, for example, could go up to [...] his or her clients and say, ‘Oh, what do you want me to put to this question’ and that, they’ll just give you, the client will just give you a tidbit and then they’ll just put that down. I think that would help." [Transcript 13]

In terms of scientific rigor, interviewees expressed concerns about a mental health assessment app’s diagnostic accuracy, stating that apps may be able to suggest a condition that is a probable explanation for a user’s mental health symptoms but that it would likely not be completely accurate:

“I don’t think an app will ever truly get a diagnosis correct. It’ll probably get a rough estimate." [Transcript 13]

Interviewees also raised concerns that due to the overlapping symptom profiles of many mental health disorders, there is a potential risk of misclassification of symptoms:

“I think not too sure about the apps for online diagnoses in general as well. I suppose with a lot of the conditions, the elements of different mental health issues, it might not be that you’ve got say bipolar […] you might have a different mental health condition and you seem to fit the criteria for bipolar." [Transcript 15]

With these concerns about diagnostic accuracy, interviewees reported a preference for apps that provide mental health screening to indicate probable present conditions, which can then be confirmed by a mental health care professional, over formal mental health diagnosis:

“I don’t think a doctor ought to diagnose someone on the basis of an app. I think they both have to go together." [Transcript 6]

In addition, a preference for an indication of where their symptoms lay on a severity scale was also mentioned by several respondents as part of the reported desire for screening, as opposed to a binary “present” or “not present” assessment outcome more akin to a diagnosis:

“I think I’d be more comfortable with saying like, you’re showing depressive symptoms of moderate severity. Here’s a list of the conditions that typically show these symptoms." [Transcript 16]

Interviewees also expressed the importance of evidence-based assessment in encouraging trust in both the assessment itself and the results:

“So yeah, I think it’s helpful if it would, if it was like a regulated test and things like that." [Transcript 4]

The importance of an evidence-based assessment was also highlighted by interviewees if the results of the assessment were intended to be shared with the user’s health care provider (eg, GP, psychiatrist):

“That’s [sending results directly to a health care professional after a digital MH assessment] a really good idea. If the app had been developed by professionals and it had been approved as being scientific, meeting all the criteria." [Transcript 15]

One source of apprehension disclosed by interviewees regarding engaging with mental health apps is the potential for nefarious digital tools (eg, apps, websites). This included tools that were either making recommendations not based on clinical evidence or tools that were perceived to have been designed with the sole intention of making a profit for the developer, rather than to help app users:

“There’s got to be something like that out there, you know, like dodgy websites, which are not quite breaking the law, but they’re not following the proper recommended guidance. Some of them can look really professional but the real interest is money really." [Transcript 15]

“I don’t like the idea of people profiting off of people’s data about mental health." [Transcript 2]

A concern shared by interviewees was the lack of regulation and quality assurance:

“I don’t know who would monitor or approve or disapprove of these apps, because there’s so many thousands, tens of thousands of apps for everything and there’s no sort of overseeing body which could say ‘you can’t say that.’” [Transcript 15]

Some interviewees expressed concerns about the appropriateness of the self-help tips offered in mental health apps. This concern focused on self-help advice offered in mental health apps often being designed for general well-being, and thus, typically not being beneficial for individuals experiencing symptoms of a mental health disorder:

[Mental health apps] try to provide solutions, and they say that “oh, just do a breathing exercise.” And you know, I used to be a yoga instructor. So I know a lot about breathing and breathing exercises, and they’re really good, but if you’re if you’re struggling, if you know if you’re having a panic attack, breathing is not going to help." [Transcript 2]

Concerning the minor theme of background and development, there was interest in ensuring that key stakeholders were included in the development and design of mental health assessment apps. In terms of including clinicians in the design, it was reported as important to verify that mental health assessment apps are designed to best support existing care pathways and address the waiting lists to access mental health services:

“I guess I’d [be] keen to, yeah, to want mental health professionals to have sort of contributed to the app to make sure it is going to reduce waiting lists, rather than just do nothing." [Transcript 16]

Beyond designing an app that can offer benefits within the clinical pathway, there was a mention of the importance of engaging with the intended population during development to establish which features and designs are required for accessibility:
So I guess in the design phases, checking with those individuals with those conditions and sort of saying, is this accessible to you? What would make it accessible to you? [Transcript 16]

Perceived value is a potential facilitator of app uptake. That is, the benefits conferred by demonstrating the efficacy of the mental health app, especially when the app offers therapeutic or self-help functionalities:

I think it always helps to know that it’s been effective for people like [...] especially for doing like therapy skills and therapy techniques. [Transcript 7]

However, the caliber of the evidence required to demonstrate the app’s efficacy was not disclosed, so it is unclear whether positive reviews or word-of-mouth recommendations are sufficient or if a more formal evidence base is necessary to promote engagement with mental health apps.

The perceived value of the app as determined by the user was deemed to impact app use and linked to drop out. Interviewees stated that they had forgotten to use or lost motivation to use apps if they did not find them valuable:

But yeah, I didn’t really find much value in it and I, I forgot to use it [...]. So I just kind of in the end, I just didn’t, didn’t bother. [Transcript 11]

With interviewees additionally stating that if the novelty of the app wears off over time there is a risk of dropout:

I only really used that for a few days. It’s one of those things, you know, download something and it looks really cool and then the novelty wears on really fast. [Transcript 5]

In contrast, interviewees discussed how apps perceived as fun encouraged continued use by incentivizing users to return through gamification:

there’s sort of incentive to play every day and you can buy him [habit tracker app mascot] outfits and stuff like that, and it’s just a bit more fun. [Transcript 4]

**Attitudes**

Attitudes toward using digital technologies for mental health were revealed to be an important theme, with issues surrounding (1) openness to digitalization, (2) interest in using a digital mental health assessment, (3) apprehension, (4) the value of reputability, and (5) stigma emerging as key minor themes.

In this study, attitudes regarding being open to digitalization were overwhelmingly positive:

Yeah, I’m more than happy with that don’t have an issue at all. I think we use apps all the time, don’t we for pretty much everything. [Transcript 11]

In contrast, the importance of being interested in using a mental health app in the first place was highlighted:

[...] don’t want to [use a mental health app]. I’m not interested. I’ve never thought about any of them, and not being interested in using a mental health app when symptoms are not present. [Transcript 6]

I’m not exactly sure why but have a huge desire not to monitor anything when, when I’m feeling fine. [Transcript 6]

Apprehension was revealed to be an important factor in determining mental health app use, particularly regarding the lack of face-to-face contact:

I find the lack of human contact, I find it, I find it the downside of it. [Transcript 14]

and distrust for apps that appear in advertisements:

I’m suspicious of some of the things that I see pushed in ads and things like that. [Transcript 4]

In contrast, regarding the minor theme of the value of reputability, interviewees stated that app endorsement from a source that the individual perceives as reputable, such as a trusted institution (ie, a university, health care service, such as the National Health Service, a mental health charity) or a direct recommendation (ie, from a health care provider, or a trusted friend or family member) could drive their intention to use the app:

I suppose anything reputable. [...] any institution that I feel comfortable with, be it a service or a, or research department, that would influence me? Yeah. [Transcript 6]

If it was given under an accredited body like NHS Wales, and Mind, then that will put a slightly different complexion on it for me. [Transcript 3]

But also friends and family. If they’ve used it, that’s important. [Transcript 11]

Finally, stigma was seen as an important driver of app use, with interviewees expressing that a mental health app could reduce feelings of judgment and isolation:

I don’t know if that maybe helps with the stigma a little bit. If you know that all of your friends have got that app downloaded, then you know that you’re not the only one that’s really struggling. [Transcript 7]

**Safety**

A major theme identified in this study was safety, comprising four minor themes: (1) data security; (2) disclaimers; (3) concerns about the potentially triggering nature of digitally delivered mental health assessment results; and (4) data sharing, consent, and safeguarding.

Interviewees expressed the importance of data security of mental health apps:

Well, all I can say is obviously privacy, confidentiality is extremely important. [Transcript 6]

I can see that the GDPR and privacy concerns would be high. [Transcript 1]

The level of trust interviewees expressed regarding apps’ data security policies varied, with some stating that mental health apps are unable to provide basic data security:

At the moment, don’t quite think we’re here. Not quite there. Purely and simply, from my perspective, in and around the areas of control and security. That’s my...
own perspective. I don’t think we’re ever going to be 100% secure. [Transcript 12]

Interviewees who expressed this sentiment also mentioned concerns about their data being easily available to those with nefarious intentions, such as hackers.

 [...] it seems self-evident that if you’re talking about your own mental health, you don’t want the whole world to be able to hack into it in any way. [Transcript 6]

Other interviewees instead assumed the relevant steps had been taken to protect their data:

I guess I’d be sort of confident if this app came into being with the people behind kind of gone through the process of making sure information is kept confidential. I wouldn’t necessarily have particular worries about kind of privacy or safety. I don’t think. [Transcript 16]

Some interviewees expressed that their use of technology and previous interactions with nonmental health apps (eg, banking or social media apps) influenced their level of trust in data security on mental health apps. They stated that they were already comfortable providing sensitive data to nonmental health apps, and thus, did not understand why providing data to mental health apps would be any different:

I wouldn’t say that I have any major concerns with regards to privacy or safety, I think because so much of my life is on my phone and it’s kind of you know, there’s so many companies that know so much about you know, if you sign up to things on your phone or apps or whatever. [Transcript 5]

In terms of actions, app developers could ease data security concerns, and interviewees mentioned a preference to remain anonymous while using the app. This reduces the potential data security risks related to data leaks:

But in terms of that being traceable, or anything that doesn’t really concern me, I’d just rather not have to put in things like my full name, date of birth card details, that sort of thing. [Transcript 4]

Interviewees expressed that the inclusion of a diagnostic disclaimer was important to ensure that app users were aware that the mental health assessment results were intended solely for screening rather than for diagnostic purposes. Interviewees additionally stated the importance of a mental health assessment app disclaimer communicating to users that any results should be shared with a relevant clinician for further confirmatory evaluations:

I think the app was using it gave you different score [...] 21 to 30 it seems like you’re likely to have ADHD, but you need to go to speak to a professional bringing [screen] shots of this app or take a print out and say perhaps the fourth one was you’ve definitely got ADHD from what you’ve told us, but you still need to be assessed by a professional. So it was like a really gentle thing. [Transcript 15]

Interviewees verbalized concerns over the potential triggering nature of receiving mental health assessment results digitally, using the words “frightened,” “worried,” and “overwhelmed.” There were 2 dimensions related to this issue, namely, concerns about the assessment’s diagnostic accuracy:

 [...] if an app tried to do diagnosis, and it completely got everything wrong, then it could lead to the person getting a bit too overwhelmed. [Transcript 13]

and a potential lack of timely access to clinicians with whom one could discuss and validate the results:

And I can’t see why anybody else would not find it frightening because if somebody was going to use this method, then let’s just you know, you can’t get a doctor’s appointment, a physical appointment about three weeks down here. So I would have to sit on that and then get a doctor’s appointment. So I, I would find it, and also seeing it in black and white what was wrong with me. No, I think that would send me into a spiral. [Transcript 3]

In contrast, another interviewee expressed that receiving the results of a mental health assessment app may be reassuring rather than triggering based on their own previous experience using digital mental health self-assessment tools:

Yes, it [receiving mental health results from a digital tool] wasn’t intimidating if you like. When I got the high score, I thought “Yeah, this is good,” I didn’t see it as a negative thing at all. [Transcript 15]

Interviewees praised the benefits of having an app that is integrated into the existing health care pathway where the results of an assessment would be directly sent to a health care professional:

I’d prefer that [mental health assessment results being sent directly to a clinician] rather than letters really. It’s much quicker, instant information. [Transcript 11]

However, related to the minor theme of data sharing and consent, interviewees indicated that the integration of app data into the existing care pathway must be authorized by the app user through a consent-driven approach to result sharing:

 [...] you shouldn’t be forced into presenting this information [results from a digital mental health assessment to a health care professional]. [Transcript 13]

with a preference for multiple opportunities to provide consent (eg, at the point of download of the app and at the point of sending the data to a clinician) to share their mental health data with a relevant health care professional:

I would just like to consent at the moment of sending. So I think there’ll [have to] be two ways of consent. There is a general consent when I joined the app, right? But there is also a consent before it’s actually actually shared. Yeah, if there are these two layers of consent. [Transcript 13]

A preference for risk safeguarding was expressed with the suggestion that mental health apps should be built with
functionality to override the consent requirement if the user discloses a substantial level of risk:

I also think it should be a bit of a disclaimer like if you disclose a level of risk, we will send it on automatically to a mental health care professional just so people who are disclosing levels, like levels of risk aren’t [just left to it]. [Transcript 16]

as well as including crisis signposting in app:

...when you are logging your mood, if you log you know, really bad, it might prompt you to say, you know, I noticed that you’re not feeling so good, would you like to call this number or would you like to look at this website. [Transcript 4]

In addition, there was a suggestion to pair requesting consent to share mental health data with health care clinicians to facilitate informed decision-making, wherein the app user has the agency to decide which care pathway they prefer to receive help from:

[...] you could have [an option saying “okay, we’ve identified this, where would you, we recommend that you should go to a GP, you know, but we also have these, these options. Where do you consent for us to send your information? [Transcript 11]

Impact

The impact of a mental health assessment app on mental health care provision was deemed an important theme in this study, with interviewees discussing issues about (1) the effects on the existing care pathway and (2) support and signposting outside formal health care. Regarding the former, interviewees positively viewed the impact that mental health assessment apps could have on existing care pathways:

So to actually have that [results of a mental health assessment completed in an app] sort of sent to someone [a clinician] and have that resource available, I think that’d be really, really valuable, actually. [Transcript 5]

I have [had] GPs in the past that haven’t really had much training or like knowledge in mental health. So I think maybe if I could then go to my GP and say, “Well, I’ve done this and it’s said that it indicates this diagnosis” I think it could maybe like make that easier. [Transcript 7]

However, the importance of the role of the health care professional in reviewing any output from a mental health assessment app:

I think it’s really important to pass on this information for the counselor of GP or whatever to look over and then they’ll decide whether that information is accurate [Transcript 13]

It means the human being can just kind of clarify answers and make sure that whatever decision the app has come to is actually accurate [unintelligible] just checking up with the actual person. [Transcript 16]

It should be emphasized that any app integrated into existing care pathways should support clinicians and not replace them:

It’s about accelerating my access to a person or a group of people that can help me and not replacing that with a digital application because I don’t believe in that. [Transcript 2]

Interviewees expressed that completing a digital mental health assessment could facilitate discussions with their health care providers:

One of my big worries is booking doctor’s appointments and struggling to word what I am trying to put across. I think a report sent across with an opinion or something, yeah, to my GP so that I do not have to do it myself and it sounds more reliable, I suppose, would be really, really helpful actually personally. [Transcript 4]

and could help triage patients to appropriate health care professionals or services:

I think on the whole, the app could make an accurate assessment of yeah, which pathway was best. [Transcript 16]

[...] for lower risk perhaps you can still defer, defer them to somewhere else to see if you can offload the pressure load of the GPs and leave it for for higher needs patients, I guess. [Transcript 14]

as well as offering tracking of mental health symptoms during treatment, which can be shared with clinicians to inform:

I can show that [data from mental health tracking app] to her [community psychiatric nurse], and she can take a screenshot for my records, and then we can just discuss if there’s any external triggers or you know how I feel about noticing the slow change in my mood by going back to the app seeing the graphs and the change. [Transcript 15]

In contrast, interviewees expressed concerns regarding the potential of a mental health assessment app to further overwhelm existing services, creating a bottleneck where clinical needs are revealed, which cannot be met by existing mental health services:

[...] is this going to open the floodgates and then there aren’t the services to meet all the huge need that you uncover. [Transcript 6]

There are additional concerns that the quality of mental health care may worsen because of digitization, with face-to-face care being replaced with digital care:

Like if it’s [an app] an option that is there as well as, but I would, I would be, my worry will be if that one, one day that [...] would be the substitute to be seen a person [Transcript 14]

Even when it is potentially inappropriate for higher-severity or complex mental health symptoms:

I guess my like, that my concern is that sometimes would it just become like, they just start signposting
you to the app instead of... even when it is not appropriate. [Transcript 7]

With this in mind, interviewees stated that there was a need for clinicians to refer patients to mental health apps to justify digitization:

I think I would ask why the doctor is presenting me with an app. When it’s something we couldn’t do with ourselves [Transcript 3]

In terms of the impact a mental health assessment app could have on support and signposting outside of formal health care, interviewees discussed the opportunities that mental health assessment apps can offer in terms of encouraging help-seeking:

I think that would be the sort of ideal outcome that I would look for if I was completing some sort of assessment. Obviously, you’re completing it because you think that there might be an issue. And then, at the end of the day, that’s the kind of first port of call that you know, you would go and see a health professional [Transcript 5]

I think it can be difficult sometimes to actually go and ask for it. Even if you know you’re really struggling, it can be hard to actually go and have a conversation. So I think you could maybe help people who are quite anxious about going to see their GP if they know that they’ll get some information first. [Transcript 7]

In addition, interviewees expressed the potential for support to be provided to users while they were on a waiting list for further assessment or appropriate treatment:

 [...] if you’re on a waiting list being told that there are these apps that might be able to help you while you’re on that waiting list to manage, you know, managing emotions or whatever it is, then that would be good. [Transcript 1]

In addition to improving access to faster help by signposting support outside of traditional care services:

it might make it [wait times] shorter because if they are then being directed to other quicker options. That might be better for the traditional services. [Transcript 11]

as well as the app having the potential to provide users with sources of help and self-help tips, rather than solely focusing on an indication of a diagnosis:

 [...] as long as it had additional information and useful links and things like that, that go alongside it, and indicators of where they can go to maybe get help, or you know, to help themselves while they’re waiting to get an appointment, for example, then that would be that would be more useful than just an indication of a diagnosis and nothing else. [Transcript 1]

Potentially, like, self-help type resources as well. So like information, and I guess there are sometimes like courses you can do on like anxiety management, or whatever. [Transcript 16]

Functionality

This major theme included the following minor themes: (1) usability, (2) features, (3) customization, (4) personalization, and (5) interoperability.

In terms of usability, interviewees commented on the importance of app design, with a focus on a preference for a professional interface that may foster a degree of trust in the reputation of the mental health app:

I guess, just the, you know, the app, if the app looked professional, and it looked well done, and you know, it doesn’t look like someone had coded it together in their bedroom or something like that. [Transcript 5]

In addition to the importance of app design, interviewees expressed that ease of use facilitates app uptake and continued app use:

I think there should be an app that’s quite basic and as well as functional but easy to understand. [Transcript 13]

with perceived difficulties in using the app constituting a potential barrier to disengagement with the mental health app:

I think being user friendly is to the real... is the real key and anything that was too wordy to read on a screen I was just Oh well I can’t deal with that. [Transcript 5]

As part of usability, interviewees commented on the importance of in-app guidance to support users in their interactions with the app:

I think it would have been better if it was more guided. You know, so perhaps, set a set schedule of tasks to do or something. I am sure there was a lot of information in it, but it just was the format that[...] I didn’t like really. [Transcript 11]

Therefore, this could be a feature included in the app to promote ease of use, particularly in self-help apps that often reportedly rely on self-motivation:

I think a lot of them are more like self-help geared so I suppose if you struggle to do sort of stuff on your own, then you might struggle to use the apps, because they are very self-guided. [Transcript 7]

Finally, in terms of usability, during the first use of the app after downloading, there was a preference for the ability to explore the app before any sort of commitment was asked (eg, creating an account or having to enter payment information). Part of this preference was related to being able to ensuring that the features included in the app were relevant to the needs of the user and suited their preferences:

I open one and it’s immediately like, sign in, well I might just delete that one because I don’t want to sign in and I’ll go for the next one. Whereas if it’s open up, and I could take a look around the features and then decide, oh, actually, there’s something that I’d like to use, then I’d be happy enough to sign up. Yeah. [Transcript 5]
A common feature mentioned by interviewees was tracking functionality, including monitoring of the user’s mood and mental health symptoms:

"[...] it would be best if you could sort of track your mood over weeks or months or days. Maybe have graphs or a little bit of information available on [...] what’s average for you." [Transcript 4]

In addition, interviewees expressed that an app with functionality to monitor both physical and mental health data would be useful for identifying triggers for changes in mood or mental health symptoms:

"It’s all in one which is quite useful because then you can see like... hmm... I think it helps identify triggers sometimes like, yeah, if I had a really bad night’s sleep, then that might explain why the next day, I wasn’t feeling very good. It’s quite helpful having it all in one place." [Transcript 7]

The final type of tracking that interviewees regarded as helpful was habit tracking, that is, a functionality where a user can set tasks to complete throughout the day with the help of reminders:

"[...] you can set tasks every morning like brush your teeth, get out of bed, go outside, then like by ticking all of those off your little bird buddy goes off on an adventure." [Transcript 4]

Interviewees expressed that in-app reminders are a helpful feature and, in some cases, are the most useful features:

"I think the most useful things for me are setting reminders to take my medication on, on an app." [Transcript 4]

Interviewees also highlighted the importance of social connectedness and the value of a mental health app that offers peer support:

"And so from my perspective, my personal opinion, is that an app would be a value if it helps me connect with other people." [Transcript 2]

In terms of features specific to mental health assessment, interviewees emphasized the importance of comprehensiveness:

"definitely more comprehensive assessments that kind of go through different types of diagnosis and criteria, like sounds like would be a lot more very valuable than just putting everyone in like either depression or anxiety buckets" [Transcript 10]

And having multiple answering modalities beyond only offering predefined answer options:

"It depends on how am I answering these questions? I mean, is it a free text? is it voice? is it video? is it typing? Is it selecting? Because if it’s yeah, if the questions are open and I can be very subjective about it, then I would like that, probably. If it’s just selecting, like PHQ and GAD, that’s kind of, I don’t find value in those." [Transcript 2]

With free-text options being important to add nuance:

"if you had a multiple choice for you to be for there to be an option at the bottom of it to say, you know, why did you answer this way or is there any additional information that you want to give because often there is" [Transcript 10]

However, despite the positive remarks provided about the possible features offered within mental health apps, interviewees reported that some features included within apps previously used by interviewees were counterproductive. Interviewees commented that some app features interfered with the usability of the app:

"[The app] helps you plan your day and to get less distractions and feel more organized throughout the day. It was beeping and it was saying ‘Have you completed the task you set this morning? How do you feel about the task? Did it go well?’ It was all these bully questions. [...] It’s too intrusive. [...] I just found it really annoying. Sometimes I didn’t want to answer any questions. But if you didn’t, you’d get a prompt an hour later or something." [Transcript 15]

Therefore, customization of app features to users’ requirements and preferences (eg, changing reminder frequency, personalizing a crisis plan, changing the design) was also highlighted as an important aspect of functionality to avoid the features becoming irritating or counterproductive, leading to potential discontinuation of use:

"I control the level of notifications. You know, some people might like lots, some might not want any. You know, times of notifications, hints, tips, that sort of thing." [Transcript 11]

"I think having the ability to set notifications at a specific time or just once a day, is really helpful to remind me to actually log what I’ve done and things like that." [Transcript 4]

In addition, customization can offer users the freedom to choose their preferred method of engagement with a mental health app. Interviewees expressed interest in various modalities of information delivery within apps, beyond written text. Specifically, there was an interest in apps offering videos that provide information about mental health disorders:

"I think having a whole library of videos [for mental health information] would help." [Transcript 13]

In addition, interviewees expressed that they would find personalization of a mental health app output (eg, self-help recommendations, psychoeducation) valuable:

"Yeah, I think as I mentioned, sort of programmed approach or maybe personalized in some way, depending on maybe an initial assessment so it’s you know more individualized." [Transcript 11]

Interviewees reported an interest in apps that are interoperable, providing the ability to link mental health apps with other health data collection devices, specifically physical monitoring devices such as Fitbit:

"[...] it could link with, you know, Google Fit, you know, because obviously exercise and you know, ..."
Discussion

Principal Findings

This study aimed to explore the perspectives of individuals with lived experiences of mental health concerns on mental health apps designed for self-assessment and triage. A semistructured interview approach was used, and the findings revealed 6 key themes: availability, accessibility, quality, attitude, safety, impact, and functionality. These themes provide insight into how potential users experiencing mental health symptoms may perceive and use mental health self-assessments and triage apps. These findings can help app developers design and improve these technologies to better support the mental health needs of current and potential future users.

Availability and Accessibility

Concerns pertaining to the theme of “availability and accessibility” were raised by interviewees in this study. They noted that mental health symptoms can make it difficult for individuals to engage with digital mental health assessments and triage tools. Indeed, mental health symptoms and cognitive deficits associated with conditions such as depression and psychosis may make it challenging for people to use such technologies [36]. This highlights the importance of designing accessible and user-friendly digital mental health tools. To achieve this, app developers should consider involving real-life patient populations in the design and evaluation of new technologies [37] to ensure that the tools are appropriate and effective for intended users.

In addition, the risk of digital exclusion was raised by the interviewees, particularly in relation to older individuals who may not be digitally literate. Previous research has shown that older adults are less likely to use technology and the internet compared with younger individuals [38]. To address this, training in digital tools for mental health may prove effective in supporting older adults to engage with these technologies and avoiding exclusion from accessing important support and resources [39]. Interviewees also mentioned that it was important to ensure that digital tools were not the only “front door” to care services, guaranteeing that those who may be excluded from engaging with such tools are still able to access help through existing pathways.

Moreover, interviewees raised concerns about the lack of diversification within the app landscape, in terms of which mental health disorder apps were available. Specifically, many interviewees referred to the perceived lack of available apps designed for neurodevelopmental disorders. To address this, app developers should avoid contributing to the perceived oversaturation of apps for general common mental health conditions (ie, depression and anxiety disorders) and instead identify opportunities to design apps for a more diverse range of conditions, especially as this study demonstrates a clear interest in accessing such apps if they are available. In addition, investigating gaps in the app market and investing in co-designing approaches with users could help improve uptake among typically excluded populations [40,41].

Finally, interviewees suggested that offering mental health apps as an employee benefit can improve accessibility. Previous research has shown that digital interventions for employees experiencing psychological distress can be highly scalable and cost-effective [42-44] conferring positive impacts on well-being and productivity outcomes such as sleep, stress, and presenteeism [44].

Quality

Interviewees identified the “quality” of available digital mental health assessments as an important consideration. They mentioned that the subjective nature of mental health symptoms could make it difficult to accurately assess and diagnose mental health conditions. However, it is worth noting that this has also been mentioned in traditional face-to-face mental health assessments. The risks of inaccurate self-reporting due to recall and perceptual biases are widely recognized [45]. For example, previous work has demonstrated only a moderate correlation between self-reported length of sleep and actigraphy measurements, with individuals overestimating sleep duration [46]. In addition, prior research on bipolar disorder shows that individuals have trouble remembering the details of earlier manic or hypomanic episodes [47,48]. This subjectivity and difficulty in accurate reporting can lead to the misclassification of symptoms and, in turn, misdiagnosis.

Furthermore, interviewees commented on their concerns that the available digital tools designed for mental health self-assessment could provide inaccurate diagnostic results. Indeed, many of the currently available apps designed for mental health do not provide evidence of their efficacy, accuracy, or effectiveness [49,50]. There is limited high-quality evidence on the diagnostic accuracy of available digital mental health assessments, which vary in their performance when compared with a gold standard clinical interview, with some showing poor discriminatory and differential diagnostic performance and others demonstrating excellent accuracy [51]. To address this, interviewees emphasized the importance of ensuring that digital mental health assessments are clinically validated and evidence-based, particularly if the results are intended to be shared with health care professionals. A further way to address this concern is for app developers to create apps that offer screening and an indication of where a user’s symptoms fall on a severity scale rather than a diagnosis, particularly given that interviewees in this study expressed a preference for screening overdiagnosis. To increase engagement and build trust in the app and its assessment results, there should be functionality to easily share results with a health care professional for evaluation and confirmation.

Another concern raised by the interviewees was the potential for nefarious digital tools and inappropriate information or self-help advice targeting vulnerable individuals. Previous work has demonstrated that these concerns may be well founded, as some available mental health apps inappropriately promote the medicalization of normal mental states [52]. These concerns also reflect the current lack of regulation and quality assurance in the digital mental health field [53].
Attitudes

The theme of “attitudes” toward digital mental health technologies was also identified in the study as an important factor influencing the use of mental health assessment and triage apps. Similar to previous research, openness to digital technologies was identified as a key driver of engagement in digital mental health technologies [54]. In addition, and perhaps unsurprisingly, this study demonstrated the importance of interest in using these technologies, with a lack of interest constituting a significant barrier to the initial uptake. In fact, some interviewees described lack of interest as the fundamental reason for not currently engaging or not intending to engage with mental health apps. Previous research has shown that providing relevant and customizable content can increase interest, and in turn, the uptake of digital mental health technologies [55]. Therefore, engaging with stakeholders in the design phase of such technologies is critical to ensure that the content is relevant to the intended user population, driving interest, and engagement. However, it is important to note that in some groups, their lack of overall interest in such digital tools will always remain a barrier, and, as previously stated, nondigital access to services must be maintained so as not to inadvertently exclude individuals.

In addition, the value of reputation was identified in this study, supporting previous studies [55]. Interviewees emphasized the importance of the app being endorsed by a reputable source, such as a research institution, health care provider, trusted friend, or family member. This can help increase trust in the app and reduce stigma. Interviewees also expressed distrust of mental health apps that are advertised in paid advertisements, as advertising may indicate that the app was designed primarily for commercial gain rather than therapeutic benefits. Therefore, the initial engagement and use of an app can potentially be increased by improving the prospective user’s perception of the app’s reputation through endorsements from trusted individuals or organizations and by ensuring that any paid advertisements are not perceived negatively.

Furthermore, beyond just passive reputation, this study additionally determined that an active recommendation of a specific app by one’s health care provider is an excellent strategy to encourage uptake, as this fosters a sense that the app will be both highly relevant and effective in managing the patient’s conditions and needs. This reflects previous qualitative findings regarding the potential importance of a health care professional’s recommendation to encourage interest in and uptake of mobile apps, specifically for managing depressive symptoms in primary care [56]. Given this evidence demonstrating the potential influence of health care professionals on the uptake of digital mental health tools, ranging from assessment and triage to management (ie, symptom tracking and self-care as an adjunct to formal pharmacological or psychological treatment), primary care clinicians should be aware of their capacity to signpost patients and identify appropriate opportunities to do so. There are resources available to support clinicians in identifying high-quality apps to recommend to patients, such as the Orcha app library [57] and the American Psychiatric Association’s app evaluation model screener [58], which could be valuable assets in encouraging digital tool uptake in patients.

Safety

With respect to the “safety” theme, some interviewees raised concerns regarding trust in digital mental health technologies, particularly in terms of data sharing and anonymity. Some individuals may be wary of sharing their sensitive, personal information or seeking support through digital mental health technologies because of doubts regarding the confidentiality or anonymity provided by these apps. Unfortunately, these concerns may be well founded, as despite mental health apps collecting some of the most sensitive personal information, their data security provisions often do not differ from those of nonmental health apps [59]. Interviewees expressed that to address these concerns, digital mental health apps must provide clear and transparent information on how they handle user data. Lamentably, despite interviewees conveying a desire for this information, many mental health apps do not offer a privacy policy to users [60]. Of those that do provide a privacy policy, many demonstrate low readability scores [61], potentially fostering a sense of mistrust in how collected data are being analyzed and used. Conversely, some interviewees expressed a more nonchalant attitude regarding data security.

Interestingly, this study identified how one’s interaction with nonmental health apps can influence one’s perception of the data security of mental health apps, with interviewees claiming that they have minimal concerns about sharing sensitive data as nonmental health apps, specifically social media and banking apps, already collect data of a perceived similar sensitivity. Despite this apparent lack of concern on the part of app users, app developers are still responsible for upholding the required levels of data security.

In addition, interviewees communicated the importance of providing users with the option to opt out of data sharing. Interviewees recommended that, ideally, this opting-in would include asking for explicit consent at multiple time points during the use of the app, before any data were inputted, and then again before sharing any calculated results with a care professional. Currently, many publicly available apps treat continued use as a proxy for the user’s consent [61] to collect and analyze mental health data rather than asking explicitly for consent periodically, despite potential changes to the app’s data collection and analytic strategy, data sharing, or privacy policy. In addition, even if mental health apps were to adopt a consent-driven approach (ie, where consent is obtained at multiple time points), problems related to consent would persist because of the low readability scores of app privacy policies. As discussed above, users may not truly understand what they are consenting to [61]. However, interviewees expressed that, in some cases, it may be necessary to override the user’s consent to share results with a health care professional if they disclose a substantial level of self-harm or suicide risk.

Another requirement raised by the interviewees was the need for a diagnostic disclaimer. This means that nondiagnostic mental health apps should clearly state that their assessments are intended for screening purposes only and should not be used as a substitute for a professional diagnosis. Many available mental health apps lack such disclaimers [62]. Providing such a disclaimer clearly in an app store description can help prevent
users from overreliance on the results of these assessments and may encourage them to seek confirmatory assessments or support from qualified professionals.

Impact
The theme of “impact” was also identified in the study, with interviewees commenting on the effects that digital mental health assessments can have on current care pathways. They suggested that digital mental health assessments can facilitate informed discussions with health care professionals, echoing a sentiment identified previously in the user feedback of a novel digital mental health assessment [63].

However, some interviewees also expressed concerns that mental health apps could further overwhelm existing mental health services, particularly if they led to an influx of new users seeking support. One method proposed by interviewees to proactively avoid overwhelming services was to co-design apps intended to be implemented in existing clinical pathways with relevant care professionals. This would ensure that they are a valuable tool and not a hindrance to the established delivery of care [64]. Although digital mental health technologies will not immediately solve issues of long waiting lists and a lack of trained mental health care professionals, they can allow cost-effective and time-efficient collection of patient and symptom data. In addition, interviewees expressed concerns that the digitization of existing mental health services may result in poorer care, particularly for those with more severe or complex mental health symptoms. This view supports the notion that digital tools should be used for augmentation, rather than replacement, of existing services to support clinicians in the delivery of care.

A concept that was discussed positively by interviewees in this study was the potential of apps to support the waitlist management of mental health services. Mental health triage apps have the potential to direct patients to the most appropriate formal care pathway or other services (ie, local charity, self-help resources, psychoeducation) based on their symptom profile, potentially alleviating the burden on the health care system by providing individuals with mild or subthreshold symptoms with self-help tips and psychoeducation, reserving GPs, or specialized services for more severe or complex cases. Moreover, interviewees overwhelmingly expressed an interest in mental health apps that can support users while they are on the waiting list before receiving formal treatment by offering not only an assessment and triage, but also self-help tips, psychoeducation, and sources of help. Psychoeducation has been demonstrated to increase mental health literacy, decrease feelings of stigma, and increase intention to seek help [65]. In addition, psychoeducation has been shown to improve outcomes in bipolar disorder, as measured by hospital admissions [66]. Considering the wait time between assessment and psychological treatment in the United Kingdom and the associated potential for the deterioration of symptoms and well-being [4,5], any opportunity to arm individuals with resources to support their own mental health should be explored. However, beyond the potential to improve patient experience while on the waitlist, more work should be done to investigate the therapeutic benefits of providing self-help information to patients awaiting formal treatment.

Functionality
Finally, in terms of “functionality,” similarly to previous work, interviewees mentioned that ease of use and in-app guidance would increase app use [55], especially for apps that require a high level of motivation, such as mental health apps. In terms of assessment specific features, interviewees mentioned the importance of comprehensive assessments to ensure that the complete picture of mental health symptoms and contributing factors is captured. In addition, interviewees highlighted the importance of including varied answering modalities to capture the nuances of experience associated with specific symptoms. This reflects the sentiment from user feedback of a digital mental health assessment, which found that questions with predefined answer options cannot always correctly capture symptoms with requests for the ability to add free-text data [63]. This study demonstrated that users are keen to engage with apps that offer a wide range of complementary functions beyond self-assessment to support mental well-being. The desirable app functions mentioned by the interviewees included mental health symptoms and habit tracking. Mental health symptoms and mood tracking are popular features of mental health apps [29] and can be valuable to users who wish to increase their awareness of their mental health concerns [67]. Beyond only mental health symptom tracking, interviewees expressed a preference for apps with the ability to track physical health alongside mental health in a single app, thereby providing more comprehensive insights (ie, menstrual cycle, exercise). Further demonstrating the importance of ease of use from the perspective of interviewees in this study, apps that offered interoperability and facilitated the ability to link mental health apps to other health data collection devices (eg, Fitbit) were preferred. This data sharing between devices could combine physical health data (ie, heart rate, sleep amount, and quality) with manually entered mental health symptom data to help individuals identify mood triggers and patterns as well as self-management of their mental health symptoms.

In addition, the opportunity to gain peer support through mental health apps was considered important by interviewees as it has the potential to address the missing “human” aspect of digital mental health technologies. In addition, some interviewees mentioned that in the past, using social media for peer support enabled them to learn more about their illness from other individuals who had similar symptoms, which is why they thought it would be beneficial to have a mental health app. Peer support has been shown to improve feelings of hope, empowerment, and social functioning [68], with the consolidation of early stage evidence investigating digital peer support demonstrating acceptability and positive effects on functioning and outcomes [69].

Although reminders were viewed as an important and useful feature of mental health apps, interviewees stated that too many reminders and notifications were also considered intrusive and could lead to app discontinuation. However, facilitating the customization of these features could promote engagement, further corroborating previous findings [63]. In addition, offering
different modalities (eg, text, audio, and video) is seen as an important factor in engagement and app usage. Therefore, app developers should ensure that such features are easily customizable to optimize usefulness from the user’s perspective (ie, by ensuring that reminders to use the app are delivered when the user can do so) and are not overwhelming.

As discussed above, there was interest from interviewees in resources to support self-management of mental health symptoms while on a waiting list (ie, self-help tips and psychoeducation). However, it is important to note that personalization was expressed as important to interviewees, with a preference for personalized rather than generic self-help tips and psychoeducational information. Therefore, although there may be temptation from app developers to create apps using generic self-help, this may impede interest and eventual engagement with their app. Therefore, offering self-help tailored to specific conditions or populations is preferable. Doing so may also go some way toward alleviating some of the concerns expressed by interviewees in the quality theme concerning the appropriateness of self-help offered in apps, providing app users an opportunity to more confidently choose apps based on what is most relevant to them, as well as ensuring that the information is suitable for their mental health symptoms beyond general mental well-being.

Creating an account by entering personal or payment information could be a barrier to app use identified in this study due to a sense of suspicion in users about data mining, reflecting previous work [29]. Interviewees expressed an interest in being able to access the app initially without creating an account, wherein they could ascertain the relevance of the app to their individual needs and preferences before choosing to provide personal details and payment information where applicable.

**Implications for Practice**

Apps adopted for mental health assessment and monitoring present an interesting use case of mobile health technology, and our understanding of their acceptability and perception of benefits and barriers to adoption continues to evolve. Findings from these interviews generated valuable insights into putative users’ perspectives, concerns, and preferences regarding the use and design of apps for mental health assessment. Taken together, these results demonstrate that there is real interest in tools designed for mental health self-assessment and triage, particularly when:

1. The self-assessment and triage tool is offered with additional complementary app features that are personalized or can be customized to the individual user.
2. Self-assessment is comprehensive and includes answering modalities beyond selecting predefined answer options to capture the nuances of symptoms and experiences.
3. The tool is easily accessible, as it does not require the entry of sensitive or financial information for use or is offered via a workplace well-being scheme.
4. The tool is recommended by or associated with a reputable source, either passively (ie, developed with expert academics) or actively (ie, a direct recommendation from a friend or trusted health care professional).

However, despite this interest, individuals have real concerns that may impede their uptake and prolong engagement. This study also elucidates some simple ways in which these concerns can be addressed:

1. It appears that by engaging in clear, transparent, and accessible communication about the app’s evidence base and privacy policy in the app description, some of the concerns related to “quality” and “safety” can be addressed before the user even downloads the app.
2. Apps that collect sensitive mental health data and have the functionality to share such data with an individual’s care provider should ask for consent multiple times to establish permission to collect, analyze, and then share.
3. Engaging in co-design activities with both users and clinicians can ensure that the app is (1) widely accessible to many users regardless of the severity or complexity of their mental health symptoms, their level of digital literacy, or the specific condition, and (2) can be effectively integrated into care pathways to support care professionals in the delivery of care. Ensuring access to publicly available digital mental health assessment and triage tools can be achieved through a diverse app marketplace offering that includes typically overlooked conditions such as neurodevelopmental disorders.

Technology integration into mental health care presents opportunities and challenges rooted in the intersection of technical and human factors. Building trust with key stakeholders, such as clinicians, patients, and commissioners, on whom the success of digital integration into existing services will depend, is crucial [70]. Careful design, evaluation of tool performance, and establishing relevance to the population of interest [71] are essential to harness a technology’s potential for improving mental health care delivery and minimizing the possible integration challenges arising from the interaction between technical and human factors. In this study, interviewees seemed to positively view the role that digital tools designed for mental health self-assessment and triage could play in established care pathways if responsibly co-designed with health care professionals for successful integration to not overwhelm services. Indeed, technology can sometimes create a barrier to forming a strong therapeutic alliance between patients and health care professionals. In this regard, efforts should be made to ensure that technology augments rather than replaces human interactions. A crucial aspect of this will be interdisciplinary collaboration and co-design of tools and integration strategies. In addition, although the potential for service digitization is certainly attractive, it should be approached cautiously. Interviewees in this study reported concerns regarding lower quality of care resulting from the integration of digital delivery, and continuous monitoring and appraisal of care quality are vital following the deployment of digital tools. In addition, engaging in conversations to explain the rationale and benefits of using digital tools in the delivery of digital care will likely build trust and drive uptake in its use.

**Strengths and Limitations**

This study has several strengths. For instance, the use of a qualitative approach allows a nuanced and in-depth exploration...
of a range of potential users’ perspectives on mental health apps specifically designed for self-assessment and triage. Qualitative research is a powerful tool for generating insights and informing practical solutions and real-world actions. By emphasizing participant perspectives, qualitative research can capture thoughts, feelings, and context, pinpointing subtleties that quantitative methods may miss. In addition, the use of PPI in this study allowed for optimization of the study design and materials, including the suitability and relevance of the interview questions to the population of interest.

Despite these strengths, the results of this study should be viewed through the lens of the questions asked in the semistructured interview as they may have shaped the findings. For example, as we specifically asked interviewees about their views regarding the privacy and security of digital tools, it may have overrepresented the importance of this theme when some individuals would not have mentioned it if not prompted.

Furthermore, insights from this study were drawn from a small cohort of participants and therefore cannot be generalized more broadly, particularly as the entirety of the sample was White. In addition, these exploratory interviews provide insights from a population recruited through web-based social media, mainly through Facebook advertisements. Thus, the resulting cohort may be biased toward individuals who are familiar with digital technologies; thus, the findings may indicate a more positive perspective than that observed in a formal health care setting. However, the cohort in this study offered a wide range of perspectives, including individuals without previous experience interacting with mental health apps and services.

Conclusions
The adoption of mental health assessment and triage apps presents a significant use case for mobile health technologies. Insights from this study indicate user preferences for mental health apps with personalized features, easy accessibility, and that are recommended by or associated with institutions or individuals perceived as reputable. Concerns about quality, safety, and data privacy can be addressed through clear communication, consent-driven data collection and sharing processes, and co-design with users and clinicians. The positive perception of digital tools in established care pathways highlights potential opportunities for commissioning mental health care services and waiting-list management. However, further research is needed to assess the suitability of digital assessment and triage tools for different psychiatric populations, and to determine their impact on clinical outcomes. In addition, steps must be taken to ensure that concerns regarding the potentially detrimental impact of digitization on care quality are addressed when referring or signposting to digital mental health tools.

Abstract

Background: Supported self-management interventions, which assist individuals in actively understanding and managing their own health conditions, have a robust evidence base for chronic physical illnesses, such as diabetes, but have been underused for long-term mental health conditions.

Objective: This study aims to co-design and user test a mental health supported self-management intervention, My Personal Recovery Plan (MyPREP), that could be flexibly delivered via digital and traditional paper-based mediums.

Methods: This study adopted a participatory design, user testing, and rapid prototyping methodologies, guided by 2 frameworks: the 2021 Medical Research Council framework for complex interventions and an Australian co-production framework. Participants were aged ≥18 years, self-identified as having a lived experience of using mental health services or working in a peer support role, and possessed English proficiency. The co-design and user testing processes involved a first round with 6 participants, focusing on adapting a self-management resource used in a large-scale randomized controlled trial in the United Kingdom, followed by a second round with 4 new participants for user testing the co-designed digital version. A final round for gathering qualitative feedback from 6 peer support workers was conducted. Data analysis involved transcription, coding, and thematic interpretation as well as the calculation of usability scores using the System Usability Scale.

Results: The key themes identified during the co-design and user testing sessions were related to (1) the need for self-management tools to be flexible and well-integrated into mental health services, (2) the importance of language and how language preferences vary among individuals, (3) the need for self-management interventions to have the option of being supported when delivered in
services, and (4) the potential of digitization to allow for a greater customization of self-management tools and the development of features based on individuals’ unique preferences and needs. The MyPREP paper version received a total usability score of 71, indicating C+ or good usability, whereas the digital version received a total usability score of 85.63, indicating A or excellent usability.

Conclusions: There are international calls for mental health services to promote a culture of self-management, with supported self-management interventions being routinely offered. The resulting co-designed prototype of the Australian version of the self-management intervention MyPREP provides an avenue for supporting self-management in practice in a flexible manner. Involving end users, such as consumers and peer workers, from the beginning is vital to address their need for personalized and customized interventions and their choice in how interventions are delivered. Further implementation-effectiveness piloting of MyPREP in real-world mental health service settings is a critical next step.

Introduction

Background

Serious mental health conditions, including schizophrenia, bipolar disorder, and major unipolar depression, are associated with longer term use of mental health services [1]. Despite this substantial need, service provision is limited by funding and workforce constraints, and additional ways of supporting individuals with serious mental ill-health are required. Self-management programs have been developed to assist individuals with serious mental health conditions to actively understand and manage their own health [2]. Core components of self-management include psychoeducation, relapse prevention; the identification and avoidance of stressors; the development of effective coping strategies; and, often, a recovery element [3,4]. There is now substantial meta-analytic evidence that the provision of supported self-management programs (ie programs with guidance from a health professional or another helper) alongside standard care improves outcomes for people experiencing serious mental health conditions, including significant reductions in symptom severity, shorter length of admission, improved functioning, and better quality of life [4].

As a result of this robust evidence base [4], global health policies increasingly emphasize the importance of self-management interventions to support individuals with severe mental illness in managing their own health [5,6], and they are now included as a best practice recommendation in clinical guidelines (eg, the United Kingdom’s 2014 National Institute for Health and Care Excellence (NICE) Guidelines for Schizophrenia [7]). Despite this recommendation, self-management interventions are not always offered as a standard in services for people experiencing serious mental ill-health [4,8]. This is in contrast to services for people experiencing chronic physical illnesses, such as diabetes [9], where self-management programs are a core component of routine practice. Overall, self-management programs have the potential to benefit individuals experiencing serious mental ill-health and reduce strain on health services and have an economic rationale for reducing treatment costs [10], but implementation challenges remain.

Self-management programs typically involve the use of a collaborative learning process that encourages people experiencing serious mental ill-health to become experts in their own recovery [2,11]. Evidence suggests that supported self-management programs, with guidance from a health professional or another helper, are preferable to independent self-management for people with serious mental health conditions [2,12]. Self-management programs in which support is provided by a peer support worker (PSW) who has experienced a mental illness themselves have demonstrated promising evidence of effectiveness [12-15].

An example of a program that showed effectiveness was the Crisis Resolution Team Optimisation and Relapse Prevention (CORE) peer-supported self-management program [2,12,16], which was implemented in a large-scale (N=441), UK-based, randomized controlled superiority trial. This trial found that peer support using a structured workbook aimed at helping consumers develop self-management strategies to support their recovery beyond the immediate crisis led to a significantly lower rate of readmission to acute care within 1 year compared with self-management alone (29% for peer-facilitated self-management vs 38% for self-management control) [12]. Replication of the CORE study findings in routine settings across the UK National Health Service services and internationally has the potential to substantially reduce the burden on the acute care system. However, it is recognized that different countries may have specific nuances based on their cultures and systems [17,18]. As such, optimizing the delivery of the intervention in these different settings would benefit from consumer-driven consultation and co-production to translate the consumers’ needs into intervention components and refine the intervention accordingly before any research and implementation occur.

The peer-supported self-management intervention used in the CORE trial was systematically adapted in a stepwise co-production and piloting process in partnership with PSWs [2] from an existing recovery resource developed by Julie Repper, Miles Rinaldi, and their colleagues in South West London [19]. This existing paper-based resource “Taking Back Control” was itself co-produced with people with lived experience expertise; has a strong recovery focus; and incorporates self-management tools, including relapse...
prevention planning, goal setting, wellness planning, and a component for recovery from a mental health crisis [2].

Since the original resource was developed in 2007, the proliferation and advancement of technology, particularly smartphones, have provided an opportunity for digital interventions to become more accessible and acceptable to people experiencing serious mental ill-health [20]. People experiencing psychosis have adopted digital technology comparably to the general population [21], and mental health interventions delivered via smartphones are acceptable and feasible for people with psychosis and have the potential to support recovery [22-24]. However, access to technology has been found to vary among people experiencing schizophrenia by age, and a proportion do not use technology to manage their condition [25]. Therefore, it is imperative to allow people to choose between paper-based and digital self-management resource mediums depending on their preferences and circumstances. Further, as the delivery of self-management interventions does not have a typical medium (digital, paper-based, verbal, or flexible delivery), delivery mode (face to face, digital, telephone, or hybrid), or support (self-directed, clinician, peer supported, or blended) [4], offering a suit of flexibly delivered personalized programs may help maximize the reach, acceptability, and appropriateness of self-management interventions when delivered in real-world services.

This study reports the translation of the CORE study self-management resources from the United Kingdom context to the Australian context, including the adaptation of paper-based resources used in the original CORE trial and the development of a digitally based resource guided by the original paper-based tools to provide flexible delivery options for consumers. Following the strong tradition of co-production [2,19], participatory design methodologies were selected for this study to adapt both the paper-based resources and develop the digital self-management resource. Integrating user feedback into the design of digital mental health interventions is the gold standard [26-30] and improves engagement with digital tools for serious mental ill-health [31]. Best practice recommendations emphasize that researchers should publish descriptions of development work, including a description of how design features are influenced by user feedback [32].

**Goals of This Study**

The overarching aims of this research study were to (1) translate the CORE paper-based and peer-facilitated self-management resources to the Australian context for successful implementation and (2) co-design and user test a digital prototype of the CORE peer-facilitated self-management resources.

**Methods**

**Study Design**

This study adopted a participatory design, user testing, and rapid prototyping methodologies. Two frameworks (Figure 1) provided an evidence-based structure for the co-design process: (1) the 2021 Medical Research Council framework for developing complex interventions [18], including developing, testing the feasibility, evaluating, and implementing the intervention (note that this study focuses on the development and feasibility stages of this framework) and (2) the co-production framework [33], which seeks consumer leadership and input from the outset, including co-planning, co-design, co-delivery, and co-evaluation. In this study, co-planning involved collaborators and researchers with lived experience informing the protocol and study design, ethics application, and recruitment; co-design involved the recruited people with lived experience defining, conceptualizing, evaluating, and designing the prototype; co-delivery involved lived experience researchers facilitating the aforementioned co-design research; and co-evaluation involved the knowledge transition team having representation from people and researchers with lived experience for analyzing and writing up the results.
Participants

The inclusion criteria for study participation required participants to be aged ≥18 years; self-identify as having a lived experience of using a mental health service, experiencing a mental health condition, or working in a mental health peer support role; have English proficiency; and be able to complete the informed consent processes.

Co-Design and User Testing Stage 1

The first round of co-design and user testing of the original co-designed UK version of the CORE paper-based self-management resource (which had five sections: (1) moving on again after a crisis, which focused on resuming routines and community support; (2) keeping well, which focused on activity scheduling and health-promoting behaviors; (3) managing ups and downs, which focused on relapse prevention; (4) goals and dreams, which provided goal-planning tools; and (5) making a personal recovery plan, which provided psychoeducation in a recovery-focused manner) [2,19] was conducted with 6 participants through audio-recorded, one-on-one, and 90-minute user experience sessions, which were held face to face or via a digital video chat depending on participant needs. Interviews were conducted by either a lived experience facilitator or a mental health clinician. During the sessions, facilitators engaged the participants in 3 phases of participatory design processes, namely discovery, evaluation, and prototyping. In the discovery phase, the facilitators used open and prompted discussions to explore participants’ practices, goals, values, and needs in relation to the self-management of serious mental health conditions. In the evaluation phase, participants tested and evaluated the self-management resource, focusing on its strengths and weaknesses. In this phase, the think-aloud methodology [34] was used to gauge the usability and desirability of the design of the paper-based self-management workbook. After this, the facilitator focused on early prototyping with participants, discussing what a digital version might look like to inform the development of a potential digital prototype. Before the end of the first round of co-design and user testing, participants were asked about their basic demographics and their views on the usability of the CORE paper-based resource through an adapted version of the System Usability Scale (SUS) [35].

Knowledge Translation Stage 1

A knowledge translation team (which included representative stakeholders with lived experience, peer support, clinical, research, and technology backgrounds) was formed and regularly met with the lead researcher (first author) via digital meeting platforms. The knowledge translation team updated the UK version of the CORE paper-based self-management resource to an Australian version based on the stage 1 feedback. Further, the knowledge translation team engaged in an interactive process of synthesizing, exchanging, and applying knowledge [36]. The ultimate goal was to translate user testing feedback into practice,
organizational management, technology development, and policy reform [36]. During stage 2, the tool was renamed My Personal Recovery Plan (MyPREP, which will be used henceforth) by the knowledge translation team.

User Testing Stage 2
A subsequent round of user testing of the high-fidelity digital prototype took place with 4 new participants using the think-aloud methodology to gauge the usability and desirability of the design of the Australian paper-based self-management workbook. After the tool was adapted based on the identified problems and suggestions, a group of 6 PSWs who would be piloting the tool in their community mental health service were provided with access to the digital and paper-based tools for a final round of qualitative feedback.

Data Analysis
The audio-recorded sessions were transcribed and anonymized. The qualitative data were subsequently interpreted using a previously established knowledge translation process for participatory design studies [37]. Specifically, the knowledge translation team developed a coding framework outlining all key concepts. Data were coded in the NVivo software (version 12; QSR International) using this framework. Data interpretation followed established thematic techniques [38], which involved an iterative and reflexive process of reading, coding, exploring the pattern and content of coded data; reflection; and discussion. Similarities and differences in opinions were examined, and differences were dealt with through discussion to reach a consensus. The knowledge translation team also identified themes and key learnings to inform the customization and configuration of the paper-based MyPREP program and the digital high-fidelity prototype. Acceptability scores were calculated using the standard SUS process [35]. Frequency and descriptive analyses of the quantitative data generated in user acceptance–testing sessions were conducted in SPSS (IBM Corp).

Ethical Considerations
Ethical approval for this study was obtained from the University of Sydney’s Human Research Ethics Committee (HREC reference number 2019/571). Informed written consent was obtained in advance from all the participants in the qualitative sessions of this study. We assert that all the procedures contributing to this work comply with the ethical standards of the relevant national and institutional committees on human experimentation and with the Helsinki Declaration of 1975, as revised in 2008.

Results

Participant Demographics
All 10 participants in the first 2 rounds of user testing identified as having lived experiences of a mental health condition and mental health service use, with 3 (30%) of the 10 participants identifying as male, 3 (30%) residing in regional areas of Australia, and 6 (60%) having a job as a PSW. The final prototype was then appraised by 6 (male: n=3, 50%; female: n=3, 50%) additional PSWs, all working in urban and suburban areas of Sydney, New South Wales, Australia.

Main Themes
The key themes identified throughout the co-design and user testing sessions were related to (1) the need for self-management tools to be flexible and well-integrated into the mental health services used by participants, (2) the importance of language and how language preferences vary among individuals, (3) the need for self-management interventions to have the option of being supported when delivered in services, and (4) the potential of digitization to allow for a greater customization of self-management tools and the development of features based on individuals’ unique preferences and needs. Further, summaries of the full recommendations of adaptations to the MyPREP paper-based and digital prototypes are presented in Multimedia Appendix 1.

The Need for Integrated and Flexible Self-Management Tools
Most participants confirmed that there was a lack of routine provision of self-management tools supporting recovery in community mental services, and these tools should be offered as a standard as early as possible:

- Honestly, I think it might have been really beneficial to start [using self-management tools] while I was inside [the hospital]. You know that that way I’m not sort of just being discharged into sudden loss of support. I’m being discharged with a plan I have got a set of actions and a structure to go back to. [P3, user testing round 1]

These participants expressed that there was a strong need for the flexible delivery of self-management tools in mental health services. That is, services should not provide just one type of medium to deliver interventions, as the needs of individuals are not uniform:

- Individuals may experience barriers [to using self-management tools] due to their lack of use in technology. Or finding it challenging to adapt to technology this resulting in becoming fearful of using technology. [P4, user testing round 2]

From what I’ve observed, especially if it’s like 60 and above, they love paper versions, even though like, I mean, some are tech savvy. Yeah, they do feel that comfort in what they know as well. But I guess it’s just about educating them a little bit more about the technology and allowing them to adapt as well. So having both options is always, always better than not having an option. [P4, user testing round 2]

Self-management tools also need to be well integrated with other plans and documentation offered in services, and digital platforms could enable this integration:

- We get given a lot of stuff when we’re coming out of the crisis, particularly for going to hospital discharge. You’ve got a discharge plan, you’ve got all your appointments, you got your medication sheets. You may even have a safety plan depending on which
Language
A major theme identified in the co-design and user testing sessions was language. Some words need to be changed to reflect the common language in Australia compared with the United Kingdom. People preferred less formal and less clinical language. Participants also liked that the language used generally did not make assumptions about the person’s situation:

I like that it’s like everyday language ‘the things I need to sort out.’ Yeah, I like that. [P1, user testing round 1]

[When speaking about the ‘people and places I can turn to’ page] I really like it. And what I like about it is it’s not assuming that those people are family members. You you’re not making people feel worse by, you know, having to put down friends or colleagues or neighbors or whatever; because family is not in your life. So ‘what support would I like?’ Yeah, that’s great. Nice basic phrasing there. [P4, user testing round 1]

The participants also discussed the importance of not having too much text on each page, as it can become overwhelming and distracting for users, especially as impaired cognition and concentration can be symptoms of mental health conditions. Decreasing the number of words on the screen should be a priority for increasing usability. This could be done by incorporating images, especially infographics, and additional features, such as read-out-loud audio and avatars:

Language, is really, really important. The less that’s on a screen or on a paper or on a document is better. Yeah, because you can’t take it in. It’s too much noise. It’s too busy. And if my concentration is already impaired, it’s not going to help me stay engaged. I’m just, I just won’t get engaged. [P2, user testing round 2]

One of the participants said the following about the name of the tool:

I don’t like the words. Actually, at first I don’t like the word recovery, I don’t like the personal, and I certainly don’t like plan... [the workbook needs] something more casual...it’s the balance between not being too positive that can be invalidating too. [P1, user testing round 1]

Further, participants emphasized that the language used in self-management tools needs to be empowering, promote self-agency, and be sensitive to the mental health situations of people, as mental health can fluctuate. Although it was generally agreed the language was used in MyPREP met this need, there were few words identified by some participants as having the potential to be disliked by some users of the tool, such as “recovery,” “triggers,” “moving on after a crisis,” “plans,” and “goals”:

And now going back to the word recovery, if we’re going to be changing it in certain instances, personal recovery. And it’s interesting because now we are having this challenge around the word recovery. Yeah, some of us are now saying, hang on, many of us are not recovering from anything. If we want to look after health and wellbeing proactively, yeah...where are you on your journey? Exploring your health journey? Or your life journey, whatever it is that you want to use. [P2, user testing round 2]

Views on language were mixed, with some reporting that they liked the language that others did not: “oh I like the words ‘moving on’” (P1, user testing round 1). Moreover, some participants reported that some terms should remain in the tool. For example, some felt that the term recovery should remain, as it promoted autonomy:

You know, I think recovery is like very self-empowering. And that puts a lot of independence on people. ...And so just thinking about perhaps placing the autonomy a little bit more on the individual as well. So that is self-directed, that is more self-directed yeah. [P1, user testing round 1]

Working on the tool with support (particularly from a peer worker) would enable these conversations about language to occur.

Supported Facilitation
Self-management tools need to be customized and personalized to the individual, and many participants felt that this needs to be carried out through conversations with facilitators and supporters, such as PSWs:

Yeah, I think, um, this [using MyPREP] would be excellent to do again, through a conversation. Yes like where, if the person accessing the service would be talking with a peer worker and then, so, yeah, ‘I believe this is what recovery is,’ ‘what you think recovery is about,’ ‘what is recovery for you,’ that sort of thing. [P2, user testing round 1]

These conversations “made it [the paper-based self-management workbook] so much more human” (P1, user testing round 1), especially because facilitators such as peer workers can tailor conversations based on individual needs while using the tool as a guide:

Yeah, I would tailor it. So it’s. Yeah, that is more for a conversation. Yeah, where the peer worker could be like, ‘So what are some signs that I could look for in you that might make me think you’re not going so well?’ [P2, user testing round 1]

Further, the accompanying psychoeducation component that helped contextualize the workbook was located at the end of the booklet in the original UK resource. Participants highlighted that this needed to be integrated with the MyPREP module activities (note that this was actioned for both the digital and paper-based Australian versions of MyPREP). Moreover, it was
emphasized that the content of this psychoeducation component could be discussed with someone such as a peer worker, clinician, or supportive other:

I think that [psychoeducation] needs to be at the front [of the MyPREP tool]. Yeah, the way I would work with it is in that context, I’d be looking through it and go, oh okay, I’ll go to the next page and then I’ve probably filled in a lot of that stuff before I’ve got to the end. It is where all the guidance around this...It might not be read, so just all of this content could be put in within the chapters. Yeah, that or a statement at the front of the elements that you feel from the information on how to help you fill it in was confined to the back of the book. A plain guide just say, Look, don’t just launch into it. But there’s some further guidance and support there on the back of the book that you can work with a friend or someone through it all with your worker. You know, because that is a lot of text there, and we are assuming the people have the ability to read and comprehend all that information. [P4, user testing round 1]

**Additional Desirable Features and Functions When Digitized**

Additional features and functions beyond those of the paper-based MyPREP workbook were highlighted by participants during the co-design process. Exemplar additional features and functions are displayed in Figure 2 and described in detail below (refer to Multimedia Appendix 2 for enhanced visibility of features on each page).

**Figure 2.** Exemplar additional features and functions. MyPREP: My Personal Recovery Plan.

On the basis of the feedback gathered during the user testing sessions, **customization** by the users themselves was enabled in the digital version so that they could adapt the content to their preferences. End users could make changes by configuring the color pallet and the voice and image of their avatar and were able to alter and flexibly select the MyPREP modules. The ability of end users to customize MyPREP was seen as very important, as it enabled a feeling of ownership over the tool. For example, the color pallet could be changed to reflect not only the preference but also the mood of the participant, which was seen as important in mental health:

I think it’s like there’s dark colors and light colors pastel. Yeah, I like that. I think that’s really nice because it’s like I said, you’re going towards personal, like being personal. And this gives choice of being personal as well. It’s cool. [P4, user testing round 2]

When you are unwell, you only see fog, color can break through. [P1, user testing round 2]

The customization of the image and voice of the avatars in the program was seen as trauma informed (as it had the potential to decrease inadvertent traumatization if someone had a previous traumatic experience with a person of a particular sex) and gender inclusive (as voice and image could be changed) and helped tailor the avatar according to the individuals’ backgrounds, such as their age. This was seen as an important feature, and additional languages could be easily integrated into the MyPREP package in the future:

You just have to think of the LGBTQ plus community as well... I think that’s because if you do like a said male or female, it’s just like ‘why only two?’ Yeah, you know, but then if it’s like I said a plant [an alternative avatar on MyPREP], it’s very cute and it has a smiley face. And I really like that because I think especially in the new generation, if you think
about it, a lot of like animations are popping up as well. So, if you want to adapt to the younger generation, they might really enjoy this thoroughly. [P4, user testing round 2]

A new feature, which was not possible in the paper version but enabled through digitization, was a “need help now” button, which was suggested by participants and provides the contact details of crisis support and additional mental health support services. This feature was developed after participants in the user testing sessions recognized and acknowledged that creating a MyPREP plan could potentially be confronting, and the individual may want additional support from others to process the information or additional mental health crisis support:

If I’m not in a good space and I’m trying to read it, I want to know I’ve got a safety button. I can go to hey, look, I’m feeling like shit, OK, and I might be reading this and you know what? I actually want to talk to someone, or I want to write to someone or chat to someone. Yeah, and I get blocked. Yes. I think, you need to have a safety, safety spot, do you need help now? Something. The hope is you read it, but it’s also a risk thing that, yeah, I think you need this. [P2, user testing round 2]

Two other new features were “my emergency contacts” and “supporter circle.” The emergency contacts feature allows users to enter the contact details of people and services they can contact during a mental health crisis. In addition, the supporter circle function was designed to allow users to share their recovery plan entries with people in their support circle (such as carers, health professionals, and peer workers) so that they could view their MyPREP entries. One of the participants expressed that it was important that the user be prompted to input contacts for both features when signing in for the first time to provide a safety net if the user became distressed in the process of completing the plan and suggested displaying these important contacts on the dashboard at all times to provide a sense of support to users:

OK, I would want them to have their emergency contacts sorted and their support circle sorted because they can’t move on after a crisis. If they don’t, if they’re unaware of their support circle, then we can’t help them to do that either if we don’t know. Especially and then managing up and ups and downs like they’re going to need their support circle and their emergency contacts. [P3, user testing round 2]

All participants acknowledged the usefulness of the supporter circle feature in providing access to the user’s professional support network, including psychologists and support workers, if the user wanted their MyPREP entries to be shared:

People that are supporting you that you want to know what’s going on? Mm-Hmm. Yeah. So, I mean, you can have them invited by, or you can share a copy, so I mean, that would be really useful for clinicians and obviously peer workers and mental health workers... [P3, user testing round 2]

It was emphasized that some may not use this feature because of privacy concerns, particularly with family or carers: “some people really don’t like family seeing this stuff” (P3, user testing round 2). Importantly, permission for viewing access could also be withdrawn by the end user at any stage:

The major function of the digital self-management tool is to assist users in systematically mapping and recording personalized self-management strategies in response to prompts to assist in their recovery from a mental health crisis. A feature that facilitated this was the avatar for read-out-loud functionality, which was viewed as especially important for those who held a preference for this or who had lower literacy skills. Further, each activity could be completed in a variety of ways based on the individual’s needs. Specifically, end users could engage in MyPREP activities by uploading voice recordings, images, emojis, and text. This was seen as a highly inclusive feature:

Oh, we got little icons. I would probably put a smiley face. Awesome, and then you can upload stuff. That’s cool, that’s like really personalized. Awesome! ...I think people get really anxious when they feel like they’re being recorded or they don’t like hearing their voice playing back, I know I don’t. So I would always go for the text. ...I think some people might like it. Some people might not want to type. [P3, user testing round 2]

These features were also seen as important motivating factors that promote better end user engagement with MyPREP:

I don’t know if people are going to struggle with doing these entries, because if they might think, OK, what is the purpose of it? But if it’s more fun and personal, it’s more fun. So, it’s like okay, I’m going to do this one. I might even put a photo of me in it and get that done. But if it’s always just bland, I don’t know. People might be like, well, especially, you know, you want that motivation. But I think this is really cool. [P4, user testing round 2]

The MyPREP module activity entries made by the end user were also editable, and there was a function in which entries could be saved so that the end user could keep a record of the changes:

This is really awesome. And it will keep the track as well. You can kind of say you can kind of go back, it can be like okay I was feeling not great on this day, what happened that day as well? ...Yes. So, you can kind of see that progress, especially for consumers who do enjoy that progress. [P4, user testing round 2]

The SUS

At the end of each user testing session, participants completed the SUS. The mean and range are listed in Table 1. The MyPREP paper version received a total SUS score of 71, indicating C+ or “good” usability. The digital version received a total SUS score of 85.63, indicating A or “excellent” usability.

</tbody>
</table>

aThe total SUS scores for the paper-based and digital versions were 71.5 and 84.4, respectively.

bOf the 6 participants in the first round of user testing, 5 (83%) completed the SUS for the paper-based version.

cOf the 4 participants in the second round of user testing, all 4 (100%) completed the SUS for the digital version.

dReverse scored item.

In a final meeting before endorsing MyPREP for piloting, the researchers met with 6 PSWs, and the tool was presented and discussed; these peer workers were then given access to the MyPREP intervention to gather their feedback. At this meeting and at follow-up, only positive additional feedback was relayed, and the peer workers emphasized that they were excited to use the tool in their service:

*I have reviewed the Workbook and honestly couldn’t find much wrong with it at all!! It’s great and I am very excited to put it into practice. My team had no feedback to give on the digital version other then it looks great and can’t wait to see it used with clients in practice!! [Peer worker 1]*

**Discussion**

**Principal Findings**

In this study, we present the user testing of an Australian version of the paper-based MyPREP and the co-design and user testing of a digital version of MyPREP. The key themes identified throughout the co-design and user testing sessions were related to (1) the need for self-management tools to be flexible and well-integrated into mental health services, (2) the importance of language and how language preferences vary among individuals, (3) the need for self-management interventions to have the option of being supported when delivered in services, and (4) the potential of digitization to allow for a greater customization of self-management tools and the development of features based on individuals’ unique preferences and needs. The resulting tool was subsequently rated using the SUS, which indicated that the end users involved in this study rated the paper-based tool as “good” and the digital version as “excellent.” Taken together, these results suggest that the digital prototype has valuable potential for use in mental health services and support the progression to piloting MyPREP in mental health services to inform a future large-scale randomized controlled trial (RCT). Early studies providing detailed descriptions of intervention development, such as this study, are now called for as best practice [32]. Specifically, it is important to include details such as important decision-making steps across all stages of development, explanations of how the information gathered from intended end users was carried out, and how intended end user input influenced how design features were incorporated into the design.

**The Need for Implementation Research**

The participants in our research also highlighted the need for the integration and coordination of self-management interventions and tools within services, as there can be a multitude of staff, documents, and plans (such as suicide prevention plans, discharge plans, wellness plans, and medication adherence plans) involved at various points throughout a consumer’s or a service user’s journey in a mental health service. Further, although the digital version of MyPREP was seen as being able to be used independently by end users at their home or within health settings, participants emphasized the need for such tools to be delivered with support from others, particularly PSWs. Although this may be explained by the fact that many of the participants were peer workers or consumer advocates themselves, this finding mirrors the current movement within mental health services toward the holistic inclusion of lived experience expertise [39]. Further, integrated staffing...
models may also be associated with better recovery, including better social functioning [40]. Taken together, implementation-focused research is needed to determine how MyPREP is actually delivered and how it can be optimized once it is introduced in real-world settings.

A recent systematic review of supported self-management interventions for people with serious mental health conditions found that there is a current lack of studies focused on implementation and that even fewer studies are based on implementation science theories [8], which are summarized in the taxonomy of implementation outcomes [41]. Although RCTs remain the gold standard approach to informing clinical decision-making and drawing causal inferences [42,43], there remain unacceptable research-to-practice gaps and a disconnect in generalizability and performance between an extremely controlled clinical trial environment and highly complex real-world mental health environments [44]. Implementation science, which is the formal study of methods to promote the systematic uptake of research findings and other evidence-based practices into routine practice, can bridge the clinical evidence-to-practice gaps by improving the quality and effectiveness of health services [44]. The hybrid implementation-effectiveness design is an innovative and rapid solution to provide high-quality evidence on effectiveness and implementation simultaneously [44,45], making it the ideal next stage of the research pipeline for the MyPREP project to determine effectiveness and implementation. This step is particularly important in our case, as the basic content of MyPREP has already been tested successfully in the CORE trial in the United Kingdom [16].

Accessibility of MyPREP

The digitization of MyPREP may have allowed it to become more accessible to end users when compared with the paper-based version, and this may partly explain the increase in usability scores, as measured using the SUS. For example, the use of the read-out-loud feature via avatars was viewed very positively by participants, as was the provision of options for writing, recording audio, and uploading images when completing MyPREP module activities. A recent systematic review suggested that developers of self-management interventions should adapt interventions to ensure greater inclusivity for participants with less formal education, as it was found that educational level was associated with engagement [8]. This is particularly critical for individuals with severe mental health conditions, given the increased rate of lower education in this cohort [46]. Indeed, the participants in our study repeatedly emphasized that plain and informal language was preferred. Further, we used Design for Dignity Principles, Web Content Accessibility Guidelines, and International Organization for Standardization standards for process improvement, safety, and quality (eg, 9241-11 ISO standard) to promote digital accessibility and ensure that the features are usable and acceptable for people with accessibility issues.

Customization of MyPREP

Customization embedded within MyPREP, such as the ability to change the color pallet and choose an avatar, was a clear theme throughout the co-design process and was rated very positively in the user testing sessions of the digital tool. Customization was important, as MyPREP is a self-management tool; the participants emphasized that these self-directed changes to MyPREP fostered a sense of autonomy, control, choice, and ownership, and this should be embedded as a standard in all features. Reviews in this area recommend that the content of self-management interventions should be tailored to the service users and have the flexibility to be personalized and customized, especially as interventions were found to not always fit end users’ needs [8].

In the future, there are plans for MyPREP to be customized further. A major example is enabling control over language. Specifically, feedback concerning the language used for the names of modules (eg, “my recovery plan,” “moving on after a crisis,” and “goals and dreams”) was liked by some participants in the user testing sessions, but not by others. This was despite MyPREP being co-produced and going through iterative co-design cycles with people with lived experience of serious mental ill-health [2,19]. The solution to this lies in customization, through which end users can adapt the names of the modules to suit their own set of beliefs and even remove modules that are not relevant to them from their MyPREP dashboard.

Limitations

This is a preliminary iterative co-design and user testing study and should be viewed as such. Similar to most user testing studies, our sample of service users was small (eg, the study by van der Krieke et al [47]). Further, we used not only advertisements across networks and services but also snowball sampling, which is a type of convenience sampling. A major disadvantage of such convenience sampling is that it risks a nonrepresentative study sample. In our case, the study sample was quite diverse in terms of age and sex. However, a large proportion of participants were consumer advocates and peer workers with considerable mental health knowledge and expertise. Further, those recruited for this study might have had a particular interest in working with digital health tools, which may have introduced avidity bias and may explain the very high SUS acceptability scores for the digital version of MyPREP. The next stage is piloting MyPREP in services to increase the representativeness of our sample and make iterative adaptations to MyPREP based on user feedback. However, overall, as the original MyPREP was trialed in the United Kingdom with at least 275 crisis care service users in a large-scale RCT (with 441 service users enrolled in the trial), this may suggest that the representativeness of our sample at this point does not pose a concern for the next stage of piloting of the Australian version in real-world mental health services.

Another limitation that is common in user testing (eg, the study by van der Krieke et al [47]) is that the presence of the facilitators over a digital meeting platform during the testing sessions may have affected the views of the participants, as they might have felt reluctant to be critical. We do not expect this to be a major limitation; however, throughout user testing, the facilitators continuously emphasized that this was an opportunity to improve the paper-based and digital prototypes and
encouraged discussion around problems and areas for improvement.

Conclusions
The co-production of the MyPREP self-management intervention and associated research in Australia are currently in their early stages. However, this co-design and user testing phase is a crucial step in adapting MyPREP to the Australian mental health setting and digital context. However, the current findings may remain relevant to implementation in any setting. Overall, the co-production process is vital, as service-wide implementations that fail to consider end user needs and organizational structures often encounter problems. Indeed, Killikelly and colleagues [31] suggest that both co-design and support from mental health staff or researchers when using the tool are 2 features that are associated with successful implementation and improve engagement with digital tools for people experiencing serious mental health conditions. To avoid implementation issues, it is essential to involve consumers and peer workers, who may support the delivery of MyPREP from the outset. In this study, feedback from these end users highlighted a strong desire for the personalized delivery of self-management interventions that offer choices and options, considering individual end users’ different needs and circumstances. MyPREP has worked toward addressing this need by offering digital and paper-based mediums, providing options for how delivery is supported (ie individuals can choose their supporters), increasing accessibility (eg, avatars and voice-recording options), and allowing customization (eg, customization of the color pallet and choice of avatars) based on users’ preferences and needs. To strengthen MyPREP's implementation in real-world Australian mental health service settings, implementation-effectiveness piloting and robust trialing are required to test and refine the tool.

Lived Experience Commentary
In our view, co-production is an umbrella term for co-family, co-creation, co-planning, co-implementation, and co-evaluation. This is a concept and philosophy in which collaboration with lived experiences is paramount. It is a way to cocreate new interventions, improve systems, and solve problems and is now being adopted in many public health policy arenas, including research.

This has moved far beyond “consumer participation,” which was enshrined in 1992 in the Australian mental health policy (1992 National Mental Health Policy endorsed by Australian Health Ministers). Back then, this was ad hoc and tokenistic. Now, as “co” is becoming more widespread, there are more genuine attempts to learn to integrate co-production as a way of doing research across the board.

In research, with co-production, we are witnessing a move from consumers and carers (or those with lived and living experience) voices from being “subjects of” to being equal collaborators, who work with researchers to influence change that benefits the service and system user. This research project has done just that. By having lived experience experts lead, participate in, and contribute to the design and facilitation of the research, we actively used lived experience knowledge and expertise in recovery planning through various stages. The recruitment of participants, data collection, workshops, one-on-one interview formats, and questions were developed and led by lived experience.

In this project, a trusting respectful alliance between research and lived experience evolved organically and naturally, providing a solid foundation to “do” this project with passion and enthusiasm, creating a safe and supportive atmosphere emulated in dealings with others. The interviewees felt more than comfortable to offer their time generously, sharing their insights into and thoughts on what would work well and what should be improved to increase engagement with and the use of this recovery-based intervention.

During different phases of this project, reciprocal positives emerged for the research team. Empowering and enabling each member to consider different perspectives and interpretations. Embracing new ways of thinking created a richer understanding of issues not considered previously. This was articulated in the ways in which the research was focused and conducted. On reflection, lessons on how this research approach will inform similar ongoing collaborations should be considered, where research projects embrace and welcome different skill sets, experiences, and knowledge.

Acknowledgments
The copyright for the Personal Recovery Plan workbook is held by South West London and St George’s National Health Service (NHS) Foundation Trust. Written permission to adapt and use the plan and distribute the adapted plan was obtained from the copyright holders by the first author at the University of Sydney.

The authors are grateful for the time and help of peer support workers (PSWs) and people with lived experience of mental health service use and mental health conditions who participated in the study. They are grateful to One Door Mental Health and Flourish Australia for supporting the recruitment for this study. They would also like to thank the Australian PSWs at One Door Mental Health, who contributed to the intervention development in Australia and will deliver the upcoming pilot. They also remain grateful to all the original PSWs, Crisis Resolution Team Optimisation and Relapse Prevention (CORE) service user and carer working groups, and the University College London (UCL) research team in the United Kingdom who originated this work (note that further information about the original study intervention, the PSWs’ training program, and the intervention’s operating procedures is available from the UCL CORE study website). The CORE study was led by professor Sonia Johnson from the Division of Psychiatry, UCL. The authors would also like to thank Aaron Schokman, Viji Venkataramani, Lei Gu, and Yang Wu for their contributions to this project.
This study was funded by an Early and Mid-Career Researcher Grant from the Brain and Mind Centre and the Moriya Elizabeth Vine Fund for Research into Schizophrenia. The preparation of this manuscript was supported partially by the Australian Government through the Australian Research Council’s Centre of Excellence for Children and Families Over the Life Course (project ID CE200100025). The original CORE study was funded by the National Institute for Health Research (NIHR) under its Programme Grants for Applied Research program (reference number RP-PG-0109-10078). The views expressed in this paper are those of the authors and not necessarily those of the NHS, NIHR, or Department of Health.

Data Availability
The qualitative data sets generated and analyzed during this study are not publicly available, as they are lengthy interview transcripts from which quotations used in this publication were selected, to ensure that individual services or participants cannot be identified. The data sets are available from the corresponding author upon reasonable request.

Authors' Contributions
AM and NG conceived this phase of the research and its design, with support from BL-E and SJ, based on the original UK Crisis Resolution Team Optimisation and Relapse Prevention (CORE) study. AM, IOAM and DP collected the data. AM, DJ, DP, and IOAM synthesized and analyzed the data. AM drafted the manuscript with support from IOAM, TC, EB, and UA. DP, JC, and AM oversaw the development of the digital resource for user testing. All the authors read and approved the final manuscript.

Abstract

Background: The prevalence of gestational diabetes mellitus (GDM) has drastically risen in recent years. For some, self-management includes the use of GDM online communities on Facebook. Such communities can fill gaps in information and support that participants are not able to access elsewhere to address unmet needs. Given the popularity of sharing information about pregnancy on Facebook and the documented benefits of diabetes online communities, the same may be true of GDM online communities.

Objective: This study aimed to categorize and quantify what is being discussed in GDM Facebook groups, including informational and emotional help-seeking behavior, and how this support and engagement may be demonstrated by peers through comments and reactions.

Methods: We sourced the data from the 2 largest Facebook groups focused on GDM in Australia. A summative content analysis was conducted on original posts across the 2 groups and coded for topics as well as help-seeking types. The coding scheme was based on the previous work of Liang and Scammon. Visible indicators of engagement, including the number of comments and “reactions,” were tabled and manually evaluated.

Results: There were 388 original posts, and the analysis produced 6 topics: GDM self-management (199/388, 51.3%), GDM clinical management (120/388, 30.9%), preparing for birth (40/388, 10.3%), mental distress (35/388, 9%), birth announcement (29/388, 7.5%), and GDM journey reflections (21/388, 5.4%). Secondary coding of help-seeking type revealed more than half of the posts were informational help-seeking (224/388, 57.7%), while a small proportion were both informational and emotional help-seeking (44/388, 11.3%), and some (12/388, 3.1%) were emotional help-seeking only. Self-disclosure was identified as a fourth category, comprising almost a quarter of all posts (90/388, 23.2%). A total of 6022 comments were posted in response to the original posts, and there were 4452 reactions across all posts. Emotional help-seeking attracted the most comments per thread (mean 21.5, SD 19.8), followed by informational and emotional help-seeking (mean 20.2, SD 14.7), informational help-seeking (mean 15.6, SD 14.6), and self-disclosure (mean 14.3, SD 21.8). Across all help-seeking categories, few reactions occurred compared to comments; in contrast, self-disclosure attracted a large number of reactions (mean 9.4, SD 45.3).

Conclusions: This is one of the first studies to examine peer support in a GDM online community on Facebook. Our findings suggest that active participants’ needs around information and support in relation to GDM are being somewhat met by peer-led online communities. Given the practical limitations of formal health care, including the provision of ongoing social support, it is important to recognize how GDM online communities can complement formal health care and help address unmet needs.

**Introduction**

Accessing health information on the web nowadays includes social media such as Facebook and, increasingly, its “group” function. Globally, the number of people engaging with Facebook groups equates to around 1.8 billion people per month [1]. The group function of Facebook is described as “a place to connect, learn, and share with people who have similar interests” [2]. Among the many “similar interests” people have are health concerns as well as life experiences such as pregnancy.

Research on pregnancy and the internet suggests that Facebook is used by some for supportive and informational purposes [3]. Given this, it is not surprising that many pregnancy Facebook groups now exist, as well as those focused on complications of pregnancy such as gestational diabetes mellitus (GDM). GDM is defined as any degree of hyperglycemia recognized for the first time during pregnancy [4]. As a condition, it affects a significant and growing proportion of pregnant women around the world each year [5]. Although GDM prevalence has drastically risen, there has been limited examination of the attendant growth of GDM online communities, including Facebook groups [6].

People may join online health communities because their family and community support networks do not include relatable others undergoing similar experiences [7], and thus they do not receive the benefit of “peer-to-peer health care” [8]. Research on diabetes online communities has found they fill gaps in information and support that participants are not able to access elsewhere [9]. Online health communities can provide both informational and emotional support, which helps people actively cope with health-related problems [10]. A study about breast cancer for women suggested that patients specifically seek out discussion groups on the web due to “unmet needs” [11], while another study suggested online health communities are where a range of desires and needs can be met by peers [12]. A scoping review of 47 studies focused on the use of diabetes online communities found a variety of psychosocial benefits, and although reports of negative consequences were low, it was also noted that diabetes online communities may not be beneficial for all [13].

In online health communities, users often demonstrate support-seeking behavior through explicitly stated requests, with posting itself a signal that the person is a potential support provider to others [10]. It is also common for users to “share” or self-disclose as a coping mechanism [14]. On Facebook, in addition to initiating posts, active engagement occurs through comments and reactions such as “likes.” The meaning of these reactions is not necessarily explicit beyond face value but can be broadly interpreted as support [15], though arguably a comment is a stronger indicator of support given the greater time and effort required to produce it.

Given the popularity of sharing information about pregnancy on Facebook and the documented benefits of diabetes online communities, the same may also be true of GDM online communities. Furthermore, health information-seeking online can also improve the patient-physician relationship if the patient discusses the information with the physician and they have a positive prior relationship [16]. This may be worthwhile considering the context of GDM, which generally requires additional health care compared to pregnancies without complications.

The aims of this study about Facebook posts and interactions within GDM Facebook groups were to examine: (1) the issues being discussed, (2) evidence for informational and emotional help-seeking behavior, and (3) how this support and engagement is demonstrated through comments and reactions.

**Methods**

**Study Design and Data Collection**

This study sourced data from 2 peer-led closed Facebook groups focused on GDM, founded, and run independently by private individuals. All original posts (ie, the first post in a thread) during a 1-week period were included, as well as replies published during the collection week. A limited period was chosen because the large volume of posts was considered sufficiently robust for the purposes of this study. These particular Facebook groups were chosen as they were the 2 largest groups focused on GDM in Australia; at the time of data collection, the combined membership of the 2 groups was over 6500 members. For this study, a “snapshot” approach was taken, with the data set copied verbatim by the first author, then fully deidentified and recollated for analysis to protect the privacy of participants. The data were then analyzed using content analysis and descriptive statistics.

**Analysis**

First, summative content analysis [17] was used to identify key topic areas from all “original posts” in a thread (ie, the first posts). This inductive approach to analyzing qualitative data started with reading through the data and identifying and quantifying certain words and content to understand contextual use before applying latent content analysis. To this end, the first author independently read and reread each post and identified keywords (eg, blood sugar and insulin) as the basis of topics. Multiple topics were allowed within a single post (ie, categories were not mutually exclusive). All authors then compared and confirmed the identified categories and interpretations.

Second, the original post in every thread was coded in terms of help-seeking type (Table 1). Here, a deductive coding scheme was used, following Liang and Scammon [10]. Visible indicators of engagement, including the number of comments, “likes,” and “reactions,” were coded and manually evaluated by the first author (SP). A total of 2 secondary authors (KC and LAE) coded a sample (n=10) of the first author’s coding to ensure consistency. The depth of analysis was further consolidated by the research team, which compared and discussed codes to provide additional perspectives.

aExemplary but not direct quotes.

Finally, as the data from the 2 Facebook groups were combined to enlarge the sample size and potentially increase heterogeneity, it was important to determine whether there were statistically significant differences in proportions between the help-seeking categories of the 2 groups. A Fisher exact test was deemed an appropriate test given the likelihood of small category sample sizes.

Ethical Considerations

Research based on Facebook posts raises important ethical questions, given the implications for privacy. Before the commencement of data collection, approval was sought and gained from Macquarie University’s Human Research Ethics Committee (5201827734364). When the first author (SP) requested permission from the administrators of both groups to join in order to conduct research, she disclosed her positionality as someone who had experienced GDM. As stipulated by the terms of the ethics approval, no identifying data would be published, including verbatim quotes.

Results

Topic Areas

A total of 388 original posts were extracted across the 2 groups, with 63 posts from one group and 325 posts from the other. From the content analysis, 6 topic areas were identified (Table 2). These were not mutually exclusive, as some longer posts were coded for more than 1 topic.

aGDM: gestational diabetes mellitus.

A number of residual topics were excluded from the main analysis given the relatively small number of posts: “other pregnancy experiences” (n=18), “humor and memes” (n=9), “postpartum concerns” (n=7), “food and diet” (n=11), and “group management” (n=3).

Help-Seeking and Engagement

Secondary coding of help-seeking type is captured in Table 3. The process identified mutually exclusive categories, where more than half of the posts were classifiable as informational help-seeking (224/388, 57.7%). A small proportion were classifiable as both informational and emotional help-seeking (44/388, 11.3%), while a minority (12/388, 3.1%) were emotional help-seeking only.

<td>1284</td>
<td>14.3 (21.8)</td>
<td>3550</td>
<td>39.4 (45.3)</td>
</tr>
</tbody>
</table>

Through the process of secondary coding we identified a distinct fourth category: self-disclosure. The intention behind such posts was not overt in terms of help-seeking (eg, “Just wanted to tell you all I gave birth to a healthy baby boy last week”). Almost a quarter of posts (90/388, 23.3%) were classifiable as self-disclosure.

A small number of posts (n=18) did not fit into any of the above 4 categories, such as posts sharing a recipe without comment or other practical matters such as offering to pass on medical supplies.

Visible indicators of engagement, namely the number of comments and reactions (including “likes”), were also tabled across all threads. A total of 6022 comments were posted in response to the original posts. The length of threads ranged from 1 to 179, with the median number of comments being 11. There were 4452 reactions across all posts. Emotional help-seeking posts were less prevalent but attracted the most comments per thread (mean 21.5, SD 19.8), followed by informational and emotional help-seeking (mean 20.2, SD 14.7), informational help-seeking (mean 15.6, SD 14.6), and self-disclosure (mean 14.3, SD 21.8).

Overall, across the 3 help-seeking categories, relatively few reactions occurred compared to comments, regardless of whether it was informational (mean 2.4, SD 20.1), informational and emotional help-seeking (mean 1.4, SD 3.9), or emotional help-seeking (mean 2.7, SD 4.4). In comparison, self-disclosure attracted a very large number of reactions (mean 39.4, SD 45.3).

Significant Differences Between the Groups

A Fisher exact test was applied to determine if there were any statistically significant differences in the proportions of help-seeking categories between the 2 Facebook groups. There were no significant differences found between the groups except for “emotional help-seeking,” with 6 posts identified for both groups, which represented a statistically significant (P=0.006) difference in the proportions of 9.5% (group 1) and 1.8% (group 2).

Upon closer examination of how emotional help-seeking posts were responded to in each group, there were other notable differences that further qualified this significant difference. In the smaller group (group 1), emotional help-seeking posts attracted far more comments in response (mean 26.8, SD 27) compared to the larger group (group 2), which had fewer comments in response to emotional help-seeking posts (mean 16.2, SD 7.9). Conversely, there were fewer reactions in group 1 (mean 1.8, SD 2.6) compared to group 2 (mean 3.5, SD 5.8).

**Discussion**

**Overview**

GDM self-management was the prevalent topic in over half the posts (199/388, 51.3%), which likely reflects a key motivation for both joining a GDM online community as well as an important reason for sustaining membership and engaging. The second most prevalent topic, GDM clinical management (120/388, 30.9%), is suggestive of the inadequacy of care provided in formal health care settings, including information provision, hence the need for additional discussion on the web with peers. This accords with how online health communities have been described as “communities of practice” due to the way learning occurs through a combination of experiential knowledge and other expert sources [18]. The topic “preparing for birth” alludes to a desire for information from peers (and expert sources), whereas “GDM journey reflections” points to expressly stated individual learning coupled with a desire to share and pass on knowledge to peers.

Informational was by far the most popular type of help-seeking, and this categorization largely overlapped with the most popular topics, demonstrating how critical information is in a peer-support context outside of formal health care. There were fewer posts where emotional help-seeking was the sole focus or in combination with informational help-seeking, but it is not surprising that these attracted the most comments per thread as empathic peers made a concerted effort to engage and offer reassuring words and engagement.

The statistically significant difference between the 2 Facebook groups in terms of the proportion of emotional help seekers warrants discussion. A possible explanation is the difference in size of the Facebook groups. Smaller-sized groups, in general, are friendlier and promote more contributions from members, with greater opportunities to speak [19], and emotional help-seeking posting also encourages supportive peers to show reciprocity by being more supportive. Examining the data from the 2 groups, there is a clear difference in terms of the volume of comments. This suggests greater intimacy and engagement in the smaller group, with comments being a better indicator of support than reactions, which are more impersonal and require less time and effort.

When we look at the posts categorized under “self-disclosure,” there are fewer comments but a much larger number of reactions. In such cases, engaging seems to be primarily enacted through a “reaction,” as peers do not necessarily see a need to comment. The general popularity of self-disclosure in GDM online...
communities is evident from this data and supports a more general observation that self-disclosing in an unprompted manner is intrinsic to the parlance of social media; that this is true of GDM online communities as many others. It has been found that self-disclosure in itself can be valuable, and with supportive conversation partners, there are positive psychological benefits, including reducing stress and improving self-affirmation [20]. In addition, previous research has found that even when someone only reads a poster’s self-disclosure without interaction, they can still develop a sense of personal connection [14]. It is useful to consider that self-disclosure can be further classified as per Malloch and Zhang [14], with factual self-disclosure revealing factual information, cognitive disclosure revealing thoughts and reasoning, and emotional disclosure revealing the poster’s feelings. This deeper categorization of self-disclosure was not undertaken in this study as it was beyond its scope, but merits further exploration in future research.

A final but nonetheless important consideration is the role of “lurkers,” who comprise the majority of participants in online communities; it is difficult to measure the true impact of interactions on all users of the groups because lurkers are not obvious [14]. For the most part, the visible support and engagement through comments and reactions is what users of a group are able to see. Given the large number of lurkers, however, we can only assume that the true engagement and utility of posts and comments are greater than what has been captured here. Furthermore, comment threads in groups can spark private messages between users, with discussions not visible to anyone else.

Strengths and Limitations

There were a number of strengths in this study. Given the dearth of literature about GDM online communities, this research illuminates an emergent phenomenon and activity experienced by many thousands around the world. The findings suggest important avenues for further inquiry in relation to GDM, in both online and offline settings.

A key limitation is that the data were only analyzed based on visible comments and reactions. Another limitation is that emoticons and photos were not systematically coded, even though they were part of the data set, as the semiotics of both were beyond the scope of this analysis. Finally, only 1 week worth of data were analyzed, and the results may vary depending on the collection period.

Conclusion

This study affirms the value of peer support that can be found in an online community. The large volume of posts and comments as well as high levels of positive engagement suggest that active participants’ needs around information and support in relation to GDM are being somewhat met by a peer-led online community. Given the practical limitations of formal health care, including the provision of ongoing social support, it is important to recognize how GDM online communities can complement health care and help address unmet needs. Furthermore, examining what information is being sought and shared by participants in GDM online communities is suggestive of gaps in information delivered through formal health care.

Acknowledgments

SP led and executed the study with design support, input, and advice from KC, LAE, and JB. KC and LAE provided statistical and methodological expertise alongside the other authors, and JB provided strategic advice. All authors reviewed and provided editorial suggestions on SP’s draft and agreed with the final submitted version.

Abstract

Background: Prior studies have demonstrated that the e-cigarette market contains a large number of brands. Identifying these existing e-cigarette brands is a key element of market surveillance, which will further assist in policy making and compliance checks.

Objective: To facilitate the surveillance of the diverse product landscape in the e-cigarette market, we constructed a semantic database of e-cigarette brands that have appeared in the US market as of 2020-2022.

Methods: In order to build the brand database, we searched and compiled e-cigarette brands from a comprehensive list of retail channels and sources, including (1) e-liquid and disposable brands sold in web-based stores, (2) e-cigarette brands sold in brick-and-mortar stores and collected by the Nielsen Retail Scanner Data, (3) e-cigarette brands compiled by Wikipedia, (4) self-reported e-cigarette brands from the 2020 International Tobacco Control Four-Country Smoking and Vaping (ITC 4CV) US survey, and (5) e-cigarette brands on Twitter. We also estimated the top 5 e-cigarette brands by sales volume in brick-and-mortar stores, by the frequency and variety of offerings in web-based shops, and by the frequency of self-reported brands from the 2020 ITC 4CV US survey.

Results: As of 2020-2022, a total of 912 e-cigarette brands have been sold by various retail channels. During 2020-2022, the top 5 brands are JUUL, vuse, njoy, blu, and logic in brick-and-mortar stores; blu, king, monster, twist, and air factory for e-liquids in web-based stores; hyde, pod mesh, suorin, vaporlax, and xtra for disposables sold in web-based stores; and smok, aspire, vaporespo, innokin, and eleaf based on self-reported survey data.

Conclusions: As the US Food and Drug Administration enforces the premarket tobacco market authorization, many e-cigarette brands may become illegal in the US market. In this context, how e-cigarette brands evolve and consolidate in different retail channels will be critical for understanding the regulatory impacts on product availability. Our semantic database of e-cigarette brands can serve as a useful tool to monitor product and marketplace development, conduct compliance checks, assess manufacturers’ marketing behaviors, and identify regulatory impacts.

https://formative.jmir.org/2024/1/e47570
Introduction

Electronic cigarettes or e-cigarettes, were introduced in the US market in 2007 [1]. As of 2022, a total of 2.55 million US high school (14.1%) and middle school (3.3%) students reported using e-cigarettes in the past 30 days [2]. Unlike cigarettes, the e-cigarette market is highly diverse, with a wide range of product configurations (eg, rechargeables vs disposables) and features (eg, flavors and nicotine concentrations). E-Cigarette market has also been characterized as highly dynamic, with leading brands constantly changing [3-7]. As of 2018, the e-cigarette market was valued at US $3.5 billion, with a large number of brands (>460) and flavors (>7700) [8,9].

The number of e-cigarette brands is an important indicator of market concentration and competitiveness, which measures the ability of a single firm, or a small group of firms, to exert monopoly power [10,11]. For example, the cigarette market is characterized as a highly concentrated oligopolistic cigarette market, with a few large cigarette companies accounting for the majority of market shares [10,12]. In contrast, before JUUL uptake, the US e-cigarette market was very competitive and comprised hundreds, if not thousands, of small manufacturers selling products to consumers and retailers [13]. However, in recent years, cigarette companies have increasingly owned or invested in e-cigarette products, taking over a significant share of the e-cigarette market [14]. As a result, the e-cigarette market may have become less competitive over time and the cigarette and e-cigarette markets are growing integrated [15].

Constructing a database of e-cigarette brands is crucial to monitor market concentration, competitiveness, and development, especially for the US e-cigarette marketplace. However, such a database has not been established yet. As prior studies demonstrated, e-cigarette retailers are dispersed in various retail channels, including brick-and-mortar stores, web-based stores, and vape shops or specialty stores [16,17]. However, only products and brands sold in brick-and-mortar stores are well-tracked by the Nielsen Retail Scanner Data. Little is known about e-cigarette brands and products sold in vape shops and web-based stores. Moreover, the few studies that examine products sold in these alternative channels suggest that products found in vape shops and web-based stores are significantly different from those in brick-and-mortar stores in terms of prices and product characteristics [18,19]. Therefore, a comprehensive database of brands is needed to identify brand differences by retail channels and assess accurately the e-cigarette market concentration and competitiveness.

A database of e-cigarette brands can also be used to identify regulatory impact by tracking the life cycle of a product and conducting compliance checks by identifying illegally sold products. In response to the substantial rise in e-cigarette use among US youth, the regulatory environment has evolved with many policy changes or proposals in recent years [20,21]. The available brands and types of e-cigarette products in the US market have been affected by the federal-level regulatory actions taken by the Food and Drug Administration (FDA) as well as state- and local-level policies that aim to curb e-cigarette use [3,21,22]. It is therefore highly warranted to have a live database of brands sold in the marketplace, which can demonstrate whether products with prohibited attributes are dropped from the market and how brands are evolving to comply with regulations.

Another function of a brand database is to assist in compliance checks. As the US FDA enforces the premarket tobacco market authorization (PMTA), many e-cigarette brands may become illegal in the US market [23]. A database of e-cigarette brands will allow the FDA and state and local agencies to identify if a certain brand is illegal or has been approved by the FDA. The brand database can also inform how e-cigarette brands evolve and consolidate with the enforcement of PMTA and answer the question of whether the PMTA makes the e-cigarette market less competitive in terms of limiting the availability of products [24,25].

The US marketplace of e-cigarette products is dynamic and rapidly changing. Therefore, a database of e-cigarette brands is also critical to tracking social media brand mentions and identifying emerging brands [26-29]. There have been attempts to identify mentions of e-cigarettes’ brand names and flavors on social media, such as Twitter (Twitter, Inc) [5,30], Reddit (Reddit Inc) [30], YouTube (Google) [29], and Instagram (Meta Platforms) [31], and to identify and classify emerging flavors in the web-based market [32], using machine learning algorithms. However, the lack of a comprehensive semantic database of e-cigarette brands that capture different purchasing channels has hindered the efforts of using these language-based algorithms to efficiently identify brands.

Given the importance of an e-cigarette brand database, this study aims to construct such a database and further assess popular and common brands reported from different sources. The database also provides a snapshot of the products that have appeared in the market as of 2022, allowing for future studies that analyze marketplace development and policy impacts.

Methods

Data Sources

We searched comprehensively and identified 6 sources that we used to create the semantic database of e-cigarette brands. These include (1) existing brand websites surveillance [8] that reported on a pre-determined list of e-cigarette brands; (2) e-cigarette brands sold in the brick-and-mortar stores reported by the Nielsen Retail Scanner Data, accessed through the Kilts Center for Marketing at the University of Chicago Booth School of Business [33]; (3) Wikipedia’s “list of electronic cigarette and...
e-cigarette liquid brands,” which was established by a community of volunteers who add brand names from data sources including peer-reviewed journal articles, news articles, reports from antitobacco organizations, and other sources, and we accessed it on November 29, 2022 [34]; (4) a list of e-cigarette brands mentioned on Twitter from May 2021 to December 2021 [5]; (5) self-reported brands from the 2020 International Tobacco Control Policy Evaluation Project’s Four-Country Smoking and Vaping (ITC 4CV) US survey; and (6) e-cigarette brands collected using web scraping of 5 popular web-based stores. The scraping data captured a wide range of e-liquid and disposable e-cigarette products and brands sold on the web, which were traditionally not well captured by other sources. The scraping data contained information of over 16,000 unique e-liquid or disposable products collected during 2021-2022. Additional details are available in Multimedia Appendix 1.

## Brand Identification

For web-based store brands, the same brand could be written in slightly different ways across stores, and we observed variations caused by (1) spaces or hyphens (such as “sad boy” vs “sadboy”); (2) pluralization (such as “bad drip” vs “bad drips”); (3) suffixes (such as “barista brew” vs “barista brew co.”, and “mr. good” vs “mr. good vape”); (4) abbreviations or aliases (such as “naked 100” vs “NKD 100”); and (5) misspelling (such as “coastal clouds” vs “costal clouds”). Using algorithms, we identified 237 unique e-liquid brand 97 unique disposable e-cigarettes in 2021-2022.

We used STATA/SE (version 17.1; StataCorp) software to convert all brand names to lowercase and remove duplicates. For brands with more than 1 product line, a research specialist from our team looked up relevant information on the web and identified them so that we extracted each brand name with multiple product lines and collections and further cleaned up the brand database. A total of 4 members from our research team reviewed the brand list to ensure accuracy. We then used this list of e-cigarette brands (based on Nielsen, Wikipedia, and data collected from web-based stores), to identify and match with the self-reported e-cigarette brands in ITC 4CV Wave 3 (2020) survey data.

Among 1696 observations from the self-reported brand variables in the ITC survey, 181 (10.7%) of them contained irrelevant or insufficient information, such as “don’t know,” and “its unbranded from the market.” For the remaining 1515 observations, 720 (47.5%) were successfully identified and matched using our initial brand list from 3 sources (Nielsen, Wikipedia, and our unique e-liquid data scraped from web-based stores). Aided by algorithms, we checked the rest of the self-reported brands that were unmatched or unidentified both by humans and by machines and extracted brand information from those observations. Since the same brand can be reported in different ways such as with or without space, we consolidated the brand names by removing the spaces and documented possible variations of a unique brand, such as “geekvape” and “geek vape” in Multimedia Appendix 2. Consequently, 167 new brand names from the ITC 4CV survey were added to our brand database.

Based on our disposable e-cigarette brand data collected from web-based stores in 2022 and the list of e-cigarette brands on Twitter from May 2021 to December 2021 collected by Tang et al [5], we then updated our brand database and in total 138 new e-cigarette brands were added from those 2 data sources.

## Identifying Top Brands

For products sold in brick-and-mortar stores, we used the Nielsen Retail Scanner data to identify the top 5 brands with the greatest sales in 2020. For self-reported brands, we used the frequency counts in the 2020 ITC 4CV US survey to identify the top brands. For products sold in web-based stores, we use the frequencies of offering (number of unique products of a brand multiplied by the number of stores that offer the brand) to identify the top 5 brands for e-liquid and disposable products, respectively.

## Ethical Considerations

In this study, we compiled data on e-cigarette brands using sources including peer-reviewed publications about brand surveillance and brand mentions [5,8], the Nielsen Retail Scanner Data [33], Wikipedia [34], a tobacco use survey, and our unique data scraped from e-cigarette web-based stores. Thus, no human subjects were involved, and the determination of no human subjects was approved by the Ohio State University institutional review board. The survey protocols and all materials including the survey questionnaire for the 2020 (Wave 3) ITC 4CV US survey were cleared for ethics by the Research Ethics Board, University of Waterloo, Canada (REB#20803/30570) and the Medical University of South Carolina (waived due to minimal risk).

## Results

In total, we identified 912 e-cigarette brands available in the United States during 2020-2021 and presented this database in Multimedia Appendix 2. As we compiled the brand database from multiple sources, we observed that e-cigarette manufacturers are creative when naming their product brands; in some cases, generic terms such as “z,” “e s,” “pods,” “something,” “mix,” and “e-hookah” are used as brand names. There are also brand names like “zoom” that could lead to ambiguous search terms and false results. We suggest that for those brands, researchers could use the brand names along with search terms such as “vape” as search terms to conduct market surveillance (eg, social media monitoring) and avoid false results.

The top 5 brands from different retail channels and resources are presented in Textbox 1, which presents the top 5 brands (by sales volume in counts) in the Nielsen Retail Scanner Data during 2020, the top 5 e-liquid brands (by frequency counts) in the scraped data during 2021, the top 5 disposable e-cigarette brands (by frequency counts) in the scraped data during 2022, and the top 5 self-reported brands (by frequency counts) in the ITC 4CV US survey during 2020.
Focused on the sales of e-cigarette products from brick-and-mortar stores, Nielsen Retail Scanner Data captured 82 brand or model names (567 product Universal Product Codes [UPCs]) in the “ELECTRONIC CIGARETTES–SMOKING” product module in 2020. Of the 82 brands or models, 59 sold at least two unique e-cigarette products. The top 5 high-level e-cigarette brand names by the number of products (ie, UPCs) in Nielsen Retail Scanner Data were njoy (70 product UPCs), vuse (64 product UPCs), blu (63 product UPCs), logic (31 product UPCs), and JUUL (30 product UPCs), which together accounted for about 45.5% (n=258) of total e-cigarette products observed in the Nielsen data. Product types varied, such as e-liquids, replacement pods, nonreplacement pods, prefilled cartridges or tanks, disposables, devices (eg, pod and mod), and starter kits (both device and pods or cartridges). Furthermore, during 2020 in brick-and-mortar stores, the top 5 brands (in descending order) by sales volume in counts were JUUL, vuse, njoy, blu, and logic, which represented about 137 million (97.9%) out of 140 million total e-cigarette sales volume in Nielsen Retail Scanner Data.

Based on the web-based store data, the top 5 e-liquid brands by frequency counts (reported in parentheses) were blu (780), king (553), monster (531), twist (488), and air factory (480). Here the frequency count for each top e-liquid brand was calculated as the number of different products from this brand offered by 5 stores, that is, a number of stores offering multiplied by brand variations. The top 5 disposable e-cigarette brands by frequency counts (reported in parentheses) sold by 5 web-based vape shops were hyde (214), pod mesh (126), suorin air bar (125), vaporlax (124), and xtra (115), which were different from the top brands in Nielsen data. Interestingly, self-reported data suggested top brands that differ from both web-based stores and Nielsen data. Based on the ITC 4CV Wave 3 US survey data, during 2020, the top 5 brands by frequency counts (ie, how often were they mentioned by participants, reported in parentheses) were smok (201), aspire (104), vapouroresso (76), innokin (65), and eleaf (64).

Discussion

Prior research used keyword searches and identified over 460 e-cigarette brands through January 2014, but the market has grown exponentially since then [35]. Although existing evidence shows that the number of e-cigarette brands has not increased much since 2014, this conclusion relied on limited resources or retail channels [8]. In this study, we used 6 different data sources to consolidate brands identified from multiple retail channels (brick-and-mortar stores, web-based stores, social media mentions, and self-reported data) and identified 912 unique e-cigarette brands as of 2020-2022. This suggests that a large number of e-cigarette brands existed in the market before the enforcement of PMTA, which is in line with the existing assessment that the e-cigarette market is more competitive than cigarettes with many e-cigarette manufacturers [10,13]. However, as tobacco companies increase their shares in the e-cigarette market by producing their own e-cigarette brands or purchasing existing e-cigarette brands, future research could use our database to map brands with tobacco company ownerships to better understand tobacco companies’ interest in e-cigarettes and the changes in the competitiveness and concentration of the e-cigarette market [15].

Regulation on e-cigarettes such as the FDA’s PMTA action might reduce competition in the marketplace, as e-cigarette brands owned by big tobacco companies may have a greater capacity to properly respond to regulatory actions (eg, file a PMTA) and remain in the market [24]. In addition, recent evidence suggests that in response to the FDA regulations that ban flavors other than menthol and tobacco in prefilled cartridges, the marketplace and consumers switch to disposables that provide a spectrum of flavors [3]. Therefore, it is important to track market development, product availability, manufacturers’ market power (ie, market concentration or competitiveness), and market responses to regulations, which this brand database can help.

Since 2021, the FDA has issued marketing denial orders (MDOs) to a number of e-cigarette companies, including prohibiting sales and distribution of all products from JUUL including devices and pods [21,36]. The FDA maintains an updated list of companies (instead of brand names) that have products currently marketed in the United States and have been issued MDOs [36]. It also announces the latest marketing decisions about e-cigarette companies and specific e-cigarette brands and models that have received MDOs [36]. After comparing the brands in the FDA’s marketing decisions from October 12, 2021, to January 24, 2023 [36], with our brand database, we found that all brands in those decisions were included in our database, which supports the validity and completeness of our database, which goes beyond the FDA list with additional brands that are not included in the decision list. This comparison also supports the potential of using this brand database to conduct compliance checks and monitor market product availability that could aid policy making.

Existing evidence from other studies shows that e-cigarette brands owned by tobacco companies typically offer a limited range of e-cigarette products, while brands owned by vape shops are much more likely to have a diverse range of flavor and nicotine options [8]; e-cigarette brands and product types are among the most important factors that influence consumers’
purchasing choices [8,37]. We also show that the most frequently mentioned e-cigarette brands by participants in a tobacco survey, the top brands by sales volume in brick-and-mortar stores based on Nielsen Retail Scanner data, and the top brands by product availability in web-based vape shops are very different, which demonstrates the importance of obtaining information from multiple data sources and purchasing channels when calculating the market share of various e-cigarette brands and the market concentration and power of each brand in the quickly changing e-cigarette marketplace.

We report the top 5 disposable e-cigarette brands (by frequency counts) from our 2022 scraped data as well as the top 5 e-liquid brands (by frequency counts) from our 2021 scraped data. Our database includes e-cigarette brands that are predominately sold in web-based stores; in particular, e-liquid brands are typically not well captured in existing data sources (eg, Nielsen Retail Scanner Data) and our database makes a contribution to the literature by providing those brands. For e-cigarette brands sold on the web, we have also observed that web-based vape shops sell a variety of products with different flavors, nicotine levels, and forms, suggesting the appeals of these brands sold in web-based stores [18,19,32,38,39].

Furthermore, to the best of our knowledge, our database containing brand names from 6 different data sources is the most comprehensive and up-to-date, and could contribute to tobacco regulatory science in multiple ways. In addition to compliance checks, product availability assessments, and market power estimations, the brand database can be used to conduct social media market surveillance using natural language processing and other machine learning techniques [40,41]. Specifically, brand search terms are key to identifying whether e-cigarettes are being mentioned in social media posts or on a website [5,31,42,43]. Therefore, our database not only provides a comprehensive list of e-cigarette brand search terms but also allows for the identification of emerging brands through techniques such as name entity recognition. Future research may also expand this database by linking e-cigarette brands with product characteristics such as flavors, nicotine levels and forms, and device types (disposables vs cartridges vs e-liquid; open vs closed systems) to facilitate rapid market surveillance.

Another potential function of this database is to assist in future tobacco survey development by allowing for a dropdown list that reflects the complexity of the e-cigarette marketplace and brands [2,44-48]. Our experience with the ITC 4CV survey suggests that respondents may have difficulties in self-reporting e-cigarette brands in an open-ended question. A drop-down list could enhance the ability of surveys to capture brands accurately.

Our study has some caveats. The brand names from our web-based vape shop data reflect a snapshot of e-liquid brands sold in popular web-based stores in 2021. As we continue our web scraping efforts, we will be able to extract brand information for a wide range of e-cigarette products sold in the web-based market, such as disposables, devices, and starter kits. Nonetheless, the e-liquid and disposable e-cigarette brand data from web-based vape shops and the list of e-cigarette brands on Twitter complements the brand information in brick-and-mortar stores from the Nielsen data, the existing list of brand names from Wikipedia (accessed on November 29, 2022), and self-reported brands from survey participants during 2020, together making our brand database the most comprehensive and up-to-date to the best of our knowledge. Another limitation is that brands in specialty vape shops are not necessarily captured in our semantic database. Future research is warranted to assess the brand information from specialty vape shops by paying visits to the stores and conducting qualitative interviews with store owners and staff members.

In conclusion, the development of a comprehensive semantic database that contains e-cigarette brands in the US during 2020-2022 demonstrates the competition of the existing e-cigarette market, as well as the use of novel techniques such as name entity recognition to identify emerging brands. It also has broader public health implications on the need to continuously monitor market concentration and manufacturers’ responses to regulations. Our database can be used to facilitate compliance checks and rapid surveillance of product availability to inform policy making.

Acknowledgments

We used data from the Nielsen Company (United States), LLC and marketing databases provided through the Nielsen Datasets at the Kilts Center for Marketing Data Center at The University of Chicago Booth School of Business. The conclusions drawn from the Nielsen data are those of the researchers and do not reflect the views of Nielsen. Abstract

Background: Many intensive care unit (ICU) staff experience intrusive memories following work-related traumatic events, which can lead to long-term mental health outcomes and impact work functioning. There is a need for interventions that target intrusive memories in this population; however, factors such as mental health stigma and difficulty in fitting interventions into busy schedules can pose barriers. The Brief Gameplay Intervention For National Health Service Intensive Care Unit Staff Affected By COVID-19 Trauma (GAINS) study tested a brief, digital imagery-competing task intervention (including computer gameplay) with the aim of reducing the recurrence of intrusive memories, which holds promise for overcoming some of these barriers.

Objective: This substudy aims to explore barriers and facilitators to the uptake and practical use of the intervention by ICU staff, along with its acceptability, and iteratively explore the impact of intervention optimizations to further refine the intervention.

Methods: The GAINS study is a randomized controlled trial comparing access to a brief digital imagery-competing task intervention for 4 weeks with usual care followed by delayed access to the intervention. The participants were ICU staff who worked during the COVID-19 pandemic and experienced intrusive memories. All participants were sent a questionnaire at 4 weeks to gather data about intervention acceptability. Nested within the randomized controlled trial, a subset of 16 participants was interviewed, and data were analyzed using thematic analysis drawing from a framework approach.

Results: Both quantitative and qualitative data indicated high acceptability of the intervention. Intervention use data show that, on average, staff were able to target approximately 73% (3.64/4.88) of their intrusive memories and engaged with the Tetris component for the full 20 minutes per session. Overall, on the acceptability questionnaire, staff found the intervention easy to use, helpful, and highly acceptable. The interviews generated four themes: approach to the intervention, positives of the intervention, negatives of the intervention, and improvements and optimizations. Findings highlighted barriers that ICU staff experienced: stigma, feeling weak for seeking help, not wanting colleagues to know they were struggling, and skepticism. However, they provided suggestions on how barriers could be overcome and discussed the advantages of the intervention when compared with other treatments. Although participants described many positive aspects of the intervention, such as being easy to use, enjoyable, and leading to a reduction in the frequency or intensity of intrusive memories, they also raised practical issues for implementation.
Conclusions: The intervention has the potential to overcome stigma and reduce the frequency of intrusive memories after traumatic events among ICU staff. Further refinement is needed to improve the adoption and reach of this intervention. A limitation is that we could not interview the National Health Service staff who were unable or unwilling to take part in the trial.

intensive care; posttraumatic stress disorder; PTSD; qualitative research; intervention study; health care professionals; digital intervention; staff well-being; pandemic; intrusive memories; work-related trauma; mobile phone

Introduction

Background

Following exposure to a psychologically traumatic event (eg, witnessing a severe injury or death) [1], intrusive memories are common, particularly in the first few days and weeks. Intrusive memories are emotional, intrusive, and primarily visual memories of the traumatic event that pop unbidden into the mind [1], that is, it takes the form of mental imagery. When they intrude repeatedly into mind, they comprise a “core clinical feature” of posttraumatic stress disorder (PTSD) [1]. Frontline health care staff are particularly at risk, with 65% of emergency nurses reporting having intrusive memories of work-related traumatic events prepandemic, such as the death of a patient [2]. For some individuals, intrusive memories persist for more than a month and thus become a core symptom of PTSD [3]. It has been known for some time that frontline health care staff experience repeated exposure to potentially traumatic events [4-7], even before the pandemic. This exposure was even worse during the COVID-19 pandemic, with 5 times more UK health care staff reporting PTSD symptoms, such as bothersome intrusive memories, in 2020 than in 2015 [8,9]. In this study, we will focus on intensive care unit (ICU) staff working during the pandemic, although it is assumed that this has wider relevance as trauma exposure and intrusive memories also affect other staff groups, and experiencing trauma was also prevalent prepandemic. A key difference with the pandemic was the increased frequency of trauma exposure for this group.

PTSD symptoms, such as intrusive memories, are associated with poorer long-term physical and mental health outcomes [10]. There is a great cost for patients and society when frontline staff are affected, with 27% of health care staff who reported PTSD symptoms believing that their work functioning was negatively impacted [6]. Furthermore, there are problems with staff shortages and dropouts, with PTSD symptoms causing 20% of staff to consider a job change [6]. Mental health problems remain the leading cause of sickness absence in the National Health Service (NHS) [11]. Owing to these factors, the mental health of frontline health care staff exposed to traumatic events is a major priority internationally [12].

Prior Work

A novel approach in this area is the development of a brief mechanism-driven behavioral intervention to reduce intrusive memories [13-15]. This brief imagery-competing task intervention for established intrusive memories after trauma consists of a reminder cue to the traumatic event, followed by playing the computer game Tetris for 20 minutes with instructions to use mental rotation during gameplay [16]. The principles of the intervention are informed by the neuroscience of memory storage and updating (so-called consolidation and reconsolidation) [17,18] and cognitive task interference [19]. The hypothesis is that the memory consolidation or reconsolidation process of a traumatic event can be disrupted by engaging in visuospatial demanding tasks, for example, Tetris, and reduce the frequency of the intrusive memories. Randomized controlled trials (RCTs) have shown that this type of intervention approach can reduce the frequency of intrusive memories soon after trauma exposure in women after traumatic childbirth [20] and after a traumatic motor vehicle accident [21,22]. In addition, the intervention has recently been found to reduce established and older intrusive memories in case series studies with patients with chronic PTSD [23], refugees [24], and most recently NHS staff exposed to work-related trauma [16,25]. In particular, ICU staff (those working in intensive care, intensive therapy, and high-dependency units) face repeated exposure to trauma as an inevitable and intrinsic part of the work setting [2]. Now that the adverse effects on staff health and well-being are becoming better recognized [12], it is imperative to find ways to address these needs.

This study is part of a Brief Gameplay Intervention For National Health Service Intensive Care Unit Staff Affected By COVID-19 Trauma (GAINS) study (ClinicalTrials.gov: NCT04992390) for health care staff in the United Kingdom who faced trauma exposure as part of their work during the COVID-19 pandemic. The intervention used a brief imagery-competing task intervention with the aim of reducing and preventing the recurrence of intrusive memories from work-related trauma exposure.

There are many barriers to the implementation of both digital and face-to-face mental well-being interventions in health care staff, specifically owing to the complexity of the role and organization of health care [26]. Personal barriers to uptake by health care staff include a perceived lack of ownership when they feel an intervention is not driven by them; feeling as though they are obliged to participate; and practical barriers to participation, such as cost, time commitments, and age [26,27]. In setting up the GAINS study in collaboration with the Intensive Care Society (ICS) in the United Kingdom, it became clear that time commitment is of particular importance, as the nature of their role as health care staff means they are working in busy and pressurized environments, even more so given staff shortage problems. Staff have indicated that financial barriers have created a perception that spending priorities prioritize patients’ needs over the well-being of the staff [26,27]. The situation is made more complex by organizational barriers,
including changes in senior management, managers being perceived as inaccessible, ongoing organizational changes and restructuring, and the influence of target-driven cultures [26]. A lack of suitable infrastructure to support digital health interventions has also been found to be a barrier to use [28], such as a lack of available computers or internet connection, which could be a potential barrier for staff working in hospital settings.

There are also huge barriers owing to stigma and inclusivity, with many health care professionals experiencing shame for struggling with their mental health [29]. A literature review found that, within the nursing population specifically, many nurses felt that they needed to keep their mental health a secret owing to fear of being judged by their colleagues [30]. This was not only because of fear of what others may think but also because of self-directed stigma, with 21% of nurses struggling with their mental health believing that this was because of a personality weakness or character defect [30]. Therefore, digital health interventions may pose a key strength because they can be accessed independently and from any location, thereby providing users with privacy and anonymity [28]. This is in contrast to, for example, attending mental health services for psychological therapy or medication. In addition, it is vital to ensure that study samples are representative, as intersectionality plays a role in this, with health care professionals from ethnic minority backgrounds experiencing increased workplace discrimination and harassment [31]. Barriers and facilitators to the implementation of mental health interventions for NHS staff will occur at the organizational and individual levels. Therefore, it is necessary to consider the barriers and facilitators that may exist at multiple levels.

This Intervention

The GAINS intervention used a secure web-based mental health and well-being platform (i-spero, P1vital Products Ltd) to allow participants to access the intervention on a smartphone, tablet, or computer. Participants had an initial guided session with a researcher over Microsoft Teams, in which they were provided with step-by-step instructions on how to use the intervention as well as explanatory videos and multiple-choice questions. Participants were assisted in briefly listing their intrusive memories during the initial session (hotspots). Subsequently, they were prompted to recall the image associated with 1 specific intrusive memory. They played the Tetris game for 20 minutes using mental rotation, in which they had to imagine how to rotate the next Tetris piece so that it could fit in the existing structure. The intervention took a total of approximately 25 minutes each time, and they could target different memories on different days. Finally, they were trained in using the i-spero (P1vital Products Ltd) platform to monitor intrusive memories in daily life [25].

The underlying principle of the intervention is its imagery-based nature and that it can be used regardless of the content of the intrusive memory (a motor vehicle accident or witnessing a patient’s death when working in the ICU). The intervention is used once per different intrusive memory, so it can also be used by someone who has experienced a single traumatic event or multiple ongoing traumatic events. It can also be used for new intrusive memories that develop during the trial. Owing to the nature of their roles, participants work in an environment where trauma can be a frequent occurrence. Therefore, choosing an intervention that can address the specific challenge of recurring and frequent trauma is crucial.

This intervention holds particular promise for overcoming some of the mentioned barriers to the implementation of mental well-being interventions after trauma in ICU settings [25]. For example, rather than focusing on a mental health diagnosis such as PTSD, the entry to accessing the intervention is a simpler index problem, namely, having intrusive memories of the traumatic event. It is brief (1 guided intervention session of 1 hour, followed by self-guided use of approximately 25 minutes per session, whereby the aim is 1 session per different intrusive memory). It is digital and can be used flexibly in different locations (eg, on a smartphone during a commute) and may have lower stigma than attending mental health services (as the intervention involves a digital task including a computer game rather than, for example, talking to a trained therapist). As the intervention can be used for new intrusive memories as they arise, it is well suited for health care staff facing repeated or ongoing trauma in their jobs. Finally, as the intervention requires minimal therapist resources, it has the potential to be more cost-effective and scalable than current evidence-based interventions that require more contact.

Aims

This qualitative substudy as part of the GAINS study had the following aims:

• To explore barriers and facilitators to the uptake and use of the imagery-based competing task intervention to reduce intrusive memories of work-related trauma in ICU staff, along with its acceptability.

• To iteratively explore the impact of optimizations made to the intervention to address some of the barriers (and enhance facilitators), allowing us to then further refine the intervention for future use by ICU staff.

Methods

Design

The GAINS study is an RCT comparing immediate access to a brief digital imagery-competing task intervention for 4 weeks (the immediate intervention arm) versus receiving usual care for 4 weeks, followed by delayed access to the intervention for an additional 4 weeks (the delayed intervention arm). This manuscript contains quantitative descriptive data from an acceptability survey completed 4 weeks after the first intervention session as well as data from the intervention itself on uptake and completion of the intervention. This descriptive data are provided as contextual information for the qualitative findings, which explore in more detail barriers and facilitators to the uptake, completion, and overall acceptability of the study. The qualitative analysis draws on 2 sources of data collection: interviews from a maximum variance sampling method in a subset of participants and free-text feedback that was sought from all participants completing the acceptability survey. The narrative feedback was used to triangulate the qualitative
Individuals who met the inclusion criteria were given the participant information sheet again, along with the opportunity to ask questions to the investigator, their general practitioner, or other independent parties to make an informed decision about whether to participate. If they were still interested in participating in the study, a researcher arranged a time to contact them by phone or video call to obtain informed consent. The participant and researcher completed, signed, and dated the consent form using a simple electronic signature via email, which included providing permission to be contacted for the qualitative interview component of the study. The consent form was retained electronically in a secure format, and participants were emailed a copy for their records.

**Study Procedures of the GAINS Study RCT**

After providing informed consent, participants were asked to complete a daily web-based intrusive memory diary for a run-in period of 1 week. Each day, the participants were asked to indicate if they had any intrusive memories and, if so, how many. Participants who met the eligibility criterion of having ≥3 intrusive memories in the run-in week were randomly allocated to either the immediate intervention arm or the delayed intervention arm in a 1:1 overall ratio. Participants were randomized through the P1vital electronic Participant Reported Outcome system (P1vital Products Ltd), and the outcome assessment was completed remotely by the participants (independently of the research team) on this platform. The qualitative team was independent of randomization, delivery of the intervention, and assessment of the quantitative outcomes. The immediate intervention group received the intervention immediately for 4 weeks, whereas the delayed group received usual care for 4 weeks, followed by the 4-week-long intervention.

**Intervention Being Trialed**

The brief digital intervention was delivered through a secure web platform that participants accessed on their smartphone or other internet-enabled device (refer to the studies by Iyadurai et al [25] and Ramineni et al [16] for complete details). Participants were provided with an initial session guided by a clinical psychologist or delegated researcher to run through the intervention as well as follow-ups and support available throughout the intervention. During the initial session (approximately 1 hour), participants were asked to briefly list the different intrusive memories they have and choose the one they wish to target first. They were then asked to complete the intervention, which included several key components: (1) the participant was asked to briefly bring to mind the intrusive image as a reminder to the specific memory, (2) they received instructions on how to play the computer game Tetris using “mental rotation,” and (3) they were asked to play Tetris using mental rotation for at least 20 minutes. During the intervention, participants were asked to rate how distressed they are feeling on 3 occasions, to rate the vividness of the image that is brought to mind, and to rate how much they were able to follow mental rotation instructions, to assess adherence to the instructions. After this first session, participants were able to use the intervention as many times as they liked over the next 4 weeks (eg, to target any other intrusive memories on their list or those

Potential participants met the inclusion criteria if they were aged ≥18 years; able to read, write, and speak in English; worked in a clinical role in an NHS ICU or equivalent during the COVID-19 pandemic; experienced at least 1 traumatic event related to their work during the COVID-19 pandemic; meeting criterion A of the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition criteria for PTSD: “exposure to actual or threatened death, serious injury, or sexual violence” by “directly experiencing the traumatic event(s)” or “witnessing, in person, the event(s) as it occurred to others”; experience intrusive memories of the traumatic event or events; experienced at least 3 intrusive memories in the week before screening; have internet access; were willing and able to provide informed consent and complete study procedures (including briefly listing their intrusive memories [without going into any detail] and playing the computer game Tetris with particular mental rotation instructions and completing a web-based intrusive memory diary); and were willing and able to be contacted by the research team during the study period. Potential participants were excluded if they had <3 intrusive memories during the run-in week.
that recur—approximately 20 min/session). The system logged intervention use data, including the number of intrusive memories on the participant’s memory list, number of intrusive memories targeted with the intervention, number of times the intervention was started and used by the participant, and the total time spent playing Tetris.

Data Collection

**Intervention Feedback Questionnaire Procedures and Analysis**

All participants were sent the Intervention Feedback Questionnaire (IFQ; Multimedia Appendix 2) 4 weeks after the first intervention session to gather information about intervention acceptability. The quantitative data from this questionnaire were analyzed descriptively by an independent and blinded statistician (BG), and the uptake and use data were analyzed by the P1Vital data management team. The qualitative research team only received the questionnaire free-text data after completing the qualitative interview analysis. PP categorized any free-text responses that fitted our qualitative themes and subthemes. SB and RM then reviewed these categorizations, and the very few instances of discrepancies were discussed to create the final structure. These data were analyzed descriptively in terms of frequency of response as a proportion of all participants and also of those who made any response at all. We then examined any data that did not fit any of our themes and considered whether there was enough detail to identify the data as a new theme or subtheme within the overall analysis. If a comment was too vague or general to determine whether it fitted the current thematic or subthematic structure or not, we did not include it in the analysis. As there is a separate trial outcome manuscript that explores the effectiveness of the intervention on a variety of outcomes [16,25], we excluded comments related specifically to the outcomes measured in the trial protocol.

**Nested Qualitative Study**

**Recruitment**

Upon completing the 4-week intervention, participants who had previously consented to be contacted for the interview component of the study were asked if they would like to take part in a qualitative interview with a researcher via an audio or a video call. Details of interested participants were stored on a password-protected file, and a researcher used selective sampling to contact participants from diverse backgrounds (age, gender, ethnicity, job role, and location) to schedule an interview.

**Interview Schedule**

This semistructured interview consisted of several questions designed to gain an in-depth understanding of participants’ experience of using the intervention, including acceptability, improvement suggestions, training or psychoeducation materials, potential barriers or facilitators to recruitment and uptake, and support needed for remote intervention delivery (Multimedia Appendix 3).

**Procedures**

Before commencing the interview, the researcher confirmed consent to audio record the interviews using a digital voice recorder, and the participants were reminded of the option to withdraw at any point. The interviews lasted approximately 30 minutes, and the audio recordings were immediately transferred to a password-protected laptop and deleted from the voice recorder. The password-protected files were then sent for transcription and anonymized.

**Data Analysis**

The interview data were analyzed using thematic analysis [32] and drawing from the framework approach by Ritchie et al [33] and Spencer et al [34]. A hybrid approach was used, where themes were generated inductively (from the data) and deductively (based on core areas of interest). This analysis approach was used as the study was exploratory at this stage, so it was important to understand the feasibility and acceptability of the intervention alongside core experiential elements that were not anticipated.

Steps of the analysis included the following:

- Familiarization with data (noting arising concepts and patterns)
- Generating an initial coding framework (iteratively and through team discussion)
- Coding of all transcripts
- Reviewing the content of codes in depth; identifying themes and subthemes; and exploring coherence, variation, consistency, and prevalence
- Creation of mind maps, showing how themes and subthemes fit together and interact, and identifying linkages

In relation to the coding processes, 1 researcher (PP) received interview transcripts, anonymized these transcripts, entered them into NVivo12 (Lumivero), and coded them. A second researcher (SB) coded a sample of transcripts, followed by discussions regarding any discrepancies. Once coding was completed, codes were explored in-depth by PP, who created summaries of coded content to allow the exploration of themes and subthemes. SB repeated the same process on a sample of codes to check for consistency and any discrepancies. PP and SB then worked together to develop and prioritize themes and categorize subthemes according to prevalence.

The analysis initially focused on the barriers and facilitators to using the intervention and how helpful the intervention was for participants, before going on to look at how it could be optimized for future participants and circulated wider.

**Results**

**Overview**

In total, 86 participants took part in the GAINS study RCT, 43 (50%) of whom were randomized to the delayed arm and 43 (50%) to the immediate arm [16,25]. Of the 73 participants approached to participate in an interview, 61 (83%) consented to being contacted, 1 (1%) declined, and 11 (15%) did not respond. The mean number of different intrusive memories listed by each participant was 4.88 (SD 2.17), and the mean number of different intrusive memories targeted per participant was 3.64 (SD 2.04). Further intervention use data are presented in Table 1. This shows that participants used the intervention
an average of 7 times over the 4-week period and spent approximately 20 minutes and 54 seconds playing Tetris per session. They were able to target an average of 73% (3.64 targeted / 4.88 total) of the intrusive memories on their list using the intervention.

</tr>
</tbody>
</table>

The median number of intrusive memories dropped from 14.50 (IQR 10.0-21.50) preintervention to 1.00 (IQR 0.0-3.0) postintervention in the immediate arm group. The median number of intrusive memories dropped from 10.00 (IQR 6.0-17.0) preintervention to 1.00 (IQR 0.0-2.50) postintervention in the delayed arm group. Furthermore, following intervention use, there was a significant reduction in PTSD symptoms ($P<.001$), insomnia ($P<.001$), and anxiety ($P=.02$) and an increase in work functioning ($P<.001$) and well-being ($P<.001$) [16,25].

Of the 86 participants, 84 (98%) completed the IFQ, which contained a mixture of quantitative (scale) and qualitative (free text) response options. The quantitative data will be provided initially, and the qualitative data will be discussed alongside the interview findings. The IFQ respondent demographics are shown in Table 2. Participants’ responses to each quantitative item of the IFQ are presented in Table 3.

\(^a\)NHS: National Health Service.

Table 2 with IQR results shows that the vast majority of participants who took part in the trial were female, working full time, educated to degree level, married or cohabiting, and from a White British or White non-British background. The sample included male, part-time, less educated, single or separated, and ethnic minority staff (from Asian, African, and mixed ethnicity backgrounds). After 4 weeks, most staff reported that the intervention was easy to use, helpful, burdensome, distressing only to a mild degree, and highly acceptable. In the future, they were highly willing to use the intervention again if it was offered to them, highly confident in recommending it to colleagues, and believed strongly that it would help other staff in health care settings who experience trauma.

In the nested qualitative interview study, 16 participants were interviewed. Table 4 shows the demographics of the interview sample. The mean age of the interviewees was 39.4 (SD 8.4) years. Following the first 8 interviews, maximum variance sampling was used to select interviewees from a range of backgrounds. This included a range of ages, genders (predominantly female), ethnicities, job roles (predominantly nurses and consultants), geographical locations, and number of intrusive memories at baseline (range 5-44).

The final 4 (25%) of the 16 interview participants who participated in the study received an optimized intervention, as this was a Bayesian adaptive RCT. The intervention was optimized as the study progressed over time [16,25] following feedback from previous participants. These optimizations included adding graphs to allow participants to see their own data for each intrusive memory, adding a video at the end of the first guided session to reinforce how to use the intervention independently, and adding an additional reminder cue in the first guided session to ensure that the memory was in their mind just before they played Tetris [16]. The topic guide (Multimedia Appendix 3) was, therefore, amended to include questions about participants’ thoughts on what was required to access the
intervention independently as well as their thoughts on the added graphs and reminders.

The themes and subthemes are outlined in Textbox 1, and example quotes illustrating each theme are provided in the text below.

Attitudinal and Emotional Responses

Experiencing Mental Health Symptoms as a Health Care Professional

Stigma and Imposterhood

Choosing whether to participate in the intervention was compounded by barriers, such as stigma surrounding mental health in ICU staff. Many participants described feeling weak for seeking help and not wanting colleagues to know that they were struggling:

I’m a healthcare professional and I do see these things all the time, but then in one way you think these are the things that will never affect you. You help the others, because I’ve always been caring and empathetic with them, but at the same time you don’t think you can be the patient. [001]

But critical care nursing has this kind of almost elitism kind of approach. And the moment you have a little bit of a weakness that’s then seen negatively and your almost- you kind of feel that someone’s going to think that you can’t do your job. [008]
sense of imposter-hood with these. Do I really- Or do I- Are my intrusive memories bad enough? Surely other people have worse ones, therefore- It was helpful getting rid of that feeling. [003]

Value of Anonymity

Overview

In addition, participants stressed how emphasizing the anonymity of this intervention could help reduce the impact of mental health stigma on taking part in the study:

Yes I think highlighting it being anonymous and it doesn’t get reported back to work would probably make people more likely to use it. And the fact that they can – you know if they can access it on their personal emails and not work emails and things like that that would probably make people more likely to use it. [013]

IFQ Data

Despite this, when asked how the intervention could be improved in the feedback questionnaire, 3 participants provided suggestions that required workplace involvement in the intervention:

Involve managers to support the staff. [IFQ004]
Time out of work to do it. [IFQ049]
For it to [be an] option within occupational health because it has impacted on NHS workers that went through the pandemic. [IFQ040]

Using a Novel Intervention

Skepticism

Overview

Participants discussed their initial skepticism when approached with information about this intervention, as its novelty, simplicity, and game design caused them to doubt its effectiveness:

Well when I first heard about it I was very, very sceptical, because yes I know that games focus your mind on something else. But I just wasn’t convinced that it was going to do anything. [005]

IFQ Data

Skepticism toward the intervention was also mentioned by a couple of participants in the feedback questionnaire when asked what they found useful about the intervention:

Amazing. I genuinely did not expect it to work. [IFQ012]
The intervention definitely targeted some of those intrusive memories popping up, working much faster than I had expected it to. [IFQ009]

Understanding How It Works Is Helpful

Overview

Therefore, participants described how increasing their understanding about how the intervention works during initial communication is important to reduce the initial skepticism about intervention efficacy:

[Once] you get over people being aware of what it’s trying to do. You know, it’s not, for example, it’s not just a distraction, it’s not trying to distract you from memories and thoughts, but this is- Try this because there is evidence as to how this will work. [010]

People might be a little bit sceptical that it would work. Well especially with nursing… as part of your training you do modules on research so I think if people are shown the research and shown that it works they’re more likely to use it. [013]

Participants suggested providing previous research and testimonials from other ICU staff during initial communication to help normalize intrusive memories and thereby encourage more professionals to seek help:

[Should] have said, look, I also have the same problems, have a personal story like that, and see somebody’s journey. Saying like, you stick with a little work and I think it reassures a little bit and I think it relates a little bit nicer to you mentally than just a- you know a scientific paper which is very objective and impartial. [011]

IFQ Data

This was further highlighted by a couple of participants in the feedback questionnaires, when asked how the intervention could be improved as something that could be offered to health care staff to help reduce intrusive memories after a work-related traumatic event:

Provide evidence and testimonies from the research participants. [IFQ018]
To make people aware of it and show success results. [IFQ006]

Positives of the Intervention

Participants discussed various positive effects of the intervention, including its effect on them, and also when compared with other treatments (which was a line of questioning).

Tracking and Intervening to Reduce Intrusive Memory Frequency and Intensity

Overview

Participants described how the intervention was helpful in reducing the frequency or intensity of intrusive memories. Moreover, they found it helpful to track their intrusive memories, as it allowed them to notice reductions and patterns and reinforced intervention use:

It was like being back inside the situation again. I could hear the voices…I was surrounded by the scenario again. And then it became just images of like trying to foreseeing those things again. And now it is just a cloud. There is nothing there. [015]

Because then you can see the trend and then you think oh, actually I haven’t had any memories for three days
or whatever. So, that kind of like spurs you on a bit and then you’re like oh, it’s working, yes that was useful. [006]

Recording the frequency of the intrusive memories and realising that they’re actually going down, it just reinforces that it is a good tool to use for that purpose. [002]

**IFQ Data**

In total, 30% (25/84) of the feedback questionnaire respondents also described how the intervention helped to reduce the frequency and intensity of intrusive memories as well as how some of these memories did not return:

That it actually helped reduce the frequency of the memories. [IFQ011]

The intervention definitely targeted some of those intrusive memories popping up...causing the memories to become less frequent as well as less distressing and vivid when they did appear. [IFQ009]

It helped to reduce my intrusive memories. It gave me something active and engaging to do if I felt distressed by my memories. [IFQ035]

**Intervention Is Easy to Use and Enjoyable**

**Overview**

Participants found the intervention easy to use, in part because of the clear instructions provided, and enjoyable:

I think it was all really straightforward. And for someone of my age, that’s- It must be easy, because I’m of the non-tech generation. [016]

You know, it is a psychological intervention and it is helping you psychologically [laughs]. But it’s also, it is a game and it, there are some enjoyable aspects to it and it’s a good way to help yourself mentally. [006]

**IFQ Data**

These positives were further emphasized in the feedback questionnaire responses, with a couple of respondents mentioning that the intervention was enjoyable and many more saying it was simple, easy to use, and intuitive:

It was enjoyable and very intuitive. [IFQ004]

It’s such a simple tool to use to target these frustrating and upsetting thoughts. [IFQ001]

It was straightforward and easy to use. [IFQ002]

However, 1 participant also explained in the feedback questionnaire that their lack of experience with Tetris made it difficult to use the intervention:

Learning to play the game as I had not used before. [IFQ034]

**Intervention Is More Convenient Than Psychological Therapies**

Participants also discussed the benefits of this treatment compared with existing treatment options for intrusive memories, such as psychological therapies. For example, unlike psychological treatment, this treatment is flexible as it does not require an appointment:

You can choose when to target those specific kind of memories rather than being reliant on, well I’ve got an appointment at 2 o’clock on this day. And there were days when I couldn’t- I didn’t have the mental capacity to just focus on kind of day to day let alone do the intervention. So I could pick and choose when I targeted those memories. (008)

It doesn’t take too much time out of the day and the emotional commitment involved is not exhausting, like some other forms of counselling I’ve had before. In fact, I feel better for it, rather than worn out. So, 20 minutes and then you can get on with things really. [003]

It’s because it is more available whenever time you want. That’s the most important thing. [007]

**No Need to Discuss Intrusive Memories**

**Overview**

Some participants also appreciated that this intervention did not require them to relive distressing memories in-depth, unlike in talking therapies:

The fact that you’re actually having a therapy session, but you don’t realise it. So, it can be less distressing as well, especially when you’ve got trauma, some people don’t really want to talk about trauma, they just want trauma to go away. [001]

Because sometimes if you have counselling, you leave the room even worse than when you came in, because you are not thinking about something and then you have to go back to the situation and seeing and then you spend the whole day crying- I’ve had counselling before and after so much crying, you are so exhausted the rest of the day after all that. [015]

**IFQ Data**

There were mixed views on this in the feedback questionnaire responses, with 1 respondent stating that the intervention was nondistressing and 3 respondents explaining that it was difficult to recall the memories as part of the intervention:

Pretty well non-distressing. [IFQ021]

Didn’t want to bring some of the more difficult intrusive memories to mind. [IFQ044]

Re living those memories was really difficult sometimes. [IFQ028]

The only difficult thing was facing the intrusive thoughts. [IFQ025]

**No Side Effects of the Intervention**

When compared with medication, the key advantages discussed were the lack of side effects, for example, on sleep or weight, and being able to directly target intrusive memories:

If you’ve got a problem, you still have the problem. Maybe the medication helps you to stay more relaxed,
but it doesn’t really have an impact on intrusive memories, and things like that. [001]
I have my own reservations when it comes to medication...I don’t want to take much of a time, you know in terms of (the drug affecting) sleep or waking or weight loss, things like that. Compared to medication, I was happy to undergo an intervention like this. [009]

In addition to discussing some of the positive effects of the intervention compared with other treatments, I participant also mentioned simply appreciating the availability of an alternative option:

Personally because I’ve had talk therapy and medication and things so, I was looking for something else to try. [006]

Cognitive and Emotional Coping

Overview

The participants described the positive effects of the intervention on their cognition, such as improved concentration and rational thinking at work. They also experienced positive changes in their emotions and other aspects of life, including feeling happier, more in control of their emotions, reduced anxiety, and sleep improvements:

That allowed your brain to then focus more on the important things. And my rational thinking at work seemed to improve as a consequence. [008]

My attention and focusing time came back. Usually, you need focal attention. I can pay attention for extended hours, but I was not able to do that. [009]

My productivity increased to the extent that people started noticing it and I became happier. I think I became my old self. [009]

I was so tearful but now, if I’m tired, I feel more comfortable, more happy, more emotionally controlled. [007]

Obviously, the sleep improvements come with not having the intrusive memory and being troubled by them. [002]

IFQ Data

The feedback questionnaires offered insights into additional positive effects of the intervention, including how it enhanced focus, served as a helpful distraction, aided in relaxation, and allowed individuals to take time out of their day.

Facilitated focus and clarification of thoughts. Organised my mind. [IFQ015]

The game was a great distraction. [IFQ022]

Intervention itself was relaxing, forcing 20 minutes of exclusive concentration on a task providing a break from a busy day. [IFQ032]

Negatives of the Intervention

Participants mentioned some negative effects related to the use of the intervention, some of which were grounded in comparison with other treatments (which was a line of questioning) and some of which were given spontaneously. There is heterogeneity of experience, and these were not discussed by everyone, and these negative effects were grouped as follows.

No Opportunity to Discuss Intrusive Memories in Detail

Overview

Participants discussed some negative effects of this intervention compared with existing treatments. For example, some participants preferred to talk to a clinician about their intrusive memories, which this intervention did not allow:

[If you are really troubled by one of the memories, I can imagine having direct psychological support to kind of work your way through that thought process, it is just a thought, calming you down, there’s none of that. [002]

IFQ Data

One participant also highlighted in the feedback questionnaire that the inability to discuss intrusive memories in detail meant that the intervention should be accompanied by another support system:

Great as a distraction technique but needs to be accompanied by another support mechanism, being given a safe space to be able to talk through experiences etc. [IFQ017]

Unclear Whether Memories Are Spontaneous

Overview

In addition, participants expressed difficulty in knowing whether memories of the traumatic event were actually spontaneous or simply because of being part of the study:

I think it’s really hard to try and differentiate between, am I putting this thought in my head? Because I know I am doing the GAINS Study, or- So I think like, after the first couple of days, I just had to just try and, like, ignore the research side of it. (004)

IFQ Data

Feedback questionnaire respondents concurred with this; with respondents explaining how processes inherent to the study, such as repeat contacts and reminder texts, could in fact remind them more about the distressing incidents:

Repeat contacts became a bit burdensome. [IFQ003]
The phone calls, texts were far more frequent than I anticipated. The reminder to do the intervention at 7 am and at night reminded me of the distressing incidents and made me more distressed. [IFQ019]

Technological Issues

Overview

Once participants had overcome the barriers to participating in the study (described previously), there were some environmental factors that affected their experience with the intervention. As this is a digital intervention, technological difficulties such as a lack of technological knowledge, reduced access to a device, and device differences were mentioned as issues:
The one thing I did find though, which I didn’t know, is when I occasionally had, I usually used my laptop if I was able, and you know, it was much easier to rotate the blocks. But I found on my mobile phone it was, it was very sensitive. [005]

Some of us are lucky to have laptops, but like, I remember at the initial start, we were told to make sure you have your laptop, because it might not work, like, on your phone or your iPad. [012]

There might be some groups that have potentially worked in different areas in part of the pandemic and they’ll be left with some of these intrusive memories that wouldn’t be so technologically fluent. [002]

IFQ Data
This was echoed by the feedback questionnaire responses, with 1 participant explaining how there were problems owing to the multiple platforms and the inability to access the intervention offline. However, there were mixed views on how well the intervention worked on mobile phones:

Multiple platforms, not an intuitive website...and it would time out if you were on a train/went offline. [IFQ002]

Didn’t work too well on my phone. [IFQ016]

I would not improve the intervention itself as it is very accessible and able to play on phone and computer. [IFQ037]

Difficult to Find Time to Use the Intervention
Overview
In addition to technological difficulties, participants described how it could be difficult to find time to use the intervention because of their busy schedules, shift patterns, and other responsibilities outside of work:

[Found] it a bit difficult to find the time with this- I’ve got a small child, I’m working almost close to full-time. My husband is a [profession name], so he does a lot of out of hours work, so a lot of the childcare and toing and froing, that comes to me. [002]

[Occasionally] I had to do it just before I went to bed after a busy day. And I didn’t like doing that because I try and reduce my mobile phone usage or computer usage late at night. [005]

Particularly about doing it during the day at work, made you think, well that’s fine, I’ve managed to push things, cleared everything up, I’ll be fine for half an hour while I do this, and then inevitably you get a phone call 10 minutes into it. [010]

I suppose compared to medication or whatever, I suppose it’s investing the time, finding the time. Taking a pill is very quick, isn’t it. [002]

IFQ Data
This was also a very common theme in the feedback questionnaire responses, with participants explaining how and why they found it difficult to find time to use the intervention (both inside and outside the workplace):

Finding the best time to do the intervention without interruption from my preschooler Vs being too tired to pay it proper attention to get the most out of it. [IFQ001]

Surprisingly difficult to find 20 mins in busy clinical day or family time daily to do game. [IFQ003]

My concern is that staff wouldn’t find the time during the working day to work on the interventions and with shift patterns may struggle to include it in their free time. [IFQ036]

Three of the feedback questionnaire respondents also highlighted how they found it difficult to remember to record and use the intervention, in part because of the lack of time:

Remembering to do the intervention regularly and record the relevant information. During the day, I don’t have time to work on the intervention so I’ve had to work time into my evening to complete the tasks. [IFQ036]

Improvements and Optimizations
Participants were asked about potential improvements or optimizations to the intervention as well as any challenges experienced while using it. The responses were grouped into the following themes, which were found to be relatively frequent and consistent.

Difficult to Focus on Mental Rotation
Overview
Participants emphasized the importance of recognizing that the mental rotation aspect was the focus rather than the Tetris score:

I had to concentrate quite a bit because when I first started using it I just was having fun playing the game [laughs]. [006]

I think we should highlight that when you do the intervention you shouldn’t really- You should focus more on the arrangement rather than aiming for a score or you should stay away from how you usually play Tetris and focus on the future blocks and the arrangement. [014]

Despite recognizing this, participants often found it difficult to concentrate or focus on mental rotation:

I was thinking about myself, my thoughts were just running away, and I wasn’t really concentrating on the Tetris game. [001]

I remember thinking first few times it [speed] increased I started to panic a bit because- And then you do stop focusing on the mental rotation because you just think, oh they’re all coming so quickly. [005]

I think it was the pre-empting the rotation that’s coming, to rotate it in your head before it actually comes onto the screen, that’s the hard bit. [012]
IFQ Data
This difficulty in concentrating was echoed by participants in the feedback questionnaires:

I think 15 mins is enough—my concentration starts to flag after this. [IFQ005]
I found I was bored quickly. [IFQ038]

How to Increase Focus on Mental Rotation
Overview
Participants provided suggestions on how to improve the intervention for future participants. One of the main suggestions was a pop-up message during gameplay to remind participants to focus on mental rotation, as participants had previously mentioned that their focus drifted from mental rotation. Participants also mentioned that the speed at which the blocks fell made it difficult to focus on mental rotation, and they suggested that capping the speed may be helpful:

I don’t know if during the Tetris game some kind of pop up could be coming up, like a reminder. Yes? A kind of- I don’t know what you say on the reminder, but something like- I don’t know, remember to focus on the next pieces. [001]
And maybe cap the speed. When it gets ridiculously fast I think you’re very aware that you’re not doing mental rotations very well. [002]

IFQ Data
Another participant mentioned capping the speed as an improvement suggestion in the feedback questionnaire:

Cap the speed of the blocks to enable proper rotation planning. [IFQ001]

Researcher Support Is Important
Overview
Researchers provided participants with support during the initial session, in which they showed the participants how to identify intrusive memory images and how to use the intervention with demonstrations showing how to autonomously identify their intrusive memory images and playing the intervention while focusing on mental rotation:

Yes, I think so. I think I had a couple of teething issues, but one of the ladies phoned me up, went through it, face-to-face, got me to play it whilst on the phone with me, so it was fine. [004]

IFQ Data
The importance of the initial session with a researcher was also highlighted by a participant in the feedback questionnaire:

Needs 1-1 at beginning when 1st doing intervention so person using it knows exactly what to do. [IFQ045]

How to Access the Intervention Independently
All participants who received the optimized intervention provided suggestions on how to make it more easily accessible independently. For example, they proposed incorporating video demonstrations showing how to autonomously identify their intrusive memory images and playing the intervention while focusing on mental rotation:

Yes, so see someone playing. And what obviously, because you cannot read their mind, but if you put like a bubble say what is doing in their mind. They are turning, they are not focusing on this, they are doing this, this. [015]
Maybe- I guess, maybe giving some examples of how to break those things [intrusive memory images] down, if that makes sense. And the different ones that are just like an image, or something that’s like a little video that plays, that sort of explanation and how to write that, maybe just some sort of video of how to break that down into something. [016]

How to Aid Incorporation of the Intervention Into Participant Lifestyle: IFQ Data
In the feedback questionnaires, a few participants explained how shorter Tetris sessions could help them incorporate the intervention into their daily lives more easily:

Perhaps if the timing the intervention had to be carried out for was shorter - I’m not sure if it would still be effective but feel 10 minutes twice a day rather than one block of 20 minutes would be easier to fit in. [IFQ009]

Is the 20 minutes a specific time or could it be reduced? Sometimes difficult in a busy working day to get full 20 minutes to spend on it. What effect with say 10 minutes? Or 5...? [IFQ021]
I was sometimes deterred from starting the intervention knowing that it would take up 20mins of time. It may seem more accessible if it only required 10 mins for example. It would be possible to do whilst on break at work etc. [IFQ023]
Other Intervention Improvement Suggestions

Overview
In addition, participants expressed a desire for the intervention to be available as an app rather than solely on the web-based platform:

I think it would have been really good if you could have had an app. And then every time you have a memory, you just tap the app, or something, and then it. Yes, and otherwise you have to, like- By the time you get home, and log it, you're like, how many did I have? [004]

I think it will help if it's an App that you can download, like Calm or what’s the other one. Then you can just go and open and do for 15, 20 minutes. [014]

There were mixed views on the use of graphs to display intrusive memory changes, with some participants not liking graphs, whereas others appreciated the ability to track progress in this way:

I'm not a great fan of graphs to be honest. [013]

And not only to see progress but to see- I guess because I could match as well, like they definitely got worse when I was on nights and I could see that, with my shift pattern and also stuff I was doing at work, just certain things that were going on and then I'd be like, I can see how that happened and where that connection is. So, it kind of makes sense to me. [016]

In general, participants appreciated receiving brief daily reminders to log their intrusive memories and engage with the intervention, as long as the reminders were not excessive and did not prompt participants who had already completed the task. However, as mentioned in a previous subtheme, some participants did find the reminders distressing as they brought the memories of traumatic incidents to mind:

A quick reminder with may be just a shortcut to the logon is fine for me. [013]

[At] least I had that reminder. And I think if I forgot one day, let's say today, tomorrow in the morning I could go back and do it...Especially when you have so many things on your mind. [015]

IFQ Data
In addition to requesting that the intervention be available in an app format, a couple of participants in the feedback questionnaire suggested that the intervention use only 1 platform instead of 2 (1 for the intervention and 1 for logging outcome measures):

I found it difficult to navigate the website, perhaps an app would have been better. [IFQ022]

It might be easier to make it all on one platform. Rather than 2 different places. [IFQ028]

Although some participants mentioned how they appreciated the text message reminders, 1 participant explained in the feedback questionnaires how reminder messages could be confusing:

I would suggest keeping up the automatic reminders to record and use the intervention. [IFQ025]

Infrequent but relevant text message feedback was useful and not overly intrusive. [IFQ032]

I get multiple reminders about completing tasks which sometimes confuses me whether I have completed it or not. [IFQ053]

Discussion

Principal Findings
This qualitative study explored barriers and facilitators to the adoption of a brief digital imagery-competing task intervention (1 guided intervention session of 1 hour, followed by self-guided use of approximately 20 min/session) to reduce intrusive memories of traumatic events from working in an NHS ICU during the COVID-19 pandemic. Overall, on the acceptability questionnaire, the health care staff found the intervention easy to use, helpful, and highly acceptable. They were highly willing to use the intervention and were confident in recommending it to colleagues and their health care organizations for staff exposed to repeated trauma. In the qualitative data collection, participants described many additional positives of the intervention, such as it being easy to use, enjoyable, and encouraging, as participants were able to track intrusive memories and notice reductions in frequency. They could modify the use of the intervention based on the intrusiveness and frequency of the traumatic memories. Compared with sessions of psychological treatment, it was considered less time consuming, more flexible when it could be used, did not require discussing unpleasant memories, and required less effort. Compared with medication, it was more specific in its effect on intrusive memories of traumatic events and did not have adverse effects on weight, sleep, or alertness. It was seen as complementary to psychological and medication treatments in those who needed them.

Although it has its advantages, participants described how the intervention may not entirely replace the need for psychological therapy to talk about the nature of intrusive memories in those who wish to or the need for medication in some instances. A key finding was that some participants preferred not to access the intervention through their workplace or for colleagues to know that they were using the intervention owing to mental health stigma, a factor that is known to affect mental health help seeking among health care professionals [35], including after witnessing trauma in the workplace [36]. An advantage of the GAINS intervention is that although it could be provided through the workplace and introduced as a normal working practice for staff in the ICU, it could also be accessed independently outside of work.

The intervention use data showed that, on average, staff engaged with the Tetris component for the full 20 minutes per session, approximately 7 times over the 4-week period. They were able to target approximately 73% (3.64/4.88) of their intrusive memories through the intervention, that is, on average, participants were able to target 3.64 intrusive memories and had 4.88 intrusive memories listed. This emphasizes that the intervention was extensively used, indicating its significant
value. When combined with qualitative findings, it appears feasible and acceptable for staff, particularly in the short term. However, there is a need to further investigate how participants use the intervention for a longer term, particularly whether it can easily fit into their daily lives.

**Comparison With Prior Work**

The findings highlighted barriers that ICU staff experience when accessing support for their mental health, such as stigma, feeling weak for seeking help [37], questioning if they were bad enough to warrant such help, and not wanting colleagues to know that they were struggling. This is consistent with previous findings investigating mental health in health care professionals [35,36] and a culture of not showing weakness in health care work settings [29]. Participants suggested that these barriers could be partially overcome by normalizing intrusive memories after trauma through testimonials from other ICU staff who participated in the GAINS study. In addition, as discussed in the existing literature [35,38], the anonymity of the intervention was important, as it was completely separated from the health care professionals’ workplace or colleagues. This suggests that staff should have the option to access the intervention through routes other than only the workplace. However, participants in the IFQ suggested that health organizations would benefit from the intervention being endorsed by senior staff members. This endorsement could occur during induction and appraisal meetings involving junior colleagues, especially in environments where staff are repeatedly exposed to trauma. If staff did find it acceptable for the intervention to be used in their work environment, it could even be incorporated into staff induction and colleagues could support one another through a “buddy system.”

In a previous meta-synthesis of digital health interventions for mental health [39], one of the key barriers to the initial approach was skepticism about how helpful a remote treatment could really be. This was also the case with the GAINS intervention. The initial skepticism was compounded by it being a simple and novel gameplay intervention, with some participants expecting the intervention to be at best a short-term distraction while they played the game. In fact, many participants went on to report long-lasting effects on the frequency and intrusiveness of their traumatic memories. Publicizing research evidence, discussing the mechanism of action of the intervention, and testimonials from ICU staff were suggested as possible avenues to counter this possible skepticism. This is consistent with the literature, which highlights the importance of users being on board with digital health interventions’ aims and understanding their purpose [40]. The suggestion to publicize research evidence and provide testimonials from ICU staff is of particular importance, as prior findings emphasize that endorsement from health care professionals is valuable and helps digital health interventions to be trusted and viewed as worthwhile [40].

There were also some factors that negatively affected participants’ experiences. In our specific population of ICU staff, it was difficult for some to find time at work to use the intervention because of their busy schedules, shift patterns, and other responsibilities, particularly while working long shifts during the pandemic. Most staff were married and had caring responsibilities, so they were trying to fit the intervention in their busy schedules, for example, on public transport commutes to work. Some struggled because they were tired, often distracted, or had technological or interoperability issues across the devices and connection points. Nevertheless, reminders to use the intervention were appreciated by the participants, as suggested by Patel et al [39]. Many also preferred not to use the intervention at work and did not have access to a personal device. Therefore, it is evident that although the intervention is currently available for use on other devices (such as mobile phones), it needs to be easier to use on these devices and not too time consuming. Borghouts et al [38] also found that engagement improves if users are able to integrate the intervention into their daily life.

Similar to prior findings [41] that integrating a human component into treatment helps retain engagement and reduce dropout, participants reported that researcher support, both before using the intervention (eg, the initial guided session) and throughout intervention use (eg, booster session), was found to be extremely helpful and important. They valued the continuous support provided to ensure they correctly used the intervention and received guidance on making adjustments when necessary. However, providing this level of support can be difficult when scaling up an intervention [41]. Participants provided suggestions on how the intervention could be more easily accessed independently, which would require fewer therapist and researcher resources and enable the intervention to spread more widely and reach a greater number of ICU staff, for example, by providing video demonstrations of someone identifying the intrusive memory images independently and playing the intervention while focusing on mental rotation. Participants’ suggestions around helping to retain a focus on mental rotation while playing Tetris are helpful to identify, as this may be one of the core aspects to the working of the intervention. They also discussed changing aspects of the game itself and whether more frequent but shorter use of the game might be effective and more feasible for staff to continue using it for a longer term.

**Limitations**

Limitations of the study include the method of recruitment and sample representativeness and the short duration of use of a novel intervention. The trial was a first trial that is being followed by further trial work to test the robustness of the findings of the first trial. Recruitment of participants through advertising in the ICS, a professional organization, may have recruited participants who would be the most receptive and enthusiastic for such interventions. The sample was geographically drawn from many parts of the United Kingdom and was representative of the NHS at large but appears to have been overrepresentative of ethnic minority staff. There were 44% (7/16) staff from ethnic minority backgrounds in our interview sample compared with 20.7% (248,400/1,200,000) in the NHS workforce [42]. However, selective sampling was used for interview recruitment to capture a broad range of experiences of using the intervention from as diverse a sample as possible, rather than to match the sample to demographic characteristics of the NHS population. Any novel intervention, both in format and purpose, may have a large halo effect in...
relation to enthusiasm to take it up and use that may not be sustained over time. There is a need to recruit larger representative samples that use this intervention. The aim of this intervention is for most individuals to only need to use it a few times (once for each distinct intrusive memory of trauma). It is designed to be brief each time it is used, and requiring only a few sessions, rather than for prolonged use like a mindfulness app. However, for people with a very large number of intrusive memories and repeated ongoing traumatic events, it would be useful to consider use over a number of months to obtain more robust data on its likely uptake, use, and acceptability, which could be generalized to the staff experiencing repeated trauma in routine health care settings. Furthermore, we were unable to interview any ICU staff who were not able or chose not to participate in the study. Therefore, it is difficult for us to know how typical our sample and findings are of the wider ICU staff population. We also could not obtain important information about any barriers to participating in these individuals and how these barriers could be overcome, as it is likely that our participants were more open to mental health support in general. Furthermore, participants who took part in the trial but did not consent to participating in an interview may have had a different (more negative) experience of the intervention, and we could not obtain information about their experiences.

Nonetheless, our participants described potential barriers to wider participation, and it appears that the intervention was able to overcome some of these to an extent, such as the anonymity of the intervention helping to reduce the impact of stigma. In addition, we used selective sampling to ensure that our sample was as diverse as possible on factors such as profession, background, ethnicity, age, NHS Trust, and baseline intrusive memory frequencies. Therefore, our sample aimed to be as inclusive as possible of our target population. Saturation of themes was reached through the interview and analysis process, suggesting that further barriers would be unlikely to be present if we had recruited more participants.

We attempted to triangulate our data by comparing feedback from the sample that completed the acceptability questionnaire (IFQ) with our qualitative interview data. Certain topics did not lend themselves to completion on the feedback questionnaire, such as discussion of stigma. However, this was often reported in the qualitative interviews with ICU staff, and the themes resonate with previous literature. The feedback questionnaire, which had a very high rate of completion, confirmed most other barriers and facilitators, identifying a new subtheme around highlighting a number of ways staff improved cognitive and emotional coping with trauma through the intervention. A limitation of our analysis is the inability to delve deeper into certain findings. For example, we could not explore how the intervention might induce relaxation nor whether the distraction and improved focus persisted beyond the gameplay or were solely experienced during the game sessions. Bringing awareness to the intrusive memories could be both a positive and a negative experience, as it might help identify a source of stress; however, some people cope with intrusive memories by suppressing them, whereas others believe it adds to distress. The feedback questionnaire provided many additional suggestions to improve the uptake, feasibility, and acceptability of the intervention that the research team and developers of the intervention could explore and consider. A key strength of the qualitative interviews was the chance to iterate findings to adapt the intervention accordingly while it was still being used in the RCT. We also interviewed some participants who received the optimized intervention to gain feedback about their experience with the optimizations so that we could further improve the intervention.

Data gathered from the use of a survey in addition to interviews demonstrate that even when interviews are repeatedly producing the same subthemes and themes, and despite maximum variance sampling on the basis of characteristics available to us, there might still be important themes that might be missed because of the limits on maximum variance sampling imposed by data protection and trial procedures. We could only be made aware of a limited amount of information without fully consenting individuals for the interview. However, the qualitative interview method delves deeper into extracting information that participants might not readily provide in a feedback survey. In addition, it is an iterative process that builds upon multiple interviews. Therefore, if a theme or subtheme is not supported in the survey feedback, it does not mean that it is unimportant or even uncommon, simply not as immediately obvious to the participants.

Future Research

Other potential issues for us to consider in the next phase are related to the practicalities of the intervention, as participants mentioned that the intervention could be difficult to fit into their extremely busy working lives during the pandemic. Health care demands have remained high; therefore, this ability to fit in may be a continued factor to consider. There was also the issue of lack of privacy when accessing the intervention at work and not having access to a personal device in this setting. As highlighted in a previous literature review [43], most intervention frameworks recognize the importance of understanding how well an intervention fits with existing organizational routines to predict its adoption and implementation on a larger scale. As the intervention can be accessed by ICU staff either at work or outside of work, we must also understand how well the intervention fits into their personal lives. Although this aspect was discussed in our findings, it is crucial to further explore the feasibility of long-term intervention use, especially considering that ICU staff regularly encounter work-related trauma. For the intervention to be beneficial, it must integrate as seamlessly as possible into their lives. An advantage of this intervention is that it can be used at any convenient time (eg, at home or on a commute). A further key issue going forward within work, and especially outside work, is data protection of sensitive information that may require training or other safeguards, for example, if staff members are overlooked while examining graphical outputs (eg, a line graph) of the frequency of traumatic memories. We may need to provide alternative ways of presenting the data to ensure that they are more widely accessible, such as through color chart indicators rather than numerical graphs.
Conclusions
Overall, the data suggest that the intervention to reduce intrusive memories after trauma is highly acceptable to ICU staff and has some unique value compared with other current approaches to staff mental well-being. Through additional refinement and gathering evidence regarding outcomes and implementation, this intervention could potentially present a much-needed approach to address the widespread issue of repeated exposure to trauma, which manifesting as intrusive memories significantly impacts on the mental health and emotional well-being of health care staff.

Abstract

Background: Medication adherence and the management of adverse drug reactions (ADRs) are crucial to the efficacy of antitumor drugs. A WeChat applet, also known as a “Mini Program,” is similar to the app but has marked advantages. The development and use of a WeChat applet makes follow-up convenient for patients with cancer.

Objective: This study aimed to assess the usability and utility of a newly developed WeChat applet, “DolphinCare,” among patients with cancer in Shanghai.

Methods: A qualitative methodology was used to obtain an in-depth understanding of the experiences of patients with cancer when using DolphinCare from the usability and utility aspects. The development phase consisted of 2 parts: alpha and beta testing. Alpha testing combined the theory of the Fogg Behavior Model and the usability model. Alpha testing also involved testing the design of DolphinCare using a conceptual framework, which included factors that could affect medication adherence and ADRs. Beta testing was conducted using in-depth interviews. In-depth interviews allowed us to assist the patients in using DolphinCare and understand whether they liked or disliked DolphinCare and found it useful.

Results: We included participants who had an eHealth Literacy Scale (eHEALS) score of ≥50%, and a total of 20 participants were interviewed consecutively. The key positive motivators described by interviewers were to be reminded to take their medications and to alleviate their ADRs. The majority of the patients were able to activate and use DolphinCare by themselves. Most patients indicated that their trigger to follow-up DolphinCare was the recommendation of their known and trusted health care professionals. All participants found that labels containing the generic names of their medication and the medication reminders were useful, including timed pop-up push notifications and text alerts. The applet presented the corresponding information collection forms of ADRs to the patient to fill out. The web-based consultation system enables patients to consult pharmacists or physicians in time when they have doubts about medications or have ADRs. The applet had usabilities and utilities that could improve medication adherence and the management of ADRs among patients with cancer.

Conclusions: This study provides preliminary evidence regarding the usability and utility of this type of WeChat applet among patients with cancer, which is expected to be promoted for managing follow-up among other patients with other chronic disease.

Introduction

Medication adherence is defined by the World Health Organization as the extent to which a person’s medication-taking behavior corresponds with agreed recommendations from health care providers [1]. Medication adherence is crucial to the efficacy of antitumor drugs. Patients with cancer have disproportionately higher burdens of comorbid chronic conditions compared to individuals without a cancer history [2]. For individuals with preexisting chronic conditions, a new cancer diagnosis can lead to tremendous challenges, including the coordination of carers and dependents as well as the management of multiple medications for comorbid conditions alongside cancer treatment [3]. Antitumor drugs are known for their numerous adverse drug reactions (ADR), which can diminish adherence to treatment and cause medical complications. Several interventions have been developed to improve medication adherence and manage ADRs in patients with cancer [4-6]. However, the effectiveness of these interventions is controversial.

WeChat is a type of social networking software that provides flash messaging services on smart terminals. In 2020, the number of monthly active WeChat users exceeded 1.1 billion, rendering it the most common smartphone app in China. It is no longer a simple social platform but has penetrated into all aspects of people’s lives, including their health [7]. With the constant development of WeChat tools, a new development environment and platform was built for the WeChat applet used by 400 million Chinese users every day [8].

The WeChat applet, also known as the “Mini Program,” is similar to the app but has marked advantages. The steps for using the WeChat applet have been simplified, and the applet can be opened directly without downloading the app package. Interestingly, there is an independent storage space among different WeChat applets. If one no longer uses the applet, one need only close the page without uninstalling the program or clearing the cache, which is convenient for users. In addition, the IT infrastructure of WeChat applets can bring about a rapid transfer of digital data between patients with cancer and doctors or pharmacists, and reduce their burden related to oncotherapy information through real-time communication. All of these make follow-up convenient for patients with cancer by using the WeChat applet.

Norman and Skinner [9] reported that participants who had a high eHealth Literacy Scale (eHEALS) score indicated that they had higher literacy skills in using the internet as a resource to obtain health information. This study selected and interviewed dozens of patients with cancer with high eHEALS scores from a tertiary hospital in Shanghai, who are willing to use an eHealth tool—the WeChat applet. If the WeChat applet can be successfully promoted in Shanghai, it will be spread sequentially in various cities throughout China. At present, the vast majority of WeChat applets are free to use, which can reduce the economic burden of follow-up among patients with cancer. However, the existing WeChat applets were developed without involving relevant stakeholders (such as health care professionals or patients) and were not subjected to mobile health app guidelines [10,11].

Usability is described as the extent to which a product can be used by specified users to achieve specified goals with effectiveness, efficiency, and satisfaction in a specified context of use [12]. Utility is defined as the functionality of the app and how useful it is to users [12]. The development phase consisted of 2 parts: alpha and beta testing. Beta testing was conducted using in-depth interviews. Alpha testing combined the theory of the Fogg Behavior Model and the usability model. The Fogg Behavior Model [13] suggests that 3 core elements—motivation, ability, and trigger—must converge at the same time for a desired behavior to take effect. Motivation and ability can be balanced against each other; for example, patients may be willing to perform a difficult task if they are highly motivated by the promise of better health outcomes. Ability refers to the patients’ skill or dexterity with respect to the simplicity (or otherwise) of using the app. A trigger is a stimulus that prompts patients to adopt and use the app (eg, an acute attack or clinician’s suggestion).

To our knowledge, no study has assessed the usability and utility of a WeChat applet for patients with cancer once it has been developed. This study aimed to assess the usability and utility of a newly developed WeChat applet—DolphinCare—among patients with cancer in Shanghai.

Methods

Study Design

A qualitative methodology was used to obtain an in-depth understanding of the experiences of patients with cancer when using DolphinCare from the usability and utility aspects.

Ethical Considerations

Ethics approval was obtained from the ethics committee of Shanghai Tenth People’s Hospital prior to the study (SHSY-IEC-5.0/22K99/PO1). The study was registered in Chinese Clinical Trial Registry (ChiCTR2200058189). Written informed consent was obtained from all study participants.

eHEALS

The modified eHEALS was used to assess participants’ literacy skills in using their smart devices to find health-related information on the internet (Multimedia Appendix 1).

Participants

We included participants who had an eHEALS score of ≥50% and were taking 2 or more prescribed medications for their tumor treatment and chronic conditions. We excluded participants aged <18 years or those who had mental disabilities. Purposive sampling was used to recruit older (≥65 years of age) and younger (<65 years of age) participants, as we required the experiences of older participants who may have more comorbidities but may not be comfortable using mobile apps, as well as younger participants who may have fewer comorbidities (than older patients) but may be more comfortable using mobile apps. The purpose of recruiting participants based...
on age was to obtain wider perspectives when using DolphinCare.

**Alpha and Beta Testing in the Development Phase**

The development phase consisted of 2 parts: alpha and beta testing. Alpha testing involved testing the design of DolphinCare using a conceptual framework (Figure 1), which combined the theory of the Fogg Behavior Model of Motivation-Ability-Triggers and the usability model. Our framework also included factors that could affect medication adherence and ADRs (Table 1).

DolphinCare was then used for beta testing (Figure 2). Beta testing was conducted using in-depth interviews from July to September 2022. The first and second rounds of in-depth interviews were both conducted at the resting area of the ward. In-depth interviews were conducted to explore the views of patients with cancer regarding the usability and utility of DolphinCare when using it for the first time. We supplemented this interview process by observing the participants and documenting these observations as field notes. This allowed us to determine whether they encountered any difficulties and whether they liked or disliked the utility of DolphinCare. In-depth interviews allowed us to focus on the individual, assist the individual in using DolphinCare, and create an environment where the individual would be able to express his or her views without being influenced by others.

The Interview Questions

The following questions were asked to the participants during the interviews:

- What is your initial impression of using DolphinCare?
- What is your feeling about using DolphinCare after a period of use?
- What motivates you to use DolphinCare?
- Can you operate DolphinCare yourself, or do you need help from others?
- Will you continue to use DolphinCare?
- What’s the operation interface of DolphinCare that left a deep impression on you?
- What’s function do you expect DolphinCare to further improve on?
- What do you think are the inconveniences of using DolphinCare?

Data Collection Process

Participants used their mobile WeChat app to acquire the official account of DolphinCare free of charge and then filled in the demographic form. Each participant was interviewed twice. During the interview, the “first impression” of participants in using DolphinCare would be captured. The researcher took detailed notes and observed for nonverbal cues during each interview. Facial expressions and body language subconsciously portrayed by the participants were noted down by the researchers. All interviews were audio recorded. The 8-item Morisky Medication Adherence Scale (MMAS-8) [14-16] is a questionnaire designed to facilitate the identification of barriers and behaviors associated with adherence to medication. The possible answers to questions 1 to 7 are “yes” (0 points) or “no” (1 point). Five of the questions are scored in reverse (ie, yes=1 and no=0). The possible answers to question 8 are “Never” (1 point), “Occasionally” (0.75 points), “Sometimes” (0.50 points), “Often” (0.25 points), and “All the time” (0 points) [17].

Data Analysis

All interviews were transcribed verbatim. An interpretive-descriptive approach was used to identify the themes that emerged from the data. This approach was used to obtain a deeper understanding of the usability and utility of the perspectives and experiences of patients with cancer in using the WeChat applet. The researchers reflected on the data and began constructing an interpretive account of what the codes signified from the participants’ perspectives, and its application in clinical practice [14]. The researchers also referred to the field notes for reflections, facial cues, and body languages observed during the interviews. The research team then met to discuss the coding of the transcripts. Any coding discrepancies were resolved through discussion until a consensus was reached.

Results

Participants

A total of 22 participants were recruited (Table 2) for the first interview. Only 20 participants (12 men and 8 women; 16, 80% of them being patients and 4, 20% being carers) were interviewed consecutively, as 2 (P13 and P14) declined to participate. The mean age of the patients and their carers was 62.4 (SD 10.25) years. The average of the number of medications among patients was 2.7.

²eHEALS: eHealth Literacy Scale.

Adoption

We used the motivation, ability, and trigger categories of the Fogg Behavior Model to explore why patients adopted the WeChat applet using data from the qualitative interviews and usage data.

Adoption: Motivation

The key positive motivators described by the interviewees were to be reminded to take their medications, to alleviate their ADRs through monitoring, and to aid in medical research. Some patients had more than 1 motivation for adoption.

**The motivation is to observe if I can improve the medication adherence, and manage my ADRs.** [Patient 10, 68 years, male]

**It [taking part in this research] could be helpful for the medical studies or something. So to advance their work.** [Patient 4, 73 years, female]

**My main motivation is to participate in this research for distracting me from my anxiety about the disease.** [Patient 7, 55 years, male]

Adoption: Abilities

Most of the patients were able to activate and use the WeChat applet by themselves. Some (typically older) patients needed assistance from younger family members.

**I’m not very good with these things but somebody younger in my family would help me for handling it.** [Patient 2, 67 years, female]

**I know how to use it … I think it is quite easy and straight forward because the layout is very clear (while showing the Homepage).** [Patient 5, 35 years, female]

Adoption: Triggers

Most patients indicated that they would receive follow-up through the WeChat applet if it was recommended by their known and trusted health care professionals.

**My trusted physician recommended me to use this ’wechat applet’ to improve my medication adherence and better manage ADRs, which makes me willing to use it.** [Patient 8, 62 years, male]
Usability Testing

They were challenges encountered when adding a new medication, with regard to patients’ understanding of their complex medication regimen.

Challenges Encountered When Adding a New Medication

Several subthemes emerged under this theme: confusion by terms used when adding medications into DolphinCare, unfamiliarity with the entered generic name of the medication, and patients’ incomprehension of their complex medication regimen.

Unfamiliarity With the Generic Name of the Medication

When entering medication details into the WeChat applet, most patients knew their medication by brand names but not generic names. DolphinCare requires users to enter the generic name of the medication, as the pharmacy label only contains the generic name.

I am not sure of accurately different names of my medications, and I almost always have my pill boxes with me. [Patient 15, 59 years, male]

I’m not too sure what is the precise name of my medication. I only know it by its brand name. So having the indication automatically linked to the medication name is good to have. [Patient 16, 64 years, female]

Utility Testing

Two themes emerged from the utility testing of DolphinCare: utilities that could improve medication adherence and the management of ADRs.

A Medication Reminder System

All participants found the medication reminder useful, including timed pop-up push notifications and text alerts.

Oh yes this was helpful. It prompted me to remind my mum to take her medications. [Patient 20, 61 years, male]

It would like to set timed pop-up push notifications to depend on what time I wake up in the morning and go to bed in the evening. [Patient 18, 62 years, female]

A Medication Adherence Scoring System

Medication adherence among patients was evaluated using the MMAS-8. When a patient uses the WeChat applet for more than 1 month, a questionnaire to evaluate their medication adherence will be provided to the patient to fill in.

I’m sorry that I wasn’t aware of the MMAS-8 questionnaire until you reminded me. Happily, my medication adherence improved after using the applet. [Patient 9, 47 years, male]

The Management of ADRs

When patients input the antitumor medication they are taking, the applet interface automatically matches the corresponding educational information of ADRs. A week later, the applet provides the corresponding collection information forms of ADRs to the patient to fill out. Health care professionals receive messages or provide web-based medication guidance to the patient based on the severity of ADRs. In addition, the WeChat applet can intelligently recognize the inspection and image reports uploaded by the patient in paper-photo versions. The WeChat applet converts the reports into text formats, and organizes and records them in the patient’s file. When there are obvious abnormalities in indicators of the reports related to ADRs, health care professionals can promptly contact the patient.

The Web-Based Consultation System

The web-based consultation system enables patients to consult pharmacists or physicians in time when they have doubts about medications or have ADRs. There will be a professional exclusively in charge of web-based consultation services during working days.

Oh this is good. This saved me the time and efforts to go to the hospital for consultation, and the response I got from online consultations was equally satisfactory. [Patient 17, 50 years, male]

Discussion

Principal Findings

DolphinCare was designed and developed on the basis of the Fogg Behavior Model. This model comprised 3 phases—motivation, ability, and triggers—which suggests that a patient is able to achieve a target behavior if he or she has high motivation, ability, and an effective trigger simultaneously. The requirement phase was based on utilities that could improve medication adherence and manage ADRs, which led to the design and development of DolphinCare until the medical personnel and patients were satisfied with the prototype. This paper focused on the usability and utility testing of DolphinCare, for which patients with cancer were recruited to use the WeChat applet and provided feedback.

To our knowledge, no previous study has reported the experiences of patients with cancer when using a WeChat applet. The patients also preferred a summary page of medication, which was accessible by tapping on the medication icon on the home page of DolphinCare; this was useful as it provided a brief overview of their medication regimen. This further enhanced the usability of DolphinCare, as it would be more patient-centered and more likely to be adopted. It is worth noting that there was no particularly negative feedback provided by the participants. This is a limitation of the study, and future research needs explore the negative feedback from patients to better improve DolphinCare.

The steps to add a medication were simplified and displayed in a layered order to prevent cognitive overload [18]. However, some participants struggled when adding a new medication due to the complexity of this task. It is challenging to input data into a small device, as it requires the user to navigate the app on a small screen [19]. Despite the challenges encountered by patients, the process of adding a new medication “manually” benefited patients with regard to their medication knowledge.
Participants had to “learn” the generic name of their medications, their administration frequency, and their purpose, which is beneficial for the patient’s treatment process.

Several studies have shown that behavioral change is achievable through active reminders, which strengthens the benefits of medication adherence apps [20,21]. A review by Santo et al [22] in 2016 revealed that only 56% of medication adherence apps adjust flexible scheduling for medication reminders. Medication reminders with flexible scheduling (where users may opt for medication reminders on alternate days or on a weekly basis) allows for personalization of the app to suit their individual needs. Participants also reported that they had a better understanding of the frequency and indication of the medication, which appeared on the reminder, thereby improving their medication knowledge. Improved patient knowledge is known to enhance their medication adherence and clinical health outcomes [23]. However, areas involving strategies to improve patients’ medication knowledge require further investigation [24]. DolphinCare offers a pop-up push notification, with a “single-click” return to the WeChat applet, which was preset every 2 days. Besides a pop-up push notification, weekly text alerts were also provided. These allowed users who were unable to take their medications at a specific time point to take them later, which actively prompted the patients to take their medications properly and on time. DolphinCare required users to acknowledge the reminder that, theoretically, would make the patients more conscious of their adherence to medications.

Symptom monitoring is especially important for patients with cancer because they can experience varying acute and chronic side effects from their treatment regimen [25]. Egbring et al [26] conducted a 3-arm randomized controlled trial for 6 weeks with 139 patients with early-stage breast cancer undergoing chemotherapy. The participants were randomly assigned to a control group, an unsupervised group that used a mobile app to record data without physician review, or a supervised group that recorded data in the app with physician review. The results revealed that participants who had physician collaboration when using the health tracking app demonstrated increased reporting of adverse effects of chemotherapy, more precise health data entries, and stabilization of daily functional activities measured using the ECOG (Eastern Cooperative Oncology Group) scale.

Our study affirmed the importance of symptom monitoring among patients with cancer, as these patients can also experience significant side effects from their treatment regimen, which influence their overall quality of life during and after their course of therapy.

The wide demographic range of the participants of this study delineates the experiences of both young and old users. The usability and utility testing of DolphinCare demonstrated the needs of patients with cancer and their caregivers better and helped tailor the WeChat applet to suit their needs. This ensured that DolphinCare would be a more patient-centered WeChat applet and more likely to be used. Our study suggests that DolphinCare can aid patients with cancer and even those with other chronic diseases to improve medication adherence and manage ADRs.

Conclusions
DolphinCare was designed and developed on the basis of the Fogg Behavior Model. This study provides preliminary evidence of the usability and utility of this type of WeChat applet among patients with cancer. This WeChat applet had usabilities and utilities that could improve the patients’ medication adherence and ADR management.

Abstract

Background: Adult day services (ADS) provide community-based health care for older adults with complex chronic conditions but rely on outdated methods for communicating users’ health information with providers. CareMOBI, a novel mobile health (mHealth) app, was developed to address the need for a technological platform to improve bidirectional information exchange and communication between the ADS setting and providers.

Objective: This study aims to examine the feasibility and acceptability of CareMOBI in the ADS setting.

Methods: A concurrent-triangulation mixed methods design was used, and participants were client-facing ADS staff members, including direct care workers (paid caregivers), nurses, and social workers. Interviews were conducted to describe barriers and facilitators to the adoption of the CareMOBI app. The acceptability of the app was measured using an adapted version of the Technology Acceptance Model questionnaire. Data were integrated into 4 themes as anchors of an informational matrix: ease of use, clinical value, fit within workflow, and likelihood of adoption.

Results: A mix of ADS staff (N=22) participated in the study. Participants reported high levels of acceptability across the 4 domains. Qualitative findings corroborated the questionnaire results; participants viewed the app as useful and were likely to implement CareMOBI in their practice. However, participants expressed a need for proper training and technical support throughout the implementation process.

Conclusions: The CareMOBI app has the potential to improve care management in the ADS setting by promoting effective communication through an easy-to-use and portable method. While the integration of CareMOBI is acceptable and feasible, developing role-specific training modules and technical assistance programs is imperative for successful implementation within the ADS setting.

Introduction

Adult day services (ADS), commonly referred to as adult day care, is a vital but overlooked source of health and social care for the burgeoning population of older adults with complex chronic conditions, particularly those with Alzheimer disease and related dementia (ADRD) [1]. ADS sites are nonresidential, congregate, and community-based facilities that offer interdisciplinary services, including opportunities for socialization, nursing care, and nutritious meals for chronically ill or functionally impaired adults. Each day in the United States, 251,100 adults with complex health and social needs receive care in the ADS setting: 65% have some combination of ADRD, diabetes, depression, heart disease, or other chronic conditions; 72% live below federal poverty lines; and 55% are from a racial or ethnic minoritized group [2]. Clients attend 2 to 5 days per week and may receive assistance with personal care, physical therapy, vital sign monitoring, and medication administration, while also participating in organized group activities [3]. ADS staff are skilled at using their in-depth, serial observations of clients to identify warning signs of acute illness and promote early clinical intervention, which are especially important in persons with ADRD, who may not be able to identify or communicate changes in their health status.

However, ADS sites face numerous barriers in communicating concerning changes in health status to primary care providers [4]. Ineffective communication in health care has been associated with costs exceeding US $10 billion, in addition to adverse outcomes and increased mortality [5,6]. We previously found that communication between free-standing community-based ADS centers is hampered by reliance on antiquated methods of information exchange that challenge information sharing and care coordination [7]. When ADS clients experience acute changes in health status or behavior, information is typically reported to primary care providers through fax or voicemail messages, which often result in nonresponse, delayed diagnosis, referral or treatment, and inadequate follow-up. Primary care providers and ADS staff have agreed that communication between them is infrequent, delayed, incomplete, and unreliable. Primary care providers prefer to communicate using direct messaging systems within their electronic health record; however, 92% of ADS sites in the United States lack the resources for interoperable electronic health record systems that enable e-communication [8]. The lack of resources shifts the burden of communication between ADS sites and primary care to the family caregiver (herein referred to as caregivers) who must deliver the information from the ADS site to the primary care provider at the point of service. Although engaged caregivers are often willing to track medical information and coordinate care, they may lack the necessary time, resources, and health education, resulting in medical errors or delays in care.
